| **keywords** | The **keywords** attribute can contain multiple string values that identify a given service. This attribute is included in the global catalog, which means that clients in any domain of a forest can search the global catalog for keywords that are associated with the service. This attribute is also indexed, which improves query performance. The installer that creates the SCP object sets the values of the keywords attribute. Typically, these values are not modified by the active service.<br><br>The exact keywords that should be included in your SCP depend on how clients search for the service. One type of keyword that is important to include is the GUID string, because globally unique identifiers (GUIDs) are guaranteed to be unique in a forest. Use the GUID string format that is returned by the **GuidToString** function in the remote procedure call (RPC) library. Also important to include are human-readable names for clients to search for a given service. The keywords in an SCP object should include GUID strings and names that identify the following data about the service:<br><br>• The company or organization, for example, Coho Vineyard.<br><br>• The product or service, for example, SQL Server. This enables client applications to find SCPs for services of that type.<br><br>• The specific version of the product or service, for example, 7.5.<br><br>For SCP objects that publish a specific set of data or capabilities for a type of service, a GUID string or name should be included that identifies the specific instance. For example, a database service might publish an SCP object for a specific database. In this case, the SCP object should include a product GUID to identify the service and another GUID to identify the database. |
| **serviceDNSName** and **serviceDNSNameType** | Client applications use the **serviceDNSName** and **serviceDNSNameType** attributes to determine the service's host computer. These attributes are not indexed, and they are not replicated as part of the global catalog.<br><br>The **serviceDNSNameType** value indicates the type of DNS name that is specified by **serviceDNSName —** usually, "A" if **serviceDNSName** contains a host name or "SRV" if **serviceDNSName** contains an SRV record name.<br><br>The **serviceDNSName** value is typically the DNS name of the service's host computer. Your service installer can call the **GetComputerNameEx** function to get the DNS name of the local computer.<br><br>For services that have DNS SRV records, **serviceDNSName** can be the name of the SRV record. A client application uses the DNS APIs to retrieve all the SRV records that match this name. The client then retrieves the DNS host name from one of the SRV records. This technique is useful for replicated services, because SRV records also include data that enables the client to select the best replica. |
| **serviceClassName** | This is a single-value property that identifies the class of service that is represented by the SCP. This attribute is not indexed, and it is not replicated as part of the global catalog.<br><br>This is a descriptive string that is specific to the service that published the SCP; for example SqlServer. For services that support mutual authentication, clients can use this property, along with the DNS name of the service's host computer, to form an SPN. |

| | |
|---|---|
| **serviceBindingInformation** | This is a multivalue property that contains string values that store data that is required to bind to a service. This property is indexed, and it is replicated to the global catalog.<br><br>The content of **serviceBindingInformation** is specific to the service that publishes the SCP; clients must interpret the binding data. In the most common case, the binding data consists of a port number on the service host computer.<br><br>Examples of service binding information include the following:<br><br>• File Service: A Universal Naming Convention (UNC) name for a share.<br><br>Example: \\MyServer\MyshareName<br><br>• Web Service: A Uniform Resource Locator (URL).<br><br>Example: http://www.cohovineyard.com<br><br>• RPC Service: RPC binding, encoded information that is used to connect to the RPC server. RPC bindings can be converted to and from strings with the RPC APIs.<br><br>Example: ncacn_ip_tcp:server.cohovineyard.com |

**SPNs**

A service principal name (SPN) is the name by which a client uniquely identifies an instance of a service. SPN structures generally follow Internet Engineering Task Force (IETF) naming conventions, and they often include the name of the computer on which the service is running. SPNs may be used to request Kerberos tickets, and they are required for mutual authentication. An example of an SPN is MyDBService/host1.cohovineyard.com, where MyDBService is the name of the service and host1.cohovineyard.com is the name of the host on which the service resides. If multiple instances of a service are installed on computers throughout a forest, each instance must have its own SPN. A given service instance can have multiple SPNs if there are multiple names that clients might use for authentication. For example, an SPN always includes the name of the host computer on which the service instance is running; therefore, a service instance might register an SPN for each name or alias of its host.

Before Kerberos can use an SPN to authenticate a service, the SPN must be registered on the account object that the instance of the service uses to log on. A given SPN can be registered on only one account. For Win32 services, a service installer specifies the logon account when an instance of the service is installed. The installer then composes the SPNs and writes them as a property of the account object in Active Directory. If the logon account of a service instance changes, the SPNs must be manually registered again under the new account.

When a client attempts to connect to a service, it locates an instance of the service, composes an SPN for that service instance, connects to the service, and presents the SPN for the service to authenticate.

**Name Formats for Unique SPNs**

An SPN must be unique in the forest in which it is registered. If it is not unique, authentication will fail. The SPN syntax has four elements: two required elements and two additional elements that can be used, if necessary, to produce a unique name, as follows:

*ServiceClass/Host:Port/ServiceName*

Each of these SPN elements is described in the following table.

**SPN Elements**

| Element | Description |
|---|---|
| *ServiceClass* | A string that identifies the general class of service, for example, SqlServer. There are well-known service class names, such as www for a Web service or ldap for a directory service. In general, this can be any string that is unique to the service class. Be aware that the SPN syntax uses a forward slash (/) to separate elements; therefore, the forward slash cannot appear in a service class name. |

| | |
|---|---|
| *Host* | The name of the computer on which the service is running. This can be a fully-qualified DNS name or a network basic input/output system (NetBIOS) name. Be aware that NetBIOS names are not guaranteed to be unique in a forest, and Active Directory does not enforce uniqueness for the host component of an SPN. |
| *Port* | An optional port number to differentiate between multiple instances of the same service class on a single host computer. This component can be omitted if the service uses the default port number that is reserved for its service class (port number 389 for LDAP, for example). |
| *ServiceName* | An optional name that is used in the SPN of a replicable service to identify the data or services that are provided by the service or to identify the domain that is served by the service. This component can have one of the following formats (each of which are guaranteed to be unique within Active Directory):<br>• The distinguished name or objectGUID of an object in Active Directory, such as a connection point object.<br>• The DNS name of the domain for a service that provides a specified service for a domain as a whole.<br>• The DNS name of an SRV or mail exchange (MX) record. |

The components that are present in a service's SPNs depend on how the service is identified and replicated. There two types of services: host-based services and replicable services.

**Host-based services**
For a host-based service, the *ServiceName* component is omitted because the service is uniquely identified by the service class and by the name of the host computer on which the service is installed, as follows:

*ServiceClass/Host*

The service class alone is sufficient to identify for clients the features that the service provides. You can install instances of the service class on many computers, and each instance provides services that are identified with its host computer. File Transfer Protocol (FTP) and Telnet are examples of host-based services. The SPNs of a host-based service instance can include the port number if the service uses a nondefault port or if there are multiple instances of the service on the host, as follows:

*ServiceClass/Host:Port*

**Replicable services**
For a replicable service, there can be one or many instances of the service (replicas), and clients do not differentiate which replica they connect to because each replica provides the same service. The SPNs for each replica have the same *ServiceClass* and *ServiceName* components, where *ServiceName* identifies more specifically the features that are provided by the service. Only the *Host* and optional *Port* components vary from SPN to SPN.

An example of a replicable service is an instance of a database service that provides access to a specified database. In this case, *ServiceClass* identifies the database application, and *ServiceName* identifies the specific database. *ServiceName* might be the distinguished name of an SCP object that contains connection data for the database. As shown in the following examples, only the value for *host* varies among the service instances:

MyDBService/*host1.cohovineyard.com*/CN=hrdb,OU=mktg,DC=*cohovineyard*,DC=com

MyDBService/*host2.cohovineyard.com*/CN=hrdb,OU=mktg,DC=*cohovineyard*,DC=com

MyDBService/*host3.cohovineyard.com*/CN=hrdb,OU=mktg,DC=*cohovineyard*,DC=com

If clients use the NetBIOS name to compose a service's SPN, each replica must also register an SPN that contains the NetBIOS name. The following examples show SPNs that are constructed by using NetBIOS host names:

MyDBService/*host1*/CN=hrdb,OU=mktg,DC=example,DC=com

MyDBService/*host2*/CN=hrdb,OU=mktg,DC=example,DC=com

MyDBService/*host3*/CN=hrdb,OU=mktg,DC=example,DC=com

Another example of a replicable service is one that provides services to an entire domain. In this case, the *ServiceName* component is the DNS name of the domain being served. A Kerberos KDC is an example of this type of replicable service.

Be aware that if the DNS name of a computer changes, that computer updates the *Host* element for all registered SPNs for that computer in the forest.

With Active Directory you can find and connect to a directory-enabled service by using attributes other than the computer name or the IP address of the computer on which the service exists. Active Directory uses other object attributes, such as the service display name (commonly called the friendly name) to find services like Dynamic Host Configuration Protocol (DHCP).

**Service Publication and SPN Processes and Interactions**
This section describes the processes and interactions that are related to service publication and SPNs.

**How a Service Publishes Its Service Information**
Typically, a setup program for a service (or an installation option for the executable routine of the service) installs the service and creates a service account, if necessary, and the SCP. At service startup, the service itself checks to ensure that the SCP contains the correct binding information.

To create an object of any kind, the process that creates the object must have permission to create a child in the container in which the object is to be created. For example, to create the object CN=MS-SQL-SQLServer,CN=dbserver,OU=ComputersOU,DC=corp,DC=cohovineyard,DC=com, the process must have permission to create a child in the CN=dbserver,OU=ComputersOU,DC=corp,DC=cohovineyard,DC=com container. To remove an object, the process that deletes the object must have permission to delete a child from the container from which the object is to be deleted. Or, the process must have permission to delete the object itself. To update a connection point object, the process performing the operation must have permission to write to the properties of the object that needs to be updated.

These permissions to create objects might not be available to a service account or computer account during the installation of a service, but an administrator, or anyone with the necessary permissions, can perform the installation. When you install a published service, you can set the protection on any connection point object to allow updates by the service at run time. This way, the service can run with a minimally privileged account as a security precaution and still be able to maintain its connection point.

**Where Services Are Published**
In the domain hierarchy of Active Directory, service-related objects can be created in three places:

- Computer object
- Organizational Unit container
- System container (or one of its children)

The following sections describe these locations in Active Directory for service-related objects.

**Computer object**
When a service that supports service publication is installed on a computer, the service generally (but not always) publishes its connection point object as a child object of the Computer object on which the service is installed.

The Computer object where the service is installed is a convenient and intuitive location for these objects, because when a Computer object is moved to a different location, Active Directory also moves any service objects on the Computer object to the new location. In addition, when a Computer object is deleted or when it is joined to a different domain, the service objects are also deleted or moved; therefore, there is less likelihood that a service will become an orphan.

### Note

- A computer must be a domain member to have a valid Computer object in the directory.

**Organizational Unit container**
An Organizational Unit container is a general-purpose container that can be used to group together and organize objects, including computer objects, for administrative purposes. Organizational Unit containers can also be used to group connection point objects together for administrative purposes.

All of the object classes that are derived from the **connectionPoint** class are valid children of the **organizationalUnit** object class, from which Organizational Unit containers are derived. This means that a service connection point object can be created in any container.

**System container**
The System container stores operational information, which is organized by domain. This information includes the default local security policy, file link tracking, network meetings, and containers for connection points to RPC and Winsock. By default, the System container is hidden, and it provides a convenient place for storing objects that are of interest to administrators but not

to users.

Services that use the Winsock RnR or RpcNs APIs to advertise themselves automatically create connection point objects in the WinsockServices and RpcServices containers.

Services that create connection point objects in the System container perform the following operations when they create a connection point object:

- They create a subcontainer in the System container and give it a name that clearly relates it to the service.

- They publish the connection point objects in the System container. For example, Microsoft NetMeeting uses the Meetings container to publish network meeting objects. When multiple products from a single vendor publish objects in this manner, the containers for each service must be created as children of a container (an object of the class **container**), and the container must be given a name that clearly relates to the particular vendor. The vendor-specific container must be created as a child of the System container.

**Publishing with the RPC Name Service**
RPC services use the RpcNs API to publish themselves in a namespace; the RpcNs APIs publish the RPC entries in Active Directory. Services create RPC bindings and publish them in the Active Directory namespace as named RPC Server entries with attributes. The attributes include the unique interface ID and a GUID that are known to clients. Clients can then search for RPC servers that offer the desired interface, import the binding, and connect to the server.

**Publishing with Winsock RnR**
Winsock services can use the RnR APIs to publish services and to locate those services. RnR publication occurs in two steps. The first step installs a service class that associates a GUID with a name for the service. The service class can hold service-specific configuration information. Services can then publish themselves as instances of the service class. After the services are published, clients can query Active Directory for instances of a given class, using the RnR APIs, and then select an instance to which to bind.

**How a Service Registers Its SPNs**
Before a client can use an SPN to authenticate an instance of a service, the SPN must be registered on the user or computer account that the service instance will use to log on. Typically, SPN registration is performed by the service installation program that installs the service.

The service installation program that installs a service instance on a host computer typically performs the following steps:

- Calls the **DsGetSpn** function to create one or more unique SPNs for the service instance.

- Calls the **DsWriteAccountSpn** function to register the names on the service's logon account.

**DsWriteAccountSpn** registers SPNs as a property of a user or computer account object in the directory. User and Computer objects have a **servicePrincipalName** attribute, which is a multivalued attribute for storing all the SPNs that are associated with a user or computer account. If the service runs under a user account, the SPNs are stored in the **servicePrincipalName** attribute of that account. If the service runs in the Local System account, the SPNs are stored in the **servicePrincipalName** attribute of the account of the service's host computer. The **DsWriteAccountSpn** caller must specify the distinguished name of the account object under which the SPNs are stored.

To ensure that registered SPNs are secure, the **servicePrincipalName** attribute cannot be written directly; it can only be written by calling **DsWriteAccountSpn**. The caller must have Write access to the **servicePrincipalName** attribute of the target account. Typically, Write access is granted by default only to domain administrators. However, there is a special case in which Active Directory allows a service running under the Local System account to register its own SPNs on the computer account of the service's host. In this case, the SPN being written must have the form *ServiceClass*/*Host*, and *Host* must be the DNS name of the local computer.

**DsWriteAccountSpn** can also remove SPNs from an account. An operation parameter indicates whether the SPNs are to be added to the account, removed from the account, or used to completely replace all current SPNs for the account.

For more information about how a service registers its SPNs, see the "Microsoft Platform SDK" on MSDN.

Host-based services that use the simple SPN format *ServiceClass*/*Host* have the option of using the **DsServerRegisterSpn** function, which both creates and registers SPNs for a service instance. **DsServerRegisterSpn** is a helper function that calls **DsGetSpn** and **DsWriteAccountSpn**.

**How a Client Application Finds a Service**
Clients find service objects by querying the directory. The client can limit the scope of the query to its domain, or it can search the entire forest by using the global catalog. In either case, the client does not need information about the location of the service to perform the search.

If the connection point objects that are being searched for are direct instances of the **serviceConnectionPoint** class, a client application can locate published services by searching for any object where **objectCategory** is equal to **serviceConnectionPoint** and **objectClass** is equal to **serviceConnectionPoint**. The **keywords**attribute contains the vendor-specific and application-specific GUID.

For more information about how a client application finds a service, see the "Microsoft Platform SDK" on MSDN.

**How a Client Composes an SPN**
To mutually authenticate a service, a client application composes an SPN for the service instance to which it wants to connect and then presents this SPN to the KDC for authentication. The client application can use **DsMakeSpnfunction** to compose an SPN. The client specifies the components of the SPN by using known information or information that is retrieved from sources other than the service itself.

The form of an SPN is as follows, where *ServiceClass* and *Host* are required and *Port* and *ServiceName* are optional:

*ServiceClass/Host:Port/ServiceName*

A client application can retrieve components of the SPN from sources such as a connection point object, user input, or hard-coded strings that are contained within the client application. For example, the client can read the **serviceDNSName** attribute of a service's connection point object to get the *Host* component. The **serviceDNSName** attribute contains either the DNS name of the server on which the service instance is running or the DNS name of SRV records that contain the host information for service replicas. The *ServiceName* component, which is used only for replicable services, can be the distinguished name of the service's connection point object, the DNS name of the domain that is served by the service, or the DNS name of SRV or MX records.

**How a Client Authenticates a Service**
The means by which a client authenticates a service ensures the authenticity of the service in two ways. First, because an SPN is constructed from several elements and must be unique, a rogue service has no way of publishing a valid SPN to the directory. Next, a given service can only be authenticated if that service can successfully exchange encrypted information with a KDC.

The Kerberos mechanism by which a client authenticates a service works as follows. When a service is installed, a service installer, running with administrator privileges, registers one or more unique SPNs for each service instance. The names are registered in Active Directory on the user or computer account object that the service instance will use to log on. When a client requests a connection to a service, it composes an SPN for a service instance, using known data or data that is provided by the user. The client then uses the Security Support Provider Interface (SSPI) negotiate package to present the SPN to the KDC for the client domain account. The KDC searches the forest for a user or computer account on which that SPN is registered. If the SPN is registered on more than one account, the authentication fails (which prevents a rogue service from attempting to impersonate a valid service). Otherwise, the KDC encrypts a message using the password of the account on which the SPN was registered. The KDC passes this encrypted message to the service instance. The service uses the SSPI negotiate package to decrypt the message (using the password that only the service and the KDC possess), which it passes back to the KDC. The KDC authenticates the service if the decrypted message matches the original message.

# Service Publication and Service Principal Names Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Service Publication and SPN Tools
- Service Publication and SPN WMI Classes
- Network Ports Used by Service Publication and SPNs

This section contains information about the tools, Windows Management Instrumentation (WMI) classes, and network ports that are associated with service publication and service principal names (SPNs).

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

**Service Publication and SPN Tools**

The following tools are associated with service publication and SPNs.

**Adsiedit.msc: ADSI Edit**

**Category**

This tool ships with Support Tools for Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
| --- | --- |

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

ADSI Edit is a Microsoft Management Console (MMC) tool that you can use to view and modify directory objects and attributes, including connection point objects, and SPN attributes.

To find more information about ADSI Edit, see "Support Tools Help" in Tools and Settings Collection.

**Repadmin.exe: Repadmin**

**Category**
This tool ships with Support Tools for Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Administrators can use Repadmin to monitor and manage replication between domain controllers. To find more information about Repadmin, at a command prompt type **repadmin /?** or see "Command-Line References" in Tools and Settings Collection.

**Setspn.exe: Setspn**

**Category**
This tool ships with Support Tools for Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Administrators can use this command-line tool to read, modify, and delete values in the **servicePrincipalNames** attribute on an Active Directory service account object.

To find more information about Setspn, see "Support Tools Help" in Tools and Settings Collection.

**Service Publication and SPN WMI Classes**

The following table lists and describes the WMI classes that are associated with service publication and SPNs.

**WMI Classes Associated with Service Publication and SPNs**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| **DS_LDAP_Class_Containment** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

| | | |
|---|---|---|
| **DS_LDAP_Instance_Containment** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

For more information about these WMI classes, see "Mapping Active Directory to WMI" in the WMI SDK documentation on MSDN.

**Network Ports Used by Service Publication and SPNs**

The network ports that are used by service publication and SPNs are listed in the following table.

**Port Assignments for Service Publication and SPNs**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | None | 389 |
| LDAP SSL | None | 636 |
| RPC Endpoint Mapper | 135 | 135 |
| Global Catalog LDAP | None | 3268 |
| Global Catalog LDAP SSL | None | 3269 |
| Kerberos | 88 | 88 |

# Active Directory Installation, Upgrade, and Migration Technologies

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Active Directory Installation Wizard
- Active Directory Preparation Tool
- Active Directory Migration Tool
- Active Directory Functional Levels
- Domain Rename

The Active Directory directory service is used in server operating system environments to manage networks comprising Microsoft Windows clients, Windows 2000 Server and Windows Server 2003 servers and domain controllers, and Windows-compatible applications and services. There are many benefits to deploying Active Directory, including centralized management, scalability, and the ability to easily delegate administrative authority.

Some of the tools that are available to help you install and manage Active Directory include the following:

- The Active Directory Installation Wizard (Dcpromo.exe), which is used to install Active Directory
- The Active Directory Preparation Tool (Adprep.exe), which is used to prepare an existing Active Directory environment for a newer version of the directory service
- The Active Directory Migration Tool (ADMT), which is used to restructure Microsoft Windows NT 4.0 or Active Directory domains
- The domain rename tools (Rendom.exe and Gpfixup.exe), which are used to rename and restructure domains and adjust Group Policy settings to accommodate the new structure

Finally, new Active Directory features are enabled in a Windows Server 2003 environment by increasing domain and forest functional levels.

**Active Directory Installation Wizard**

The Active Directory Installation Wizard (Dcpromo.exe) configures a server to be a domain controller by installing Active Directory. Using the Active Directory Installation Wizard you can either add a domain controller to an existing domain or create the first domain controller in a new domain. The wizard provides the option to do this.

You can run the Active Directory Installation Wizard from the command line, or from the Configure Your Server Wizard. You can also install Active Directory using an unattended setup script called an answer file.

When running the wizard from the command line, you can append the **/adv** switch to the **dcpromo** command to populate the directory using a backup of system state data from another domain controller in the same domain. Installing from backup media reduces the amount of data that must be replicated over the network, thus reducing the time required to install Active Directory.

Before installing Active Directory, the wizard verifies that the server is eligible to run Active Directory by checking certain criteria. The following are examples of some of the criteria that the wizard checks before allowing an Active Directory installation to proceed:

- There is sufficient disk space on the computer to store the Active Directory database.

- You have sufficient privileges to install Active Directory on the computer.
- The computer is running a correct version of the operating system.

After all prerequisites have been met, a user interface is used to gather information specific to the environment in which Active Directory will be installed, such as the Domain Name System (DNS) name and the storage locations for the Active Directory database and the SYSVOL shared folder. If you are installing Active Directory using an answer file, you will prepopulate the script with this information. Finally, the wizard configures Active Directory and makes the server a domain controller.

**Active Directory Preparation Tool**
The Active Directory Preparation Tool (Adprep.exe) prepares your infrastructure for a new version of Active Directory. Adprep.exe is located on the Windows Server 2003 operating system CD and can only be run from the command line.

To prepare your Windows 2000 forest and domains for upgrade to Windows Server 2003 Active Directory, or to prepare for new Windows Server 2003–based domain controllers, you must:

- Run **adprep /forestprep** once on the schema master to prepare the forest.
- Run **adprep /domainprep** once on the infrastructure master in each domain in which you plan to install a Windows Server 2003–based domain controller.

Adprep.exe performs a collection of operations that prepare the forest and domains for an Active Directory upgrade, including:

- Extending the current schema with new schema information, while preserving previous schema modifications in your environment.
- Allowing applications to access data in Active Directory after security settings have been improved.

**Active Directory Migration Tool**
The Active Directory Migration Tool (ADMT) is used to consolidate Windows NT 4.0 or Active Directory domains to improve manageability, scalability, and security. You can use ADMT to restructure your Windows NT 4.0 domains to an Active Directory forest or to restructure Windows Server 2003 Active Directory domains within and between Active Directory forests.

When you use ADMT to migrate a user or group from either a Windows NT 4.0 domain to an Active Directory forest or between two Active Directory forests, you can use security identifier (SID) history to maintain resource permissions during migration so that access to resources is not interrupted.

ADMT includes wizards that automate common migration tasks, such as copying users, groups, and service accounts; moving computers; migrating trusts; and performing security translation. ADMT is available on the Windows Server 2003 operating system CD, in the Admigration.msi file in the \i386\admt directory. You can perform ADMT tasks by using the ADMT console, by using a command-line procedure, or by using a script. When running ADMT from the command line, you can use an option file to specify command-line options.

**Active Directory Functional Levels**
Although most Active Directory features are available by default, certain new features of Windows Server 2003 Active Directory, such as efficient group membership replication and domain rename, cannot be enabled until all domain controllers within a given scope (domain or forest) are running Windows Server 2003.

Windows Server 2003 Active Directory does not automatically enable such a feature even when all domain controllers within a forest are running Windows Server 2003. Instead, the responsibility for the decision is administrative so that you can still add domain controllers that are running earlier versions of Windows. By advancing the functional level of a Windows Server 2003 domain or forest, you enable new features within that scope.

Functional levels protect against incompatibility. Before you raise a functional level, Active Directory verifies that all domain controllers are running the correct version of the operating system. After you raise the functional level, Active Directory no longer allows the introduction of a domain controller with an incompatible version of Windows.

**Domain Rename**
Domain rename capabilities are available in a Windows Server 2003 forest that has a forest functional level of

Windows Server 2003. These capabilities are not available in Windows 2000 Server operating systems.

The structure of an Active Directory forest is the result of the order in which you create domains and the hierarchical names of those domains. Beginning with the forest root domain, all child domains derive their distinguished names and default DNS names from the forest root domain name. The same is true of every additional tree in the forest. The way to change the hierarchical structure of an existing domain tree is to rename the domains. For example, you can rename a child domain to have a different parent or rename a child domain to be a new tree-root domain. In each case, you reposition an existing domain to create a different domain-tree structure. Alternatively, you can rename domains without affecting the structure. For example, if you rename a root domain, the names of all child domains below it are also changed, but you have not created a different domain-tree structure.

The ability to rename domains provides you with the flexibility to make important name changes and forest structural changes as the needs of your organization change. Using domain rename, you can not only change the name of a domain, but you can change the structure of the domain hierarchy and change the parent of a domain or move a domain residing in one domain tree to another domain tree. The domain rename process can accommodate scenarios involving acquisitions, mergers, or name changes in your organization, but it is not designed to accommodate forest mergers or the movement of domains between forests.

The domain rename process involves making basic changes independently at each domain controller in a forest. You set up an administrative computer from which you issue commands that are executed remotely at each domain controller. These commands update the directory database at each domain controller individually with the changes that are necessary for renaming the domains; that is, the updates that rename the domains do not spread across the forest through Active Directory replication.

Rendom.exe is a new tool that is included with Windows Server 2003. You use the Rendom tool to carry out the following multiple steps in the domain rename process:

- Freeze the current state of the forest so that no changes can occur while a domain rename operation is being performed.
- Prepare the contents of the forest for a domain rename operation. Rendom runs multiple scripts that perform this preparation.
- Execute a domain rename operation.
- Clean up old domain names.

Another tool, Gpfixup, is provided to reinstate Group Policy from the original domains into the newly named domains in the forest.

In Windows Server 2003, domain rename is intended to be a supported method for renaming domains when domain renames are necessary; *it is not intended to make domain rename a routine operation*. The domain rename process is complex and requires a great deal of care in planning and execution. In addition, the time that is required for a complete domain rename operation is directly proportional to the size of an Active Directory forest in terms of its number of domains, domain controllers, and member computers. Therefore, although domain rename is possible in Windows Server 2003, it should not be undertaken lightly.

# Active Directory Functional Levels Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Active Directory Functional Levels Technical Reference**

Domain and forest functional levels provide a way to enable advanced Active Directory features that are appropriate to the Microsoft Windows Server operating systems running on domain controllers on your network. Different functional levels exist for both domains and forests so that your organization can maximize the capabilities of Active Directory Domain Services (AD DS) within each domain or forest that you maintain.

This subject explains the advanced features that are provided at each domain and forest functional level and how to use Active Directory administration tools to raise the functional level.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

# What Are Active Directory Functional Levels?

Updated: November 19, 2014

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Active Directory Functional Level Scenarios
- Active Directory Functional Level Dependencies and Rollback Options

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

In Active Directory Domain Services (AD DS), domain controllers can run different versions of Windows Server operating systems. The functional level of a domain or forest depends on which versions of Windows Server operating systems are running on the domain controllers in the domain or forest. The functional level of a domain or forest controls which advanced features are available in the domain or forest.

Ideally, all servers in an organization could run the latest version of Windows and take advantage of all the advanced features that are available with the newest software. But organizations often have a mixture of systems, generally running different versions of operating systems, which are migrated to the latest version only as organizational requirements demand additional functionality, either for the entire organization or for a specific area of the organization.

AD DS supports phased implementation of new versions of Windows Server and advanced features on domain controllers by providing multiple functional levels, each of which is specific to the versions of Windows Server operating systems that are running on the domain controllers in the environment. These functional levels provide configuration support for the AD DS features and ensure compatibility with domain controllers running earlier versions of Windows Server.

AD DS does not automatically enable advanced features, even if all domain controllers within a forest are running the same version of Windows Server. Instead, an administrator raises a domain or forest to a specific functional level to safely enable advanced features when all domain controllers in the domain or forest are running an appropriate version of Windows Server. When an administrator attempts to raise the functional level, AD DS checks whether all domain controllers are running an appropriate Windows Server operating system to ensure the proper environment for enabling new Active Directory features.

Raising the functional level allows the introduction of advanced features but also limits the versions of Windows Server that can run on domain controllers in the environment. AD DS has two types of functional levels:

- **Domain functional level**. Six domain functional levels are available:

  Windows 2000 mixed (the default in Windows Server 2003)

  Windows 2000 native

  Windows Server 2003 interim

  Windows Server 2003

  Windows Server 2008

  Windows Server 2008 R2

  Setting the functional level for a domain enables features that affect the entire domain and that domain only. If all domain controllers in a domain are running Windows Server 2008 R2 and the functional level is set to Windows Server 2008 R2, all domain-wide features are available.

> **Note**
> The default domain functional level for Windows Server 2008 and Windows Server 2008 R2 is set to the existing value of the forest functional level.

- **Forest functional level**. Five forest functional levels are available:

  Windows 2000 (the default in Windows Server 2003 and Windows Server 2008)

  Windows Server 2003 interim

  Windows Server 2003 (the default in Windows Server 2008 R2)

  Windows Server 2008

  Windows Server 2008 R2

  Setting the functional level for a forest enables features across all the domains within a forest. If all domain controllers in a forest are running Windows Server 2008 R2 and the functional level is set to Windows Server 2008 R2, all forest-wide features are available.

> **Note**
> In addition to the Windows Server 2008 R2 forest functional level requirement, the Active Directory Recycle Bin feature must be enabled before it becomes available for use. For more information, see the Active Directory Recycle Bin Step-by-Step Guide (http://go.microsoft.com/fwlink/?LinkID=178657).

When domain controllers running earlier versions of Windows Server are included in your domain or forest with domain controllers running later versions of Windows Server, advanced Active Directory features are limited.

The concept of enabling additional functionality in AD DS exists in Windows 2000 with mixed and native modes. Mixed-mode domains can contain Windows NT 4.0 backup domain controllers and cannot use Universal security groups, group nesting, and security identifier (SID) history capabilities. When the domain is set to native mode, Universal security groups, group nesting, and security identifier (SID) history capabilities are available. Domain controllers running Windows NT 4.0 or Windows 2000 Server are not aware of Windows Server 2003 or higher domain and forest functional levels.

**Active Directory Functional Level Scenarios**

Functional levels provide a method for any organization to introduce the latest Active Directory functionality. The advanced functionality can be optimized immediately, or phased in over time, depending on the needs of each organization. The following scenarios describe how functional levels can meet a range of deployment needs:

- A small organization running only Windows Server 2008 R2 on domain controllers. In this scenario, a small organization might be creating an AD DS infrastructure for the first time, using only two domain controllers in a forest with a single domain. By installing Windows Server 2008 R2 on both domain controllers and selecting the Windows Server 2008 R2 forest functional level during the AD DS installation on the first domain controller, the organization can immediately take advantage of all of the advanced Active Directory features that are available.

> **Note**
> The option to select the domain or forest functional level during AD DS installation is available only in Windows Server 2008 and Windows Server 2008 R2.

- A mid-size organization with accelerated upgrade requirements. In this scenario, a mid-size organization might have a native mode Windows Server 2003 domain, and would now like to start upgrading domain controllers to Windows Server 2008. Upgrading to Windows Server 2008 on some domain controllers, while maintaining some previously installed domain controllers running Windows Server 2003, enables the mid-size organization to take advantage of much of the latest functionality, even though all domain controllers are not running Windows Server 2008. Later, after all domain controllers running Windows Server 2003 have been upgraded to Windows Server 2008, the organization can raise the forest functional level to take advantage of all advanced Active Directory features.

- A large organization with phased upgrade requirements. In this scenario, an enterprise with a mature and complex forest with multiple domains, some of which are still running Windows 2000 Server, might now be ready to install one or more new domain controllers running Windows Server 2008. Members of the organization might want to raise functional levels in a phased manner (one domain at a time). They could target certain domains that are running Windows 2000 domain controllers and upgrade them first to Windows Server 2003 and then to Windows Server 2008. After they upgrade all domain controllers in the domain, they could raise the functional level of only that domain to Windows Server 2008 to take advantage of additional Active Directory features.

  After they are satisfied with the results of that domain, members of the organization can carry out a similar exercise in other domains. After upgrading every domain in the forest to Windows Server 2008, they can finally raise the functional level of the forest to Windows Server 2008 to take advantage of the advanced Active Directory features for Windows Server 2008.

**Active Directory Functional Level Dependencies and Rollback Options**

Active Directory domain and forest functionality has the following dependencies:

- After all domain controllers are running an appropriate version of Windows Server, the domain or forest must be configured to support the appropriate domain or forest functional level. That is, to provide support in a domain or forest for advanced Active Directory features, an administrator must raise the domain functional level or forest functional level, which can only be done if the domain controllers are each running the appropriate version of Windows Server.

- After the domain functional level is raised, domain controllers running earlier versions of Windows Server cannot be introduced into the domain. After the forest functional level is raised, domain controllers running earlier versions of Windows Server cannot be introduced into the forest.

- With versions of Windows Server that are earlier than Windows Server 2008 R2, you cannot roll back or lower a functional level under any circumstances. If you have to revert to a lower functional level with a version of Windows Server that is earlier than Windows Server 2008 R2, you must rebuild the domain or forest or restore it from a backup copy.

- After you set the domain functional level to a certain value in Windows Server 2008 R2, you cannot roll back or lower the domain functional level, with one exception: when you raise the domain functional level to Windows Server 2008 R2 and if the forest functional level is Windows Server 2008 or lower, you have the option of rolling the domain functional level back to Windows Server 2008. You can lower the domain functional level only from Windows Server 2008 R2 to Windows Server 2008. If the domain functional level is set to Windows Server 2008 R2, it cannot be rolled back, for example, to Windows Server 2003.

- After you set the forest functional level to a certain value in Windows Server 2008 R2, you cannot roll back or lower the forest functional level, with one exception: when you raise the forest functional level to Windows Server 2008 R2 and if the Active Directory Recycle Bin is not enabled, you have the option of rolling the forest functional level back to Windows Server 2008. For more information about the Active Directory Recycle Bin, see What's New in AD DS: Active Directory Recycle Bin (http://go.microsoft.com/fwlink/?LinkId=141392). You can lower the forest functional level only from Windows Server 2008 R2 to Windows Server 2008. If the forest functional level is set to Windows Server 2008 R2, it cannot be rolled back to Windows Server 2003, for example.

# How Active Directory Functional Levels Work

Updated: November 19, 2014

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- The Architecture of Active Directory Functional Levels
- Physical Structure for Active Directory Functional Levels
- Processes and Interactions with Active Directory Functional Levels
- Related Information

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

Different Active Directory features are available at different functional levels. Raising domain and forest functional levels is required to enable certain new features as domain controllers are upgraded from earlier versions of Windows Server to later versions. Even for a new installation of Windows Server 2003 Active Directory (as opposed to an upgrade), an administrator must raise functional levels to obtain the full capabilities of Windows Server 2003 Active Directory. However, in Windows Server 2008 and Windows Server 2008 R2, you can select a domain or forest functional level during the installation of Active Directory Domain Services (AD DS).

**The Architecture of Active Directory Functional Levels**

Active Directory functional levels are of two types, as shown in the following table.

**Domain and Forest Functional Levels**

| Type of Functional Level | Description |
| --- | --- |
| Domain functional level | Domain functional levels enable features that affect the entire domain and that domain only. They also control which Windows Server operating systems can be run on domain controllers in the domain. |
| Forest functional level | Forest functional levels enable features across all domains within a forest. They also control which Windows Server operating systems can be run on domain controllers in all domains in the forest. |

The following table shows the relationship and dependencies between domain and forest functional levels.

**Relationship Between Domain and Forest Functional Levels**

| Domain Functional Level | Forest Functional Level |
| --- | --- |
| Windows 2000 mixed | Windows 2000 |
| Windows 2000 native | Windows 2000 |
| Windows Server 2003 | Windows Server 2003 |
| Windows Server 2008 | Windows Server 2008 |

| | |
|---|---|
| Windows Server 2008 R2 | Windows Server 2008 R2 |

Another domain functional level, Windows Server 2003 interim, is available for upgrades directly from Windows NT 4.0 to Windows Server 2003.

**Default Windows Server 2003 Active Directory Features Available with All Functional Levels**

Although many new features in Windows Server 2003 Active Directory have operational requirements that are available only at specific functional levels, most Windows Server 2003 Active Directory features are available by default at all functional levels. When the first Windows Server 2003–based domain controller is deployed in a domain or forest, a set of default Active Directory features becomes available. The following table summarizes the Active Directory features that are available by default on any domain controller running Windows Server 2003.

**Default Windows Server 2003 Active Directory Features**

| Feature | Functionality |
|---|---|
| Multiple selection of user objects | Allows you to modify common attributes of multiple user objects at one time. |
| Drag and drop functionality | Allows you to move Active Directory objects from container to container by dragging one or more objects to a location in the domain hierarchy. You can also add objects to group membership lists by dragging one or more objects (including other group objects) to the target group. |
| Efficient search capabilities | Search functionality is object-oriented and provides an efficient search that minimizes network traffic associated with browsing objects. |
| Saved queries | Allows you to save commonly used search parameters for reuse in Active Directory Users and Computers. |
| Active Directory command-line tools | Allows you to run new directory service commands for administration scenarios. |
| **InetOrgPerson** class | The **InetOrgPerson** class has been added to the base schema as a security principal. It can be used in the same manner as the user class. |
| Application directory partitions | Allows you to configure the replication scope for application-specific data among domain controllers. For example, you can control the replication scope of Domain Name System (DNS) zone data stored in Active Directory so that only specific domain controllers in the forest participate in DNS zone replication. |
| Ability to add additional domain controllers by using backup media | Reduces the time it takes to add an additional domain controller in an existing domain by using backup media. |
| Universal group membership caching | Prevents the need to locate a global catalog across a wide area network (WAN) when logging on by storing universal group membership information on an authenticating domain controller running Windows Server 2003. |
| Secure Lightweight Directory Access Protocol (LDAP) traffic | Active Directory administrative tools sign and encrypt all LDAP traffic by default. Signing LDAP traffic guarantees that the packaged data comes from a known source and that it has not been tampered with. |
| Partial synchronization of the global catalog | Provides improved replication of the global catalog when schema changes add attributes to the global catalog partial attribute set. Only the new attributes are replicated, not the entire global catalog. |
| Active Directory quotas | Quotas can be specified in Active Directory to control the number of objects a user, group, or computer can own in a given directory partition. Members of the Domain Admins and Enterprise Admins groups are exempt from quotas. |

For more information about new AD DS features in Windows Server 2008, see What's New in AD DS in Windows Server 2008 (http://go.microsoft.com/fwlink/?LinkId=180673). For more information about new AD DS features in Windows Server 2008 R2, see What's New in Active Directory Domain Services (http://go.microsoft.com/fwlink/?LinkId=139655).

**Domain Functional Level**
Domain functional levels represent the extension of the mixed and native domain modes that were available in Windows 2000:

- In Windows 2000 Active Directory, certain features are enabled only when all domain controllers in a domain are running Windows 2000 and the domain mode is set to native mode. Otherwise, the domain is running in mixed mode, where only features that are compatible with Windows NT 4.0–based domain controllers are operational. The domain administrator must change the mode from mixed to native and ensure that Windows NT 4.0–based domain controllers are no longer required in the domain.

- In AD DS, the domain functional levels that correspond to mixed mode and native mode are the Windows 2000 mixed and Windows 2000 native functional levels, respectively. Raising the domain functional level from Windows 2000 mixed to Windows 2000 native is still based on the discretion of the administrator, and Active Directory does not verify that the domain has no Windows NT 4.0–based domain controllers in the domain.

Before a domain can be raised to other functional levels, all domain controllers in the domain must be running a corresponding or later version of Windows Server. For example, before a domain can be raised to the Windows Server 2008 domain functional level, all domain controllers must be running Windows Server 2008 or Windows Server 2008 R2. Before allowing the administrator to raise a domain to this functional level, AD DS verifies that all domain controllers in the domain are running an appropriate version of Windows Server.

For those organizations that are upgrading from Windows NT 4.0 directly to Windows Server 2003, another domain functional level called Windows Server 2003 interim accommodates only domain controllers that are running Windows NT 4.0 and Windows Server 2003 and it excludes Windows 2000–based domain controllers. For more information about this interim domain functional level, see "Functional Levels When Upgrading Windows NT 4.0 Domains" later in this section.

Just as in Windows 2000 where you could not revert from a native mode to a mixed mode domain, raising the domain functional level is not reversible, except for specific situations in Windows Server 2008 R2. For more information, see Active Directory Functional Level Dependencies and Rollback Options. The only changes that occur in an environment when raising the functional level is the availability of advanced Active Directory features.

The default domain functional level for a new Windows Server 2003 installation or upgrade is Windows 2000 mixed in all cases, except when you are upgrading a Windows 2000 domain that is in native mode. In this case, the default domain functional level is Windows 2000 native.

For new domain installations in Windows Server 2008 and Windows Server 2008 R2, the default domain functional level is automatically computed and set to the existing forest functional level or the value that is set for the forest functional level when you run Dcpromo.exe.

**Features Enabled by the Domain Functional Level**
Various features are enabled at different domain functional levels, and only certain operating systems are supported on domain controllers at each level. For more information, see Understanding AD DS Functional Levels (http://go.microsoft.com/fwlink/?LinkId=180702)

**Forest Functional Level**
Forest functional levels are new in Windows Server 2003. Features that become available at forest functional levels must be compatible with all domain controllers in the forest.

**Features Enabled at Forest Functional Levels**
Various features are enabled at different forest functional levels, and only certain operating systems are supported on domain controllers at each level. For more information, see Understanding AD DS Functional Levels (http://go.microsoft.com/fwlink/?LinkId=180702)

As a side effect of raising the forest functional level to Windows Server 2003, the following new attributes are replicated to the partial attribute set of the global catalog:

- **Ms-DS-Trust-Forest-Trust-Info**

- **Trust-Direction**

- **Trust-Attributes**

- **Trust-Type**

- **Trust-Partner**
- **Security Identifier**
- **Ms-DS-Entry-Time-To-Die**
- **MSMQ-Secured-Source**
- **MSMQ-Multicast-Address**
- **Print-Memory**
- **Print-Rate**
- **Print-Rate-Unit**
- **MS-DRM-Identity-Certificate**

When the forest functional level is Windows Server 2003 or Windows Server 2003 interim, the global catalog is present on Windows Server 2003 domain controllers. Therefore, replication traffic due to the addition of these attributes to the partial attribute set is not significant. This is because of the feature, new in Windows Server 2003, that allows partial synchronization of the global catalog.

**Functional Level for Windows Server 2008 and Windows Server 2008 R2 Deployments**
In a new deployment of AD DS that does not involve upgrading an existing domain, if the first domain controller in the forest is running Windows Server 2008 or Windows Server 2008 R2, you can choose the forest and domain functional levels during the AD DS installation of the first domain controller in the forest root domain. You can choose the domain functional level during the AD DS installation of the first domain controller for each additional domain in the forest. You can choose different functional level values for the forest and for each domain that you create within the forest, but the domain functional level can never be lower than the forest functional level.

If you do not specify a higher value when you create the forest root domain for Windows Server 2008, the default forest functional level is Windows 2000. If you do not specify a higher value when you create the forest root domain for Windows Server 2008 R2, the default forest functional level is Windows Server 2003.

If you do not specify a higher value when you create a domain in Windows Server 2008 or Windows Server 2008 R2, the default domain functional level is set to the current value of the forest functional level or, in the case of the forest root domain, the value that you choose for the forest functional level during the installation of AD DS.

**Functional Level for Windows Server 2003 Deployments**
In a new deployment of Windows Server Active Directory that does not involve upgrading an existing domain, the first domain controller is created by installing Active Directory on a server that is running Windows Server 2003 and it becomes the domain controller for the forest root domain. The forest functional level of the newly created forest is Windows 2000 and the domain functional level is Windows 2000 mixed. Immediately raising the domain level and then the forest level to Windows Server 2003 provides full Windows Server 2003 functionality with no further intervention. All domains created subsequently in the forest are created at the Windows Server 2003 functional level.

**Functional Level When Upgrading Windows NT 4.0 Domains**
Active Directory provides an intermediate functional level called Windows Server 2003 interim for user environments that currently have only Windows NT 4.0-based domain controllers and that have the following domain upgrade plans:

- Plan to upgrade to a Windows Server 2003 forest directly from Windows NT 4.0.
- Do not plan to install domain controllers running Windows 2000 at any time.

Moving to the Windows Server 2003 interim forest functional level is especially useful for large groups (greater than 5,000 members) in an existing deployment for which upgrading to Windows 2000 would require breaking those groups into smaller groups. Windows 2000 replication limits the size of Windows 2000 groups; Windows Server 2003 replication supports large groups (greater than 5,000 members) because of the link-valued replication feature, which is available only if the forest functional level is Windows Server 2003 interim or higher.

**Note**

- The Windows Server 2003 interim functional level does not support domain controllers that are running Windows 2000, Windows Server 2008, or Windows Server 2008 R2. For this reason, if domain controllers that run Windows 2000, Windows Server 2008, or Windows Server 2008 R2 are in your current deployment or there are plans to install them in the future, do not use the Windows Server 2003 interim functional level.

**Physical Structure for Active Directory Functional Levels**

Each functional level has requirements that are enforced by AD DS. AD DS includes an attribute that enables domain controllers to recognize the current functional level of any domain and of the forest. A numbering system identifies the different functional levels. The Windows Server 2003, Windows Server 2008, Windows Server 2008 R2 operating systems also use these level numbers as built-in indicators that enable domain controllers to identify the highest and lowest supported levels.

**Internal Representation of Functional Levels**

Internally, functional levels are represented as positive integers. The following table lists the domain and forest functional levels that are available in AD DS and their corresponding integer values.

**Active Directory Domain and Forest Functional Levels**

| Domain Functional Levels | Forest Functional Levels |
|---|---|
| 0 — Windows 2000 mixed | 0 — Windows 2000 |
| 0 — Windows 2000 native | 0 — Windows 2000 |
| 1 — Windows Server 2003 interim | 1 — Windows Server 2003 interim |
| 2 — Windows Server 2003 | 2 — Windows Server 2003 |
| 3 —Windows Server 2008 | 3 —Windows Server 2008 |
| 4 —Windows Server 2008 R2 | 4 —Windows Server 2008 R2 |

Both Windows 2000 mixed and Windows 2000 native domain functional levels are internally represented by the integer 0.

**Storage of Functional Levels**

In an AD DS forest, the value of the functional levels of domain controllers, domains, and forests are stored in an **msDSBehaviorVersion** attribute. This attribute is present on three different objects in the directory, each of which is authoritative for identifying the functional level of one of these three respective scopes (domain controller, domain, or forest). When enforcing domain and forest functional levels, Active Directory uses the value of **msDSBehaviorVersion** on the appropriate object to detect the current functional level.

**Note**

- The functional level of a domain controller cannot be raised. Its functional level is fixed by the operating system.

The following table summarizes the storage of functional levels in the **msDSBehaviorVersion** attribute on the three defining objects and directory partition locations for the three respective scopes.

**Storage of Functional Levels in msDSBehaviorVersionAttribute**

| Functional Level Scope | Object | Directory Partition Where Object Is Located |
|---|---|---|
| Domain controller | NTDS Settings object (class **nTDSDSA**) | Configuration |
| Domain | Domain object (class **domainDNS**) | Domain |
| Forest | Partitions container object (class **crossRefContainer**) | Configuration |

**Storage of Domain Controller Functional Levels**

Beginning with Windows Server 2003, the operating system has two built-in, fixed values that identify the functional levels of

AD DS with which it is compatible, as follows:

- A fixed value that indicates the highest functional level that is supported by the current product release. Windows Server 2003 operating systems have a value of 2, indicating that Windows Server 2003 is the highest functional level supported. Because Windows 2000 and Windows NT 4.0 do not recognize functional levels, a domain controller running one of these operating systems has an implied highest functional level value of 0.

- A fixed value that indicates the lowest functional level that is supported by the current product release. Windows Server 2003 operating systems have a value of 0, indicating that they support both Windows 2000 and Windows NT 4.0. Windows 2000 and earlier operating systems have an implied lowest functional level value of 0.

AD DS uses these values to prohibit introduction of domain controllers that are running incompatible operating systems into the domain or forest.

When AD DS is installed to create a domain controller, the highest fixed value that is present in the operating system is stored in the **msDSBehaviorVersion** attribute of the NTDS Settings object (class **nTDSDSA**) associated with the domain controller. This value indicates the functional level of the domain controller. The NTDS Settings object is stored in the configuration directory partition (cn=NTDS Settings,cn=*ServerName*,cn=servers,cn=sites,cn=configuration,dc=*ForestRootDomainName*). Because every domain controller holds a copy of the configuration directory partition, any domain controller can discover the functional level of any other domain controller in the forest.

Absence of this attribute on the NTDS Settings object indicates that the domain controller is running Windows 2000, and is treated as having a value of 0. Windows NT 4.0–based domain controllers do not have an NTDS Settings object.

**Storage of Domain Functional Levels**
The functional level of a domain is identified by the value in the **msDSBehaviorVersion** attribute on the domain object (class **domainDNS**) in the domain directory partition (dc=*DomainName*,dc=*ForestRootDomainName*). On the basis of this value, certain features are enabled that have an impact in the scope of a single domain only. Absence of this attribute on a domain object is equivalent to domain functional level 0.

**Storage of Forest Functional Levels**
The functional level of a forest is identified by the value in the **msDSBehaviorVersion** attribute on the Partitions container object (class **crossRefContainer**) in the configuration directory partition (cn=partitions,cn=configuration,dc=*ForestRootDomainName*). On the basis of this value, certain features are enabled that affect the entire forest. Absence of this attribute on the Partitions container is interpreted as forest level 0.

**Processes and Interactions with Active Directory Functional Levels**
Functional levels protect against incompatibility. Before raising a functional level, AD DS verifies that all domain controllers are running the correct version of the operating system. After raising the functional level, AD DS no longer allows the introduction of a domain controller that is running an incompatible version of Windows Server.

Forest and domain functional levels are restrictive for domain controllers only. Clients can interact with Active Directory regardless of the domain or forest functional level that is in effect. In a domain that has a functional level of Windows Server 2008 R2, domain controllers can still authenticate computers that are running earlier versions of Windows.

**Raising Domain Functional Levels**
The domain functional level can be raised by using Active Directory Domains and Trusts or Active Directory Users and Computers, which are Active Directory administrative tools that are available on each domain controller. The ability to raise the domain functional level depends on the operating systems that are running on domain controllers in the environment:

- If an environment has domain controllers running Windows NT 4.0 as well as domain controllers running Windows 2000 in the domain, Windows Server 2003–based domain controllers can be introduced, but the domain functionality is essentially that of a Windows 2000 mixed-mode domain. Domain controllers that run Windows Server 2008 or Windows Server 2008 R2 cannot be installed in a domain that has domain controllers running Windows NT 4.0.

  It is possible to raise the domain functional level directly to Windows Server 2003 from Windows 2000 mixed after all domain controllers in the domain are upgraded to Windows Server 2003.

- After all Windows NT 4.0–based domain controllers in an environment are upgraded to either Windows 2000 or Windows Server 2003, the domain functional level can be raised to Windows 2000 native, which provides functionality that is essentially that of a Windows 2000 native-mode domain.

- After all domain controllers in the domain are upgraded to Windows Server 2003, the domain functional level can be raised to Windows Server 2003, which provides all Windows Server 2003 domain-level features.

- After all domain controllers in the domain are upgraded to Windows Server 2008, the domain functional level can be raised to Windows Server 2008, which provides all Windows Server 2008 domain-level features.

- After all domain controllers in the domain are upgraded to Windows Server 2008 R2, the domain functional level can be raised to Windows Server 2008 R2, which provides all Windows Server 2008 R2 domain-level features.

**Note**

- Raising the domain functional level cannot be reversed, except for specific situations in Windows Server 2008 R2. In all other cases, after the domain functional level is raised, domain controllers that are not supported at that level can no longer be introduced. For more information, see Active Directory Functional Level Dependencies and Rollback Options.

The following requirements apply to raising all domain functional levels:

- Raising the domain functional level requires Domain Admins credentials.

- The domain functional level can be raised on only the primary domain controller (PDC) emulator operations master. AD DS administrative tools (Active Directory Domains and Trusts and Active Directory Users and Computers) automatically target the PDC emulator when the domain functional level is raised.

**Raising Forest Functional Levels**

When Windows Server 2003 is installed on the first domain controller in the forest, the forest functional level is set to Windows 2000. The forest retains this level until an administrator changes it. Raising the forest level to Windows Server 2003 has the following requirements:

- All domain controllers in the forest are running Windows Server 2003.

- All domains in the forest have either the Windows 2000 native or the Windows Server 2003 functional level.

Therefore, if any domains are operating at the Windows 2000 mixed domain functional level, even if all domain controllers are running Windows Server 2003, AD DS does not allow the forest functional level to be raised to Windows Server 2003.

If all domain controllers in the forest are running Windows Server 2003, but some or all domains in the forest are still operating at the Windows 2000 native domain functional level, AD DS automatically raises the functional level of those domains to Windows Server 2003 when the forest functional level is raised to Windows Server 2003. This same behavior occurs at when the forest functional level is raised to higher values. In other words, if you raise the forest functional level to Windows Server 2008 R2, if all domains have domain controllers running Windows Server 2008 R2, they are automatically raised to the Windows Server 2008 R2 domain functional level.

Active Directory Domains and Trusts can be used to raise the forest functional level.

**Note**

- Raising the forest functional level cannot be reversed, except for specific situations in Windows Server 2008 R2. In all other cases, after the forest functional level is raised, domain controllers that run earlier versions of Windows Server can no longer be introduced into the forest. For more information, see Active Directory Functional Level Dependencies and Rollback Options.

The following requirements apply to raising all forest functional levels:

- Raising the forest functional level requires Enterprise Admins credentials.

- The forest functional level can be raised on only the schema operations master. Active Directory Domains and Trusts automatically targets the schema operations master when the forest functional level is raised.

**Enforcing Functional Levels**
To ensure consistent functionality across the domain controllers in a domain or forest, AD DS checks for functional levels, as follows:

- At domain controller creation.
- After a directory restore.
- At domain controller startup.
- When raising functional levels.

The Active Directory Domain Services Installation Wizard, the application that installs AD DS when a new domain controller is created, ensures that a domain controller is not created in a domain or forest that cannot support it. The wizard verifies whether the current domain or forest functional level falls within the highest and lowest fixed values for the operating system on the new domain controller. If the values are not compatible, the AD DS installation fails. For example, if the domain has the functional level Windows Server 2003 (domain level 2), an attempt to install AD DS on a Windows 2000–based server to create an additional domain controller fails because the highest and lowest fixed value supported by Windows 2000 is 0. Similarly, if the forest has a functional level of Windows Server 2003 (forest level 2), an attempt to install AD DS to create a new domain on a Windows 2000–based server fails.

AD DS likewise prevents restoring a domain controller into a domain or forest that has an incompatible functional level.

When a domain controller starts, an additional test is performed to verify whether the highest fixed value of the operating system matches the value of the **msDSBehaviorVersion** attribute on the NTDS Settings object of the domain controller.

**Checks for Raising Domain and Forest Functional Levels**
AD DS determines whether the functional level can be raised, as follows:

- The ability to raise the domain functional level depends on the functional levels of all domain controllers in the domain. In general, the functional level of the domain can be no higher than the lowest functional level of any domain controller in the domain.
- The ability to raise the forest functional level depends on the functional level of all domain controllers in the forest. In general, the forest level can be no higher than the lowest functional level of any domain controller in the forest.

### Note

- The ability to raise domain and forest functional levels is provided in the administrative tools Active Directory Users and Computers (raise domain functional level) and Active Directory Domains and Trusts (raise domain and forest functional levels).

**Verifying the Minimum Required Functional Level of Domain Controllers**
When an administrator attempts to raise the functional level of the forest or domain, AD DS checks the value of **msDSBehaviorVersion** on the NTDS Settings object of every domain controller within the scope (forest or domain) to determine if that value is equal to or greater than the desired functional level. If it is not, AD DS prevents raising the functional level.

For example, if the request is received to raise the domain level to 2 (Windows Server 2003), AD DS checks that the value of **msDSBehaviorVersion** on the NTDS Settings object on all domain controllers in the domain is 2 or higher before making the change. If all domain controllers are running Windows Server 2003, the value of **msDSBehaviorVersion** on the NTDS Settings object of each domain controller is 2, and thus AD DS allows raising the functional level of the domain to Windows Server 2003.

If any domain controller is running Windows 2000, the fact that **msDSBehaviorVersion** attribute is missing on the NTDS Settings object indicates Windows 2000 and an implied value of 0, and AD DS will prevent raising the domain functional level to Windows Server 2003. However, Windows NT 4.0–based domain controllers do not have an NTDS Settings object, so AD DS cannot check these computers directly for functional level. For this reason, AD DS performs an additional check to rule out the existence of Windows NT 4.0–based domain controllers.

**Ruling out Windows NT 4.0–Based Domain Controllers When Raising the Forest Level to Windows Server 2003**

When a member of the Enterprise Admins group attempts to raise the forest functional level to Windows Server 2003 (level 2), AD DS checks for the absence of Windows NT 4.0–based domain controllers by checking the **ntMixedDomain** attribute of the domain object. The **ntMixedDomain** attribute identifies a Windows 2000 domain as being in mixed mode or native mode.

The **ntMixedDomain** attribute on the domain object indicates the status of mixed or native domain mode as follows:

- **ntMixedDomain** value of 1 indicates mixed mode (Windows NT 4.0–based domain controllers can be present in the domain).
- **ntMixedDomain** value of 0 indicates native mode (no Windows NT 4.0–based domain controllers can be present in the domain).

To rule out the existence of Windows NT 4.0–based domain controllers when raising the forest functional level to Windows Server 2003 (level 2), AD DS verifies that the **ntMixedDomain** attribute has a value of 0 for every domain in the forest.

**Ruling out Windows NT 4.0 Domain Controllers When Raising the Domain Level to Windows Server 2003**

Unlike the behavior when raising the forest functional level, AD DS does not check for the absence of Windows NT 4.0–based domain controllers at the time an administrator raises the domain functional level. Just as in Windows 2000, a domain administrator is responsible for ensuring that no Windows NT 4.0–based domain controllers are running in the domain before raising the domain functional level from Windows 2000 mixed to Windows 2000 native or Windows Server 2003.

**Note**

- If an administrator changes the mode of a Windows 2000 domain from mixed to native mode or raises the domain functional level from Windows 2000 mixed to Windows 2000 native (or Windows Server 2003) when Windows NT 4.0–based domain controllers are present in the domain, the remaining Windows NT 4.0–based domain controllers no longer participate in the Active Directory forest. Therefore, the domain administrator must be absolutely sure that no Windows NT 4.0–based domain controllers are operating in the domain before raising the domain functional level to Windows 2000 native or Windows Server 2003.

When the domain functional level is raised to Windows Server 2003, AD DS not only raises the domain functional level to 2, but also changes the **ntMixedDomain** value from 1 to 0. When the domain functional level is raised to Windows 2000 native, AD DS only changes the **ntMixedDomain** value from 1 to 0.

**Checks for Raising the Functional Level to Windows Server 2003 Interim (Level 1)**

When attempting to raise the forest functional level to Windows Server 2003 interim, AD DS verifies that all domain controllers in the forest are at level 1 or higher (by checking the **msDSBehaviorVersion** attribute on the NTDS Settings object for each domain controller in the forest, to ensure that it is at level 1 or higher). However, it does not verify that all domains have a Windows 2000 native functional level (the **ntMixedDomain** attribute value of the domain object is 0).

The absence of this check allows Windows NT 4.0–based domain controllers to coexist with Windows Server 2003–based domain controllers, but it precludes future introduction of Windows 2000–based domain controllers into the domain or forest. This is because the highest and lowest functional level supported by Windows 2000 is 0 (which is less than 1), and when you attempt to install AD DS on a Windows 2000 server, the Active Directory Domain Services Installation Wizard will determine that the forest is at level 1 and it will prevent the installation.

When the forest functional level is raised to Windows Server 2003 interim, AD DS raises the forest functional level to 1. Consequently, every domain also raises its functional level (the domain functional level) to 1 (and therefore every domain is also at Windows Server 2003 interim level), but leaves the **ntMixedDomain** value at 1, thus allowing Windows NT 4.0-based domain controllers to coexist with Windows Server 2003–based domain controllers.

There is no administrative user interface (UI) for raising the forest and domain functional levels to Windows Server 2003 interim. An LDAP application, such as ADSI Edit or Ldp in Windows Support Tools, can be used, or a script can be used. In either case, the value of the **msDSBehaviorVersion** attribute should be modified to 1.

# Active Directory Functional Levels Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Tools for Managing Active Directory Functional Levels
- Network Ports Used to Raise Active Directory Functional Levels
- Related Information

| Note |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

This section contains information about the tools that are associated with Active Directory functional levels.

**Tools for Managing Active Directory Functional Levels**
The following tools are associated with Active Directory functional levels.

**Domain.msc: Active Directory Domains and Trusts**

**Category**
An Active Directory Administrative Tools Microsoft Management Console (MMC) snap-in that is automatically installed on all domain controllers.

**Version compatibility**
This tool is compatible with domain controllers running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition. This tool can also be run on computers running Windows XP Professional. Updated versions of this tool can also be run on later versions of Windows. For more information, see How to Administer Microsoft Windows Client and Server Computers Locally and Remotely (http://go.microsoft.com/fwlink/?LinkID=177813).

Active Directory Domains and Trusts provides a graphical user interface (GUI) that can be used to manage Active Directory forests, domains, and trusts. Specific to functional levels, this tool can be used for the following:

- To view the current domain functional level by viewing the properties of the domain object.
- To view the current forest functional level by viewing the properties of the **Active Directory Domains and Trusts** node.
- To raise a domain functional level.
- To raise a forest functional level.

**Dsa.msc: Active Directory Users and Computers**

**Category**
An Active Directory Administrative Tools MMC snap-in that is automatically installed on all domain controllers.

**Version compatibility**
This tool is compatible with domain controllers running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition. This tool can also be run on computers running Windows XP Professional. Updated versions of this tool can also be run on later versions of Windows. For more information, see How to Administer Microsoft Windows Client and Server Computers Locally and Remotely (http://go.microsoft.com/fwlink/?

LinkID=177813).

Active Directory Users and Computers provides a GUI that can be used to manage users and computers in Active Directory domains. Specific to functional levels, this tool can be used for the following:

- To view the current domain functional level by viewing the properties of the domain object.
- To raise a domain functional level.

In addition, LDAP Query can be used in this tool for the following:

- To identify domain controllers running Windows NT 4.0.
- To connect to a domain.

**Adsiedit.exe: ADSI Edit**

**Category**
This tool is included with Support Tools for Windows Server 2003, and it is automatically installed on domain controllers that run Windows Server 2008 or Windows Server 2008 R2.

**Version Compatibility**

| Can be run from | Can be run against |
|---|---|
| Computers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server |

Updated versions of this tool can also be run on later versions of Windows. For more information, see How to Administer Microsoft Windows Client and Server Computers Locally and Remotely (http://go.microsoft.com/fwlink/?LinkID=177813).

ADSI Edit is an MMC tool that uses Active Directory Service Interfaces (ADSI), which ultimately uses the Lightweight Directory Access Protocol (LDAP) protocol. This tool can be used to view and modify directory objects in the Active Directory database. Specific to functional levels, this tool can be used to edit the value of the **msDS-Behavior-Version** attribute of the Partitions container to raise the forest functional level to Windows Server 2003 interim, which cannot be done by using the Active Directory MMC administrative tools.

The **msDS-Behavior-Version** attribute is set in the ADSI Edit console on the Partitions container object (class **crossRefContainer**) in the configuration directory partition (cn=partitions,cn=configuration,dc=*ForestRootDomainName*). Raising the forest functional level to Windows Server 2003 interim requires changing the default value of the attribute from 0 to a value of 1.

To find more information about ADSI Edit, see “Support Tools Help” in Tools and Settings Collection.

**Ldp.exe: Ldp**

**Category**
This tool is included with Support Tools for Windows Server 2003, and it is automatically installed on domain controllers that run Windows Server 2008 or Windows Server 2008 R2.

**Version Compatibility**

| Can be run from | Can be run against |
|---|---|
| Computers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server |

Updated versions of this tool can also be run on later versions of Windows. For more information, see How to Administer Microsoft Windows Client and Server Computers Locally and Remotely (http://go.microsoft.com/fwlink/?LinkID=177813).

Ldp is a GUI tool that can be used to perform LDAP operations (such as connect, bind, search, modify, add, or delete) against any LDAP-compatible directory, such as AD DS.

Specific to functional levels, Ldp can be used as an alternative to ADSI Edit to modify the value of **msDS-Behavior-Version** attribute of the Partitions container object (class **crossRefContainer**) in the configuration directory partition (cn=partitions,cn=configuration,dc=*ForestRootDomainName*) and raise the forest functional level to Windows Server 2003 interim, which cannot be done by using the Active Directory administrative MMC tools.

The **msDS-Behavior-Version** attribute is set in Ldp by using the **Replace** operation in the **Modify** dialog box to change the default value of the attribute from 0 to a value of 1, which raises the forest functional level to Windows Server 2003 interim.

To find more information about Ldp, see "Support Tools Help" in Tools and Settings Collection.

#### Dcpromo.exe: Active Directory Domain Services Installation Wizard

**Category**
A wizard that is included with Windows Server. It is available from the command line or from the Configure Your Server Wizard on any computer running Windows Server 2003 or from Server Manager on servers that run Windows Server 2008 or Windows Server 2008 R2.

**Version compatibility**
This tool is compatible with computers running all editions of Windows Server 2003, Windows Server 2008, and Windows Server 2008 R2, except Web Edition.

The Active Directory Domain Services Installation Wizard provides a GUI for setting up a domain controller by installing AD DS and, optionally, DNS. Specific to functional levels, the wizard can be used on a Windows NT 4.0 PDC when you are upgrading it to Windows Server 2003 and forming a new forest to raise the forest functional level to Windows Server 2003 interim, if appropriate.

**Network Ports Used to Raise Active Directory Functional Levels**
The following table shows the network ports that are used to raise functional levels.

### Port Assignments for Raising Active Directory Functional Levels

| Service Name | TCP |
|---|---|
| LDAP | 389 |
| LDAP SSL | 636 |

In addition, replication to all domain controllers requires the ports that are used for replication. For more information about the ports that are used for replication, see Active Directory Replication Tools and Settings in this collection.

# Active Directory Installation Wizard Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Active Directory Installation Wizard Technical Reference**
The Active Directory Installation Wizard is used to install the Active Directory directory service on a computer running Microsoft Windows 2000 Server and Microsoft Windows Server 2003. The wizard provides a user interface for gathering information about your computing environment. It also checks prerequisites for installing Active Directory, such as available disk space and operating system version, to ensure that the server is capable of becoming a domain controller. If all prerequisites are met, the Active Directory Installation Wizard uses the information gathered to configure Active Directory.

This subject explains what the Active Directory Installation Wizard is and how it works for Windows Server 2003 and Windows 2000 Server. For information about using the Active Directory Domain Services Installation Wizard in Windows Server 2008 R2 and Windows Server 2008, see AD DS Installation and Removal Step-by-Step Guide (http://go.microsoft.com/fwlink/?LinkID=139657).

**In this subject**

- What Is the Active Directory Installation Wizard?
- How the Active Directory Installation Wizard Works

# What Is the Active Directory Installation Wizard?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**What Is the Active Directory Installation Wizard?**

**In this section**

- Active Directory Installation Wizard Scenarios
- Active Directory Installation Wizard Dependencies
- Related Information

The Active Directory Installation Wizard is used to install and configure Active Directory in Windows Server 2003 and Windows 2000 Server, and to remove Active Directory when a domain controller is decommissioned. Understanding the processes that occur when the Active Directory Installation Wizard runs can help you recognize and troubleshoot issues that might arise during the installation or removal of a domain controller.

| **Note** |
| --- |
| This topic explains what the Active Directory Installation Wizard is for Windows Server 2003 and Windows 2000 Server. For information about using the Active Directory Domain Services Installation Wizard in Windows Server 2008 R2 and Windows Server 2008, see AD DS Installation and Removal Step-by-Step Guide (http://go.microsoft.com/fwlink/?LinkID=139657). |

Active Directory is not installed by default on a computer running Windows Server 2003. When you install Windows Server 2003, the computer assumes the role of a standalone server or a member server that is a part of a domain. For the computer to become a domain controller, you must use the Active Directory Installation Wizard to install and configure Active Directory.

**Active Directory Installation Wizard Scenarios**

You can create two types of domain controllers by using the Active Directory Installation Wizard:

- Domain controller for a new domain
- Additional domain controller for an existing domain

When you create a domain controller for a new domain, the domain can be one of the following types:

- Domain in a new forest.

  Select this domain type if you are creating the first domain in your organization or if you want the new domain to be independent of your existing forests. This first domain is the forest root domain.

- Child domain in an existing domain tree.

  Select this domain type if you want the new domain to be a child of an existing domain.

- Additional domain tree in an existing forest.

  Select this domain type if you want to create a domain tree that is separate from any existing domain trees.

  For more information about the Active Directory logical structure, see "Domains and Forests Technical Reference."

**Active Directory Installation Wizard Dependencies**

Active Directory installation has the following dependencies.

**Network Configuration**
Unstable or problematic network configurations are either recognized during the installation of Active Directory and prohibit you from continuing, or they create complications in your environment after the installation is complete. Before installing Active Directory, ensure that your network is properly configured.

**DNS Configuration**
Before installing Active Directory, plan your Domain Name System (DNS) namespace to support Active Directory and determine which servers will host the DNS zones. Consider the following DNS configuration options based on your environment:

1. Allow the Active Directory Installation Wizard to configure the DNS server.

   Consider this option if you do not have DNS configured in your environment or you have a DNS server hosted by an Internet Service Provider (ISP). During the Active Directory installation, the wizard installs and configures DNS.

   If you do not have an existing DNS configuration, the user interface portion of the Active Directory Installation Wizard gives you the opportunity to either configure the DNS client or install the DNS Server service. If the server on which Active Directory is being installed is pointing to an existing DNS server that is hosted by an ISP, that DNS server is added as a forwarder.

2. Point to an existing DNS server.

   Configure the server on which you are installing Active Directory to point to an existing DNS server in your environment before running the Active Directory Installation Wizard.

3. Configure DNS yourself.

   Only configure DNS yourself if you have planned your DNS namespace to support Active Directory and understand the process for configuring DNS. If you choose to configure DNS, use the following guidelines:

   - Configure the server with a static IP address.
   - Configure the DNS server settings on the TCP/IP properties page to use the local computer as the preferred DNS server. All DNS server addresses should belong to DNS servers in the forest. Do not configure DNS servers in your forest to point to ISP DNS servers. To view the current IP configuration and verify that the local computer is pointing to itself for its preferred DNS server, type **ipconfig /all** at the command prompt.
   - Configure the DNS Forward Lookup zone to accept dynamic updates. If dynamic updates are not allowed, all DNS record registration must be completed manually.
   - Configure the DNS server to forward DNS requests to the appropriate ISP or corporate DNS servers to ensure that names outside of the DNS namespace can be resolved.
   - If the **Enable Forwarders** check box is unavailable, the DNS server is attempting to host a root zone, identified by a zone named only with a period, or dot (.). This root zone is created by default only on Windows 2000–based DNS servers. It is not created by default on DNS servers that are running Windows Server 2003. You must delete the root zone to enable the DNS server to forward DNS requests.

**Disk Space Recommendations**
At minimum, a domain controller requires available free disk space for the Active Directory database, Active Directory log files, SYSVOL, and the operating system. Use the following guidelines to determine how much disk space to allot for your Active Directory installation:

- On the drive that will contain the Active Directory database, Ntds.dit, provide 0.4 gigabytes (GB) of storage for each 1,000 users. For example, for a forest with two domains (domain A, domain B), with 10,000 and 5,000 users respectively, provide a minimum of 4 GB of disk space for each domain controller that hosts domain A and a minimum of 2 GB of disk space for each domain controller that hosts domain B.

- On the drive containing the Active Directory log files, provide at least 500 MB of available space.
- On the drive containing the SYSVOL shared folder, provide at least 500 MB of available space.
- On the drive containing the Windows Server 2003 operating system files, to run setup, provide at least 1.25 GB to 2 GB of available space.

To prevent single disk failures, many organizations use a redundant array of independent disks (RAID). For domain controllers that are accessed by fewer than 1,000 users, you can locate all four components on a single RAID 1 array. For domain controllers that are accessed by more than 1,000 users, place the log files on one RAID array and keep the SYSVOL shared folder and the database together on a separate RAID array.

The above figures are recommendations only and should be tested in a lab environment before deploying Active Directory and monitored closely in your production environment. It is always a best practice to allow for future growth of objects in Active Directory. For more information about object growth and database capacity in Active Directory, see "Data Store Technical Reference."

**Client Operations**
Windows Server 2003–based domain controllers implement security settings that require clients and other servers to communicate with those domain controllers in a more secure way. Windows 95–based clients and clients running Windows NT 4.0 with service pack 3 or earlier cannot meet the logon or resource access requirements of a Windows Server 2003–based domain controller. Prior to installing Active Directory, take an inventory of your client operating systems and take the necessary actions to ensure continued access to domain controllers in your environment.

For more information about new security settings that are implemented by domain controllers running Windows Server 2003, see "How the Active Directory Installation Wizard Works."

**Administrative Rights**
You must be an Administrator on the local computer to run the Active Directory Installation Wizard if you are creating the first domain controller in a forest. If you are creating a child domain or a new tree domain in an existing forest, you must provide the credentials of a member of the Enterprise Admins group.

**Availability of the Domain Naming Master**
If you are creating an additional domain in an existing forest or removing a domain from a forest, the Active Directory Installation Wizard must access the domain naming operations master or it generates an error. Verify that the domain controller holding the role of domain naming master for the forest is online. If the domain naming master has recently been offline, ensure that inbound replication of the configuration partition has completed since the computer was restarted.

**Forest and Domain Preparation**
If you are upgrading an existing Windows 2000 domain to Windows Server 2003 or adding a Windows Server 2003–based domain controller to an existing Windows 2000 domain, you must prepare the forest and each domain in the forest by using the Active Directory Preparation Tool (ADPrep.exe). The tool performs the following tasks:

- Tightens security on resources that use the Everyone group to grant access by:
    - Improving default security descriptors.
    - Changing group memberships; for example, the Anonymous Logon group is no longer a member of the Everyone group.
    - Improving security settings by adding access control entries (ACE) to the following pre-existing, non-schema objects:

      CN=AIA,CN=Public Key Services,CN=Services,CN=Configuration,DC=X container

      CN=CDP,CN=Public Key Services,CN=Services,CN=Configuration,DC=X container

      CN=Configuration,DC=*ForestRootDomain* container
- Creates new objects used by individual applications.

- Creates new containers that can be used to verify that the preparation was successful.
- Updates the Active Directory schema.

  The Active Directory Preparation tool merges your current schema with new schema information provided by the tool. Previous schema modifications in your environment are not affected by this operation.

Adprep includes the following two switches: **Adprep /forestprep** to prepare the forest, and **Adprep /domainprep** to prepare each domain.

Run **Adprep /forestprep** on the domain controller holding the schema operations master role for the forest before you install Active Directory on a Windows Server 2003-based member server or standalone server to create an additional domain controller in an existing forest during Active Directory installation. After **Adprep /forestprep** runs successfully, you can run **Adprep /domainprep**. However, before running **Adprep /domainprep** in an existing domain, changes made to the forest after running **Adprep /forestprep** must have replicated to the infrastructure operations master in that domain.

You must successfully run **Adprep /domainprep** in each domain before you join a Windows Server 2003–based member server or standalone server to a domain as an additional domain controller.

**Adprep /domainprep** must run successfully in a domain before you can upgrade existing Windows 2000–based domain controllers to Windows Server 2003.

**Domain Controller Configuration**

Before installing Active Directory, consider the status of the computer that you will configure as a domain controller. If the computer is running Windows NT 4.0 or Windows 2000, determine whether or not the computer can be upgraded to Windows Server 2003. If you are upgrading, determine if your environment should be prepared for the upgrade and whether it will be necessary to complete the Active Directory Installation Wizard. These decision points are outlined in the following table.

**Decision Points for Domain Controller Configuration**

| Operating System | Upgradeable to Windows Server 2003? | Use the Active Directory Preparation Tool? | Install Active Directory? |
|---|---|---|---|
| Windows NT 4.0 Workstation | NO | N/A | N/A |
| Windows NT 4.0 Member Server | YES | It is not necessary to run ADPrep. | Only if the computer is to become a domain controller. |
| Windows NT 4.0<br><br>PDC or BDC | YES | It is not necessary to run ADPrep. | YES - Active Directory must be installed. |
| Windows 2000 Professional | NO | N/A | N/A |
| Windows 2000 Member Server (SP4) | YES | YES - The upgrade cannot proceed until you run ADPrep. | Only if the computer is to become a domain controller. |
| Windows 2000 domain controller | YES | YES - The upgrade cannot proceed until you run ADPrep. | NO - Active Directory is installed. |

**Windows Time Service Configuration**

After installing Active Directory on the first domain controller in a new forest, it is important to correctly configure the Windows Time service. The Windows Time service provides time synchronization to peers and clients, ensuring that time is consistent throughout an enterprise. If the Windows Time service is not properly configured, Kerberos authentication will fail, adversely affecting Active Directory replication, user logon, and shared folder access.

By default, the first domain controller deployed holds the PDC emulator operations master role, and should be set to synchronize time with a valid Network Time Protocol (NTP) source. If no source is configured, the service will log a message to the event log, and use the local clock when providing time to clients. Although internet NTP sources are valid for this configuration, we recommend that a dedicated hardware device, such as a GPS, or radio clock be employed in the interest of security.

# How the Active Directory Installation Wizard Works

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**How the Active Directory Installation Wizard Works**

**In this section**

- Active Directory Installation Wizard Architecture
- Active Directory Installation Methods
- Active Directory Installation Wizard Prerequisites
- Active Directory Installation Wizard User Interface
- Active Directory Installation Wizard Directory Configuration Process
- Active Directory Removal
- Related Information

This section details the architecture of the Active Directory Installation Wizard for Windows Server 2003 and Windows 2000 Server, methods for invoking the wizard, and the directory configuration process. This section also details the removal of Active Directory from a domain controller.

| **Note** |
| --- |
| This topic explains how the Active Directory Installation Wizard works for Windows Server 2003 and Windows 2000 Server. For information about using the Active Directory Domain Services Installation Wizard in Windows Server 2008 R2 and Windows Server 2008, see the AD DS Installation and Removal Step-by-Step Guide (http://go.microsoft.com/fwlink/?LinkID=139657). |

You can use the Active Directory Installation Wizard to install Active Directory on a computer, making that computer a domain controller. Before installing Active Directory to create the first domain controller in a forest, ensure that your network is online and functioning properly and that you have designed your Domain Name System (DNS) namespace and have a plan for installing and configuring DNS.

**Active Directory Installation Wizard Architecture**

The Active Directory Installation Wizard (Dcpromo.exe) architecture verifies that certain prerequisites are met prior to an Active Directory installation, gathers information specific to your operating environment, and configures Active Directory. It works differently depending on the installation scenario you choose and the installation method you are using. The following figures illustrate how the Active Directory Installation Wizard works when creating the first domain controller in a forest, an additional domain controller in an existing domain, and the installation process when installing Active Directory from media, which is a new feature in Windows Server 2003 Active Directory.

### Active Directory Installation on the First Domain Controller in a Forest

When you install Active Directory on a computer that is the first domain controller in a forest, the Active Directory Installation Wizard checks prerequisites and gathers information from you through the wizard user interface. It invokes the Active Directory installer (Ntdsetup.dll) through a remote procedure call (RPC) interface, exposed by the Lsass.exe security subsystem, to install the first domain controller in the forest. As the installer works, directory information is written to the Ntds.dit file by Esent.dll. If you select the option to install DNS, the Active Directory Installation Wizard contacts the DNS Server service, which in turn accesses Sysocmgr.exe and Dns.exe, the components that install and start DNS. After the Active Directory installation is complete and the computer restarts, the DNS Server service configures the Active Directory–integrated DNS zones and sends the DNS configuration information back to Active Directory.

**Active Directory Installation on an Additional Domain Controller in an Existing Domain**

When you install an additional domain controller in an existing forest, the Active Directory Installation Wizard checks prerequisites, gathers information from you through the wizard user interface, and invokes the Active Directory installer (Ntdsetup.dll) through an RPC interface exposed by the Lsass.exe security subsystem. The installer contacts an existing domain controller. The existing domain controller replicates all domain, forest, and directory partition information back to the new domain controller. As the installer works, directory information is written to the Ntds.dit file by Esent.dll. If you select the option

to install DNS, the Active Directory Installation Wizard contacts the DNS Server service, which in turn accesses Sysocmgr.exe and Dns.exe, the components that install and start DNS. After the Active Directory installation is complete and the computer restarts, the DNS Server service configures the Active Directory–integrated DNS zones and sends the DNS configuration information back to Active Directory.

**Active Directory Installation from Media**

When you install Active Directory on an additional domain controller from backup media, the Active Directory Installation Wizard checks prerequisites, gathers information from you through the wizard user interface, and invokes the Active Directory installer (Ntdsetup.dll) through an RPC interface exposed by the Lsass.exe security subsystem. As the installer works, directory information is written to the Ntds.dit file by Esent.dll. When you install from backup media, all domain information is backed up from a domain controller in the same domain and restored to the local computer. The installer accesses the restored files to configure the directory service. A domain controller is contacted over the network to replicate any changes that have been made since the backup media was created. The result is less information being sent over the network and a faster Active Directory installation. If you select the option to install DNS, the Active Directory Installation Wizard contacts the DNS Server service, which in turn accesses Sysocmgr.exe and Dns.exe, the components that install and start DNS. After the Active Directory installation is complete and the computer restarts, the DNS Server service configures the Active Directory–integrated DNS zones and sends the DNS configuration information back to Active Directory.

The architectural components in each of the preceding diagrams are explained in the following table.

**Active Directory Installation Wizard Architectural Components**

| Component | Description |
|---|---|
| Dcpromo.exe | The Active Directory Installation Wizard. |
| Lsass.exe | The LSA security subsystem, which provides services to both the kernel mode and the user mode for validating access to objects, checking user privileges, and generating audit messages. |
| Ntdsetup.dll | The Active Directory installer. |
| Esent.dll | Extensible storage engine (ESE). Communicates directly with individual records in the directory data store on the basis of the object's relative distinguished name attribute. |
| Ntdsa.dll | The directory service module that supports the Windows Server 2003 replication protocol and Lightweight Directory Access Protocol (LDAP), and manages partitions of data. |

| | |
|---|---|
| Ntds.dit | Directory database or data store. Requires NTFS formatting and is manipulated only by the ESE database engine. Encryption of the Ntds.dit file or related log files, their parent folders, or storage drive is not recommended and not supported. |
| Schema.ini | Contains the information necessary for creating the default directory objects and the default security for the Ntds.dit, as well as the Active Directory display specifiers. |
| Dns.exe | The executable from which the DNS Server service is run. |
| Sysocmgr.exe | The System Optional Component Installation Manager interprets INF files and installs optional components such as the DNS Server service. |

**Active Directory Installation Methods**
You can install Active Directory using any of the following four methods:

- Install from the command line
- Install from the Configure Your Server Wizard
- Install unattended by using an answer file
- Install from media

**Installing from the Command Line**
You can initiate an Active Directory installation from the command line any time after Windows Server 2003 has been installed. To install Active Directory by using the command line, in the Run dialog box, type **dcpromo** and click **OK**.

**Installing from the Configure Your Server Wizard**
You can install Active Directory at any time by using the Configure Your Server Wizard. The Manage Your Server dialog box automatically appears when you restart the server after installing Windows Server 2003. To invoke the Configure Your Server Wizard, select **Add or remove a role**. Select the **Domain Controller (Active Directory)** role in the Configure Your Server Wizard, and then click **Next**. The Active Directory Installation Wizard starts.

**Installing Unattended by Using an Answer File**
You can run the Active Directory Installation Wizard without having to be present to answer the questions by using an answer file. An answer file is a text file that you populate with the parameters that the wizard needs to install Active Directory. You can use an answer file to install Windows Server 2003 and include the options necessary to subsequently install Active Directory. Alternatively, you can create an answer file that contains only the options necessary for installing Active Directory. These parameters include the domain controller type (additional domain controller for an existing domain or a new domain controller for a new domain), the configuration of the domain that is being created (new forest, new tree root, or new child) and Active Directory forest and domain functional levels.

The answer file options for installing Active Directory are in the DCInstall section of the Unattend.txt file. You can find instructions for creating an answer file for an Active Directory installation in the Deploy.cab file in the Support\Tools folder on the Windows Server 2003 product CD. Inside the Deploy.cab file, open Ref.chm to access the Unattend.txt file. In the left pane, expand **Unattend.txt**, and click **DCInstall**. In Windows 98, Windows 2000, and Windows Server 2003, use Windows Explorer to extract this document. In Windows 95 and earlier, or from MS-DOS, use the **Extract** command to open the file. You can rename the Unattend.txt file and save it in any location. The Unattend.txt file also contains sample answer files. After creating the answer file, append the **/answer** switch to the **dcpromo** command when installing Active Directory from the command line.

You can run this answer file after Windows Server 2003 setup is complete and after you have logged on to the system.

**Installing from Media**
When you install from media, you can pre-populate Active Directory with system state backup data from an existing Windows Server 2003–based domain controller that belongs to the same domain in which this server will become an additional domain controller. This backup can be stored on a local CD, DVD, or hard disk partition. Then, the system state backup must be restored locally on the server you are installing Active Directory on. When the data is restored, proceed with the Active Directory installation.

To install Active Directory from media, append the **/adv** switch to the **dcpromo** command when installing from the command line to enable install from media options in the Active Directory Installation Wizard.

When you select the option to copy domain information from backup files, you must identify the location of the files. If the domain controller from which you restore the system state data is a global catalog server, you have the option make this new domain controller a global catalog server. Once you have selected an option, the wizard proceeds with the installation.

The install from media feature in Windows Server 2003 reduces the time required to install directory information by reducing the amount of data that is replicated over the network. Installing from media is most beneficial in environments with very large domains or for installing new domain controllers that are connected by a slow network link. If the computer on which Active Directory is being installed is located in close proximity to another domain controller and the network connections are optimal, installing from media will only be slightly faster than copying the information over the network.

When you install Active Directory on Windows 2000 Server, the computer has to populate its entire directory service with directory information replicated from another domain controller, which requires time for the replication to occur across the network.

**Active Directory Installation Wizard Prerequisites**
The Active Directory Installation Wizard confirms several configuration and security parameters before it begins collecting information from you. The following prerequisites must be met before an Active Directory installation proceeds:

- An installation or removal operation of Active Directory must not already be in progress.
- Command line parameters must be correct if you are installing from media or using an answer file.
- You must be logged on to the local computer as a member of the Administrators group. If the credentials provided at logon are insufficient, you cannot continue.
- Certificate Services must not be installed on the computer. Changing the computer name or domain membership of a certification authority (CA) invalidates the certificates that are issued from that CA. Uninstall Certificate Services and reinstall after the Active Directory installation is complete.
- The computer must be running in normal mode. If the computer is running in safe mode, an error message advises you to restart in normal mode.
- If you have previously removed Active Directory from the computer, and you are attempting a new Active Directory installation, you must restart the computer before the new installation proceeds.
- The computer must be running Windows 2000 Server, Windows Server 2003 Standard Server, Windows Server 2003 Enterprise Server, or Windows Server 2003 Datacenter Server.
- At least one logical disk drive must be formatted with the NTFS file system. You can only install the SYSVOL shared folder on a drive that is formatted with NTFS and we also recommend installing the Active Directory database on an NTFS formatted drive.
- There must be sufficient free disk space on the computer. The Active Directory Installation Wizard requires at least 20 MB of free disk space on the computer or it does not proceed. For more information about the disk space requirements for installing Active Directory, see "What Is the Active Directory Installation Wizard?."
- If the computer's name has been changed, you must restart it after the name change for the wizard to proceed. The wizard also checks to see that the computer name conforms to DNS naming requirements.
- If Terminal Server is running on the computer, a warning indicates that installing Active Directory on a computer running Terminal Server changes the local security policy, allowing only administrators to log on to the computer. You can cancel the wizard and remove Terminal Server.

After all installation prerequisites are met, the Active Directory Installation Wizard continues with the user interface portion of the installation process.

**Active Directory Installation Wizard User Interface**
Use the user interface portion of the wizard to select the type of domain controller you want to create and to gather specific information about your environment for the proper configuration of that domain controller.

**Verifying Client Operating System Compatibility**
Domain controllers running Windows Server 2003 have improved security settings that might affect clients that are running older versions of Windows. Server message block (SMB) packet signing and secure channel signing are security policies that are enabled by default on domain controllers running Windows Server 2003.

Clients running Windows NT 4.0 with Service Pack 2 or earlier, and clients running Windows 95 without the Directory Service Client Pack, do not support SMB packet signing and cannot authenticate to a domain controller running Windows Server 2003.

Clients running Windows NT 4.0 with Service Pack 3 or earlier do not support secure channel signing. These clients cannot establish communications with a Windows Server 2003–based domain controller. To ensure successful communication, upgrade these clients to a later version of the Windows operating system or service pack. However, if you cannot upgrade your clients, you must disable secure channel signing on all domain controllers running Windows Server 2003 so that the traffic passing through the secure channel does not need to be signed or encrypted.

### Note

- Secure channel signing does not affect Windows 95 clients.

**Choosing Additional Domain Controller or Member Server**
When you upgrade an existing Windows NT 4.0 backup domain controller (BDC) to Windows Server 2003, the Active Directory Installation Wizard executes immediately when the operating system upgrade is complete and gives you the following options:

- Install Active Directory, creating an additional domain controller in the domain.
- Convert the BDC to a member server joined to the domain.

### Note

- You must upgrade and install Active Directory on the Windows NT 4.0 primary domain controller (PDC) in a domain before you can install Active Directory on a Windows NT 4.0 BDC.

**Copying Domain Information**
If you are creating an additional domain controller in an existing domain and you are installing Active Directory by using the install from media installation method, the Copying Domain Information page appears in the wizard. This wizard page, rather than the /adv switch used with the dcpromo command, determines how the Active Directory installation is performed. This wizard page presents you with the following options for copying domain information:

- Over the network from a domain controller
- From these restored backup files

The **Over the network from a domain controller** option simply performs the standard Active Directory installation without using any backup media. If you want to install from media, you must select **From these restored backup files**. Copying the restored information from local media is the recommended option and will result in a faster Active Directory installation.

**Providing the System Key**
If you are installing from media and system key protection was enabled on the domain controller from which you created the system state backup, the Active Directory Installation Wizard looks for the system key in the restored Active Directory files and prompts you accordingly:

- If the system key was stored on the domain controller's hard disk, the system key is stored in the backup files and available to the wizard and you are not prompted for it.
- If a system key password was set on the domain controller, then the same password is set on the system key in the backup files and the wizard prompts you for the password.
- If the system key for the domain controller was stored on a floppy disk, then the system key is not present in the backup files. The wizard prompts you for the floppy disk that contains the system key.

**Configuring the Global Catalog**
If you are installing from media by using the system state backup of a global catalog server, you will be asked if you want to configure the new domain controller as a global catalog server as well.

You can designate a domain controller as a global catalog server at any time by using the Active Directory Sites and Services console. Therefore, you do not need to specify whether a domain controller will be a global catalog server during the Active Directory installation. However, if a global catalog server is required in the site in which you are installing the domain controller, designating the domain controller as a global catalog server during the Active Directory installation eliminates the additional configuration step.

**Contacting an Active Directory Domain Controller**
If you upgrade a Windows NT 4.0 BDC to Windows Server 2003 and then install Active Directory, the domain controller must be able to contact an Active Directory domain controller for the domain of which it was previously a member. If this is the first Windows NT 4.0 BDC being upgraded, the PDC must have already been upgraded and the BDC must be able to contact it. If this is an additional BDC, it must be able to contact either the PDC or another domain controller from its domain. If the BDC successfully contacts an Active Directory domain controller for the domain, the wizard proceeds without any notification.

If the domain controller is not able to successfully contact an Active Directory domain controller, but is able to contact a non-directory service (pre-Windows 2000) domain controller, it might be for one the following reasons:

- The primary domain controller (PDC) for the domain of which the BDC was a member has not been upgraded to Windows Server 2003.

- Network configuration or connectivity problems are preventing a domain controller from being contacted.

If the BDC cannot contact the PDC for any of the above reasons, the Cannot Contact an Active Directory Domain Controller wizard page will advise you of the issue. You can either stop to investigate and correct the problem before continuing, or choose the option to make the BDC a member server in the Active Directory domain.

**Providing Network Credentials**
To create a new domain controller in an existing forest, the Active Directory Installation Wizard requires that you provide valid network credentials in the form of a user name, password, and domain name. The wizard accepts the user name in the form of a logon user identifier – for example, johnSmith – or in the form of domain\user name. We do not recommend using a user principal name (UPN) formed as johnSmith@*domainName*.

- To create an additional domain controller for an existing domain, you must provide credentials for a member of either the Enterprise Admins group or the Domain Admins group for the domain to which you are adding the additional domain controller.

- To create a child domain in an existing domain tree, you must provide credentials for either a member of the Enterprise Admins group or an account that has been delegated the authority to create the new child domain by a member of the Enterprise Admins group.

- To create a new tree-root domain, you must you must provide credentials for either a member of the Enterprise Admins group or an account that has been delegated the authority to create the new tree-root domain by a member of the Enterprise Admins group.

### Note

- Network credentials are not required to create a new forest. The Active Directory Installation Wizard skips this step and immediately prompts you to enter a valid DNS name. All other configurations require you to provide network credentials before entering a valid DNS name.

**Providing a New Domain Name**
To create a domain controller in a new domain, you must provide a DNS name for the new domain. Acceptable naming conventions for domain names include the letters A through Z, numerals 0 through 9, and a hyphen (-). A dot (.) separates the discrete parts of a domain name, commonly known as labels. Each domain label cannot be longer than 63 bytes. Fully qualified domain names cannot:

- Have a single label.

Although Dcpromo.exe in Windows Server 2008 and Windows Server 2003 allows you to create a single-label DNS domain name, you should not use a single-label DNS name for a domain for several reasons. In Windows Server 2008 R2, Dcpromo.exe does not allow you to create a single-label DNS name for a domain. For more information, see http://go.microsoft.com/fwlink/?LinkId=92467.

| **Note** |
| --- |
| DNS names that do not contain a dot (.) cannot be registered on the internet and require additional configuration to be dynamically registered by DNS clients. |

- Exceed 64 characters.
- Contain embedded spaces.
- Be solely numeric.

To create a new child domain, you must provide the full DNS name of a parent domain. The wizard verifies that the parent domain exists. If the wizard does not recognize the DNS name of the parent domain, an error message states that the specified domain could not be contacted and that you should verify that the DNS name is typed correctly. If the DNS name of the parent domain is correct, there might be a problem with your DNS configuration.

The Active Directory Installation Wizard uses the domain controller Locator to verify that the DNS name is unique in the forest.

**Generating a NetBIOS Domain Name**

The Active Directory Installation Wizard generates a NetBIOS name from a valid DNS domain name, except when upgrading a Windows NT 4.0 PDC. When you upgrade a PDC running Windows NT 4.0, the NetBIOS name by default is the previous NetBIOS name of the domain and you cannot select a new name.

NetBIOS-created names have a 15-character limit. If your existing Windows NT 4.0 domain name is 15 characters in length, and your new domain name is more than 15 characters, the NetBIOS name truncates at the 15-character limit. If your domain name is truncated this way, a new NetBIOS name is created that is identical to your previous Windows NT 4.0 domain name, and domain creation fails. Domain creation also fails if your previous NetBIOS name contains embedded spaces; however, the Active Directory Installation Wizard ignores leading and trailing spaces.

In all other installation scenarios, the Active Directory Installation Wizard prompts you to either change or accept the NetBIOS name that is derived from the domain name. The wizard then uses the domain controller Locator to verify that the NetBIOS name that you have accepted is unique on the network.

**Using DNS Registration Diagnostics**

If you are installing Active Directory to create the first domain controller in a new forest, DNS must be installed on your computer. If you are installing an additional domain controller in an existing domain, DNS must be configured properly on your network. If DNS is not installed on the computer, the wizard prompts you to configure the DNS client and does not proceed until the configuration is complete. After the wizard verifies that the DNS client is installed, it proceeds with the Active Directory installation. During the Active Directory installation, DNS diagnostic tests verify that your DNS configuration supports Active Directory. The tests validate the full DNS name, verify that the appropriate DNS SRV resource records exist, and report the most common DNS misconfiguration scenarios.

For more information about DNS SRV resource records, see "How DNS Support for Active Directory Works."

When you install Active Directory on the first domain controller in a new domain, the Active Directory Installation Wizard performs a DNS query for the DNS name of the Active Directory domain specified in the wizard. The DNS query ensures that network hosts and services can locate the domain controller hosting the Active Directory domain. The wizard queries the DNS servers configured for its network connection for the start of authority (SOA) resource record for the zone that contains the DNS name of the Active Directory domain. After the SOA resource record is received and the name of the primary server is extracted from the response, the new domain controller queries DNS for the address (A) resource record for the primary DNS server name. After the new domain controller determines the IP address of the primary DNS server, it sends a dynamic update request to determine whether or not the DNS server exists and is capable of accepting DNS dynamic updates.

When you install Active Directory on an additional domain controller in an existing domain, a DNS server running on the network is assumed and a search for an authoritative DNS server is not performed.

The results of these diagnostic tests are displayed on the DNS Registration Diagnostics page of the Active Directory Installation Wizard. If the wizard detects a problem with the DNS configuration, it provides details about the problem. You can use the

information provided on this page to repair the problem and run the wizard again.

If DNS is not installed on the computer, you are given the option to install it now or after the Active Directory installation has completed. If you choose to install DNS during the Active Directory installation, a DNS server is installed locally and configured with a primary DNS zone that matches the name of the new Active Directory domain. The wizard configures DNS to accept dynamic updates and to modify the computer's IP configuration so that the domain controller points to its local DNS server as the preferred DNS server.

**Verifying Active Directory Forest and Domain Functional Levels**
Windows Server 2003 forest and domain functional levels provide a system for safely enabling new Windows Server 2003 features. Before you can install Active Directory, the Active Directory Installation Wizard ensures that the domain or forest can support the domain controller.

For example, if the forest functional level is Windows Server 2003, you cannot create a new domain on a Windows 2000–based server. Similarly, if the domain functional level is Windows Server 2003, you cannot install Active Directory on a Windows 2000–based server to create an additional domain controller in an existing domain. The system also prevents restoring a domain controller with information from a domain controller that has an incompatible functional level.

When upgrading a PDC running Windows NT 4.0 and configuring it as the first domain controller in a new forest, the Active Directory Installation Wizard prompts you to raise the forest functional level to Windows Server 2003 interim, because it is assumed that the forest does not contain Windows 2000 domain controllers. The Windows Server 2003 interim forest functional level allows only Windows Server 2003–based and Windows NT 4.0–based domain controllers to co-exist in a forest.

After all Windows NT 4.0 PDCs and BDCs are upgraded to Windows Server 2003, the forest functional level can be raised to Windows Server 2003.

When you upgrade from Windows 2000 to Windows Server 2003, the Active Directory Installation Wizard does not prompt you to raise the forest functional level. After an upgrade or clean installation of a Windows Server 2003–based domain controller, the default domain functional is Windows 2000 mixed and the default forest functional level is Windows 2000. These functional levels allow for the existence of domain controllers running Windows Server 2003, Windows 2000 or Windows NT 4.0. Functional levels can be raised manually when conditions in the domain or forest are appropriate.

For more information about functional levels, see "Active Directory Functional Levels Technical Reference."

**Selecting a Location for Database and Log Folders**
The Active Directory Installation Wizard displays the default location for the Active Directory database (Ntds.dit), and log files and enables you to specify an alternative location or accept the location provided.

During Windows Server 2003 installation, the Ntds.dit Active Directory database template is placed in a default location, the %*systemroot*%\System32 directory. In this location, the Ntds.dit database template does not function as the directory database; it exists as a template that is used to create the user's Active Directory database files when Active Directory is installed. The Ntds.dit template enables you to install Active Directory without using the Windows Server 2003 product CD.

We recommend that you install the Ntds.dit database template on an NTFS volume. For optimal domain controller performance, select separate physical hard disks for the Ntds.dit database template and the Active Directory log files.

**Selecting a Location for the Shared System Volume**
The Active Directory Installation Wizard displays the default location for the system volume (SYSVOL) and enables you to specify an alternative location or accept the location provided. An NTFS volume is required for the SYSVOL shared folder.

For optimal performance on domain controllers that are accessed by more than 1,000 users, place the log files on one physical hard disk and keep the SYSVOL shared folder and the Ntds.dit database together on a separate physical hard disk.

**Assigning Permissions to User and Group Objects**
When you create a domain controller for a new domain, the Active Directory Installation Wizard prompts you to select default permissions for user and group objects. It provides you with the following two options:

- **Permissions compatible with pre-Windows 2000 Server operating systems**
- **Permissions compatible only with Windows 2000 or Windows Server 2003 operating systems**

**Permissions compatible only with Windows 2000 or Windows Server 2003 operating systems** is the default selection and adds the Everyone security identifier (SID) and the Anonymous Logon SID to the Pre-Windows 2000 Compatible Access local group. The Pre-Windows 2000 Compatible Access local group has access to the user and group object attributes that

existed in Windows NT 4.0 and that are required by certain applications to function with Active Directory.

If you include the Everyone SID in an ACL or group membership in Windows 2000 or earlier operating systems, you allow authenticated users, guest users, and anyone with an anonymous logon to gain access to many resources. In Windows Server 2003, the Everyone SID no longer allows access to anonymous users. This change was made to disallow inappropriate access to resources by anonymous users and to avoid granting accidental access to anonymous users.

**Note**

- The Everyone SID contains an access token for every user account in the forest, including the Guest account. The Anonymous Logon SID contains only an access token for anonymous users. Select the **Permissions Compatible with pre-Windows 2000 servers** option to populate the Pre-Windows 2000 Compatible Access group with both SIDs.

In Windows Server 2003, the Anonymous Logon SID was created for backward compatibility with any pre-Windows 2000 application requiring less strict permissions than those granted by Windows 2000–based and Windows Server 2003–based domain controllers. For example, if you have Windows NT 4.0–based Remote Access service servers that are running on Windows NT 3.*x* or Windows NT 4.0–based computers, or if these applications are running on Windows 2000 or Windows Server 2003 computers that are located in a Windows NT domain, choose the **Permissions compatible with pre-Windows 2000 servers** option to add the Anonymous Logon SID to the pre-Windows 2000 Compatible Access local group so that the user and group object attributes that existed in Windows NT 4.0 can be accessed.

**Choose Permissions compatible only with Windows 2000 or Windows Server 2003** only if all of your server-based applications are running on Windows 2000–based or Windows Server 2003–based servers that are members of Windows 2000 or Windows Server 2003 domains. This option prevents the Pre-Windows 2000 Compatible Access group from being populated. This group remains empty when high-security is required in pure Windows 2000 and Windows Server 2003 environments.

**Providing an Administrator Password**

When you upgrade a Windows NT 4.0 BDC and select the member server option to make the computer a member server in the new Active Directory domain, you are electing to place the computer in a new role as a member server in the new Active Directory domain. As part of this process, all users and groups that were previously created on the computer are deleted and all built-in groups are recreated. After this conversion process completes, the previous Windows NT 4.0 administrator account is no longer valid, and a new password is necessary to access the new administrator account. You must assign a new server administrator password that will have access to the newly created groups.

**Providing a Directory Services Restore Mode Administrative Password**

On every new domain controller, whether it has been upgraded from a Windows NT 4.0–based domain controller or it was made a domain controller after a clean installation of Windows Server 2003, the Active Directory Installation Wizard prompts you for an Administrator account password that is to be used for authenticating to the Security Accounts Manager (SAM) database when the computer is started in Directory Services Restore Mode.

Starting a domain controller in Directory Services Restore Mode causes the domain controller to temporarily operate as a stand-alone server. When operating in this mode, the SAM database uses a minimal set of user and group definitions stored in the registry.

**Summary**

The Active Directory Installation Wizard enables you to review and confirm the configuration options you selected and enables you to move back through the wizard and make corrections. After you verify your Active Directory configuration settings, click **Next** to complete the interactive portion of the Active Directory Installation Wizard and begin the directory service configuration.

**Active Directory Installation Wizard Directory Configuration Process**

After gathering all necessary information from the user, the Active Directory Installation Wizard begins the configuration of the directory.

**Creating the SYSVOL Shared Folder**

When you create a domain, the Active Directory Installation Wizard also creates the SYSVOL folder, which contains the shared system volume, SYSVOL. SYSVOL provides a default location for files that must be shared throughout an Active Directory domain. SYSVOL creation requires an NTFS volume. Active Directory does not function if the SYSVOL folder is not properly configured and shared. When it is created, the SYSVOL folder is shared automatically by the Net Logon service.

The SYSVOL folder also includes the NETLOGON shared folder. The NETLOGON shared folder includes system policies and user-based logon and logoff scripts for network clients that do not run Windows 2000 or Windows Server 2003. On servers that are upgraded from Windows NT 4.0, files that were located in the original NETLOGON shared folder

(\\%systemroot%\SYSTEM32\REPL\Import\Scripts) are moved to the \\<DomainName>\SYSVOL\<FullyQualifiedDomainName>\Scripts folder in the SYSVOL tree.

The SYSVOL folder also includes:

- File system junctions.
- User logon, logoff, startup, and shutdown scripts.
- Windows 2000 and Windows Server 2003 Group Policy objects.
- File Replication service (FRS) staging directories and files.

  FRS replicates the SYSVOL shared folder. After Active Directory is installed and the domain controller is restarted, FRS actually creates the system volume objects in the system volume directory and enables replication of the SYSVOL shared folder on the domain controller. The new domain controller advertises itself in DNS as a domain controller only after SYSVOL is replicated to all domain controllers in the forest.

**Creating Directory Partitions**

The Active Directory Installation Wizard copies the Ntds.dit Active Directory database template from its location in the *%systemroot%*\System32 directory to the destination specified in the wizard and configures the local server to host the directory service. This process includes the creation of the directory partitions and the default domain security principals.

The Ntds.dit Active Directory database template includes a default copy of the schema, and the schema.ini file, which specifies the default structure of the configuration and domain directory partitions. The Ntds.dit template is used in the following manner:

- When you install Active Directory on a computer that is going to be the root of a forest, the Active Directory Installation Wizard uses the default copy of the schema and the information in the schema.ini file to create the new Active Directory database.
- When you install the first domain controller in a new domain that is not the root of the forest, the wizard synchronizes the schema and configuration directory partitions with the schema and configuration directory partitions of the forest root. From the Ntds.dit template, only the information in the schema.ini file that specifies the structure of the domain directory partition is used.

The following directory partitions are created as default partitions on the first domain controller in a forest, and they are updated through replication on every subsequent domain controller that is created in the forest:

- The schema directory partition is created as cn=schema,cn=configuration,dc=*forestRootDomain*. The schema.ini file is used to create default directory objects, and display specifiers, which are the containers of objects that describe how your Active Directory Users and Computers administrative console appears. Schema.ini implements default security on the directory database.
- The configuration directory partition is created as cn=configuration,dc=*forestRootDomain*.
- The domain directory partition is created as dc=*domainName* and contains the security principals for the domain.

  If you install a new domain controller from a backup of an existing domain controller by using **dcpromo /adv**, the domain directory partition is restored from the backup media onto the new domain controller.
- Two DNS application directory partitions below the forest root domain are automatically created by the DNS Server service when the computer restarts after the Active Directory Installation Wizard has finished. One application directory partition is created for the forest, ForestDnsZones, and one for the domain, DomainDnsZones. You can use the DNS administrative tool or the dnscmd.exe command-line tool, located in the \Support\Tools directory on the Windows Server 2003 product CD, to use these application directory partitions for DNS zone storage.

  **Note**

- If you are installing an additional domain controller in an existing forest, the domain controller holding the domain naming operations master role must be online, available, and running Windows Server 2003 for these application directory partitions to be created. If the domain naming master is unavailable or is running Windows 2000, the DNS Server service will attempt to create the application directory partitions again at a later time.

**Replicating Directory Partitions**
When you create a new domain in an existing forest, the schema and configuration directory partitions are updated on the new domain controller through replication from a source domain controller and a new domain directory partition containing all of the default domain objects is created.

**Note**

- All data replicated during the installation of Active Directory is compressed. After you have completed the wizard and the domain controller is restarted, the Knowledge Consistency Checker (KCC) reconfigures compression according to site boundaries.

When you install an additional domain controller in an existing domain, all three directory partitions are updated through replication from a source domain controller. Because of the large amount of data that must be synchronized when you install an additional domain controller, you might opt to delay full replication until the computer is restarted. To stop the replication process, click the **Finish Replication Later** button when it appears. Clicking the **Finish Replication Later** button causes only critical information, such as the schema directory partition, the configuration directory partition, and some objects from the domain directory partition, to replicate. After these critical items replicate and the computer restarts, replication continues as part of the normal replication activity of the domain controller. The domain controller does not advertise itself as such until replication completes.

The computer on which you install Active Directory uses the domain controller Locator to find a domain controller in the parent domain (for a new child domain) or in its own domain (for an additional domain controller in an existing domain) to act as the source domain controller for replication. The computer queries the source domain controller for the distinguished names of the Configuration container and the Schema container by posting an LDAP query that is based on the NULL distinguished name, which retrieves the root attributes of the Active Directory tree. The source domain controller replicates the schema directory partition and configuration directory partition (in that order), referenced only by their distinguished names. After the directory partitions have been replicated to the computer on which you are installing Active Directory, the GUIDs of the containers are established from the replicated data, although the directory partitions continue to be referenced solely by the distinguished name string for the duration of the installation process.

Failure to fully replicate any of the directory partitions results in the failure to install Active Directory. To ensure complete synchronization, there is a critical point in the replication process beyond which the process cannot be terminated: Prior to replication of the attributes from the domain directory partition, you can cancel the installation process. After the domain directory partition is replicated, you cannot cancel the installation process.

**Creating the Domain**
Regardless of the type of domain that you create, the Active Directory Installation Wizard performs the following operations during the installation process:

- Sets the computer Domain Name System (DNS) root domain name to the name of the new domain by using this format:

  *<computerName>.<domainName><forestRootDomainName>*

- Determines whether the server is joined to a domain. If the computer is a member server of a domain and if you are logged on as an administrator, the wizard removes the computer from the domain and reuses the account. If you are not logged on as an administrator, the wizard alerts you that an administrator must remove the computer account for the server from the domain.

- Creates a computer account in the Domain Controllers container in the new domain. The account is added to the Domain Controllers global group in the Users container. This account allows the computer to authenticate to other domain controllers.

- Applies the password you have provided for the administrator account that will be used when you start the domain controller in Directory Services Restore Mode.

- Creates a cross-reference object in the Configuration container. When the configuration directory partition is replicated to the new domain controller, a cross-reference object is created on the domain naming master and is then replicated throughout the forest. This object is used by LDAP to locate resources in other domains.

- Modifies the Local Security Authority (LSA) membership policy to distinguish the computer as a domain controller.

- Removes the **Start** menu shortcut to the local security settings and adds two new shortcuts to the following Group Policy security setting nodes:

    - Domain security settings for all users and computers.

    - Security settings that are specifically targeted at domain controllers.

**Creating a Forest Root Domain**

The following operations occur when you create the forest root domain:

- Creation of the Schema container and the Configuration container.

- Assignment of the PDC emulator, RID master, domain naming master, schema master, and infrastructure master roles to the domain controller.

### Note

- Creating a new forest does not affect any existing domain and, therefore, does not use a source domain controller during the installation of Active Directory.

**Creating a New Child Domain**

The following operations occur when you create a child domain in an existing domain tree:

- Verification of the name that you provide as a valid child domain name.

- Location of a source domain controller in the parent domain.

- Synchronization of the system time of the child domain with the system time of the source domain controller.

- Creation of parent-child trust objects in the System folder on both the parent domain and the child domain. These objects (class **trustedDomain**) identify two-way transitive trust relationships between the child domain and the parent domain.

- Replication of the Schema container and the Configuration container from the source domain controller in the parent domain.

- Assignment of the PDC emulator, RID master, and infrastructure master roles to the domain controller.

**Creating a New Tree-Root Domain in an Existing Forest**

When you create a new tree-root domain, its creation depends on other domains in the forest. The Active Directory Installation Wizard creates various new accounts, trust relationships, and cross-reference objects to incorporate the new tree-root domain into the forest.

The following operations occur when you create a new tree-root domain in an existing forest:

- Location of a source domain controller in the forest root domain.

- Synchronization of domain system time with the system time of the source domain controller.

- Creation of a tree-root trust relationship between the tree root domain and the forest root domain, and creation of a trust object (class **trustedDomain**) in both domains. The tree-root trust relationship is two-way and transitive.

- Assignment of the PDC emulator, RID master, and infrastructure master roles to the domain controller.

**Creating an Additional Domain Controller in an Existing Domain**
To add an additional domain controller to an existing domain, install Active Directory on a Windows Server 2003-based member server. The same verification and configuration processes occur as during the creation of a new domain. There are no specific namespace or TCP/IP checks and there are no operations master roles assigned.

However, if any of the following operations fail, the installation of Active Directory cannot proceed.

- Joining the computer to the domain. If the additional domain controller is already a member of a domain prior to the Active Directory installation, the computer is removed from the previous domain and rejoined to the new domain for which it is a new domain controller. Changing the join state might change the computer name as well. If the Active Directory Installation Wizard changes the join state of the computer and the Active Directory installation fails elsewhere in the wizard, you must restart the computer before attempting the installation again.

- Forced synchronization from the source server to the RID master, which ensures that a relative identifier pool is quickly provided to the new domain controller. The RID master does not have to be available during the installation of Active Directory, but it must be available at some point after the installation to transfer relative identifiers to the new domain controller.

After these operations succeed, the replication process begins.

**Setting Services to Start Automatically**
During your Active Directory installation, the following services are configured to start automatically:

- The RPC Locator, which enables distributed applications to use the Microsoft RPC name service. The RPC Locator manages the RPC name service database. For more information about the RPC Locator, see the Software Development Kit (SDK) on MSDN.

- The Net Logon service, which runs the Locator algorithm. Net Logon also is responsible for creating a secure channel between clients and domain controllers during the logon process, registering service (SRV) resource records in DNS, and supporting the Windows NT 4.0 replication protocol (LMRepl).

- The Key Distribution Center (KDC) service, which runs on a physically secure server and maintains a database with account information for all security principals in its realm — the Kerberos v5 authentication protocol equivalent of a Windows Server 2003 domain.

- IsmServ (Intersite Messaging [ISM] service), which is used for mail-based replication between sites and for calculating the least expensive routes between sites. Active Directory includes support for replication between sites by using Simple Mail Transfer Protocol (SMTP) over the IP transport. SMTP support is provided by the SMTP service, which is a component of Internet Information Services (IIS). The set of transports that are used for communication between sites must be extensible; therefore, each transport is defined in a separate add-in dynamic link library (DLL). These add-in DLLs are loaded into the ISM service, which runs on all domain controllers that are candidates for performing communication between sites. The ISM service directs send requests and receive requests to the appropriate transport add-in DLLs, which then route the messages to the ISM service on the destination computer.

- TrkSvr (Distributed Link Tracking Server service), which runs on each domain controller in a domain. This service enables client applications to track linked documents that have been moved to a location on another NTFS volume in the same domain, in another domain, or in a workgroup. The Distributed Link Tracking Server service helps resolve shortcuts and OLE links to NTFS-resident files that have undergone a name change, a path change, or both.

- W32time (Windows Time service), which synchronizes clocks between clients and servers that run Windows Server 2003. Time synchronization is automatic. For more information about the Windows Time service, see "How the Windows Time Service Works."

**Setting Security**
During the installation of Active Directory, security is enabled on directory service and file replication directories for access

control, and actions allowed on domain objects are set through Group Policy.

**Access Control**
Default access control lists are configured on file and directory objects. Access control lists are also configured for the following registry keys and file system objects, including all child objects:

- HKEY_LOCAL_MACHINE\SOFTWARE
- HKEY_LOCAL_MACHINE\SYSTEM
- HKEY_USERS\DEFAULT
- PROGRAM FILES
- %WINDIR%

For more information about access control, see "How Security Descriptors and Access Control Lists Work."

**Group Policy**
Group Policy is replicated from only the first domain controller in a domain to all additional domain controllers. In the case of the first domain controller, the following security templates in the %Windir%\Inf directory are used to configure default Group Policy:

- DCFirst.inf is used to define the default Password, Lockout, and Kerberos Group Policy settings for the default Domain Group Policy object.
- DefltDC.inf is used to define the Audit and User Rights Group Policy settings for the default Domain Controllers Group Policy object.
- DCUp.inf is used to define Windows Server 2003–specific settings during the upgrade of a Windows NT 4.0–based domain controller.

### Note

- To verify that Group Policy has replicated and been properly configured and applied, look in the Application log in Event Viewer for event ID 1704. If event ID 1704 is present, policy propagation succeeded.

Domains and domain controllers have default security policies. The domain controller security policy has precedence over the domain security policy. For example, if you want to grant the Add Workstation to Domain privilege to a user, you modify the default domain controller security policy rather than the default domain security policy.

For more information about Group Policy, see "Core Group Policy Technical Reference."

**Security Accounts Manager (SAM) Database**
When a Windows NT 4.0 PDC is upgraded to Windows 2000 or Windows Server 2003, the Active Directory Installation Wizard initializes immediately at the end of setup. When Active Directory is installed, local accounts located in the Windows NT 4.0 registry-based SAM database are migrated to Active Directory as domain accounts. The existing SAM is deleted, and a new, smaller registry-based SAM is created and used for starting the new domain controller in Directory Services Restore Mode for system repair. In Directory Services Restore Mode, the operating system is running without Active Directory and all user validation occurs through the SAM database in the registry.

### Note

- When you upgrade a Windows NT 4.0 PDC to a Windows 2000–based or Windows Server 2003–based domain controller, the previous SAM database is deleted to prevent password attacks.

If Active Directory is removed from the server, the new SAM is available for local user and group accounts on the member server. The computer SID does not change during the installation or removal of Active Directory.

**Site Determination**

The Active Directory Installation Wizard determines the site to add the new domain controller. It first checks the existing site of the source domain controller to find the subnet of the computer that you are installing. If the subnet is not found, you can add the computer to an existing site. You can create a new site for this domain controller after the Active Directory installation is complete. You can then move the domain controller from the installation site to the new site.

**Note**

- To automatically place the domain controller in the correct site, all domain controllers in the forest must have the correct site and subnet information before installing Active Directory.

During site determination, the wizard attempts to use the domain controller Locator to find the site you specified or the site in which the computer is currently located. DNS checks the site name to test that it is a valid label. A valid DNS label must contain at least one non-numeric character to distinguish it from an IP address. If the domain controller Locator does not return a site for the computer (that is, the computer's subnet is not associated with a site), the site of the source domain controller is used as the site for the new domain controller.

When you are installing the first domain in a new forest, the default site, Default-First-Site-Name, is used.

**Note**

- When you are performing an unattended installation, you can specify a site with the SiteName parameter in the answer file. For more information about unattended installation of Active Directory, see "Active Directory Installation Methods" earlier in this subject.

After the correct site is determined, the wizard verifies that a site object exists in Active Directory for that site and that a server object exists for the additional domain controller. If a server object does not exist, one is created. If the server object exists, the associated NTDS Settings object is deleted and then recreated for the new domain controller. An NTDS Settings object is created for each domain controller in the forest. If the NTDS Settings object already exists, the wizard performs as if this domain controller is being reinstalled.

**Note**

- The NTDS Settings object is always created on a remote server (the source domain controller) for an additional domain controller. For a new domain, the NTDS Settings object is created on the computer that has the domain naming master role. During replication of the Configuration container, the NTDS Settings object is replicated to all domain controllers.

**Active Directory Removal**

The Active Directory Installation Wizard also removes Active Directory. When you start the wizard on a domain controller, the computer is identified as a server that contains Active Directory, and the wizard prompts you for the information that is required to remove Active Directory.

When you remove Active Directory, you remove all short cuts that were added when Active Directory was installed, and you restore the local policy shortcut. You also restore the shortcut on the **Administrative Tools** menu that provides access to the local security settings for the member server or for the standalone server.

If the Active Directory Installation Wizard recognizes that the computer is a global catalog server, it advises you so that you can make sure that other global catalog servers are accessible to users. The wizard then asks you to indicate whether the domain controller you are decommissioning is the last domain controller in the domain.

**Providing Administrative Credentials to Remove Active Directory**

To remove Active Directory, you must provide the following administrative credentials:

- To remove Active Directory from a domain controller that is the last domain controller in a child domain, you must provide credentials for a member of the Enterprise Admins group.

- To remove Active Directory from a domain controller that is the last domain controller in a tree-root domain, you must provide credentials for or be logged on as a member of the Enterprise Admins group.

- To remove Active Directory from a domain controller that is the last domain controller in the forest, you do not have to provide credentials. However, you must log on to the domain as an administrator or as a member of the Domain Admins group.

- To remove Active Directory from a domain controller that is not the last domain controller in the domain, you do not have to provide credentials. However, you must be logged on as a member of either the Domain Admins group or the Enterprise Admins group.

In many cases, removing Active Directory requires Enterprise Admins credentials. The authority to create or remove a domain can be delegated, in which case the credentials of the delegated user suffice.

**Removing Active Directory from an Additional Domain Controller or the Last Domain Controller**
When you remove Active Directory from either an additional domain controller or from the last domain controller in the domain, the Active Directory Installation Wizard performs the following operations:

- Replication of changes to the configuration directory partition and the schema directory partition. For an additional domain controller, it replicates changes to the configuration, schema, and domain directory partitions.

- Transfer of any operations master roles that the domain controller is holding to another domain controller. While it is possible to allow the Active Directory Installation Wizard to do this, it is not recommended that you rely on the wizard to perform this action. Controlling where operations masters are placed ensures that you can locate and administer each operations master role as necessary.

- Removal of the system volume objects from the directory database; the system volume objects from the NtFrs database; and deletion of the SYSVOL directory hierarchy. NtFrs requests that the Net Logon service remove the share from the system volume.

- Removal of the NTDS Settings object and cross-reference objects.

- Update of DNS to remove the Locator records. (When the NTDS Settings object is deleted, the Directory System Agent (DSA) notifies the Net Logon service, and the Net Logon service removes the records).

- Creation of the local SAM database in the same manner as during a new installation, including creation of the local administrator account and setting the password.

- Modification of the LSA membership policy to distinguish whether the computer is a standalone server or a member server.

- Stop of the Net Logon service and other services. The same services that were started during the installation of Active Directory procedure are stopped. Services that relate only to the directory service are configured to not start automatically.

**Removing Active Directory from an Additional Domain Controller**
When you remove an additional domain controller, The Active Directory Installation Wizard:

- Locates a source domain controller in the same domain where the additional domain controller account exists and replicates changes to it.

- Sets the computer account type to member server and moves the computer account for the additional server from the Domain Controllers container to the Computers container.

**Removing Active Directory from the Last Domain Controller**
When you remove the last domain controller in the domain, The Active Directory Installation Wizard:

- Verifies that no child domains exist.

- Locates a source domain controller in the parent domain and replicates changes to it.

- Removes Active Directory objects specific to this domain from the forest. The wizard contacts the domain naming master and removes the NTDS Settings and cross-reference objects.

- Removes trust objects on the parent server. The trustedDomain objects in the System folder are deleted.
- Places the server in a workgroup called "Workgroup."

If the NTDS Settings object is not removed successfully from Active Directory (for example, if a server fails during the removal of Active Directory), remove the object manually by using ntdsutil.exe.

**Removing Active Directory from a Domain Controller that Hosts an Application Directory Partition**
In Windows Server 2003, non-domain data that is not of global interest can be stored on and replicated between designated domain controllers located in different domains throughout the forest by using application directory partitions. For example, you can store data that is specific to a single application in an application directory partition.

When you are removing a domain controller on which an application directory partition is present, the Active Directory Installation Wizard blocks the removal of that domain controller if it determines that the domain controller hosts the last copy of the application directory partition in the forest. If the removal of Active Directory is blocked, a dialog box lists the application directory partitions existing on the computer. Click **Next** to remove the application directory partitions from the domain controller and continue with the removal of Active Directory.

If at least one other replica of the application directory partition is located in the domain, the wizard skips the dialog box mentioned above and proceeds with the removal of Active Directory. Any changes to the application directory partition are replicated to another replica before it is destroyed.

**Provide a New Administrator Password**
When Active Directory is removed from a computer, all users and groups that were created on the computer are deleted and all built-in groups are recreated. You must assign a new server administrator password that will have access to the newly created groups.

# Domain Rename Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Domain Rename Technical Reference**
Microsoft Windows Server 2008 R2, Windows Server 2008, and Windows Server 2003 operating systems provide the capabilities to rename domains in an Active Directory Domain Services (AD DS) directory service forest after the forest structure is in place. These domain rename capabilities are available in a forest that has a forest functional level of Windows Server 2003 or higher. These capabilities are not available in Microsoft Windows 2000 Server operating systems.

| **Note** |
| --- |
| In Windows Server® 2003 and Microsoft Windows® 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008, the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

You can use the domain rename process to change the names of your domains, and you can also use it to change the structure of the domain trees in your forest. This process involves updating the Domain Name System (DNS) and trust infrastructures as well as Group Policy and service principal names (SPNs).

The structure of an Active Directory forest is the result of the order in which you create domains and the hierarchical names of those domains. Beginning with the forest root domain, all child domains derive their distinguished names and default DNS names from the name of the forest root domain. The same is true of every additional tree in the forest. The way to change the hierarchical structure of an existing domain tree is to rename the domains. For example, you can rename a child domain to have a different parent or rename a child domain to be a new tree-root domain. In each case, you reposition an existing domain to create a different domain-tree structure.

Alternatively, you can rename domains without affecting the structure of the forest. For example, if you rename a root domain, the names of all child domains below it are also changed, but you have not created a different domain-tree structure.

This technical reference subject does not provide procedural information that you need to perform a domain rename operation. Rather, it provides essential background information that you must thoroughly understand before undertaking a domain rename operation in a production environment. This technical reference subject does include information about where to obtain the tools and procedures for a domain rename operation.

# What Is Domain Rename?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**What Is Domain Rename?**

**In this section**

- Domain Rename Constraints and Capabilities
- Core Scenarios for Domain Rename
- Domain Rename Dependencies and Interactions with Other Technologies
- Related Information

You can use the domain rename process to change the names of your domains, and you can also use it to change the structure of the domain trees in your forest. This process involves updating the Domain Name System (DNS) and trust infrastructures as well as Group Policy and service principal names (SPNs).

The ability to rename domains provides you with the flexibility to make important name changes and forest structural changes as the needs of your organization change. Using domain rename, you cannot only change the name of a domain, but you can change the structure of the domain hierarchy and change the parent of a domain or move a domain residing in one domain tree to another domain tree. The domain rename process can accommodate scenarios involving acquisitions, mergers, or name changes in your organization, but it is not designed to accommodate forest mergers or the movement of domains between forests.

**Note**

Domain rename is intended to be a supported method for renaming domains when domain renames are necessary; *it is not intended to make domain rename a routine operation*. The domain rename process is complex, and it requires a great deal of care in planning and execution. In addition, the time that is required for a complete domain rename operation is directly proportional to the size of an Active Directory forest in terms of its number of domains, domain controllers, and member computers. Therefore, although domain rename is possible, it should not be undertaken lightly.

The domain rename operation is not supported in Microsoft Exchange Server 2007 or Exchange Server 2010. DNS domain rename is supported in Exchange Server 2003. However, renaming of the NetBIOS domain name is not supported in any version of Exchange Server. Other non-Microsoft applications might also not support domain rename. For more information about other Microsoft applications that are incompatible with domain rename, see article 300684 (http://go.microsoft.com/fwlink/?LinkId=185229) in the Microsoft Knowledge Base.

In Windows Server® 2003 and Microsoft Windows® 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008, the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory.

For information about methods of merging forests, see “Windows 2000/2003: Multiple Forests Considerations White Paper” on the Microsoft Web site.

**Domain Rename Constraints and Capabilities**

The domain rename capabilities provide solutions to some of the problems that are not addressed in Windows 2000 Server. In a Windows 2000 Server forest, you cannot rename domains after the forest structure is in place without moving domain contents or recreating them.

Although you can rename domains in forests that do not include domain controllers that run Windows 2000, there are some important constraints on these operations. The constraints on domain rename in forests with and without Windows 2000 Server are described in the next two sections, followed by a description of the domain rename capabilities in Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2.

**Domain Rename Constraints in Windows 2000 Server**

The constraints that are associated with changing domain names or restructuring domain trees in Windows 2000 Server Active Directory are prohibitive.

In a Windows 2000 Server forest, you cannot:

- Change the DNS name or the network basic input/output system (NetBIOS) name of a domain. Although you cannot rename a domain, you can achieve the same results by moving its contents into a new domain that has the name that you want the existing domain to have. You can use Active Directory Object Manager (MoveTree) in Windows 2000 Server family Support Tools to move directory objects between domains.

- Move a domain in a forest in a single operation. You can make copies of items in a domain and move items from a domain, but you cannot move the entire domain itself within a forest.

- Split a domain into two domains in a single operation. To split a domain, you must create a new domain and then move users and resources from the existing domain into the new domain.

- Merge two domains into a single domain in a single operation. To merge domains, you must move all the contents from one of the domains into the other domain and then demote all domain controllers in the empty domain and decommission it.

In a Windows 2000 Server forest, significant administrative overhead is associated with performing manual move operations to rename one or more domains or to restructure a domain tree.

**Domain Rename Constraints in Windows Server 2003 and later**
Domain rename is not a trivial operation, and there are important constraints on the domain rename operation in a forest that has domain controllers that run Windows Server 2008 R2, Windows Server 2008, or Windows Server 2003. When you decide whether to rename or restructure domains in an existing forest, be sure to consider what you *cannot* do with domain rename and restructuring. Although a forest has domain rename and restructuring capabilities, certain types of structural changes are not supported.

In a forest with domain controllers that run Windows Server 2003 or later, you cannot:

- Change which domain is the forest root domain. Changing the DNS name or the NetBIOS name (or both) of the forest root domain is supported.

- Drop domains from the forest or add domains to the forest. The number of domains in the forest before and after the domain rename and restructuring operation must remain the same.

- Rename a domain with a name that was taken from another domain in a single domain rename and restructuring operation.

**Domain Rename Capabilities in Windows Server 2003 and later**
Tools are provided that you can use to safely rename domains to restructure a forest, reapply preexisting Group Policy to the new forest structure, and clean up the old domain names that you will no longer use.

The domain rename process involves making basic changes independently at each domain controller in a forest. You set up an administrative computer from which you issue commands that are executed remotely at each domain controller. These commands update the directory database at each domain controller individually with the changes that are necessary for renaming the domains; that is, the updates that rename the domains do not spread across the forest through AD DS replication.

You use the Rendom tool to carry out the following multiple steps in the domain rename process:

- Freeze the current state of the forest so that no changes can occur while a domain rename operation is being performed.

- Prepare the contents of the forest for a domain rename operation. Rendom runs multiple scripts that perform this preparation.

- Execute a domain rename operation.

- Clean up old domain names.

Another tool, Gpfixup, is provided to reinstate Group Policy from the original domains into the newly named domains in the forest.

The Rendom tool, the Gpfixup tool, and the instructions for using them are available on the Windows Server 2003 operating system CD. These tools are also built into domain controllers that run Windows Server 2008 R2 or Windows Server 2008, and they are available in Remote Server Administration Tools (RSAT). You can also download these tools and instructions from Windows Server 2003 Domain Rename Tools on the Microsoft Web site.

| **Note** |
| --- |
| The versions of the domain rename tools that are available at the Microsoft Web site are updated to perform domain rename operations in a forest that has Exchange Server 2003 with Service Pack 1 (SP1) deployed. Versions of the tools that are available on the Windows Server 2003 operating system CD do not have this capability. |

**Core Scenarios for Domain Rename**

By using domain rename capabilities, you can make several kinds of changes to an existing forest. For example, you can perform domain rename to:

- Rename domains without repositioning any domains in the forest structure.
- Create a new domain-tree structure by repositioning domains within a tree.
- Create a new tree root.
- Create a new domain-tree structure by repositioning domains to a different tree.
- Reuse a domain name.

**Domain Rename Without Repositioning**

You can rename domains without restructuring the forest in terms of the parent-child relationships between existing domains. For example, suppose that an existing cohovineyard.com forest for the Coho Vineyard company has four domains with the following names:

- cohovineyard.com (root)
- eu.cohovineyard.com
- hr.cohovineyard.com
- sales.cohovineyard.com

The company decides to expand into wine bottling and distribution and wants to change its name from Coho Vineyard to Coho Winery. The AD DS domain names must now reflect the new company name. As shown in the following figure, the target forest still has four domains with the following new names:

- cohowinery.com (root)
- eu.cohowinery.com
- hr.cohowinery.com
- sales.cohowinery.com

By renaming the forest root domain, a condition is created in which all child domains in the tree must be renamed to preserve

the original forest structure, as shown in the following figure.

(In the following series of figures, two-way arrows indicate two-way, transitive trust relationships.)

**Domain Rename of Four Domains Without Repositioning Domains**

**Domain Rename with Repositioning in the Same Tree**

You can change the structure of a domain tree by renaming a child domain to appear in a different location in the tree. For example, in the cohowinery.com forest, the products.sales.cohowinery.com domain is currently a child of the sales.cohowinery.com domain, placing it two levels below the forest root domain. If the Products division is no longer a subdivision of the Sales organization as a result of an internal reorganization, the company might want to change the domain structure to put the Products organization at the same level as the Sales organization. The following figure shows how changing the parent of products.sales.cohowinery.com results in a restructured domain tree.

**Domain Rename to Change the Parent of a Child Domain**

**Domain Rename with Creation of a New Tree Root**

When you restructure a forest, you can move a domain (except the forest root domain) anywhere within the forest in which the domain resides. You can even move a domain so that it becomes the root of its own domain tree. For example, in the cohowinery.com forest, the domain for the European branch of the company, named eu.cohowinery.com, is a child of the forest root domain. Company management determines that the European division's internal domain name should better reflect its Internet DNS name, cohovineyardandwinery.com. In the target forest structure shown in the following figure, the eu.cohowinery.com domain is moved so that it becomes its own tree-root domain named cohovineyardandwinery.com.

**Domain Rename to Create a New Tree Root**

**Domain Rename with Repositioning to a Different Tree**

By renaming domains, you can effectively move a child domain to a different parent, even if the parent is in a different tree. For example, in the current example forest structure, the domain for the Human Resources (hr) organization is a child of cohowinery.com. This domain has domain controllers in the United States. However, changes in the company have prompted the Human Resources organization to move its location to Europe. Company management wants to move the hr.cohowinery.com domain so that it becomes a child of the domain cohovineyardandwinery.com, residing in another domain tree. As shown in the following figure, the hr.cohowinery.com domain is renamed to hr.cohovineyardandwinery.com.

**Domain Rename to Move a Domain to a Different Tree**

**Reusing a Domain Name**

As described in Domain Rename Constraints in Windows Server 2003 and later, the domain rename operation cannot rename two or more domains so that one domain gives up its name and another domain assumes the same name in a single forest restructuring operation. For example, in the Current Forest configuration in the preceding figure, you cannot use a single domain rename operation to restructure the current forest so that the cohovineyardandwinery.com domain is named something else and the hr.cohowinery.com domain assumes the name cohovineyardandwinery.com.

However, you can accomplish the desired result by first performing the domain rename operation to rename the cohovineyardandwinery.com domain to something else. When you are absolutely sure that the first domain rename operation is complete, you can then perform the domain rename operation again so that hr.cohowinery.com assumes the domain name cohovineyardandwinery.com.

**Domain Rename Dependencies and Interactions with Other Technologies**

So that they can interact in a forest structure, AD DS domains require proper configuration and functioning of the following technologies:

- DNS: AD DS clients, including domain controllers, use DNS zone data to locate resources in a forest. Without a proper DNS infrastructure, AD DS security and replication services cannot function. In a domain name operation, DNS names of

domain controllers and member computers must also change, as follows:

  - The DNS names of domain controllers must change to match the new domain names by changing the primary DNS suffix.

  - The DNS names of member computers change automatically in one of two ways: by configuring the primary DNS suffix to change when the domain name change replicates (with a potentially significant replication impact) or by applying Group Policy to configure the primary DNS suffix change before the domain rename.

- SPNs: SPNs are used for mutual authentication between domain controllers during replication. To ensure that replication can occur following a domain rename operation, the SPN values must change on the domain controllers.

- Trust: Two-way, transitive trust relationships between parent and child domains provide the security infrastructure that is required for resource sharing between domains in the same forest and for delegating management of AD DS objects. To change the structure of a domain tree, you must manually create the trust relationships that enable parent-child relationships in the new structure.

In addition to these basic requirements, when the following features are in effect, they require appropriate changes in the forest in preparation for the domain rename operation:

- Distributed File System (DFS): Folder redirection and roaming user profiles can be used to locate the user's home directory and user profile, respectively, in a network location. When these features are applied using domain-based DFS paths, these paths must change to reflect the new domain names.

- Certification authorities (CAs): Management of enterprise certificates through a domain rename procedure requires that CAs not be installed on domain controllers and that they be configured with appropriate Uniform Resource Locators (URLs).

# How Domain Rename Works

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**How Domain Rename Works**

**In this section**

- Domain Rename Processes and Interactions
- Related Information

You can use the domain rename process to change the names of your domains, and you can also use it to change the structure of the domain trees in your forest. This process involves updating the Domain Name System (DNS) and trust infrastructures as well as Group Policy and service principal names (SPNs).

Because the domain rename process involves updating the DNS and trust infrastructures as well as Group Policy and SPNs, a domain rename operation affects every domain controller in the forest. Domain rename is a multistep process that results in updates to the directory and in other side effects. This section provides details about the domain rename process and its interactions with Active Directory Domain Services (AD DS), DNS, Group Policy, and security.

| **Note** |
| --- |
| In Windows Server 2003 and Microsoft Windows 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008, the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

It is imperative that you not attempt a domain rename operation until you read and understand the contents of this technical reference. The domain rename operation is not supported in Microsoft Exchange Server 2007 or Exchange Server 2010. DNS domain rename is supported in Exchange Server 2003. However, renaming of the NetBIOS domain name is not supported in any version of Exchange Server. Other non-Microsoft applications might also not support domain rename. For more information about other Microsoft applications that are incompatible with domain rename, see article 300684 (http://go.microsoft.com/fwlink/?LinkId=185229) in the Microsoft Knowledge Base.

**Rules for a Well-Formed Forest**

The domain rename capabilities that result in the restructure of a forest support any set of changes to the DNS names and network basic input/output system (NetBIOS) names of the domains in a forest that results in the forest being “well-formed.”

In a well-formed forest, the following conditions are true:

- The DNS names of the domains in the forest form one or more trees.
- The forest root domain is the root of one of these trees.
- An application directory partition cannot have a domain directory partition as a child.

**Domain Rename Conditions and Effects on Service**

An understanding of the conditions and effects of the domain rename process, and a willingness to fully accommodate them, are important prerequisites for undertaking the process.

The following conditions and effects are inherent in the domain rename process:

- Domain rename is supported in a forest in which Exchange Server 2003 with Service Pack 1 (SP1) is deployed. However, domain rename is not supported in an Active Directory forest in which Exchange 2000 Server is deployed. When the domain rename tool detects this condition, it will not proceed with the domain rename process.

  Domain rename is also not supported in a forest in which Exchange Server 2007 or Exchange Server 2010 is deployed.

- Remote management (also known as headless management) is helpful in the domain rename process. Each domain controller in the forest is contacted individually with the domain rename changes; the changes do not spread across the forest through AD DS replication. This condition does not imply that each domain controller in the forest has to be visited physically by an administrator. However, if you want to rename a domain in a large forest, it is highly recommended that you implement remote management of the domain controllers in the forest. In the event that some domain controllers do not respond during the domain rename process, remote management greatly improves your ability to troubleshoot the problem.

- The forest is out of service for a short period of time. Forest service is interrupted during the time it takes for each domain controller to perform the directory database updates that are necessary for the domain rename and to then reboot. The time that the forest is out of service is proportional to the number of domain controllers in the forest. This relatively short service interruption is preferable to the alternative of having the forest in odd "in-between" states for a much longer period of time.

- All domain controllers must either complete the domain rename operation successfully or be eliminated from the forest. The domain rename takes effect even if it is impossible to update some domain controllers in the forest. For the domain rename operation to be complete, every domain controller in the forest must be contacted and updated. If you declare your domain rename operation complete without updating some number of domain controllers because you could not contact them, you must remove all the domain controllers that you could not contact from the forest.

- Each member computer that is joined to a renamed domain must be rebooted twice after all domain controllers are updated. Computers running Windows NT 4.0 must be unjoined and then rejoined to the renamed domain instead of being rebooted.

- If you want DNS host names of domain controllers to match a new domain name, you must perform domain controller rename procedures after the domain rename operation is complete. The DNS host names of *domain controllers* are not changed automatically by the domain rename operation to reflect the new domain name. In other words, the primary DNS suffix of a domain controller will not match the new domain DNS name after the domain has been renamed. Having the host name of a domain controller decoupled from its domain name has no impact on forest service. However, domain controller rename requires a separate, multistep procedure after the domain rename operation is complete.

- The DNS suffix of host names for member computers in a domain that is being renamed might not match the new DNS name of the domain for a period of time. By default, the DNS suffix portion of *member computer* names is updated automatically when the domain to which the computers are joined changes (as happens when you rename a domain). In general, the period of time during which the DNS name of the domain does not match the DNS suffix of member computer names is proportional to the number of computers in the domain. In some cases, you might want to configure the computers to keep the computer names from being updated automatically.

**Domain Rename Processes and Interactions**

Domain rename is implemented in a monitored, step-by-step process that ensures that every domain controller in the forest completes its changes one step at a time — that is, the next step in the process cannot occur until the current step is complete at every domain controller in the forest.

**The Domain Rename Tool (Rendom)**

Rendom.exe is the command-line utility for renaming domains. Rendom is included on the Windows Server 2003 operating system CD. However, an updated version of Rendom is available for download in Windows Server 2003 Domain Rename Tools on the Microsoft Web site. This version of Rendom makes domain rename possible in forests that have Exchange Server 2003 with SP1 deployed.

Rendom.exe is built into domain controllers that run Windows Server 2008 R2 and Windows Server 2008. It is also available in Remote Server Administration Tools (RSAT).

**The Domain Rename State File**

When you issue the first command to begin the domain rename process, Rendom generates an XML-structured text file, called a state file, which contains a list of all the domain controllers in the forest. As domain controllers progress through the various steps in the procedure, Rendom updates the state file to track the state of each domain controller relative to the completion of the domain rename process.

As you perform each step in the domain rename operation, Rendom automatically updates the state file. By using the state file to monitor the state of completion of each domain controller in the state file, you receive the information that you need to

issue the next Rendom command in the sequence.

**Domain Controller States**
Rendom records four states of completion for each domain controller in the state file:

- Initial: Each domain controller that is reachable during the domain rename procedure starts out from the Initial state.
- Prepared: When the domain rename instructions that are written by Rendom have been verified by a domain controller independently, it advances to the Prepared state.
- Final: From the Prepared state, a domain controller advances to one of two Final states. The domain rename process stops when every domain controller in the forest has reached either of the following states:
    - Done: This state signifies that the domain rename is complete at that domain controller.
    - Error: This state implies that some irrecoverable error has occurred, and further progress on the domain rename is deemed to be impossible at that domain controller.

The steps in the domain rename procedure that attempt to take a domain controller from the Initial state to the Prepared state and from the Prepared state to a Final state can be executed only after every domain controller in the forest has reached the required state. A step can be executed multiple times for any domain controllers that cannot be reached in an initial attempt. Each such additional execution of the same step attempts to contact only those domain controllers that have not achieved the required state.

For more information about the contents of the state file, see Domain Rename Script and State File.

**General Steps in the Domain Rename Process**
The following set of steps is a very high-level representation of what happens during the domain rename process. A more detailed explanation of each step is provided later in this section, beginning with "Specifying the Target Forest Structure."

| **Note** |
| --- |
| Do not try to complete the following general steps or any steps that are described in this technical reference. Do not undertake any domain rename procedures until you read and understand all information in this technical reference. The fully documented set of procedures, including all the tasks that you perform, is provided in Administering Active Directory Domain Rename (http://go.microsoft.com/fwlink/?LinkID=187639). |

The general steps in the domain rename procedure are as follows:

1. Before beginning the domain rename process, prepare a list of domains in the forest: Specify the new forest structure that will be represented by the set of changed domain names in the forest.

   Be sure to avoid any possible name conflicts with the new names that you choose. Name conflicts can cause unpredictable and severe results. For example, a conflict with the NetBIOS name can render a domain controller unusable because you might not be able to properly remove AD DS from it.

2. To begin the domain rename procedure, generate a script that contains the instructions for renaming domains in the forest: Generate domain rename instructions that are encoded as a special script based on the specified new forest structure and transfer it to every domain controller in the forest.

3. Verify that all domain controllers are adequately prepared to make the necessary updates to rename the domains: Verify the validity of the domain rename instructions (in the script) at every domain controller, and verify that every domain controller is ready to execute those instructions.

4. Execute the actual domain rename instructions: Execute the domain rename instructions at every domain controller in the forest. At this step, a brief interruption in the forest service may occur.

5. Fix up Group Policy: Update metadata in the directory so that policy settings can continue to be applied after the domain rename.

6. Clean up all domain rename–related metadata that is written to the directory so that the directory is ready for another round of the domain rename operation, if necessary: After the domain rename procedure is complete, remove all metadata that the domain rename operation writes to the directory.

**Requirements for Domain Rename**
Before a domain rename operation begins, the following requirements must be met:

- The forest functional level must be Windows Server 2003 or higher.
- If the position of domains will change, trust relationships must be created to provide trust between any domain that will be renamed (and therefore repositioned) and the domain that is to be its parent in the new structure.
- DNS zones must exist for the new domains.
- Domain-based Distributed File System (DFS) folder redirection paths must be redirected to a server-based path.
- Domain-based roaming user profiles must be relocated to a server-based share or stand-alone DFS path.
- Computers in the to-be-renamed domains must be configured to change their host names to reflect the new domain names.
- Certification authority (CA) requirements must be met.

**Forest Functional Level Requirement**
The domain rename operation is supported in an AD DS forest if—and only if—no domain controllers in the forest are running Windows 2000 Server and the forest functional level has been raised to Windows Server 2003 or higher. Raising the forest functional level to Windows Server 2003 requires that all domains in the forest have a domain functional level of at least Windows 2000 native, regardless of what domains you are renaming.

For more information about forest and domain functional levels, see "Active Directory Functional Levels Technical Reference."

**Trust Relationship Requirement**
You can use the domain rename process to reposition any domain in the domain tree hierarchy of a forest, with the exception of the forest-root domain. Remember that although you can rename the forest root domain (you can change its DNS and NetBIOS names), you cannot reposition it in such a way that you designate a different domain to become the new forest root domain. If your domain rename operation involves restructuring the forest through repositioning of the domains in the domain tree hierarchy, as opposed to simply changing the names of the domains in place, you must first create the necessary shortcut trust relationships between domains so that the new forest structure has two-way, transitive trust paths between every pair of domains in the target forest, just as your current forest does.

**Types of trust relationships**
A hierarchy of AD DS domains is implemented by trust relationships between domains. The following types of trust relationships are established between domains in an AD DS forest:

- Parent-child: The trust that is established when you create a new domain in an existing tree in the forest. The AD DS installation process creates a transitive, two-way trust relationship automatically between the new domain (the child domain) and the domain that immediately precedes it in the namespace hierarchy (the parent domain).
- Tree-root: The trust that is established when you add a new domain tree to the forest. The AD DS installation process creates a transitive, two-way trust relationship automatically between the domain that you are creating (the new tree-root domain) and the forest root domain.
- Shortcut: A manually created, one-way or two-way, transitive trust relationship between any two domains in the forest that is created to shorten the trust path.

The effect of the transitive, two-way trust relationships that are created automatically by the AD DS installation process is that there is complete trust between all domains in a forest — every domain has a transitive trust relationship with its parent domain, and every tree-root domain has a transitive trust relationship with the forest root domain. If you use the domain rename process to restructure an existing forest by altering the domain tree hierarchy, the necessary trust relationships are not

created automatically. Therefore, as part of the preparation phase of the domain rename process, you must manually create the trust relationships that are required to preserve complete trust between all domains in your new forest after it is restructured.

**Precreating trust relationships for a restructured forest**
If you plan to use the domain rename process to reposition one or more domains in the domain tree hierarchy, for each domain that you plan to reposition, you must create the necessary shortcut trust relationships between the domain that you want to reposition and its new parent domain (or the forest root domain if the repositioned domain becomes a tree root). These newly created trust relationships substitute for the required tree-root or parent-child trust relationships that will be missing in the restructured forest.

**Precreating a parent-child trust relationship**
For example, suppose that the Coho Winery company wants to restructure the cohowinery.com forest so that the products.sales.cohowinery.com domain becomes a child of the cohowinery.com domain. Before the domain rename operation is performed to carry out this restructure, a two-way, transitive, shortcut trust relationship between products.sales.cohowinery.com and cohowinery.com must be created first. This trust relationship establishes the basis for the two-way, parent-child trust relationship that will be required for the targeted parent and child domains.

The following figure shows the before and after domain structures and the shortcut trust relationship that will serve as a parent-child trust relationship in the target forest.

**Shortcut Trust Relationship That Becomes a Parent-Child Trust**

**Precreating multiple parent-child trust relationships**
For scenarios in which you want to restructure a domain that is both a child domain and a parent domain, you might need to create shortcut trust relationships in two places. For example, suppose the Coho Winery company wants to restructure the cohowinery.com forest to move the hr.sales.cohowinery.com domain so that it becomes a child of the eu.cohowinery.com domain. At the same time, the company wants to make its child domain, payroll.hr.sales.cohowinery.com, a direct child of its current grandparent domain, sales.cohowinery.com. To perform this restructure operation, shortcut trust relationships must be created that become the parent-child trust relationships for the new forest after the restructure, as follows:

- A two-way, transitive, shortcut trust relationship is created between the eu.cohowinery.com and hr.sales.cohowinery.com domains, which will effect a two-way, transitive, parent-child trust relationship between eu.cohowinery.com and hr.eu.cohowinery.com after the restructure.

- A two-way, transitive, shortcut trust relationship is created between the sales.cohowinery.com domain and the payroll.hr.sales.cohowinery.com domain, which will effect a two-way, transitive, parent-child trust relationship between sales.cohowinery.com and payroll.sales.cohowinery.com after the restructure.

The following figure shows the before and after domain structures and the shortcut trust relationships that will serve as parent-child trust relationships in the target forest.

**Shortcut Trust Relationships to Reposition Two Domains**

**Precreating a tree-root trust relationship with the forest root domain**

When a domain is renamed to become a new tree root, the new tree-root domain must have a two-way, transitive trust relationship with the forest root domain. For this scenario, you create a two-way, shortcut trust relationship between the domain that you want to rename to become a new tree-root domain and the forest root domain.

For example, suppose that there is a deep tree in the cohowinery.com forest and the Coho Winery company wants to create a new tree by moving the lowest-level domain, eu.sales.cohowinery.com, to become a tree-root domain. The following figure shows the two-way, shortcut trust relationship that is created, and the tree-root trust relationship that it provides after restructure, when the eu.sales.cohowinery.com domain is renamed to create the tree-root domain cohovineyardandwinery.com.

**Shortcut Trust Relationship Providing a Tree-Root Trust Relationship**

**DNS Zones Requirement**

When an application or client requests access to AD DS, the domain controller locator (Locator) mechanism finds an AD DS server (that is, a domain controller).

In response to client requests for AD DS services, the Locator uses service (SRV) resource records in DNS to locate domain controllers. When DNS SRV resource records are not available, directory clients experience failures when they try to access AD DS. Therefore, before you rename an AD DS domain, you must be sure that the appropriate DNS zones exist for the forest and for each domain. If the appropriate DNS zones do not exist, you must create the DNS zone or zones that will contain the SRV resource records for the renamed domains. It is also highly recommended that you configure the DNS zone or zones to allow secure dynamic updates. This DNS zone requirement applies to each domain that is renamed as a part of the domain rename operation.

The DNS requirements for renaming an AD DS domain are identical to the DNS requirements for supporting an existing AD DS domain. Your current DNS infrastructure already provides the necessary support for your AD DS domain's use of its current name. Usually, you simply mirror the existing DNS infrastructure to add support for the new name of your domain.

For example, suppose the Coho Vineyard company wants to rename its existing AD DS domain sales.cohovineyard.com to marketing.cohovineyard.com. If the SRV resource records that are registered by the domain controllers in the AD DS domain named sales.cohovineyard.com are registered in the DNS zone named sales.cohovineyard.com, a new DNS zone called marketing.cohovineyard.com must be created, corresponding to the new name of the AD DS domain.

For more information about how DNS provides support for AD DS, see DNS Support for Active Directory Technical Reference. For more information about the Locator, see Locator mechanism.

**Folder Redirection and Roaming User Profile Requirement**

If you are using Folder Redirection or roaming user profiles, you might need to relocate the network paths for them before the domain rename operation. If you place Folder Redirection or roaming user profiles (and the home directory) on a network location by using a domain-based, Distributed File System (DFS) namespace, renaming the domain invalidates the path to this domain-based namespace, and Folder Redirection or roaming user profiles that use this path stop working. For roaming user profiles, this prevents user logons until the paths are fixed. However, if the NetBIOS name of a domain is used to connect to a domain-based DFS namespace and the NetBIOS name of the domain is not changed during a domain rename operation, the path to the domain-based DFS namespace continues to be valid. The same is true for the fully qualified domain name (FQDN); if the FQDN name of a domain is used to connect to a domain-based DFS namespace and the FQDN name of the domain is not changed during a domain rename operation, the path to the domain-based DFS namespace continues to be valid. If you are not using DFS namespaces at all and paths are not specified to server names using FQDNs, the paths will continue to be valid.

For more information, see Relocate Folder Redirection and Roaming User Profiles (http://go.microsoft.com/fwlink/?LinkId=205684).

**Computer Host Name Requirement**

By default, the primary DNS suffix of a member computer of an AD DS domain is configured to change automatically when domain membership of the computer changes. The same default behavior is true when the DNS name of the domain to which a computer is joined changes. Therefore, a rename of an AD DS domain can cause modification of the primary DNS suffix and, consequently, of the full DNS host names of the computers that are the members of the renamed domain.

For example, if the sales.cohowinery.com domain is renamed to marketing.cohowinery.com, the primary DNS suffix of the member computers of this domain might also change from sales.cohowinery.com to marketing.cohowinery.com, depending on whether the default behavior is in effect. If the default behavior is in effect, the full DNS host name of a computer in the renamed domain will change from *hostName*.sales.cohowinery.com to *hostName*.marketing.cohowinery.com.

**Conditions for automatic computer name change**

The primary DNS suffix, and therefore the full DNS name of a member computer in an AD DS domain, changes when the domain is renamed if both of the following conditions are true:

- The primary DNS suffix of the computer is configured to be updated when domain membership changes.
- No Group Policy setting specifies that a primary DNS suffix is applied to the member computer.

| **Note** |
| --- |
| The DNS host names of domain controllers in a renamed domain do not change automatically to use the new domain DNS name as the primary DNS suffix, regardless of the primary DNS suffix configuration. In other words, unlike the names of member computers, the DNS names of domain controllers in a renamed domain remain unchanged. You can rename the domain controllers in a separate step, using a special domain controller rename procedure, after the domain rename operation is complete. |

**Replication effects of renaming large numbers of computers**
If the conditions that prompt automatic update of the primary DNS suffix for all computers in the domain are true, and if there are a large number of member computers in the domain that are being renamed, replication of that many changes might cause excessive traffic on your network. The replication traffic that results from member computer names being updated is a function of the number of computers that are members of the renamed domain. This replication "storm" that can result from thousands of computer names being changed at approximately the same time is a problem for only the largest deployments. You can avoid this condition by changing the setting the prompts automatic update of the primary DNS suffix. If you do not think that the resulting replication traffic poses any problem to your infrastructure (that is, a risk of network congestion or saturation), this preparatory step is not required.

A computer name change triggers update of the **dnsHostName** and **servicePrincipalName** attributes on the corresponding computer account in AD DS. These attributes are typically updated during a reboot of the member computer, as required by the domain rename procedure after the domain is renamed. Update of these attributes by a large number of computers in a short period of time might trigger replication activity that saturates the network. Moreover, a computer name change triggers updates of the host address (A) and pointer (PTR) DNS resource records in the DNS database. Such updates also cause additional replication traffic, regardless of whether DNS zones are stored in AD DS or in some other DNS store. For these reasons, you should prepare for the domain rename operation in advance by reconfiguring the default behavior that changes the primary DNS suffix on member computers when a domain is renamed.

**Group Policy revision of the primary DNS suffix before a domain rename**
To avoid replication and other update traffic that is caused by automatic update of the primary DNS suffix on all member computers following a domain rename, you can use Group Policy to revise the primary DNS suffix to the new domain name before the domain rename operation. When you use Group Policy for this purpose, member names are not automatically updated, but they have the correct primary DNS suffix when you perform the domain rename.

Rather than going to each computer and changing the setting so that the computer name is not updated automatically when the domain name changes, you can use Group Policy to establish the primary DNS suffix for all computers in the domain as the target DNS domain name. Using Group Policy to establish the primary DNS suffix has the following beneficial effects:

- You disable the default behavior of updating the DNS suffix when the DNS domain name changes, thereby avoiding excessive replication traffic.

- The computer names are preconfigured to have a primary DNS suffix that matches the target domain name after the domain rename operation.

| **Note** |
| --- |
| The primary DNS suffix does not have to match the new domain name. If your current implementation uses a primary DNS suffix that does not match the DNS name of the domain to which the member computers are joined and if you do not want the DNS suffix to change after the domain rename, you can ensure that these computers are not renamed after the domain rename by verifying that at least one of the two conditions in "Conditions for automatic computer name change" earlier in this section is not satisfied. |

You can use the Group Policy setting **Primary DNS Suffix** to establish the primary DNS suffix for the domain as the new DNS domain name. When this Group Policy setting is in effect, it overrides the default behavior of changing the primary DNS suffix when the DNS name of the domain changes. In this case, the computer names remain the same when you rename the domain, and replication of name changes does not occur.

However, just as automatic change of the primary DNS suffix causes replication, setting **Primary DNS Suffix** causes replication as well. For this reason, Group Policy should be applied in stages to member computers. To apply Group Policy to all member computers in the domain or domains being renamed — while also avoiding replication on a large scale, divide computer objects among several locations in AD DS, either organizational units (OUs) or sites or both.

**Configuration requirements before application of Group Policy**
When you apply the Group Policy setting **Primary DNS Suffix**, the DNS suffix of member computers no longer matches the DNS name of the domain of which they are members. To allow the member computers of a domain to have a primary DNS suffix that does not match the DNS domain name, you must first configure the domain to accept the names that the DNS suffix can have. This configuration must be in place before you can set Group Policy to apply to a set of computers.

The **msDS-AllowedDNSSuffixes** multivalued attribute of the domain object (the domainDns object for the domain) contains a list of DNS suffixes that member computers of the AD DS domain can have. The Group Policy setting **Primary DNS Suffix** uses the values in this attribute. By editing this attribute to add the primary DNS suffix of the new domain, you make it possible

for Group Policy to set the new domain name as the primary DNS suffix.

**CA Requirements**

Management of enterprise certificates can continue during a domain rename procedure when the following requirements are in effect before domain rename:

- The CAs are not installed on domain controllers.
- As a best practice, all the CAs should include both Lightweight Directory Access Protocol (LDAP) and Hypertext Transfer Protocol (HTTP) Uniform Resource Locators (URLs) in their Authority Information Access (AIA) and certificate revocation list (CRL) distribution point extensions.

| **Note** |
| --- |
| If any certificate that is issued by a CA has only one of these URL types, the certificate may or may not work. Depending on the complexity of your domain configuration, the steps described in the "Step-by-Step Guide to Implementing Domain Rename" (in Windows Server 2003 Domain Rename Tools on the Microsoft Web site) might not be sufficient for proper management of CAs after the domain rename operation. Anyone who undertakes domain rename in an environment that uses certificates must have considerable expertise in managing Microsoft CAs. |

If one or more of the following conditions exist at the time of domain rename, CA management is not supported:

- The CA is configured to have only LDAP URLs for its CRL distribution point or AIA. Because the old LDAP extensions are invalid after the domain rename operation, all the certificates that are issued by the CA are no longer valid. As a workaround, you have to renew the existing CA hierarchy and all issued End Entity certificates.
- An interdomain trust relationship is based on cross-certification with name constraints. After the domain rename operation, the name constraints might not be valid. As a workaround, you have to reissue cross-certificates with appropriate name constraints.
- An e-mail name in the style of Request for Comments (RFC) 822, "Standard for the Format of ARPA Internet Text Messages," is used in the AD DS user account. If the CA (or the certificate template) is configured to include RFC 822–type e-mail names and this e-mail name style is used in the certificates that are issued, these certificates will contain an incorrect e-mail name after a domain rename operation. You should change any such user accounts before any certificates are issued.

For more information about certificates and CAs, see "Certificates Technical Reference" and "CA Certificates Technical Reference."

**Specifying the Target Forest Structure**

After you plan your domain rename, you begin the domain rename process by using the domain rename tool (Rendom) to make a list of the domain names, including application directory partition names, in the current forest structure. After you use Rendom to create this list, you create the new forest structure by editing the names in the list. In accordance with the DNS hierarchical naming scheme, the structure of the forest is implicit in the set of DNS names for the domains and the application directory partitions that make up the forest. In addition to specifying DNS name changes for domains and application directory partitions, you can also change the NetBIOS name of any domain. Changes to the DNS and NetBIOS names of the domains and to the DNS names of the application directory partitions that constitute the forest are supported, subject to the constraints outlined in "Domain Rename Constraints" in What Is Domain Rename?.

**Current Domain Names: Generating the Forest Description File**

The **rendom /list** command generates the current forest description and writes it to an output file (which has the default name Domainlist.xml) using an XML-encoded structure. This file contains a list of all domains and application directory partitions in the forest, along with their corresponding DNS and NetBIOS names. (Application directory partitions do not have NetBIOS names.) Each domain and application directory partition is also identified by a globally unique identifier (GUID), which does not change with a domain rename. To simplify specifying the new forest structure, Rendom gathers and compiles the current forest structure automatically in such a way that the new forest structure can be overlaid on top of the current forest structure.

The following figure shows an example forest description file that is generated for a forest that has three domains named cohovineyard.com (the forest root domain), sales.cohovineyard.com, and hr.sales.cohovineyard.com, as well as four application directory partitions named DomainDnsZones.hr.sales.cohovineyard.com, DomainDnsZones.sales.cohovineyard.com, DomainDnsZones.cohovineyard.com, and ForestDnsZones.cohovineyard.com that are used by DNS. In the example,

nonvariable values are designated in bold text.

**Forest Description File (Domainlist.xml) from the rendom /list Command**

```
             <Forest>
<Domain><!-- PartitionType:Application --><GUID>78438a56-f4a7-383a-5c82-
fe05a76ed464</GUID><DNSname>DomainDnsZones.hr.sales.cohovineyard.com</DNSname>
    <NetBiosName></NetBiosName><DcName></DcName></Domain><Domain>
    <GUID>89cf8ae3-f4a3-453b-ac5c-cb05a76bca40</GUID>
    <DNSname>hr.sales.cohovineyard.com</DNSname><NetBiosName>HR</NetBiosName><DcName>
</DcName></Domain><Domain><!-- PartitionType:Application --><GUID>b9748a56-c4a7-385a-
5d84-7490e76ba484</GUID><DNSname>DomainDnsZones.sales.cohovineyard.com</DNSname>
<NetBiosName></NetBiosName><DcName></DcName></Domain><Domain><GUID>89238a56-f3a1-343b-
bc5c-cb05a76bc341</GUID><DNSname>sales.cohovineyard.com</DNSname>
    <NetBiosName>SALES</NetBiosName><DcName></DcName></Domain><Domain><!--
PartitionType:Application --><GUID>ea658a56-f4a7-383a-5c82-cb05a76bdf35</GUID>
<DNSname>DomainDnsZones.cohovineyard.com</DNSname><NetBiosName></NetBiosName><DcName>
</DcName></Domain><Domain><!-- PartitionType:Application --><GUID>ea658a56-f4a7-383a-
5c82-cb05a76bd461</GUID>
    <DNSname>ForestDnsZones.cohovineyard.com</DNSname><NetBiosName></NetBiosName>
<DcName></DcName></Domain><Domain><! — ForestRoot --><GUID>34fg8ae3-f4a3-453b-ac5c-
3ce5a76bca42</GUID><DNSname>cohovineyard.com</DNSname>
<NetBiosName>COHOVINEYARD</NetBiosName><DcName></DcName></Domain></Forest>
```

**Target Domain Names: Editing the Forest Description File**

The current forest description file that is generated by the **rendom /list** command is a text file that you can edit to express the target forest structure as new domain names. To express the new structure, you simply modify the **<DNSname>** and **<NetBiosName>** fields to contain the new names where they are needed.

**Note**

- The domain GUID value in the <GUID> field represents a fixed name for a domain, and it cannot be modified. The GUID provides a permanent identity that can be used to identify a renamed domain in the new forest structure.

For example, using the preceding forest description file, if you want to change the DNS name of the hr.sales.cohovineyard.com domain to payroll.sales.cohovineyard.com and change its NetBIOS name from HR to PAYROLL, you replace the variable values in the appropriate lines in the forest description file as follows. (Nonvariable values are designated in bold text.)

- Current DNS and NetBIOS names:

  <**DNSname**>hr.sales.cohovineyard.com**</DNSname>**

  <**NetBiosName**>HR<**/NetBiosName**>

- Modified DNS and NetBIOS names; the two lines above are modified as follows:

  <**DNSname**>payroll.sales.cohovineyard.com<**/DNSname**>

  <**NetBiosName**>PAYROLL<**/NetBiosName**>

Based on the new forest structure, Rendom reads information for each domain from the directory and then generates a set of directory update instructions. By default, the information that is collected by Rendom is retrieved from any available domain controller in each domain. However, you have the option to specify a particular domain controller in each domain from which to retrieve the information that is required to generate the domain rename update instructions. To use this option, simply add the DNS host name of the desired domain controller in the <**DcName**><**/DcName**> field of the forest description file.

After you edit the forest description file, you can use the **rendom /showforest** command to display the new forest structure that is contained in the file. (This command does not have any effect on the directory itself.) The user-friendly format uses indentations to reflect the domain hierarchy in the forest.

**Transferring Domain Rename Instructions to AD DS**

After you create the new forest structure by editing the forest description file, the next step in the domain rename process involves translating the new forest structure into a sequence of directory update instructions to be executed individually on each domain controller in the forest. This translation occurs when you issue the **rendom /upload** command, and the resultant

domain rename instructions are uploaded to the configuration directory partition at the domain controller that is currently the domain naming operations master for the forest. The instructions are then replicated to all other domain controllers in the forest through normal replication of the configuration directory partition. Only after these rename instructions replicate to every domain controller in the forest and the required conditions are verified at each domain controller can each domain controller proceed with executing the rename instructions.

The following sections describe the details of the changes that are produced by the **rendom /upload** command. The actual sequence of actions that occur in response to the command are described in "Actions Performed by Rendom in Response to the **rendom /upload** Command" later in this section.

**Domain Rename Script and State File**

To transform the current forest structure into the target structure, Rendom translates the new forest description to a set of update instructions that the domain controller uses to update its replica directory partitions to make the name changes effective. The **rendom /upload** command generates the required domain rename instructions, which are encoded in a special script format that is private to the implementation. The **rendom /upload** command also generates the state file that is used to track the progress of the domain rename operation.

### Note

- The actions that are performed by the **rendom /upload** command and the resultant changes that are made to the directory are in preparation for the rename operation. No domain name changes occur at this step.

**Domain rename script for update instructions**

The script that is generated by the **rendom /upload** command is private to the domain rename procedure, and it does not create the directory changes themselves. Rather, the script provides instructions for domain controllers to execute in response to Rendom commands. The script is an XML-encoded document that has three components:

- Test: a read transaction to validate that the directory replica at the domain controller is in an appropriate state to perform an action.

- Action: an update transaction to be performed on the directory database at the domain controller.

- Signature: a cryptographic hash that proves to the domain controller that the script was prepared by the Rendom utility (and, therefore, that it is authentic and correct) and not manually by someone acting as an administrator.

**State file for tracking**

While translating the forest description to the update instruction script and transferring the script containing the description to the directory, Rendom also generates the state file (which has the default name DClist.xml). This file is structured as an XML-text document to facilitate tracking the state of each domain controller as it progresses through the various steps of the domain rename process. This file contains an entry for every domain controller in the forest. Each domain controller is identified by its DNS host name, along with fields for its current state and the last error encountered on the domain controller while it processed the domain rename instructions.

**Preparing Domain Controllers for Domain Rename**

When you run the **rendom /upload** command, certain changes occur on the domain naming operations master in preparation for the actual execution of domain rename. On the domain naming master, the XML-encoded script that contains the domain rename instructions is written to the single-valued, octet-string attribute **msDS-UpdateScript** on the Partitions container object (cn=partitions,cn=configuration,dc=*ForestRootDomain*) in the configuration directory partition. The Partitions container can be updated only on the domain controller that is the domain naming master for the forest; therefore, the **msDS-UpdateScript** attribute is necessarily changed on the domain controller that holds the domain naming operations master role (also known as the flexible single master operations (FSMO) role). From this source domain controller, the script that is stored in the **msDS-UpdateScript** attribute replicates to all domain controllers in the forest through normal replication of the configuration directory partition.

**Establishing a DNS Alias for a New Domain Name**

In addition to the **msDS-UpdateScript** value being written to the Partitions container, the new DNS name of each domain being renamed is also written by Rendom to the single-valued, Unicode-string attribute **msDS-DnsRootAlias** on the cross-reference object (class **crossRef**) that corresponds to that domain. Again, because cross-reference objects are stored in the Partitions container and the Partitions container can be updated only on the domain naming master, the **msDS-DnsRootAlias** attribute can be changed only on the domain controller that holds the domain naming operations master role. From this source domain controller, the DNS name in the **msDS-DnsRootAlias** attribute replicates to all domain controllers in the forest through normal replication of the configuration directory partition.

**Locator mechanism**

AD DS clients require DNS so that they can locate domain controllers. The Locator is an algorithm that runs in the context of the Net Logon service. The Locator finds the best domain controller for a request, based on network proximity, by using the resource records that are registered by domain controllers in DNS. During the installation of AD DS, the SRV and A resource records are dynamically registered in DNS by the Net Logon service. Both types of records are necessary for the functionality of the Locator mechanism. To find domain controllers in a domain or forest, a client queries DNS for the SRV and A DNS resource records of the domain controller. The resource records provide the client with the names and IP addresses of the domain controllers. In this context, the SRV and A resource records are referred to as Locator DNS resource records. Every domain controller also registers a canonical name (CNAME) record for use by AD DS replication.

The general format for DNS resource records includes several fields, including, but not limited to, the following:

```
Owner name    time to live    record class    record type    data/host name
```

According to the client request, the Locator can use various specified criteria that map to values in the SRV resource records to locate domain controllers with specific roles or capabilities. For example, the Locator can find a domain controller that has a full, writable replica of a domain directory partition; a domain replica in a specified site; or a domain controller that is a global catalog server. The owner name in an SRV resource record provides the specific information about the type of domain controller to be located. For example, a domain controller can be located in a specific site by using the following format:

```
_Service._Protocol.SiteName._sites.DnsDomainName
```

The following owner name in an SRV resource record specifies a domain controller (identified by the LDAP service running over the TCP protocol) in the East site and the Cohowinery.com domain:

```
_ldap._tcp.east._sites.cohowinery.com
```

For more information about the Locator and the DNS resource records that are registered by a domain controller, see "How DNS Support for Active Directory Works."

**Publishing two sets of Locator SRV resource records in DNS**

The directory service is extended in Windows Server 2003 and later forests to use the **msDS-DnsRootAlias** attribute to support the concept of a DNS alias for a domain. The presence of this attribute prompts the Net Logon service running on the domain controller to register the DNS domain name value of this attribute in DNS.

With the addition of the **msDS-DnsRootAlias** attribute, the Net Logon service has the ability to register not one but two domain names in DNS. The identities of the real (original) domain name and the alias (target) domain name are established by publishing two sets of resource records in DNS, as follows:

- The real domain name is published in DNS. Each domain normally has a single DNS name. The domain-specific DNS records that are published by the Net Logon service are derived from the **dnsRoot** attribute on the cross-reference object for the domain, which holds the real DNS name of the domain (as opposed to an alias). The forest-specific DNS records are derived from the cross-reference object for the forest root domain, which holds the real name of the forest root domain. The Net Logon service running on a domain controller also responds to Locator pings for the domain name and performs secure channel setup between a computer that is joined to the domain and the domain controller on which the Net Logon service runs.

- The alias domain name is published in DNS. Soon after the **msDS-DnsRootAlias** attribute value on a cross-reference object is set on a domain controller, either by an originating write or by a replicated write, the Net Logon service on the domain controller additionally publishes a parallel set of DNS Locator records for the domain alias name that is held in the **msDS-DnsRootAlias** attribute. The domain-specific DNS records are derived from the **msDS-DnsRootAlias** attribute on the cross-reference object for the domain, and the forest-specific DNS records are derived from the **msDS-DnsRootAlias** attribute on the cross-reference object for the forest root domain. Further, on domain controllers for a domain whose **msDS-DnsRootAlias** value is set, the Net Logon service responds to the Locator pings for the DNS alias as if the value in **msDS-DnsRootAlias** were the real domain name. Also, secure channel setup from a domain member that connects to a domain controller for a domain that is named in the **msDS-DnsRootAlias** attribute succeeds as if it were the real domain name.

Note that in the published SRV resource record corresponding to the alias domain name, the owner field reflects the new domain name, whereas the host name field reflects the actual DNS name of the domain controller. For example, if the domain cohovineyard.com is being renamed to cohowinery.com, the Net Logon service publishes the following two SRV resource records for the LDAP service on a domain controller named DC01 in that domain:

```
_ldap._tcp.cohovineyard.com  SRV  0  0  389  dc01.cohovineyard.com
_ldap._tcp.cohowinery.com  SRV  0  0  389  dc01.cohovineyard.com
```

Note that in the second SRV record above, the owner field corresponds to the new name to which the domain will be renamed, and the host name field reflects the true DNS name of the domain controller.

**Prepublishing CNAME Records for Replication**

The set of domain-specific resource records that are published in DNS by the Net Logon service running on a domain controller includes a DNS CNAME record that AD DS uses for replication.

The owner name of the CNAME record is provided by:

```
<DsaGuid>._msdcs.<DnsForestName>.
```

which allows a domain controller to locate a replication partner in the forest.

To find its replication partner, the domain controller requires knowledge of only the GUID of the directory system agent (DSA) object for that domain controller (as represented by **DsaGuid** in the CNAME record). The DSA GUID is the GUID of the NTDS Settings object (class **nTDSDSA**). Its value is stored in the **objectGUID** attribute of the NTDS Settings object, which is a child of the domain controller server object. These objects reside in the Sites container in the configuration directory partition. If the forest root domain is being renamed, it is essential that this CNAME record is published beforehand in DNS so that replication continues to work after a domain controller is updated to change the forest root domain name. If the DNS CNAME records for the new forest root domain name are not published beforehand for each domain controller, and records for the old forest root name are replicated among DNS servers that use AD DS to store DNS zones, replication is interrupted as a result of a cyclic condition. This condition generates the following error: "Cannot replicate because the CNAME record cannot be read from the local DNS replica; the CNAME record is not present in the local DNS replica because it is not replicating." Prepublication of the DNS records shortens the period during which the directory service is unavailable during the forest restructuring.

Note that in the prepublished CNAME resource record that corresponds to the new forest name, the owner field reflects the new forest name and the host name field reflects the actual DNS name of the domain controller. For example, if the forest cohovineyard.com is renamed to cohowinery.com, the following two CNAME resource records are published by the Net Logon service for a domain controller named DC01 in that domain:

```
<DsaGuid>.cohovineyard.com  IN  CNAME  dc01.cohovineyard.com
<DsaGuid>.cohowinery.com  IN  CNAME  dc01.cohovineyard.com
```

Note that in the second SRV record above, the owner field corresponds to the new name to which the forest will be renamed, and the host name field reflects the true DNS name of the domain controller.

Before the domain rename process can continue to the next step, the prepublished CNAME records corresponding to the value in **msDS-DnsRootAlias** must replicate to all DNS servers that are authoritative for those records.

**Establishing SPNs for a New Domain Name**

The DSA on every domain controller writes a set of SPNs to the **servicePrincipalName** attribute on the domain controller computer object in the domain directory partition. Among other things, SPNs are used for mutual authentication between domain controllers during AD DS replication. The specific SPN that is used for mutual authentication between replication partners has the following three-part format:

```
E3514235-4B06-11D1-AB04-00C04FC2DCD2/<DsaGuid>/<DnsForestName>
```

where the first part is the remote procedure call (RPC) interface GUID for AD DS replication, the second part is the GUID of the DSA object for the domain controller, and the third part is the DNS name of the forest root domain.

**Prepublishing Two Sets of SPNs**

Soon after the value for the **msDS-DnsRootAlias** attribute on a cross-reference object is set on a domain controller, either by an originating write or by a replicated write, the DSA on the domain controller rewrites the SPNs on the domain controller computer object so that each SPN that includes the domain name (or the forest root name) is present in two versions — one for the actual domain (or forest root) name and one for the alias that is held in the **msDS-DnsRootAlias** attribute of the domain (or forest root) cross-reference object. The SPN values that correspond to the domain name alias require prepublication for the same reason that the DNS CNAME records do, that is, to shorten a cyclic condition that produces the following error: "Cannot replicate because the SPN needed for mutual authentication cannot be read from the directory replica; the required SPN value is not present in the directory replica because it is not replicating." Prepublication of the SPNs shortens the period during which the directory service is unavailable during the forest restructuring.

Before the domain rename process can continue to the next step, the prepublished SPNs that correspond to the value in **msDS-DnsRootAlias** must replicate to all domain controllers in the domain as well as to all global catalog servers in the

forest.

**Actions Performed by Rendom in Response to the rendom /upload Command**
The following sequence of actions occurs in response to the **rendom /upload** command:

- Rendom connects to the domain controller that holds the domain naming operations master role for the forest and validates the forest description against the current state of the forest. If any of these validity checks fails, the command fails now. The following requirements are verified:
    - Each existing domain is part of the new forest.
    - The new forest is well formed.
    - The new forest does not reassign domain names that are being relinquished as part of the current domain rename operation.
- While it is still connected to the domain naming master, Rendom retrieves all the information that is needed to compute the list of rename instructions for updating the configuration and schema directory partitions.
- Rendom connects to a randomly selected domain controller (or the domain controller that is specified in the **<DcName></DcName>** field of the domain entry in the forest description file) for each domain, one by one, and retrieves all the information that is needed to compute the list of rename instructions for updating each domain.
- Rendom computes the full list of domain rename instructions for updating the entire forest (creates the script) and computes a signature to include in the script so that the authenticity of the script can be proven to a domain controller.
- While it is still connected to the domain naming master, Rendom writes the resulting script to the **msDS-UpdateScript** attribute of the Partitions container.
- While it is still connected to the domain naming master, Rendom writes the **msDS-DnsRootAlias** attribute of all cross-reference objects for domains that are being renamed.

On the control station (the computer from which the Rendom commands are issued), Rendom writes a new state file to track the progress of every domain controller in the forest. The state file contains an entry for every domain controller in the forest, with each domain controller entry marked to be in the Initial state.

**Note**

- Because the **msDS-UpdateScript** and **msDS-DnsRootAlias** attributes are first written to the directory on the domain controller holding the domain naming operations master role and then replicated to the remaining domain controllers in the forest, if the domain naming master is unavailable during the **rendom /upload** operation, the process cannot continue.

**Side effect of the rendom /upload command on forest configuration**
If certain types of changes in the forest are made after the domain rename operation begins, these changes can affect the outcome of the rename operation and cause it to fail in such a way that some of the domain controllers can never complete the domain rename process. To prevent this situation, successful execution of the **rendom /upload** command freezes the forest configuration with respect to these types of changes after the domain rename operation begins. The following operations cannot be performed in a forest after the **rendom /upload** command has completed successfully:

- The addition or removal of a domain or application partition
- The addition or removal of a domain controller into or from an existing domain
- The addition or removal of trusts, including cross-forest trusts. (Note that attributes of an existing trust can be changed during this frozen configuration. For example, a unidirectional trust can be converted to a bidirectional trust.)

The forest configuration remains frozen as long as the **msDS-UpdateScript** attribute of the Partitions container has a value

that indicates that a domain rename operation is in progress. The forest configuration becomes unfrozen at the conclusion of the domain rename operation through execution of the **rendom /end** command.

#### Verifying Domain Controller Readiness

This step of the domain rename process verifies that the directory database at each domain controller in the forest is adequately prepared to perform the directory modifications that are dictated by the script in the **msDS-UpdateScript** attribute. In response to the **rendom /prepare** command, the necessary verification is performed on each domain controller through execution of the test component of the script in **msDS-UpdateScript** as a read-only transaction on the local directory database. The test checks for the following conditions:

- The correct script in **msDS-UpdateScript** replicating to this domain controller
- Any trust relationships that are required by the new forest structure
- Prepublished SPNs for all domain controllers
- Name conflicts that are attributable to administrative errors since the time the script in **msDS-UpdateScript** was created. For example, an administrator might have mistakenly removed a trust that is required in the new forest or created a computer account whose **SamAcountName** equals the new name of some trusted domain, creating a name conflict with an interdomain trust account.

In addition, the test includes an authorization check on each domain controller to determine whether or not the user running the **rendom /prepare** command is authorized to execute the domain rename instructions that are contained in **msDS-UpdateScript**. The authorization check verifies that the user has Write permission on the **msDS-UpdateScript** attribute on the Partitions container. If the user is not authorized, the command fails with an error.

#### Actions Performed in Response to the rendom /prepare Command

The following sequence of actions occurs in response to the **rendom /prepare** command:

- Rendom issues a special RPC (for internal use only) to every domain controller in the forest in turn, requesting authorization and verification of readiness as encoded in the test component of the script in **msDS-UpdateScript**. Rendom issues the RPC to multiple domain controllers at a time with a high degree of concurrency, while ensuring that resource limits on the computer that is executing the command are not exceeded. The RPC request and response are signed and sealed for integrity and privacy.
- In response to the RPC, each domain controller performs the authorization check, ensures the authenticity of the script in **msDS-UpdateScript** by validating the signature, and verifies the test component of the domain rename script before responding. If any of these checks fails on a domain controller, the RPC returns an error for that domain controller.
- Rendom updates the state file with the state of each domain controller that was successfully contacted and verified. The state of each successfully verified domain controller is updated from the Initial state to the Prepared state. The Prepared state indicates that the domain controller authorized the execution of the restructure and that the contents of its directory database are consistent with the rename instructions that are contained in **msDS-UpdateScript**. If a domain controller cannot be contacted or if it fails any of the checks, its corresponding state in the state file remains as Initial with an appropriate error code and message to indicate the cause of failure.

#### Executing Domain Rename Instructions

In the final step of the domain rename process, the directory database at each domain controller in the forest is updated individually to implement the new forest structure. This process does not rely on AD DS replication. Rather, the action component of the script in **msDS-UpdateScript** performs the required modifications to the directory database locally on each domain controller as a single update transaction. The action component of the script is the actual update of the domain name. The **rendom /execute** command performs this final update step.

### Note

- The actions that are performed at this step make the actual domain name changes effective at each domain controller. This step causes a brief interruption in service. Before this point in the process, forest service is not disrupted.

#### Single-User Mode

To perform the action component of the script in **msDS-UpdateScript**, the directory service on each domain controller enters a special mode called single-user mode. In single-user mode, AD DS refuses service to all normal clients of the directory service, including LDAP, Messaging API (MAPI), replication, Security Accounts Manager (SAM), Kerberos, and other directory service RPCs. In this mode, only the directory service itself can read and write the local directory database, using a single thread. The single-user mode is needed because the domain rename updates that the directory service performs invalidate internal directory data structures. After the directory service performs these updates in single-user mode, the domain controller reboots. After the reboot, the internal data structures are rebuilt to a consistent state.

**Update Transaction**

All the directory updates that are specified by the action component of the script in **msDS-UpdateScript** are performed within an Extensible Storage Engine (ESE) database transaction. If no errors occur, the transaction is committed; otherwise, the entire transaction is rolled back. Domain controllers that commit the update transaction in single-user mode and then reboot are considered to have completed the domain rename.

**Entering single-user mode**

As part of a successful update transaction, the nonreplicated, single-valued integer attribute **msDS-ReplicationEpoch** on the NTDS Settings object for the domain controller is updated to a new value through incrementation of its current value. If two domain controllers have different **msDS-ReplicationEpoch** values, no directory replication RPC interaction is allowed between them. In addition to replication, nested group membership evaluation and global catalog lookups are also discontinued. Because the domain rename procedure involves making these updates independently at all domain controllers in the forest, it is impossible to modify these domain controllers simultaneously. The goal of the **msDS-ReplicationEpoch** attribute is to minimize potentially complex interactions, including replication, between those domain controllers that have completed the domain rename and those domain controllers that have not yet completed the domain rename.

**Switching real and alias DNS names**

Further, as part of a successful update transaction, the values of the **dnsRoot** and **msDS-DnsRootAlias** attributes on the cross-reference objects of renamed domains are interchanged so that the new domain name, formerly stored in **msDS-DnsRootAlias**, becomes the effective domain name that is stored in **dnsRoot**. The old domain name is saved as a DNS alias until a subsequent step removes it.

**Actions Performed in Response to the rendom /execute Command**

The following sequence of actions occurs in response to the **rendom /execute** command:

- Rendom checks to ensure that all domain controllers in the state file are marked with a current state of Prepared. If the state of any domain controller is not Prepared, Rendom reports an error and the process cannot continue.

- When all domain controllers in the state file are in the Prepared state, Rendom issues a special RPC (for internal use only) to every domain controller in the forest requesting execution of the directory updates that are encoded in the action component of the script in **msDS-UpdateScript**. Rendom issues the RPC to multiple domain controllers at a time with a high degree of concurrency, while ensuring that resource limits on the computer that is executing the command are not exceeded. The RPC request and response are signed and sealed for integrity and privacy.

- In response to the RPC, each domain controller first verifies the test component of the domain rename script in **msDS-UpdateScript** (just as in the previous step that checks for domain controller readiness). The domain controller then performs the action component of the script in an update transaction, as described in "Update Transaction" earlier in this section. If any check fails on a domain controller or if the update transaction cannot be successfully committed, the RPC returns an error for that specific domain controller.

- Rendom updates the state file with the state of each domain controller that was successfully contacted. For each domain controller that successfully completed the update, Rendom changes the state from Prepared to the final state of Done. If a domain controller cannot be contacted or if it fails any of the checks, its corresponding state in the state file remains Prepared, with an appropriate error code and message to indicate the cause of failure. If the RPC returns with an error that is deemed irrecoverable, the corresponding state for the domain controller is updated to the final state of Error, with an appropriate error code and message to indicate the cause of failure.

**Determining Domain Rename Completion**

In a large forest, some number of domain controllers might prove impossible to contact during the domain rename process. These domain controllers never reach the final state of Done. You must decide how long to continue to try to reach domain controllers that are unreachable and how long to retry failed update attempts on domain controllers that have reached the Error state. When further progress in the forest is not possible, declare the domain rename process to be complete. All domain controllers that did not reach the final Done state, because they were either unreachable or finished in the Error state, must be

demoted or removed from service, if demotion is not possible. For a forest to function without problems after a domain rename, only domain controllers that have reached the Done state can exist in the forest.

**Reconciling Group Policy After a Domain Rename**

When the DNS name of a domain changes, any references to Group Policy objects (GPOs) in the renamed domain through Group Policy links (the **gpLink** attribute) on sites, domains, and OUs are rendered invalid because they are based on the old domain name. Further, the optional attribute **gpcFileSysPath** on a GPO that holds a uniform naming convention (UNC) path to a Group Policy templates folder located in the SYSVOL of the renamed domain is also rendered invalid because the path uses the old domain DNS name. To correct the severed Group Policy links and the invalid UNC paths in GPOs in the renamed domain, you can use a Group Policy tool, Gpfixup.exe, to refresh the Group Policy links and the UNC paths in GPOs that are based on the new domain name. The Gpfixup tool is available for download in Windows Server 2003 Domain Rename Tools on the Microsoft Web site. The tool is built into domain controllers that run Windows Server 2008 R2 and Windows Server 2008. It is also available in Remote Server Administration Tools (RSAT). Run Gpfixup once for every renamed domain soon after the actual domain rename operation is complete and before another domain rename operation is performed.

### Note

- Gpfixup refreshes all intradomain GPO references or links (that is, where the link and the target GPO are in the same domain) in the renamed domain. However, cross-domain references to GPOs in the renamed domain (that is, where the link is in a different domain from the domain containing the GPO) are not rebuilt automatically by this tool. For these cross-domain references to work, you must repair the cross-domain links manually by deleting the old Group Policy links and re-establishing new links.

**Removing Old Domain Names After a Domain Rename**

Following completion of the domain rename process for a forest, you use the **rendom /clean** command to remove the old domain names from AD DS. This cleanup step removes all values of **msDS-DnsRootAlias** from the domain naming operations master, and removal of this value is replicated to all domain controllers in the forest. Because this attribute holds the old domain name after the domain rename is completed, replication of the removal of the **msDS-DnsRootAlias** attribute value to all domain controllers in the forest prompts the Net Logon service on the domain controller to deregister the DNS Locator resource records for the old domain name. In the course of this deregistration, the DNS CNAME resource records, which are used by AD DS replication, are also removed for the old domain name. In addition, the cleanup procedure removes the **msDS-UpdateScript** attribute value from the Partitions container on the domain naming master.

After you run the **rendom /clean** command successfully, the new forest is ready for another forest restructuring operation.

# Core Operating System Collection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Core Operating System Collection**
The Microsoft Windows Server 2003 operating systems contain core technologies that provide basic functionality such as printing, device management, data recovery and troubleshooting.

**Recovery and Reliability**
Recovery and reliability technologies help you to prevent problems such as data loss and system instability during all phases of operation — from startup through shutdown. In the event of a problem, these technologies help you to recover and repair your data and operating system.

**Device Management Technologies**
Device management provides a way for Microsoft Windows Server 2003 to uniformly notify all applications and system components of changes that may affect their operation or access to resources.

Applications and system components use and process device messages between the operating system and devices to take advantage of new resources when they become available and to prevent loss of data when existing resources become unavailable. Device messages notify applications of device change events, such as the removal of a hardware device; power messages notify applications of power management events. Applications and device drivers can also define and use custom messages to enable notification of other types of events.

**Printing Technologies**
Network printing is the collection of software components in the Microsoft Windows Server 2003 operating systems that provide network printing services for client computers. In addition to providing services to clients running versions of the Windows operating system, Windows Server 2003 can provide network printing services to client computers running other operating systems when the appropriate components are installed.

In some small offices, it might be practical to have a printer attached to every computer, but in an organization consisting of more than a few computers, sharing printing resources is desirable. Larger organizations with many users might be spread out over a large area and consist of multiple computing platforms. Windows Server 2003 gives you options for printing to remote printers in a variety of network configurations and from a variety of computing platforms.

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Network Printing?**

**In this section**

- Common Printing Scenarios
- Dependencies and Interactions

Network printing is the collection of software components in Windows Server 2003 that provide network printing services for client computers. In addition to providing services to clients running versions of the Windows operating system, Windows Server 2003 can provide network printing services to client computers running other operating systems when the appropriate components are installed.

In some small offices, it might be practical to have a printer attached to every computer, but in an organization consisting of more than a few computers, sharing printing resources is desirable. Larger organizations with many users might be spread out over a large area and consist of multiple computing platforms. Windows Server 2003 gives you options for printing to remote printers in a variety of network configurations and from a variety of computing platforms.

Running on a variety of client platforms, applications send print jobs to printers that are connected to a print server running Windows Server 2003. The printer can be connected to the print server through internal network adapters, external network adapters, or another server. This subject discusses the nature and action of components involved in providing network printing services on Windows Server 2003.

**Common Printing Scenarios**

With network printing services in Windows Server 2003, you can provide printing services for a variety of client operating systems, including non-Windows operating systems and older versions of Windows. The following scenarios describe the printing services provided by Windows Server 2003 to various client platforms.

**Printing From Client Computers Running Windows 2000 and Windows XP**

Client computers running Windows 2000 or Windows XP are able to send print jobs to print servers running Windows Server 2003 with no additional software. They are also able to use the Active Directory directory service to locate print devices with the capabilities and location that the user desires.

**Printing From Client Computers Running Windows 95, Windows 98, and Windows NT**

Client computers running Windows 95, Windows 98, and Windows NT can use Windows Server 2003 network printing services without adding software. However, to use Active Directory to search for print devices, these clients must have Active Directory Client Extensions installed.

In Windows Server 2003, printer drivers for client computers running Windows 95, Windows 98, or Windows Millennium Edition can be installed on the print server. When a client then connects to the server, it downloads the drivers from the server and begins printing.

**Printing From Client Computers Running Other Microsoft Operating Systems**

Client computers running Windows 3*.x* and MS-DOS operating systems use their own printer drivers. Clients with these systems can get a list of all available printers in a domain but cannot use Active Directory. These clients can print to a print server running Windows Server 2003 if a local printer is installed and the local port is redirected to the shared printer on the print server running Windows Server 2003.

**Printing From UNIX-Based Clients**

Computers running UNIX-based operating systems, and other systems that use the client program line printer remote (LPR), can send printing jobs to the receiving utility, line printer daemon (LPD), on a print server running Windows Server 2003. LPR clients must comply with Request for Comments (RFC) 1179. For more information about LPR, see RFC 1179 in the IETF RFC Database.

The combination of the LPR and LPD was developed for UNIX-based computers, but it is widely used for many operating systems. Both utilities are included in Print Services for UNIX.

**Printing From NetWare Clients**

With File and Print Services for NetWare installed on a print server running Windows Server 2003, the server appears to a NetWare client as a NetWare 3.*x*–compatible file and print server. File and Print Services presents the same dialog boxes to the client as a NetWare-based server uses to process a print job from a client. A user can display and search for printers on the print server running Windows Server 2003 just like in a NetWare environment.

**Printing From Macintosh Clients**

Macintosh clients can send print jobs to a print server that is running Windows Server 2003 when Print Server for Macintosh is installed on the server. To the Macintosh-based client, the server appears to be an AppleTalk printer on the network, and no reconfiguration of the client is necessary.

**Dependencies and Interactions**

The following software components might be required to provide print services to clients, depending on the client platform.

- **Active Directory Client Upgrade.** Clients that are running Windows 95, Windows 98, and Windows Millennium Edition can use Windows Server 2003 network printing services without adding software. However, to use Active Directory for a printer search, these clients must have Active Directory Client Extensions installed.

- **Network Redirector.** Computers running MS-DOS, Windows 3.0, and Windows 3.1 send documents for printing to local ports. To print to network print servers, clients running these operating systems require a network redirector for printing. A redirector is not necessary for Microsoft Windows for Workgroups because the redirector is built in. In these cases, install Microsoft Network Client 3.0 for MS-DOS or Windows 3.*x*.

- **Print Services for UNIX.** To accept printing jobs from LPR clients, Windows Server 2003 must have the LPD service installed. LPD is provided by Print Services for UNIX.

- **File and Print Services for NetWare.** To accept printing jobs from NetWare clients, Windows Server 2003 must have the File and Print Services for NetWare installed.

- **Print Server for Macintosh.** To accept printing jobs from AppleTalk clients, like a Macintosh computer, Windows Server 2003 must have the Print Server for Macintosh installed.

# How Network Printing Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Network Printing Works**
**In this section**

- Terms and Definitions
- Network Printing Architecture
- Network Printing Protocols
- Network Printing Processes and Interactions
- Network Ports used by Network Printing
- Related Information

Network Printing enables users in locations geographically separate from each other and from their print devices to produce documents for themselves and others. Print servers enable multiple clients to share one or more print devices. By using the Active Directory directory service in the Windows 2000 Server and Windows Server 2003 operating systems, users can locate printers in a target location that supports the features necessary to produce their documents.

This section describes the components and processes of network printing with print servers running Windows Server 2003.

**Terms and Definitions**
The following three terms are data types associated with Network Printing.

**RAW**
Data type used in a page description language that is ready to be sent to a print device; for example, PCL or PostScript. This is the default data type for print jobs on computers that are not running Windows XP Professional or Windows 2000. These RAW files are device-dependent; that is, the spooled data is destined and formatted for a particular device.

**EMF**
Data type used between print clients running Windows XP Professional and print servers running Windows Server 2003. With an enhanced metafile (EMF), the Graphics Device Interface (GDI) releases console control after generating the EMF. The EMF data is then interpreted in the background on a spooler thread and sent to the printer driver. Splitting the rendering of a print job in this way is especially useful for very large documents because the application is not tied up for the entire rendering time.

EMF spool files are encoded to provide greater printer independence. For example, a graphic measuring 2 inches by 4 inches on a video graphics adapter (VGA) display and stored in an EMF maintains those dimensions whether it is printed on a 300-dpi laser printer or a 75-dpi dot-matrix printer. The EMF data type also ensures that the print server uses the fonts you specified.

**TEXT**
Data type used to send a simple-text print job to a printer (such as a PostScript device) that cannot interpret simple text. The spooler creates a new print job, embedding the text in print instructions that are derived from the printer's defaults for font, form, and orientation. Several character sets are in common use, and text files do not indicate which one to use. The TEXT data type uses the ANSI character set, so it might print some characters incorrectly if the application uses a different set.

**Network Printing Architecture**
Network printing components include a server spooler on a print server running a product in the Windows Server 2003 family and a client spooler running on a client computer. Because print jobs usually originate on a client computer, this section first describes the architecture of the client spooler.

**Client Spooler**
The client spooler (Winspool.drv) is the component on Windows operating systems that delivers print jobs from applications on the client computer to print servers. On client computers running Windows XP Professional or Windows 2000 operating systems, print jobs are delivered directly to the client spooler; on other Windows operating systems, a redirector is necessary to deliver print jobs to the client spooler, and on non-Windows operating systems, other mechanisms are required to complete

a print job.

The following figure shows the components involved in generating and sending print jobs to the print server.

**Components of Client Computers That Generate and Send Print Jobs**

**Note**

- The preceding figure is a simplification of network printing processes. Specific platforms use different components and processes. For information about printing processes specific to your environment, you might need to refer to documentation specific to your platform.

Windows clients and non-Windows clients include the following operating systems:

**Windows Clients**
Client computers running Windows 95, Windows 98, Windows Millennium Edition, Windows 2000, Windows XP, or Windows Server 2003.

**Non-Windows Clients**
Client computers running UNIX, Apple Macintosh, or MS-DOS. This group also includes NetWare clients.

The following table defines the client components that generate and send print jobs.

**Components of Client Computers That Generate and Send Print Jobs**

| Component | Description |
|---|---|
| Windows Application | Any program that creates printable data. |
| Non-Windows Application | Any program that creates printable data. |
| Client Spooler | Processes and sends print jobs from the client to the print server. |
| Graphics Device Interface (GDI) | Provides services to the printer driver, including caching, client-server communications, and character conversion. |
| Printer Driver | Communicates with print devices to generate output from data supplied by the GDI. |

| | |
|---|---|
| Line Printer Remote (LPR) | Protocol that sends print jobs to a server running the server-side protocol, Line Printer Daemon (LPD). |
| AppleTalk | Protocol used by Macintosh clients and Windows servers, when Services for Macintosh is installed on the servers. |
| NetWare | Protocol used by NetWare clients for file and print services and by Windows servers when NWLink is installed on the server. |
| Local Print Device | Prints device-specific data. This device is attached to a local port on the server. |
| Remote Print Device | Prints device-specific data. This device is directly connected to the network and managed by this print server. |
| Remote Print Server | Accepts print jobs for print devices it manages. |

**Server Spooler**

Windows Server 2003 accepts and delivers print jobs using a variety of protocols to serve a diversity of client computers and print devices. The server spooler is the primary component of network printing architecture on Windows Server 2003. The server spooler and its components are consolidated into a single architecture, providing smooth background printing by using background thread processing. Because the thread processing for one print job must complete before the processing begins for the next print job, the spooler passes data to the printer only when the printer is ready to receive more data.

The following figure illustrates the server spooler and how it processes a print job.

**Components of Windows Server 2003 Print Server**

The following table defines the components of network printing on Windows Server 2003.

**Components of Network Printing on Windows Server 2003**

| Component | Description |
|---|---|
| Print Spooler Service | Manages the printing process, which includes retrieving the location of the correct printer driver, loading the driver, spooling high-level function calls into a print job, scheduling the print job for printing, and so on. |
| Print Router | Routes print jobs. The print router determines which print provider to call based on a printer name or other information supplied with the print job. |
| Local Print Provider | Provides job control and printer management capabilities for all printers that are accessed through the print monitors of the local print provider. |
| Print Monitor | Directs print jobs to the language monitor and port monitor. |
| Language Monitor | Provides bidirectional communication between the print device and the client. |
| Local and Remote Port Monitors | Sends print jobs to print devices that are attached to local and remote ports. |
| Graphics Device Interface (GDI) | Provides services to the printer driver, including caching, client-server communications, and character conversion. |
| Printer Driver | Communicates with print devices to generate output from data supplied by the GDI. |
| Remote Print Provider | Directs print jobs to remote print servers. |
| Local Print Device | Prints device-specific data. This device is attached to a local port on the server. |
| Remote Print Device | Prints device-specific data. This device is directly connected to the network and managed by this print server. |
| Remote Print Server | Accepts print jobs for print devices it manages. |

**Network Printing Protocols**
The following protocols are used by Windows Server 2003 when providing network print services. Note that some protocols might not be used, depending on the needs of the client computers.

**Server Message Block (SMB)**
A file-sharing protocol designed to allow network computers to transparently access files that reside on remote systems over a variety of networks. The SMB protocol defines a series of commands that pass information between computers. SMB uses four message types: session control, file, printer, and message.

**Line Printer Remote (LPR)**
A connectivity tool that runs on client computers and that is used to print files to a computer running a Line Printer Daemon (LPD) server.

**Line Printer Daemon (LPD)**
A service on a print server that receives print jobs from Line Printer Remote (LPR) tools that are running on client computers.

**remote procedure call (RPC)**
A message-passing facility that allows a distributed application to call services that are available on various computers on a network. Used during remote administration of computers.

**Internetwork Packet Exchange (IPX)**
A network protocol native to NetWare that controls addressing and routing of packets within and between local area networks (LANs). IPX does not guarantee that a message will be complete (no lost packets).

**Internet Printing Protocol (IPP)**
The protocol that uses the Hypertext Transfer Protocol (HTTP) to send print jobs to printers throughout the world. Windows 2000, Windows XP, and Windows Server 2003 support Internet Printing Protocol (IPP) version 1.0.

**Transmission Control Protocol/Internet Protocol (TCP/IP)**
A set of networking protocols widely used on the Internet that provides communications across interconnected networks of computers with diverse hardware architectures and various operating systems. TCP/IP includes standards for how computers communicate and conventions for connecting networks and routing traffic.

**AppleTalk**
The set of network protocols on which AppleTalk network architecture is based. The AppleTalk Protocol is installed with Services for Macintosh to help users' access resources on a network.

**Simple Network Management Protocol (SNMP)**
A network protocol used to manage TCP/IP networks. In Windows, the SNMP service is used to provide status information about a host on a TCP/IP network.

**Network Printing Processes and Interactions**
This section briefly describes the network printing process on the client and then the server, followed by a more detailed description of the components and their activities. This section describes a fully functional network with all required software installed on the server and the clients. It also assumes that the print server is running Windows Server 2003.

**Print Client Processing**
The components and processes involved in printing vary depending on the client and the operating system, even within the Windows family of operating systems. Because of differences between print clients, the components used in the server process can also vary. Since the following description of the printing process is simplified, the print clients can be grouped into Windows and non-Windows platforms.

**Client Computers Running a Windows Operating System**
On client computers running Windows 2000 or Windows XP operating systems, the client spooler sends an enhanced metafile (EMF) through the client spooler to the spooler on the print server.

The client spooler forwards information and data from the GDI and the printer driver as an EMF to the spooler on the print server. The client spooler does this by making a remote procedure call (RPC) to the server spooler (Spoolsv.exe), which makes a direct application programming interface (API) call to the print router (Spoolss.dll). The print router polls the remote print providers, and the remote print provider (Win32spl.dll) makes an RPC to the server spooler, which receives the print job over the network.

On clients running Windows 95, Windows 98, or Windows Millennium Edition, a Windows-based application creates an EMF, which is then rendered to a page description language (PDL). Next, the print job is sent to a local printer port, where it would go if printing to a local printer, by the Server Message Block (SMB) redirector. The redirector delivers the job to the print server service running on the print server.

On clients running Windows NT 4.0, applications create output in a page-description language (PDL). Next, the PDL data is sent with an RPC over SMB to the server spooler.

**Client Computers Running a Non-Windows Operating System**
On client computers running a non-Windows operating system, or using an application that is designed for a non-Windows operating system, a software component performs functions similar to that of the Graphics Device Interface (GDI). Next, the device information and print data are sent to the print server. Windows Server 2003 can accept print jobs sent from a client using Line Printer Remote (LPR), AppleTalk, and NetWare when the server is running, respectively, the Line Printer Daemon (LPD) service, Print Server for Macintosh, or File and Print Services for NetWare. Typically, such clients would be running UNIX, Apple Macintosh, and NetWare, though additional software could enable them to use a protocol associated with a different system. Also, a client might send a print job by using Internet Printing Protocol (IPP).

**Print Server Processing**
On the print server, the service that initially receives incoming print jobs depends on the protocol used by the client to submit the print job. Print jobs sent by way of AppleTalk are received by the Service for Macintosh component, print jobs sent by way of LPR are received by the LPD service, and print jobs sent by way of SMB are received by the Server service.

However, print jobs from most client computers running Windows are received by the Spooler service by way of RPC. This includes print jobs from client computers running Windows 2000 and Windows XP, and it is print jobs from such clients that this section describes.

The Spooler service, Spoolsv.exe, is an executable file that is installed as a service. The spooler is loaded when the operating system starts, and it continues to run until the operating system is shut down. The Spooler service manages the printing process, which includes such tasks as retrieving the location of the correct printer driver, loading that driver, spooling high-level function calls into a print job, and scheduling the print job for printing. When the tasks for a particular print job are complete, the Spooler service passes the job to the router.

The spooler router, Spoolss.dll, determines which print provider to call, based on a printer name or other information provided with the print job. If the print job is for a printer served by the local server, the provider is the local print provider, Localspl.dll; if the print job is for a printer served by a remote server, the job is routed to a remote print provider.

The print provider is the software that supports the specified print device. The local print provider, Localspl.dll, actually calls the printer driver to render the print job. The print provider is also responsible for spooling the print job.

After a print job is spooled, it is the Print Monitor that directs the output to the appropriate port monitor. Port monitors provide a communications path between the print spooler and the port drivers that access the port hardware. Port monitors serve both local print devices connected directly to the server and remote print devices connected directly to the network.

In addition to the port monitor, when the target print device supports two-way communication, a language monitor provides a communication path for configuration and status information. The language monitor supports delivery of unsolicited information from the printer, for example, notice that it has run out of paper.

**Printing Components in Detail**
The following sections cover in greater detail some of the components on the client and server involved in network printing.

**Remote Print Provider**
When the server spooler receives a print job from the client spooler, the print router queries the remote print providers, and gives control of the print job to the first provider that recognizes the destination printer. Remote print providers can be created by other companies; Microsoft supplies the following three remote print providers:

**Win32spl.dll**
Win32spl.dll is the remote print provider on a Windows-based network. Win32spl.dll sends jobs to print servers running Windows NT 4.0 or Windows for Workgroups. For a print server running Windows Server 2003, Win32spl.dll makes an RPC to the spooler on the server (Spoolsv.exe), which makes a call to the print router (Spoolss.dll). The print router receives the job over the network and passes it to the local print provider as if a local client had submitted it.

**Inetpp.dll**
Inetpp.dll performs specific processing on Internet print servers. For an Internet print server, Inetpp.dll recognizes the printer name by its URL and submits the print job to the appropriate printer by using IPP.

**Nwprovau.dll**
Nwprovau.dll performs specific processing on NetWare print servers. For a NetWare print server, Nwprovau.dll recognizes the printer name when the print router on the print server running Windows Server 2003 polls it. Nwprovau.dll takes control of the print job and sends a message to the NetWare Workstation Service, which in turn passes control to the NetWare redirector. The NetWare redirector sends the print job to the NetWare print server.

**Print Router**
When submitting a document for printing, the application communicates with the client side of the spooler (Winspool.drv). Winspool.drv makes an RPC connection to the server side of the spooler (Spoolsv.exe), which makes a direct API call to the print router (Spoolss.dll), which is also on the server side of the spooler. The print router passes the print job to the local print provider.

**Graphics Device Interface (GDI)**
The GDI calls the printer driver and provides information about the type of printer needed and the data type used. The printer driver responds by sending printer data to the GDI, which the GDI passes to the spooler.

Computers running Windows 2000, Windows XP Professional, and any 32-bit version of Windows Server 2003 can run 16-bit applications through a process called Windows on Windows (WOW). WOW allows 16-bit applications to run on an x86-based computer.

WOW interacts with the applications through the GDI and with printer drivers through the device driver interface (DDI). The GDI also provides services to the printer driver, including caching, client and server communications, and conversion from American National Standards Institute (ANSI) character set to Unicode.

### Note

- The 64-bit versions of Windows XP Professional and Windows Server 2003 do not support 16-bit applications. However, WOW 64 does allow 32-bit applications to run on 64-bit versions of Windows XP Professional and Windows Server 2003.

**Printer Drivers**
A printer driver is a software program that understands how to communicate with printers and plotters (devices used to draw charts, diagrams, and other line-based graphics). Printer drivers translate the information that an application sends through the

GDI into drawing commands that the printer understands. These drawing commands are for creating text and graphics. Various drivers must be installed on the print server to support different hardware and operating systems. For example, an administrator who uses a computer that is running Windows Server 2003 and who shares a printer with clients that are running Windows 95, Windows 98, and Windows Millennium Edition, might need to install the appropriate drivers so that clients that are running these versions of Windows are not prompted to install the missing drivers.

The printer driver sends information about the printer settings, including the specifications that are needed to produce each character of the document, to the GDI. The printer driver also transmits helper services or utilities required to make the output print correctly.

Some kernel-mode printer drivers might cause the system to stop responding. Windows Server 2003 gives you the ability to control the installation of printer drivers. By default, all editions of Windows Server 2003 block the installation of kernel-mode drivers, but you can allow their installation by disabling the Group Policy setting **Disallow installation of printers using Kernel Mode drivers**. This setting affects only the installation of new kernel-mode drivers. If you are upgrading your system, existing kernel-mode drivers are unaffected.

Windows Server 2003 provides the following three generic printer drivers:

- Universal (Unidriver)
- PostScript
- HP-GL/2 plotter

**Universal printer driver (Unidriver)**
The Unidriver is also called the raster driver because it supports raster (bitmap) graphics printing and is compatible with many printers. This driver supports the following features:

- Color printing at various depths, such as 4 bits per pixel (bpp), 8 bpp, and 24 bpp.
- Scalable TrueType and OpenType fonts, device fonts (including double-byte), grayscale printing, font substitution, run length encoding (RLE), Tag Image File Format (TIFF) version 4.0, and Delta Row Compression (DRC).
- An extension interface that allows printer manufacturers to customize the driver for specific models.
- Vector graphics languages HP-GL/2 and PCL-XL, monochrome, and color. This is a change from the version of Unidriver that shipped with Windows 2000. (The added HP-GL/2 support, which is used with normal PCL5e printers, is different from the HP-GL/2 for plotters, which is used only for plotters.)

The Unidriver contains the following component files:

- Unidrv.dll is the printer graphics driver file for printer languages based on raster images, including most inkjet and dot-matrix printer languages.
- Unidrvui.dll is the configuration file. It displays the user interface for Unidrv.dll.
- Unires.dll, Stdnames.gpd, Ttfsub.gpd and some other support files.
- Raster minidriver, which has the file name extension .gpd, is the data file, and is also called the characterization file. The file name depends on the printer or printer family.

**PostScript printer driver**
The Windows Server 2003 PostScript driver sets up the print jobs for printers that have an onboard PostScript interpreter. This driver automatically supports key features — including binary transfer compression, resolution, and paper source — for printers reporting as PostScript levels 1, 2, and 3. Its output is fully compliant with Document Structuring Convention (DSC) 3.0, a structural specification for PostScript documents.

This driver contains the following component files:

- Pscript5.dll is the driver file.

- Ps5ui.dll is the configuration file. It displays the user interface for the driver file, reports device capabilities to applications, and handles DevMode settings. Ps5ui.dll also allows you to enable TrueType and OpenType font substitution and image color matching and to determine whether color matching needs to be done on the host or on the printer.

- The data file, which has the file name extension .ppd, is also known as a characterization file. The file name preceding the .ppd extension varies and is typically determined by the printer manufacturer. PPD files are the only printer driver files that are generally binary-compatible across processors and platforms.

**HP-GL/2 plotter driver**

The Windows Server 2003 plotter driver supports diverse plotters that use the HP-GL/2 language; however, Windows Server 2003 does not support HP-GL. The output from an HP-GL/2 driver requires a plotting device that can process all the enhancements built into the HP-GL/2 language.

This driver contains the following component files:

- Plotter.dll is the driver file.

- Plotui.dll is the configuration file. It displays the user interface for Plotter.dll.

- The driver contains a data file, which has the file name extension .pcd. The file name preceding the .pcd extension varies and is typically determined by the plotter manufacturer.

**Local Print Provider**

The local print provider, Localspl.dll, writes the job data to a spool (.spl) file. It also tracks administrative information, such as user name, document name, and data type, in a shadow (.shd) file. Spooling protects a print job by saving it on disk. If a power failure or other disaster occurs before all jobs in the queue are printed, the .spl and .shd files preserve the documents and prevent loss of data after processing resumes.

### Note

- If the print job is only partially saved to disk, the spooler might recognize the print job as corrupt and delete it upon restart.

Next, Localspl.dll polls the print processors for recognition of the document data type. If no data type has been set, Localspl.dll receives the job and uses the default data type.

By default, .spl and .shd files are written to the folder *systemroot*\System32\Spool\Printers, and they are deleted after the job prints. If the hard disk partition containing Windows Server 2003 does not have enough space for these files, you can change the location of the folder. You might also move the spool files if you want to move the spooling load to a separate disk array.

### Note

- Do not attempt to spool to the root of a disk, such as D:\. This causes the files to spool to the old default spool folder.

**Print Processor**

The print processor is a part of the spooler process. If the job type is EMF, the print processor works with GDI to move the spooled print jobs from the hard disk to the printer driver. If the data type is RAW, the print processor helps in moving the job directly to the printer. The print processor controls certain features of the print job, depending on the kind of job. For example, if the data type of the spooled job is EMF, the print processor can help in printing the document in reverse order or it can print it in booklet form instead of the default one-page-per-sheet form. Winprint.dll is the name of the default print processor on Windows Server 2003. Winprint.dll is part of Localspl.dll.

Software vendors can develop their own print processors for custom data types. A printer vendor can also develop a custom print processor if the vendor has its own printer driver or supports a data type other than the three that WinPrint.dll supports. Also, a vendor can write a custom print processor if the vendor wants to add functionality that Winprint.dll does not provide. Usually, the print processor is installed when the printer driver is installed.

**Print Monitors**

Windows Server 2003 supports two kinds of print monitors:

- Language monitors
- Port monitors

  Port monitors are further subdivided into:

  - Local port monitors
  - Remote port monitors

**Language monitor**
The language monitor provides the common language that is needed for the client and printer to understand each other in bidirectional communication so that you can configure the printer and monitor printer status. You can request configuration and status from the printer, and the printer can send unsolicited status information (such as "Paper tray empty") to the client.

Windows Server 2003 includes Pjlmon.dll, a language monitor that uses Printer Job Language (PJL). PJL is the language that implements the bidirectional communication; it does this by using a parallel port connection, such as one between a Hewlett-Packard LaserJet 5Si and the computer. Any bidirectional printer that uses PJL can use Pjlmon.dll.

If a printer uses a different printer language, the vendor can develop a language monitor for it. A vendor might also develop a language monitor to add data, such as printer-specific control information, to the print stream that is going to a unidirectional printer.

To take advantage of bidirectional printing, you need a bidirectional printer, and a correctly configured bidirectional port and port monitor. The standard port monitor supports bidirectional communication by default.

**Local port monitor**
The local port monitor controls parallel and serial input/output (I/O) ports where a printer might be attached. The local port monitor sends print jobs to local devices, including those on familiar ports such as LPT1, COM1, or FILE (Print to File).

A second local port monitor, Usbmon.dll, controls communication through universal serial bus (USB) ports. Usbmon.dll installs automatically whenever you plug a USB printer into the correct physical port on your computer. If USB has been enabled in the BIOS, Windows XP Professional detects the device and displays its settings on the screen.

Installation opens the USB Root Hub and a generic USB printer port (for example, USB001, USB002), and copies the printer Plug and Play driver.

**Remote port monitors**
All other port monitors that are supplied with Windows Server 2003 are remote monitors that enable printing to remote printers. An example is the standard TCP/IP port monitor.

**Network Ports Used by Network Printing**
The following table lists services used in network printing and the protocols they provide in the network printing process. Not all services are installed or active at all times, and the protocols used in network printing depend on the type of clients submitting jobs to the print server.

### Port Assignments for Network Printing

| Service Name | UDP | TCP |
|---|---|---|
| Services for Macintosh (uses AppleTalk) | 201, 202, 204, 206 | 201, 202, 204, 206 |
| Internet Printing Protocol (uses HTTP) | 80 | 80 |
| NWLink (uses IPX/SPX) | 213 | 213 |
| LPDSVC (accepts LPR) | 515 | 515 |
| LPR Port (sends LPR) | 721-731, >1023 | 721-731, >1023 |
| Server (using SMB) | 137, 138 | 139 |
| Server (using RPC) | 530 | 530 |

| | | |
|---|---|---|
| Standard Port Monitor (using SNMP) | 161, 162 | 161, 162 |
| Standard Port Monitor (using LPR) | > 1023 | > 1023 |
| Standard Port Monitor (using RAW) | 2000, 2501-2503, 3001, 6869, >=9100 | 2000, 2501, 2503, 3001, 6869, >=9100 |

Standard LPR, according to RFC 1179 from the Internet Engineering Task Force, uses ports 721 through 731 to send data. However, Windows Server 2003 can be configured on a per-port or per-server basis to use port number higher than 1023 for sending data with LPR.

Also different from RFC 1179 is the standard port monitor, which sends documents to a printer by using either the RAW or LPR printing protocol. Together, these protocols support most current TCP/IP printers.

The RAW protocol is the default print protocol for most print devices. To send a job formatted with RAW, the print server opens a TCP stream to the printer's port 9100 or another port number and selects the connections to multiport external devices. For example, on certain print devices port 9101 goes to the first parallel port, 9102 goes to the second parallel port, and so on.

The standard port monitor uses the LPR protocol when you specify LPR protocol during port installation or reconfiguration, or when the RAW protocol cannot be established.

The standard port monitor deviates from the LPR standard in the following ways:

- The standard port monitor does not conform to the RFC 1179 requirement that the source TCP port must lie between port 721 and port 731. The standard port monitor uses ports from the general, unreserved pool of ports (1024 and above).

- The standard port monitor sends a print job to the spooler without determining the actual job size and designates a default job size, regardless of the actual size of the job. The LPR standard states that print jobs must include information about the size of the job the port monitor sends. Sending a print job that contains job size information requires that the port monitor spool the job twice — once to determine size, and once to send the job to the spooler. Spooling the job once, by using the standard port monitor, improves printing performance.

# Network Printing Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Printing Tools and Settings**

**In this section**

- Network Printing Tools
- Network Printing Registry Entries
- Network Printing Group Policy Settings
- Network Printing WMI Classes
- Network Ports Used by Network Printing
- Related Information

**Network Printing Tools**

The following tools are associated with Network Printing.

**Prndrvr.vbs**

**Category**

Operating system tool.

**Version compatibility**

Runs on Windows Server 2003. Cannot run on or target computers running earlier versions of Windows.

You can use the Prndrvr.vbs script to administer printer drivers, for example, use this script to add, delete, and list drivers, either locally or remotely.

Prndrvr.vbs is written in VBScript and uses the Windows Management Instrumentation (WMI) print provider to administer the printing sub-system.

**Prnjobs.vbs**

**Category**

Operating system tool.

**Version compatibility**

Runs on Windows Server 2003. Cannot run on or target computers running earlier versions of Windows.

The Prnjobs.vbs script controls print jobs. With this script, you can pause, resume, cancel, and list print jobs, either locally or remotely.

Prnjobs.vbs is written in VBScript and uses the Windows Management Instrumentation (WMI) print provider to administer the printing sub-system.

**Prncnfg.vbs**

**Category**

Operating system tool.

**Version compatibility**

Runs on Windows Server 2003. Cannot run on or target computers running earlier versions of Windows.

You can use the Prncnfg.vbs script to get and set printer configuration or to rename a printer, either locally or remotely.

Prncnfg.vbs is written in VBScript and uses the Windows Management Instrumentation (WMI) print provider to administer the printing sub-system.

**Prnqctl.vbs**

**Category**

Operating system tool.

**Version compatibility**
Runs on Windows Server 2003. Cannot run on or target computers running earlier versions of Windows.

The Prnqctl.vbs script is used to print a test page, pause or resume a printer, and clear a printer queue, either locally or remotely.

Prnqctl.vbs is written in VBScript and uses the Windows Management Instrumentation (WMI) print provider to administer the printing sub-system.

**Prnmngr.vbs**
**Category**
Operating system tool.

**Version compatibility**
Runs on Windows Server 2003. Cannot run on or target computers running earlier versions of Windows.

With the Prnmngr.vbs script, you can add and delete printers, and list printers and printer connections. You can also use it for getting and setting the default printer.

Prnmngr.vbs is written in VBScript and uses the Windows Management Instrumentation (WMI) print provider to administer the printing sub-system.

**Prnport.vbs**
**Category**
Operating system tool.

**Version compatibility**
Runs on Windows Server 2003. Cannot run on or target computers running earlier versions of Windows.

Use the Prnport.vbs script to add, delete, and list Standard TCP/IP ports. You can also use it for getting and setting the port configuration.

Prnport.vbs is written in VBScript and uses the Windows Management Instrumentation (WMI) print provider to administer the printing sub-system.

**PrintUI.dll**
**Category**
Operating system tool.

**Version compatibility**
Runs on Windows 2000, Windows XP, and Windows Server 2003.

PrintUI.dll allows you to modify or delete local printers. It also allows you to add printer connections for users based on their computer names rather than by having users add their own printers. As a result, you can control most of the end user's printing experience by running a local or remote batch file or a logon script that contains PrintUI.dll commands.

You are encouraged to use the VBScripts listed in the WMI Print Provider or the PrnAdmin sections instead of using this utility.

**PrnAdmin**
**Category**
Resource Kit tool.

**Version compatibility**
The PrnAdmin utility lets you use scripts that perform administrative printer functions. You can create your own scripts or modify one of the sample scripts that are provided with PrnAdmin. Either way, you can manage both local and remote printers by using PrnAdmin.

PrnAdmin is written in VBScript, and its file name is Prnmgr.vbs.

PrnAdmin performs these functions:

- Adds or deletes the following:
    - Local or remote printers.
    - Printer connections.

    - Local or remote forms.
    - Ports on local or remote servers.
    - Printer drivers on local or remote servers.
- Enumerates ports, drivers, printers, or forms on local or remote printers.
- Pauses, resumes, or clears the print jobs of a local or remote printer.
- Configures a local or remote printer.

To find more information about PrnAdmin, see "Resource Kit Tools Help" in the Tools and Settings Collection.

**Network Printing Registry Entries**
The Windows platforms that use these registry entries and subkeys are noted in the **Version** portion of the listings. Many registry elements that are noted as being for Windows XP and Windows Server 2003 might also work on older versions of Windows; check documentation specifically for those versions for more details.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following registry entries and subkeys are associated with Network Printing.

For more information about registry entries, see the "Registry Reference" in the Tools and Settings Collection.

**CurrentControlSet\Control\Print**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Print.

**BrowsePrintWorkstations**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print

**Version**
Windows XP and Windows Server 2003.

Used to calculate the number of clients in whose browse list the printer appears.

**EnableBroadcastSpoolerStatus**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print

**Version**
Windows XP and Windows Server 2003.

Specifies whether the system sends spooler and job status messages when the job count changes.

**MaxRpcSize**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print

**Version**
Windows XP and Windows Server 2003.

Specifies the maximum size, in bytes, of incoming data blocks from a remote procedure call (RPC).

**Monitors**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print

**Version**
Windows XP and Windows Server 2003.

The Monitors subkey stores entries for print monitors installed on Windows Server 2003. The Monitors subkey contains a subkey for each port monitor that stores configuration data for the port monitor installed on the system.

**NetPrinterDecayPeriod**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print

**Version**
Windows XP and Windows Server 2003.

Specifies how long a network printer remains in the browse list.

**PendingUpgrades**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print

**Version**
Windows XP and Windows Server 2003.

The PendingUpgrades subkey is used by Windows Server 2003 during setup.

**Providers**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print

**Version**
Windows XP and Windows Server 2003.

The Providers subkey contains information about the network printers. The printers listed in this subkey are not hosted locally, but they are printers to which the local computer is connected.

**ServerThreadTimeout**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print

**Version**
Windows XP and Windows Server 2003.

Specifies the amount of time that the server thread is idle before it notifies other print servers of its printers.

**SpoolerPriority**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print

**Version**
Windows XP and Windows Server 2003.

Specifies the priority class of the print spooler process. The priority of the print spooler process establishes a range of priority for print spooler threads.

**environment-name**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Environments

**Version**
Windows XP and Windows Server 2003.

The *environment-name* subkey represents a computing platform environment and stores entries that apply only to that environment.

**Version-number**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Environments*environment-name*\Drivers

**Version**
Windows XP and Windows Server 2003.

The Version-*number* subkey contains information about the drivers for a print environment. There is a different number for each version of the printer driver. Version-2 drivers are for Windows NT 4.0; Version-3 drivers are for Windows 2000 and Windows Server 2003.

**driver-name**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Environments*environment-name*\Drivers\Version-*number*

**Version**
Windows XP and Windows Server 2003.

The *driver-name* subkey contains information about necessary files and settings for the specified printer driver.

**Version**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Environments*environment-name*\Drivers\Version-*number**driver-name*

**Version**
Windows XP and Windows Server 2003.

Stores the version number of the installed printer driver specified by *driver-name* in the registry path.

**monitor**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Monitors

**Version**
Windows XP and Windows Server 2003.

The *monitor* subkey contains information about the status and drivers of the monitors used by the computer, and the actual name of the subkey corresponds to a unique monitor.

**Ports**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Monitors*monitor*

**Version**
Windows XP and Windows Server 2003.

The Ports subkey contains information about the current availability of the ports.

**StatusUpdateEnabled**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Monitors*monitor*\Ports

**Version**
Windows XP and Windows Server 2003.

Specifies whether the port monitor is able to update the spooler with the port status.

**StatusUpdateInterval**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Monitors*monitor*\Ports

**Version**
Windows XP and Windows Server 2003.

Specifies how often the port monitor updates the spooler with port status.

**EventLog**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Providers

**Version**
Windows XP and Windows Server 2003.

Specifies the level of detail of events that the print spooler logs for local print jobs.

**NetWare or Compatible Network**
**Registry path**

HKLM\SYSTEM\CurrentControlSet\Control\Print\Providers

**Version**
Windows XP and Windows Server 2003.

Stores options for printing when using print resources on NetWare servers.

**RestartJobOnPoolEnabled**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Providers

**Version**
Windows XP and Windows Server 2003.

Specifies whether a print job to a local printer can be restarted after an error.

**RestartJobOnPoolError**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Providers

**Version**
Windows XP and Windows Server 2003.

Specifies how long the print monitor waits after an error occurs before starting a print job on another port in the print pool.

**DisplayName**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Providers\NetWare or Compatible Network

**Version**
Windows XP and Windows Server 2003.

Specifies the localized name of the print service provider displayed in the Print Manager and Printers main window.

**Name**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Providers\NetWare or Compatible Network

**Version**
Windows XP and Windows Server 2003.

Specifies the dynamic-link library (DLL) for the NetWare or Compatible Print Service provider. This DLL is stored in *systemroot*\Winnt\System32.

**Timeout**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Control\Print\Providers\NetWare or Compatible Network

**Version**
Windows XP and Windows Server 2003.

Specifies how often Windows Server 2003 updates the print queue of a NetWare server. The value of this entry specifies the time interval between automatic refresh updates.

**Microsoft\Windows NT\CurrentVersion\Print**
The following registry entries are located under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print.

**Printers**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print

**Version**
Windows XP and Windows Server 2003.

The Printers subkey contains information about the local printers.

**Providers**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print

**Version**
Windows XP and Windows Server 2003.

The Providers subkey contains information about the network printers. The printers listed in this subkey are not hosted locally, but the local computer is connected to them.

**printer-name**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Printers

**Version**
Windows XP and Windows Server 2003.

The *printer-name* subkey stores information about printers connected to the print server.

**DefaultSpoolDirectory**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Printers

**Version**
Windows XP and Windows Server 2003.

Specifies the folder holding spooled files that the system is printing on a local printer.

**PrinterDriverData**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Printers*printer-name*

**Version**
Windows XP and Windows Server 2003.

The PrinterDriverData subkey contains configuration data for the specified printer.

**SpoolDirectory**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Printers*printer-name*

**Version**
Windows XP and Windows Server 2003.

Stores a printer-specific location for spool files. The value of this entry takes precedence over the global default stored in the **DefaultSpoolDirectory** entry.

**Transparency**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Printers\printer-name\PrinterDriverData

**Version**
Windows XP and Windows Server 2003.

Specifies the background mode when the value of the registry entry **Winprint_TextNoCRTranslation** is set to 1. If the background mode is set to transparent, then the driver will not print the background of the document, regardless of color.

**Winprint_TextNoCRTranslation**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Printers*printer-name*\PrinterDriverData

**Version**
Windows XP and Windows Server 2003.

Enables or disables carriage return translation. By default, Windows Server 2003 translates a carriage return to a carriage return plus a line feed.

**Winprint_TextNoTranslation**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Printers*printer-name*\PrinterDriverData

**Version**
Windows XP and Windows Server 2003.

Enables or disables carriage return and line feed translation. By default, Windows Server 2003 translates a carriage return or a line feed to a carriage return plus a line feed.

**server-name**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Providers\LanMan Print Services\Servers

**Version**
Windows XP and Windows Server 2003.

The *server-name* subkey stores information about printers connected to the print server specified by *server-name*.

**Printers**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Providers\LanMan Print Services\Servers*server-name*

**Version**
Windows XP and Windows Server 2003.

The Printers subkey contains information about the individual network printers to which the local computer is connected.

**Providers**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Providers\LanMan Print Services\Servers*server-name*

**Version**
Windows XP and Windows Server 2003.

The Providers subkey stores configuration data used by the specified server.

**EventLog**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Providers\LanMan Print Services\Servers*server-name*\Providers

**Version**
Windows XP and Windows Server 2003.

Specifies the level of detail of events that the print spooler logs for the specified server.

**RestartJobOnPoolEnabled**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Providers\LanMan Print Services\Servers*server-name*\Providers

**Version**
Windows XP and Windows Server 2003.

Specifies whether a print job on the print server, specified in the registry path by *server-name*, can be restarted after an error.

**RestartJobOnPoolError**
**Registry path**
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Print\Providers\LanMan Print Services\Servers*server-name*\Providers

**Version**
Windows XP and Windows Server 2003.

Specifies how long the print monitor for the printer server, specified in the registry path by *server-name*, waits after an error occurs before starting a print job on another port in the print pool.

**Network Printing Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with Network Printing.

### Group Policy Settings Associated with Network Printing

| Group Policy Setting | Description |
|---|---|

| | |
|---|---|
| Allow printers to be published | Determines whether the computer's shared printers can be published in Active Directory. |
| Disallow installation of printers that use kernel-mode drivers | Determines whether printers using kernel-mode drivers can be installed on the local computer. If enabled, prevents a printer that is using kernel-mode drivers from being installed on the local computer. |
| Automatically publish new printers in Active Directory | Determines whether the Add Printer Wizard automatically publishes the computer's shared printers in Active Directory. |
| Allow pruning of published printers | Determines whether the domain controller can prune (delete from Active Directory) the printers published by this computer. |
| Printer browsing | Announces the presence of shared printers to print browse master servers when Active Directory is not available. |
| Prune printers that are not automatically republished | Determines whether the system prunes printers that are not automatically republished. (Applies to printers running on operating systems other than Windows 2000 or Windows Server 2003. Also applies to printers running on Windows 2000 or Windows Server 2003 that are published outside of their domain.) |
| Directory pruning interval | Specifies how often the pruning service on a domain controller contacts computers to verify that their printers are operational. |
| Directory pruning retry | Specifies how many times the pruning service on a domain controller repeats its attempt to contact a computer before pruning the computer's printers. |
| Directory pruning priority | Sets the priority of the pruning thread. |
| Check published state | Directs the system to periodically verify that printers published by this computer still appear in Active Directory. Also specifies how often the system repeats verification. |
| Web-based printing | Determines whether Internet printing is supported on this server. (If you disable this policy, Internet printing is not supported.) |
| Custom support URL in the Printers and Faxes folder | Adds a customized Web page link to the Printers and Faxes folder. By default, the Printers and Faxes folder includes a link to the Microsoft Support Web page or to the Web page for the vendor of the currently selected printer. You can use this policy to replace the default link with a link to your organization's Web page. |
| Computer location | Specifies the default location criteria used when searching for printers. |
| Pre-populate printer search location text | Enables the physical Location Tracking support feature of Windows Server 2003 printers. If you disable this policy or do not configure it, Location Tracking is disabled. Printer proximity is estimated based on IP address and subnet mask. |
| Allow print spooler to accept client connections | Determines how clients access the print server over the network. By default, this policy setting automatically enables connections upon creation of the first shared printer or clustered server spooler resource. |
| Point and Print restrictions | Restricts a client computer's ability to connect to and install a printer driver from print servers. By default, this policy setting allows managed clients to use Point and Print only with servers within their forest. An administrator can use this setting to add servers to the list of trusted print servers. Disabling this setting enables connections to any accessible print server. |

For more information about Group Policy settings, see the "Group Policy Settings Reference" in the Tools and Settings Collection.

**Network Printing WMI Classes**

The following table lists and describes the WMI classes that are associated with Network Printing.

**WMI Classes Associated with Network Printing**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_Printer | \root\cimv2 | Windows XP and Windows Server 2003 ; supported as read-only in Windows 2000 |
| Win32_PrinterConfiguration | \root\cimv2 | Windows XP and Windows Server 2003 |
| Win32_PrinterController | \root\cimv2 | Windows XP and Windows Server 2003 |
| Win32_PrinterDriver | \root\cimv2 | Windows XP and Windows Server 2003 |
| Win32_PrinterDriverDll | \root\cimv2 | Windows XP and Windows Server 2003 |
| Win32_PrinterSetting | \root\cimv2 | Windows XP and Windows Server 2003 |
| Win32_PrintJob | \root\cimv2 | Windows XP and Windows Server 2003 ; supported as read-only in Windows 2000 |
| Win32_TCPIPPrinterPort | \root\cimv2 | Windows XP and Windows Server 2003 |

For more information that describes many WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by Network Printing**

The following table lists services used in network printing and the protocols they provide in the network printing process. Not all services are installed or active at all times, and the protocols used in network printing depend on the type of clients submitting jobs to the print server.

**Port Assignments for Network Printing**

| Service Name | UDP | TCP |
|---|---|---|
| Services for Macintosh (uses AppleTalk) | 201, 202, 204, 206 | 201, 202, 204, 206 |
| Internet Printing Protocol (uses HTTP) | 80 | 80 |
| NWLink (uses IPX/SPX) | 213 | 213 |
| LPDSVC (accepts LPR) | 515 | 515 |
| LPR Port (sends LPR) | 721-731, >1023 | 721-731, >1023 |
| Server (using SMB) | 137, 138 | 139 |
| Server (using RPC) | 530 | 530 |
| Standard Port Monitor (using SNMP) | 161, 162 | 161, 162 |
| Standard Port Monitor (using LPR) | > 1023 | > 1023 |
| Standard Port Monitor (using RAW) | 2000, 2501-2503, 3001, 6869, >=9100 | 2000, 2501, 2503, 3001, 6869, >=9100 |

Standard LPR, according to RFC 1179 from the Internet Engineering Task Force, uses ports 721 through 731 to send data. However, Windows Server 2003 can be configured on a per-port or per-server basis to use port number higher than 1023 for sending data with LPR.

Also different from RFC 1179 is the standard port monitor, which sends documents to a printer by using either the RAW or LPR printing protocol. Together, these protocols support most current TCP/IP printers.

The RAW protocol is the default print protocol for most print devices. To send a job formatted with RAW, the print server opens a TCP stream to the printer's port 9100 or another port number and selects the connections to multiport external

devices. For example, on certain print devices port 9101 goes to the first parallel port, 9102 goes to the second parallel port, and so on.

The standard port monitor uses the LPR protocol when you specify LPR protocol during port installation or reconfiguration, or when the RAW protocol cannot be established.

The standard port monitor deviates from the LPR standard in the following ways:

- The standard port monitor does not conform to the RFC 1179 requirement that the source TCP port must lie between port 721 and port 731. The standard port monitor uses ports from the general, unreserved pool of ports (1024 and above).

- The standard port monitor sends a print job to the spooler without determining the actual job size and designates a default job size, regardless of the actual size of the job. The LPR standard states that print jobs must include information about the size of the job the port monitor sends. Sending a print job that contains job size information requires that the port monitor spool the job twice — once to determine size, and once to send the job to the spooler. Spooling the job once, by using the standard port monitor, improves printing performance.

# Recovery and Reliability Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The recovery and reliability technologies in the Microsoft Windows Server 2003 family help you to prevent problems such as data loss and system instability during all phases of operation —from startup through shutdown. In the event of a problem, these technologies help you to recover and repair your data and operating system.

**Recovery and Reliability Technologies Components**
The recovery and reliability technologies can help you to protect your data, prevent server instability and diagnose performance problems.

**Volume Shadow Copy Service**
The Volume Shadow Copy service provides an infrastructure for creating consistent point-in-time copies known as shadow copies. The Volume Shadow Copy service can produce consistent shadow copies by coordinating with business applications, file-system services, backup applications, and storage hardware. Several features in Windows Server 2003 use the Volume Shadow Copy service, including Shadow Copies for Shared Folders and Backup.

**Backup**
The Backup utility helps you protect your data in the event your hard disk fails or files are accidentally erased due to hardware or storage media failure. By using Backup you can create a duplicate copy of the data on your hard disk and then archive it on another storage device, such as a hard disk or a tape. Backup takes advantage of the Volume Shadow Copy service to create an accurate copy of the contents of your hard drive, including any open files or files that are being used by the system.

**Shadow Copies for Shared Folders**
Shadow Copies for Shared Folders provides you with point-in-time copies of files that are located on shared resources, such as a file server. With Shadow Copies for Shared Folders, you can quickly recover deleted or changed files that are stored on the network without administrator assistance, which can increase productivity and reduce costs.

**Recovery Console**
Recovery Console is a character-mode environment that you can run from the Windows Server 2003 operating system CD or install on x86-based computers as a startup option. Using Recovery Console, you can enable and disable services, format drives, read and write data on a local drive (including drives formatted to use NTFS), and perform many other administrative tasks. Recovery Console is particularly useful if you need to repair your system by copying a file from a floppy disk or CD-ROM to your hard disk, or if you need to reconfigure a service that is preventing your computer from starting properly.

**Emergency Management Services**
Emergency Management supports remote management and system recovery for servers that are not accessible through a standard network connection, such as a Local Area Network (LAN) or the Internet. By using Emergency Management Services in conjunction with other software and hardware components, you can remotely perform tasks such as recovering unresponsive servers or powering servers off and on, even if you cannot access the servers through a conventional connection. Emergency Management Services can also help you to save space, energy, and the cost of hardware because it supports servers that are configured without a locally attached keyboard, monitor, or mouse. Emergency Management Services helps you to return servers to a state where it is possible to manage them using standard tools — Windows technologies that rely on a standard network connection.

**Shutdown Event Tracker**
Shutdown Event Tracker is a technology that provides you with a way to consistently track why IT professionals restart or shut down servers. It is enabled by default, and is a routine part of the computer shutdown process. Shutdown Event Tracker gathers the reasons that users give for restarting or shutting down servers. This data can help you to create a comprehensive picture of the performance and reliability of your system environment.

# Recovery Console Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Recovery Console Technical Reference**
Recovery Console is a character-mode environment that you can run from the Microsoft Windows Server 2003 operating system CD or install on x86-based computers as a startup option. You should use Recovery Console only when other startup options have failed to start your system. Recovery Console is particularly useful if you need to repair your system by copying a file from a floppy disk or CD-ROM to your hard disk, or if you need to reconfigure a service that is preventing your computer from starting properly.

In contrast to normal or Safe Mode, the Windows graphical user interface (GUI) is not available within Recovery Console. You should only use Recovery Console if you are an advanced user who can use basic commands to identify and locate problem drivers and files.

# What Is Recovery Console?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Recovery Console?**

**In this section**

- Related Information

Recovery Console is a character-mode environment that you can run from the Microsoft Windows Server 2003 operating system CD or install on x86-based computers as a startup option. You should use Recovery Console only when other startup options have failed to start your system.

In contrast to normal or Safe Mode, the Windows graphical user interface (GUI) is not available within Recovery Console. You should only use Recovery Console if you are an advanced user who can use basic commands to identify and locate problem drivers and files. In addition, you will need the password for the built-in Administrator account to use Recovery Console.

With Recovery Console, you can enable and disable services, format drives, read and write data on a local drive (including drives formatted to use the NTFS file system), and perform many other administrative tasks. Recovery Console is particularly useful if you need to repair your system by copying a file from a floppy disk or CD-ROM to your hard disk, or if you need to reconfigure a service that is preventing your computer from starting properly.

You can use Recovery Console to help you recover from the following problems:

- Corrupted or deleted startup files caused by incompatible software, user error, or virus activity.
- Disk problems related to damage to the master boot record (MBR), partition table, or boot sector on x86-based systems.
- A partition boot sector that has been overwritten by the setup program.

If critical system files, such as Ntldr.exe or Ntoskrnl.exe, are missing or corrupted, you can restore them by starting Recovery Console and copying undamaged files from the Windows Server 2003 operating system CD or other removable disk media.

Boot sector damage can be caused by incompatible software, hardware problems, virus activity, or attempting to configure your computer as a multiple-boot system. For example, setup programs for other operating systems might not be compatible with Windows Server 2003 and might attempt to overwrite the boot sector or startup files. To prevent problems, avoid configuring multiple-boot configurations on computers running Windows Server 2003.

### Note

- Before you install Recovery Console, you need to be aware of certain disk and file system limitations. Recovery Console is sensitive to file-system changes. If you install Recovery Console to a hard disk that uses the FAT file system, converting to the NTFS file system causes Recovery Console to stop functioning. You must reinstall Recovery Console after converting to NTFS.

# Recovery Console Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Recovery Console Tools and Settings**

**In this section**

- Recovery Console Tools
- Recovery Console Group Policy Settings
- Related Information

This section lists the tools and the syntax that you can use with Recovery Console. Recovery Console is a character-mode environment that you can run from the Windows Server 2003 operating system CD or install on x86-based computers as a startup option. You should use Recovery Console only when other startup options have failed to start your system. You will need the password for the built-in Administrator account to use Recovery Console

You can use the Recovery Console Group Policy settings to enable the **set** command to customize Recovery Console or to enable logon to the console without the administrator password.

**Recovery Console Tools**

The following tools are associated with Recovery Console. When using Recovery Console, you can view and reuse previous commands by pressing the UP ARROW and DOWN ARROW keys, which move you forward or backward through your command history.

For the list of Recovery Console commands that follow, brackets ([]) enclose optional parameters and a pipe (|) separates mutually-exclusive choices. Recovery Console commands and parameters are not case sensitive.

**Attrib**

Use the **attrib** command to change the file attributes for a single file or folder. Use the following syntax:

```
attrib
-|+[c][h][r][s] [drive:][path]filename
```

| Parameter | Description |
|---|---|
| + | Sets an attribute. |
| - | Clears an attribute. |
| c | Sets or clears a compressed file attribute. |
| h | Sets or clears a hidden file attribute. |
| r | Sets or clears a read-only file attribute. |
| s | Sets or clears a system file attribute. |
| drive: | Specifies the drive letter to use. |
| path: | Specifies the directory path to use. |

You should also follow these guidelines when you use the **attrib** command:

- You must set or clear at least one attribute.
- You can change attributes for only one file or directory at a time.
- You can view attributes by using the **dir** command.

- Do not separate attribute parameters with spaces.
- You can set multiple attributes simultaneously.
    - To change multiple attributes in the same way, use either the set or clear parameter (+ or –). Include all the attribute options to be changed, and do not separate them with spaces. For example, to set the compressed, hidden, and read-only attributes for a single file, type the following:

      ```
      attrib +chr filename
      ```

    - To change multiple attributes in different ways, use the set parameter (+) and include all the attribute letters to be set, followed without a space by the clear parameter (–) and all the attribute letters to be cleared. For example, to set the compressed and hidden file attributes and to clear the read-only file attribute, type:

      ```
      attrib +ch-r filename
      ```

**Batch**

Use the **batch** command to run the commands specified in a text file. Use the following syntax:

```
batch
inputfile [outputfile]
```

| Parameter | Description |
|---|---|
| `inputfile` | Specifies the text file (by using [*drive*:][*path*][*filename*] format) that contains the list of commands you want to carry out. |
| `outputfile` | If specified, stores the output of the **batch** command in the specified file. If you do not specify a value for *outputfile*, the **batch** command displays its output on the screen. Specify *outputfile* by using [*drive*:][*path*][*filename*] format |

The **batch** command cannot call itself recursively. Do not include the **batch** command in the file specified by the *inputfile* parameter.

**Bootcfg**

For x86-based systems, use the **bootcfg** command to scan your hard disks and use the information to modify the contents of the Boot.ini file or rebuild a new copy. Always back up the Boot.ini file before modifying it. Use the following syntax:

```
bootcfg [/add] [/default]| [/list] [/rebuild] [/scan]
```

| Parameter | Description |
|---|---|
| `/add` | Adds a Windows installation to the operating system boot menu list. |
| `/default` | Sets the default boot menu. |
| `/disableems` | Disables redirection in the Windows loader |
| `/ems` | Enables redirection in the Windows loader for a specific configuration. |
| `/list` | Lists the entries already in the boot menu list. |
| `/rebuild` | Scans hard disks for Windows installations and selects which to add. |
| `/scan` | Scans all disks for Windows installations and displays the results. |

**Note**

- The Recovery Console **bootcfg** command is not the same as the Windows Server 2003 Bootcfg.exe command-line tool. Bootcfg.exe resides in the *systemroot*\System32 folder and is a stand-alone command-line tool that you cannot use in

**Cd or Chdir**

Use the **cd** or **chdir** command to display the name of the current volume or directory, or to change to the folder specified. The **chdir** command only operates within the system directories of the current Windows installation, removable media, the root directory of any hard disk partition, or the local installation sources. Use the following syntax:

```
cd [path]|[..]|[drive:]
```

–or–

```
chdir [path]|[..]|[drive:]
```

If you want to display the current volume and folder, use the **cd** or **chdir** command without parameters.

| Parameter | Description |
|---|---|
| `path` | Specifies the directory that you want to change to. |
| `..` | Displays the parent folder. |
| `drive:` | Specifies the drive that you want to change to. |

These commands treat spaces as delimiters, which require that a space is inserted before all arguments, including double periods. Use quotation marks to enclose a path or file name that contains a space.

**Chkdsk**

Use the **chkdsk** command to check a volume, and if needed, to repair the volume. Also, use **chkdsk** to recover and move readable information before marking bad sectors as unusable. Use the following syntax:

```
chkdsk [drive:] [/p]|[/r]
```

You can use the **chkdsk** command without parameters. When you do not specify a volume, **chkdsk** runs on the current volume.

| Parameter | Description |
|---|---|
| `drive:` | Specifies the volume that you want **chkdsk** to check. |
| `/p` | Performs an exhaustive volume check. This parameter does not make any changes to the volume. |
| `/r` | Locates bad sectors and recovers readable information before marking them as unusable. Implies /p. |

Chkdsk requires the file Autochk.exe. If **chkdsk** cannot find Autochk.exe in the *systemroot*\System32 directory, it attempts to locate Autochk.exe on the Windows Server 2003 installation CD.

**Cls**

Use the **cls** command to clear the screen and redisplay the command prompt. Use the following syntax:

**cls**

**Copy**

Use the **copy** command to copy a single file to a specified location. Use the following syntax:

```
copy
source
destination
```

| Parameter | Description |
|---|---|
| `source` | Specifies the file (by using [*drive*:][*path*][*filename*] format) that you want copied. |

| | |
|---|---|
| `destination` | Specifies the destination (to by using [*drive*:][*path*][*filename*] format) that you want the file *source* file copied format. |

You should also follow these guidelines when you use the **copy** command:

- You cannot use wildcard characters (for example: * and ?) with the **copy** command.
- If you do not specify a destination directory, the **copy** command uses the current folder by default.
- If you do not specify a destination file name, the **copy** command uses the existing file name by default.
- If the *destination* file name already exists, you are warned before overwriting it.
- Compressed files from the Windows Server 2003 operating system CD are automatically expanded as they are copied.
- The source can be removable media, any directory within the system directories of the current Windows installation, the root of any drive, the local installation sources, or the Cmdcons directory.
- The destination can be any of the same locations as the source except removable media. If a destination is not specified, it defaults to the current directory.

**Del or Delete**

Use the **del** or **delete** command to delete a file or folder. Use the following syntax:

```
del [drive:][path]filename
```

–or–

```
delete [drive:][path]filename
```

| Parameter | Description |
|---|---|
| `drive:` | Specifies the volume of the file that you want to delete. |
| `path` | Specifies the directory of the file that you want to delete. |
| `filename` | Specifies the file that you want to delete. |

You cannot use wildcard characters with this command. The **delete** command only operates within the system directories of the current Windows installation, removable media, the root directory of any hard disk partition, or the local installation sources.

**Dir**

Use the **dir** command to display a list of the files and folders in a directory and to specify a particular file or group of files for which you want to see a listing. Multiple file names can be used. File names can be separated by spaces, commas, or semicolons. You can use wildcard characters (? and *) in the *filename* parameter to display a group of files.

**Dir** also lists the disk's volume label and serial number, and the total number of files listed, their cumulative size, and the free space (in bytes) remaining on the disk. For each file and subdirectory, **dir** lists the file name extension, the file size in bytes, the date and time the file was last modified, and the following file attributes, if applicable:

Use the following syntax:

```
dir [drive:][path][filename]
```

| Parameter | Description |
|---|---|
| `drive:` | Specifies the volume of the directory for which you want a listing. |

| | |
|---|---|
| `path` | Specifies the directory for which you want a listing. |
| `filename` | Specifies the file for which you want a listing. |

In Recovery Console, the **dir** command functions differently that the command line because it lists all folders and files, including those with hidden and system attributes set. For each file and subdirectory, the **dir** command lists its attributes (if they apply) by using the following abbreviations.

**a**
Archive

**c**
Compressed

**d**
Directory

**e**
Encrypted

**h**
Hidden

**p**
Reparse point

**r**
Read-only

**s**
System file

**Disable**
Use the **disable** command to disable a service or driver. Use the following syntax:

```
disable
servicename
```

| Parameter | Description |
|---|---|
| `servicename` | Specifies the service or driver that you want to disable. |

Use a related command, **listsvc,** to view a list of service and driver names for your system. The **disable** command displays the previous start type of the service before changing it to SERVICE_DISABLED. Record this value so that you can restore the original state of the service after troubleshooting a problem.

There are five startup types. The first three, SERVICE_AUTO_START, SERVICE_DISABLED, and SERVICE_DEMAND_START, correspond to the standard startup types, Automatic, Disabled, and Manual, which you typically configure using the Services snap-in in the Computer Management administrative tool. The last two, SERVICE_BOOT_START and SERVICE_SYSTEM_START, are commonly used to configure the way device drivers load, for example, when Windows starts.

**Diskpart**
Use the **diskpart** command to manage the partitions on your hard disk. For example, you can use **diskpart** to create or delete disk partitions. Use the following syntax:

```
diskpart[/add|/delete] [device-name|drive-name|partition-name] [size]
```

| Parameter | Description |
|---|---|
| `/add` | Creates a new disk partition. |
| `/delete` | Deletes an existing partition. |

| | |
|---|---|
| device-name | Specifies the name of the device for which you want to create or delete a partition, for example, \Device\HardDisk0. To obtain the name of a device, view the output of the **map** command. |
| drive-name | Specifies the drive letter of the partition that you want to delete, for example, D:. Use only with **/delete**. |
| partition-name | Specifies the partition that you want to delete and can be used in place of the *drive-name* parameter. For example,\Device\HardDisk0. Use only with **/delete**. |
| size | Specifies the size, in megabytes, of the partition you want to create. Use only with **/add**. |

If you do not use a parameter, a user interface for managing your partitions appears.

**Note**

- This command can damage your partition table if the disk has been upgraded to a dynamic disk. Do not modify the structure of dynamic disks unless you are using the Disk Management snap-in.

**Enable**

Use the **enable** command to enable or change the startup type of a service or driver. Use the following syntax:

```
enable
servicename [start_type]
```

| Parameter | Description |
|---|---|
| servicename | Specifies the service or driver that you want to enable. |
| start_type | Specifies the startup type for a service or driver. Valid values are:<br>• SERVICE_BOOT_START<br>• SERVICE_SYSTEM_START<br>• SERVICE_AUTO_START<br>• SERVICE_DEMAND_START |

Use the related command, **listsvc,** to view a list of service and driver names for your system. The **enable** command displays the previous start type of the service before changing it. Record this value so that you can restore the original state of the service after troubleshooting a problem.

If you do not specify a new start type, the enable command displays the previous start type.

**Exit**

Use the **exit** command to close Recovery Console and restart your computer. Use the following syntax:

**exit**

**Expand**

Use the **expand** command to expand a compressed file that is stored on the Windows Server 2003 operating system CD or from within a cabinet (.cab) file, and copy it to a specified destination. If the destination is not specified, the file is copied to the current directory. Use the following syntax:

```
expand
source [/f:filespec] [target] [/y]
expandsource [/f:filespec] /d
```

| Parameter | Description |
|---|---|
| source | Specifies the file that you want to expand (by using [*drive*:][*path*][*filename*] format). You cannot use wildcard characters (* and ?). |

| | |
|---|---|
| `target` | Specifies the destination folder and/or file name for the new file by using [*drive*:][*path*][*filename*] format. |
| `/f:filespec` | Specifies the specific file(s) that you want to expand if the source contains more than one file. Wildcards are optional. |
| `/y` | Specifies that the confirmation prompt (that appears when attempting to overwrite an existing file) is not required. |
| `/d` | Specifies that files display, but does not expand the files in the .cab file. |

You cannot specify removable media such as a floppy disk drive or a CD-ROM as the destination.

**Fixboot**

Use the **fixboot** command to rewrite the boot sector code to a hard disk. This is useful for repairing a corrupted boot sector on x86-based systems. If you need to replace the boot sector of a volume that is not the system volume, then you must specify the appropriate drive letter. Use the following syntax:

```
fixboot [drive:]
```

| Parameter | Description |
|---|---|
| `drive:` | Specifies the volume drive letter on which to rewrite a new boot sector. |

If you do not specify a drive, the default is the system boot volume.

**Fixmbr**

Use the **fixmbr** command to rewrite the master boot code of the master boot record (MBR) of the startup hard disk. This command is useful for repairing corrupted MBRs. Use the following syntax:

```
fixboot [device-name]
```

| Parameter | Description |
|---|---|
| `device-name` | Specifies the name of the device that needs a new MBR, for example, \Device\HardDisk1. |

If you do not specify a device, the default is disk 0. If disk 0 is not the device that needs repairing, you can obtain the device name of other disks by using the **map** command.

If the **fixmbr** command detects an invalid or nonstandard partition table signature, it prompts you for permission before rewriting the MBR.

Use this command with care because it can damage your partition table if any of the following applies:

- A virus is present and a non-Microsoft operating system is installed on the same computer.
- A nonstandard MBR is installed by a non-Microsoft disk utility.
- A hardware problem exists.

Always run antivirus software before using this command.

When you run the **fixmbr** command, it only overwrites the master boot code and leaves the existing partition table intact. If corruption in the MBR affects the partition table, running the **fixmbr** command might not resolve the problem.

**Format**

Use the **format** command to format the specified volume to the specified file system. Use the following syntax:

```
format [drive:] [/q] [/fs:file_system]
```

| Parameter | Description |
|---|---|

| | |
|---|---|
| `drive:` | Specifies the drive letter for the volume you want to format. |
| `/q` | Specifies a quick format (clears only the table of contents). |
| `/fs:file-system` | Specifies the file system you want to use. Valid values for *file-system* include FAT, FAT32, and NTFS. |

Consider the following guidelines before using the **format** command:

- If a file system is not specified, the **format** command defaults to the NTFS file system.
- If you choosing FAT for the file system, this command formats a volume as FAT16. FAT16 volumes cannot be larger than 4 GB. Limit FAT16 partitions to2 GB to increase storage efficiency and to maintain compatibility with MS-DOS, Windows 95, Windows 98, and Windows Millennium Edition.
- Windows Server 2003 can format FAT32 volumes up to 32 GB in size. For larger volumes, use NTFS.

**Help**

Use the **help** command to view Help information for Recovery Console commands. Use the following syntax:

```
help [command]
```

| Parameter | Description |
|---|---|
| `Command` | Specifies the drive letter for the volume you want to format. |

Use the *command* parameter to specify a name of any Recovery Console command.

If you do not specify a parameter, Help lists information about all the supported commands.

**Listsvc**

Use the **listsvc** command to view details about the services and drivers on your system, including service start types. Use the following syntax:

```
listsvc
```

Use the **listsvc** command together with the **disable** and **enable** commands. The information displayed is extracted from the registry file System that is located in the *systemroot*\System32\Config folder. If the file System is damaged or missing, the information displayed might be inaccurate.

**Logon**

Use the **logon** command to detect and logon to Windows installations. Use the following syntax:

```
logon
```

You must correctly enter the local administrator password within three attempts or the computer will restart.

**Map**

Use the **map** command to list all drive letters, file system types, volume sizes, and mappings to physical devices that are currently active. Use the following syntax:

```
map [arc]
```

| Parameter | Description |
|---|---|
| `Arc` | Use the **arc** parameter to force the use of the Advanced RISC Computing (ARC) specification format to describe paths instead of using device paths. You can use this information to create or repair the Boot.ini file. |

If you do not use the **arc** parameter, the **map** command displays device names. The **map** command also displays the type of file system and the size of each disk in megabytes (MB).

The **map** command might not work correctly with systems that are using dynamic disk features.

**Md or Mkdir**

Use the **md** or **mkdir** command to create a new directory or subdirectory. Use the following syntax:

```
md [drive:]pathmkdir [drive:]path
```

| Parameter | Description |
|---|---|
| drive: | Specifies the volume on which to create a folder. |
| path | Specifies the name of the folder to create. |

The **md** or **mkdir** command has the following limitations:

- You cannot use wildcard characters with this command.
- The command only operates within the system directories of the current Windows installation, removable media, the root directory of any hard disk partition, or the local installation sources.
- This command might not display all the volumes on a disk or the correct volume sizes on dynamic disks.

**More or Type**

Use the **more** or **type** command to display the contents of a text file. Use the following syntax:

```
more [path\]filenametype [path\]filename
```

| Parameter | Description |
|---|---|
| filename | Specifies the file name to view. |
| path | Specifies the folder where the file is located. |

If a text file is too large to fit on one screen, use the following page viewing options:

- ENTER Scroll down one line at a time.
- SPACEBAR Scroll down one page at a time.
- ESC to quit viewing the text file.

**Rd or Rmdir**

Use the **rd** or **rmdir** command to delete a directory or subdirectory. Use the following syntax:

```
rd [drive:]pathrmdir [drive:]path
```

| Parameter | Description |
|---|---|
| drive: | Specifies the volume on which to delete a folder. |
| Path | Specifies the name of the folder to delete. |

The **rd** or **rmdir** command has the following limitations:

- You cannot use wildcard characters with this command.
- The path must be empty or the command will fail.
- The command operates within the system directories of the current Windows installation, removable media, the root directory of any hard disk partition, or the local installation sources.

**Ren or Rename**

Use the **ren** or **rename** command to rename a file or directory. Use the following syntax:

```
ren [drive:][path]name1 name2rename [drive:][path]name1 name2
```

| Parameter | Description |
|---|---|
| drive: | Specifies the volume drive letter on which the file to be renamed resides. |
| path | Specifies the path to the file or folder to be renamed. |
| name1 | Specific the file or folder to be renamed. |
| name2 | Specifies the new name for the file or folder. |

You cannot use wildcard characters with this command.

**Set**

Use the **set** command to set Recovery Console environment variables. Recovery Console disables the **set** command by default. To enable the **set** command, you must enable the **Allow floppy copy and access to all drives and all folders** Group Policy setting. For more information about the Group Policy settings for Recovery console, see "Recovery Console Group Policy Settings" later in this topic.

Use the following syntax:

```
set [variable = [TRUE|FALSE]]
```

| Environment Variable | Description |
|---|---|
| AllowWildCards | Set to TRUE to enable wildcard character (* and ?) support for some commands, such as DEL, that do not otherwise support them. |
| AllowAllPaths | Set to TRUE to allow access to all files and folders on the computer. |
| AllowRemovableMedia | Set to TRUE to allow files to be copied to removable media, such as floppy disks. |
| NoCopyPrompt | Set to TRUE to suppress the confirmation prompt that appears when overwriting a file. |

To display the list of current environment variables, use the **set** command without specifying a parameter. All Recovery Console environmental variables are set to FALSE by default.

**Systemroot**

Use the **systemroot** command to set the current directory to the *systemroot* directory of the Windows Server 2003 installation with which you are currently working. Use the following syntax:

```
systemroot
```

**Recovery Console Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with Recovery Console.

**Group Policy Settings Associated with Recovery Console**

| Group Policy Setting | Description |
|---|---|
| **Allow floppy copy and access to all drives and all folders** | Must be enabled in order to use the **set** command to customize Recovery Console |

| | |
|---|---|
| **Recovery Console: Allow automatic administrative logon** | Allows you to to bypass the logon process when Recovery Console starts. Activating this policy eliminates a security barrier intended to protect your computer against unauthorized users. Therefore, It is important that you enable this policy only on systems that have secure consoles, such as those in locked rooms. |

# Emergency Management Services Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Emergency Management Services Technical Reference**
Emergency Management Services is a feature of the Microsoft Windows Server 2003 operating systems that supports remote management and remote system recovery for servers that are not accessible through a standard network connection, such as a local area network (LAN) or the Internet. By using Emergency Management Services in conjunction with other software and hardware components, you can remotely perform tasks such as recovering unresponsive servers or powering servers off and on, even if you cannot access the servers through a conventional connection. Emergency Management Services can also help you to save space, energy, and the cost of hardware because it supports servers that are configured without a locally attached keyboard, monitor, or mouse.

Emergency Management Services helps you to return servers to a state where you can manage them using standard tools — Windows technologies that rely on a standard network connection. These tools include Microsoft Management Console (MMC), Systems Management Server, Telnet, Terminal Services Remote Desktop for Administration, Windows Management Instrumentation (WMI), and the Remote Command Service (Rcmd.exe and Rcmdsvc.exe).

# What Is Emergency Management Services?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Emergency Management Services?**

**In this section**

- Common Emergency Management Services Scenarios
- Technologies Related to Emergency Management Services
- Emergency Management Services Dependencies
- Related Information

Before the introduction of Windows Server 2003, you could remotely manage servers running the Windows operating system only by using a conventional in-band connection — one that uses a computer's standard communication channel, typically a network connection. If a server stopped responding, you had to manage it locally. With Windows Server 2003, you can use Emergency Management Services to manage servers remotely even when they are not responding over the network. Emergency Management Services is included with Windows Server 2003, Standard Edition, Windows Server 2003, Enterprise Edition, Windows Server 2003, Datacenter Edition, and Windows Server 2003, Web Edition.

Emergency Management Services supports out-of-band connections — those using an alternate communication channel, most commonly a serial port. Unlike in-band connections, out-of-band connections do not rely on operating system network drivers to function. If you use Emergency Management Services with the appropriate hardware, you can remotely perform almost all management tasks. This capability can help you to efficiently manage large numbers of servers with high availability requirements, especially servers configured without a locally attached keyboard, monitor, and mouse. Some computer firmware may also allow you to configure a server without a keyboard controller and video adapter. Because these components are optional, Emergency Management Services can present significant savings in space, energy consumption, and hardware costs.

**Common Emergency Management Services Scenarios**

You can use Emergency Management Services to remotely troubleshoot problems that arise during any of the following system states:

**Powering on or off**

The computer is powering up or is in the process of shutting down.

**Firmware initializing the system**

The computer is running the Power on Self Test (POST), performing rudimentary hardware checks, and determining the devices that are available.

**Windows loading**

This is the startup phase in which the Windows loader and kernel load and initialize system components such as drivers and services. For multiple-boot systems, the Windows loader might display a boot menu listing the operating systems that are installed. Based on your selection, the appropriate system files are loaded and initialized.

**Windows running**

Windows Server 2003 starts without problems and transitions into one of the following states:

- Text-mode setup phase
- GUI-mode setup phase
- Normal operation

**Windows experiencing problems**

Windows Server 2003 is experiencing software or hardware problems that might adversely affect system responsiveness or might interrupt network connectivity. Certain processes might have depleted system resources, a situation that prevents you

from accessing the remote server using an in-band connection.

**Windows unresponsive**
If Windows Server 2003 is unresponsive to normal in-band connection methods, you can use Emergency Management Services to attempt recovery. For example, if a Stop error occurs, you can use Emergency Management Services to view Stop message information and restart the system. However, if software or hardware problems are sufficiently severe, Emergency Management Services might become unavailable. In these situations, the ability to remotely recover from problems depends on the hardware features built into the system firmware, motherboard, service processor, and uninterruptible power supply (UPS).

**Technologies Related to Emergency Management Services**
When servers can be accessed over the standard network, you should manage them using an in-band connection. Examples of Windows Server technologies that use an in-band connection include:

- Group Policy
- Microsoft Management Console (MMC)
- Systems Management Server
- Telnet
- Terminal Services Remote Desktop for Administration
- Windows Management Instrumentation Command-line (WMIC)
- Windows Script Host (WSH)

The purpose of Emergency Management Services is to help you return a server to a state where in-band management is possible. Unexpected events, however, can interrupt in-band connectivity. For example, a network adapter problem or system instability can cause a server to become unresponsive to management attempts from client computers that use an in-band connection. Because Emergency Management Services removes dependence on operating system network drivers, client computers can communicate with servers through the out-of-band port in situations such as these, so you can attempt to bring the servers back into service remotely. Emergency Management Services is designed to be a last resort option for remote management. You should first try in-band tools.

**Emergency Management Services Dependencies**
Emergency Management Services has the following dependencies:

- **Windows loader or Windows kernel (Ntoskrnl.exe).** Emergency Management Services requires that the loader or the kernel of the Windows Server 2003 operating system be at least partially functioning.

- **Serial ports.** To perform out-of-band management, you need to establish a secure connection through a serial port, phone line, or additional network connection. The serial port, also known as a communication (COM) port, is the most common out-of-band interface. It is the default out-of-band device for Emergency Management Services. The serial port used for Emergency Management Services must be a 16550 Universal Asynchronous Receiver/Transmitter (UART). If your system firmware is compatible with Emergency Management Services, we recommend that you configure it to use the same serial port settings.

  It is important to note that Emergency Management Services and the Windows debugger cannot share the same COM port. The system can have only a single out-of-band management port. Windows Server 2003 does not support a configuration in which one out-of-band port sends outgoing communication and a different out-of-band port (on a second device) receives incoming data.

- **Client terminal software.** You can access all Emergency Management Services output by using terminal emulation software such as Telnet and HyperTerminal. The software you choose should support serial port and terminal definition settings that are compatible with Emergency Management Services, as well as with your system firmware. If possible, use software that supports the VT-UTF8 protocol because it provides for multilingual versions of Windows. If English is the only language you need to support, the VT100+ terminal definition is sufficient. At a minimum, you can use the VT100 terminal definition.

# How Emergency Management Services Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Emergency Management Services Works**

**In this section**

- Terms and Definitions
- Emergency Management Services Architecture and Interfaces
- Emergency Management Services Physical Structures
- Emergency Management Services Processes and Interactions
- Ports Used by Emergency Management Services
- Related Information

Emergency Management Services is a technology in Windows Server 2003 that supports remote management and system recovery for servers that are not accessible through an in-band connection. An in-band connection is a connection between two computers that relies on a standard network, such as a local area network (LAN) or the Internet, and on standard remote administration tools, such as Remote Desktop or Telnet. You can use this type of connection to remotely manage computers only if both the local and remote computers are in a functional state and accessible on the network.

Emergency Management Services redirects text output to the out-of-band connection. An out-of-band connection is a nonstandard connection between two computers, such as a serial port connection, and is useful when a remote server cannot access the network or is not fully functional. Emergency Management Services provides a command-line environment for managing a server through the out-of-band port. The capability of redirecting text output is also known as console redirection.

Emergency Management Services consists of the following three components:

- Console Redirection
- Special Administration Console (SAC) environment
- !Special Administration Console (!SAC) environment

Emergency Management Services also supports headless operation for computers that have the appropriate out-of-band components. (Headless operation refers to computers that function without a local display or input devices, such as a keyboard or mouse.)

The following sections provide an in-depth view of how Emergency Management Services works in an optimal environment. An optimal environment for Emergency Management Services is defined as follows:

- Emergency Management Services is one part of a complete management solution that includes in-band as well as out-of-band technologies. To support this solution, you have selected and configured the hardware that will allow you to access and manage the server at all times.
- Your system firmware supports console redirection and the Serial Port Console Redirection (SPCR) table. If it does not, you must enable and configure Emergency Management Services manually.
- You have configured your hardware and Emergency Management Services to use the highest baud rate possible. This gives you the best performance, and also prevents a slow text-mode setup process.
- If you are using Emergency Management Services with a serial port, you are using a null modem cable with carrier

detect.

- If you choose to use a service processor, purchase one that supports Emergency Management Services. A service processor can provide additional management functionality that complements that of Emergency Management Services.

- You have configured your server to restart automatically if a Stop error occurs. This allows the server to restart without requiring you to use Emergency Management Services or the power switch to reboot it manually.

- Your hardware and firmware support the same terminal type that Emergency Management Services uses, preferably VT-UTF8 or VT100+. To prevent incompatibility, you must at least select hardware and firmware that support VT100. If the terminal types are not the same, it can be extremely difficult to send the proper command escape sequences.

- You have limited physical access to your server. You protect sensitive areas such as racks, computer labs, server farms, and data centers by locking them, choosing hardware with built-in security features, and setting up a separate network dedicated exclusively to traffic management.

**Terms and Definitions**

Before you review the Emergency Management Services architecture, it is helpful to understand the terms associated with this technology. The following is a brief introduction to the three components of Emergency Management Services and a glossary of terms associated with each component.

**Console Redirection**

Emergency Management Services provides console redirection, or the ability to send and receive character-mode output or input by using the out-of-band port. This functionality enables you to manage a remote server that would otherwise be inaccessible. For example, a server that supports console redirection is able to receive keyboard input from a managing client computer and to send character-mode output back to the client computer by using the out-of-band port. If you enable console redirection, you can still use local input and display devices. Therefore, it is possible for a computer running Windows Server 2003 to process in-band, out-of-band, and local console input and output (I/O) simultaneously.

Console redirection uses a character-mode display instead of a graphical user interface (GUI) for the following reasons:

- **Hardware compatibility**. A character-mode display provides compatibility with different types of communication media, from relatively slow serial port connections to higher speed technologies. The serial port is the most commonly used out-of-band device.

- **Software compatibility**. A character-mode display simplifies interoperability issues with different types of terminals and terminal emulation software, including those running on other operating systems such as UNIX.

You can use Emergency Management Services in conjunction with hardware that increases your ability to access a remote server through out-of-band means. Windows Server 2003, hardware integrated into the motherboard, or add-in devices can provide the following types of console redirection:

- **Firmware console redirection**. System firmware that supports console redirection provides for remote management before Windows Server 2003 starts. Types of firmware include basic input/output system (BIOS) for x86-based computers and Extensible Firmware Interface (EFI) for Itanium-based systems.

- **Emergency Management Services console redirection**. Windows Server 2003 components, such as the Windows loader (Ntldr), support console redirection.

- **Service processor console redirection**. If your server includes a specialized hardware component called a service processor, the service processor can also provide console redirection. For more information about service processors, see “Service Processors” later in this section.

**Firmware Console Redirection**

Your computer’s firmware might support console redirection and can work in conjunction with Emergency Management Services to give you greater control over a remote server. Typically, firmware for Itanium-based computers supports console redirection. For x86-based computers, contact your computer manufacturer for information about firmware console redirection functionality. If your x86-based computer does not support firmware console redirection, you might be able to

obtain a firmware upgrade.

You can use firmware console redirection to remotely manage a server from restart until the initial load of Windows Server 2003. Without firmware console redirection, you cannot manage your computer remotely until Windows Server 2003 starts.

**Note**

- A service processor can provide console redirection before Windows Server 2003 starts, even without firmware console redirection.

With firmware console redirection, you can perform the following remote management tasks before Windows Server 2003 starts.

- **Remotely view startup progress.** You can remotely view computer status before Windows Server 2003 starts, such as power-on self-test (POST) information, disk-related error messages, and other text displayed by the computer's firmware. A computer that has firmware console redirection typically allows the POST to complete successfully without an attached keyboard, mouse, or display device.

- **Remotely view and edit firmware settings.** You can remotely access the configuration program provided by the computer firmware to change hardware settings. For example, you can remotely disable integrated peripherals or change the boot device order. Without firmware console redirection, you must make these types of changes locally.

- **Remotely view and respond to Pre-Boot eXecution Environment prompts.** If a server's firmware supports the Pre-Boot eXecution Environment (PXE) standard, you can use firmware console redirection to remotely view and respond to the F12 network boot prompt.

- **Remotely view and respond to the boot from CD prompt.** With firmware console redirection, you can remotely respond to the **Press Any Key to Boot from CD** prompt when starting your server by using the CD for Windows Server 2003.

#### Emergency Management Services Console Redirection

If Emergency Management Services is enabled when Windows Server 2003 starts, the operating system assumes the responsibility for console redirection from the firmware. The ability to redirect console I/O to the out-of-band port is built into the Windows Server 2003 components listed in the following table.

**Components that Support Emergency Management Services Console Redirection**

| Windows Server 2003 Component or Feature | Description |
|---|---|
| Windows loader for x86-based computers (Ntldr) | The Windows Server 2003 operating system loader. When Ntldr is running, you can remotely view and select the Recovery Console or, on x86-based multiple-boot computers, which operating system to start. |
| Windows kernel (Ntoskrnl.exe) | The core (also called the kernel) of the Windows Server 2003 operating system. Code that runs as part of the kernel does so in privileged processor mode and has direct access to system data and hardware. The Windows kernel supports console redirection, which enables you to remotely view system information during normal operation, or remotely view Stop message text when a system problem occurs. |
| Recovery Console | A command-line environment that enables you to perform advanced troubleshooting and maintenance tasks, such as disabling a driver that you suspect is causing a startup problem. |
| Command Prompt (Cmd.exe) | A character mode command shell user interface that provides an environment for running commands and applications. |

| | |
|---|---|
| Text-mode Setup (including the CD-ROM Setup loader) | The initial portion of the Windows Server 2003 installation process when Setup displays character mode prompts and status information text. During text-mode setup, files are copied from the distribution folder to the local hard disk. |
| Startrom.com at 9600 baud for x86-based computers | Starts the x86-based Remote Installation Services (RIS) process. This file is downloaded and run by the RIS client to initiate the operating system installation procedure. Only special versions of Startrom.com that use 9600 baud support Emergency Management Services console redirection. For more information about Startrom.com, see "Remote Installation Services" later in this chapter. |

Emergency Management Services does not provide console redirection for the components listed in the following table.

**Components that Do Not Support Emergency Management Services Console Redirection**

| Windows Server 2003 Component | Description |
|---|---|
| The **Press Any Key to Boot from CD** prompt | This prompt appears when you start your system by using the Windows Server 2003 operating system CD. |
| GUI-mode Setup | Emergency Management Services processes only character-mode input and output. Emergency Management Services cannot display GUI-mode graphics, such as windows and dialog boxes, and it cannot redirect mouse input. You can, however, perform Special Administration Console (SAC) commands and monitor setup logs during GUI-mode setup. |
| Startrom.com at baud rates greater than 9600 | Startrom.com supports Windows Emergency Management Services console redirection only at 9600 baud. |
| Operating system boot menu for Itanium-based computers | For Itanium computers, the EFI boot manager (IA64ldr), not the Windows loader, displays the list of operating systems installed on the system. To remotely view and select boot manager menu items on Itanium-based systems, you must enable firmware console redirection. |

**Special Administration Console**

Special Administration Console (SAC), a kernel-mode component, is the primary Emergency Management Services command-line environment. You can use SAC to remotely manage a server through its out-of-band port when Windows runs in GUI mode.

SAC is available early in the startup process. You can use it to manage a server during normal system operation, safe mode, and the GUI phase of Windows Server 2003 setup. When Emergency Management Services is enabled, SAC is always active as long as the kernel is running. SAC is a separate environment from the Windows Server 2003 command prompt (Cmd.exe). You can remotely monitor the status of a server or troubleshoot problems by using terminal software to access SAC.

You can use SAC to perform the following remote tasks when the operating system is functioning normally:

- Gather server information, such as computer name and IP address.
- Obtain a list of the services and applications running on the computer.
- Restart or shut down a server as part of planned maintenance.
- Change the system time and date.

You can use SAC to perform the following troubleshooting tasks:

- Raise or lower the priority of a process, or end a process that is consuming excessive processor time or other system resources. By establishing an out-of-band connection to SAC, you can continue to manage a server even when low

system resources have caused it to become unresponsive to in-band management tools.

- Restart or shut down a server that has stopped responding to in-band commands and tools.
- View or change a server's Transmission Control Protocol/Internet Protocol (TCP/IP) networking information to resolve issues, such as problems caused by a duplicate IP address.
- Maintain communication with a server during network outages. For example, you might want to verify that a connectivity issue is caused by a problem that affects the primary network rather than by a problem with the server hardware or a driver.
- Generate a list of drivers for diagnostic purposes.
- View setup logs to determine the cause of a problem that prevents Windows Server 2003 installation from completing.

**Note**

- SAC usage is not safeguarded by password and logon requirements. You must secure physical access to computers running Emergency Management Services by placing the appropriate restrictions on all connecting terminals.

**!Special Administration Console**

!Special Administration Console (!SAC) is an abbreviated version of SAC that accepts input and sends output through the out-of-band port. !SAC is a separate entity from SAC and the Windows Server 2003 command prompt. !SAC can become available while a computer is running Windows Server 2003 in normal mode, safe mode, or the GUI-mode phase of Windows Server 2003 setup. Unlike SAC, you cannot invoke !SAC directly. After a specific failure point is reached, Emergency Management Services components make the transition from SAC to !SAC.

!SAC provides a subset of SAC commands and enables you to perform a limited set of tasks, including the following:

- Remotely view Stop message text.
- Restart the computer.
- View an abbreviated log of loaded drivers and some kernel events.
- Obtain computer identification information.

**Glossary of Emergency Management Services Terms**

The following terms are used to describe the components and processes of Emergency Management Services.

**Bootcfg**

Configures, queries, or changes Boot.ini file settings.

**Console redirection**

Sending and receiving character-mode output or input by using the out-of-band port. A server that supports console redirection is able to receive keyboard input from a managing client computer and send character-mode output back to the client computer by using the out-of-band port. Enabling console redirection does not prevent you from using local input and display devices. Therefore, it is possible for a computer running Windows Server 2003 to process in-band, out-of-band, and local console input and output (I/O) simultaneously.

**GUI mode**

The portion of Setup that uses a graphical user interface (GUI).

**in-band remote management tools**

Microsoft Management Console (MMC), Systems Management Server, Telnet, Terminal Services Remote Desktop for Administration, Windows Management Instrumentation (WMI)

**Service processor**

A micro controller that operates independently of the computer processor(s) and operating system and uses its own custom firmware. Service processors are typically integrated into the motherboard or a PCI adapter.

**Setup logs**
A program used by Remote Installation Services (RIS) that is the first file downloaded to the client using Trivial File Transfer Protocol (TFTP). Startrom.com is a small program that displays the **Press F12 for Network Service Boot** prompt. If F12 is pressed within three seconds, the Client Installation Wizard (OSChooser) is downloaded to begin the remote installation process.

**Stop error**
A serious error that affects the operating system and that could place data at risk. The operating system generates an obvious message, a screen with the Stop error, rather than continuing on and possibly corrupting data. Also called a fatal system error.

**terminal concentrator**
A network-capable management device that consolidates serial access to multiple servers. Terminal concentrators have at least one Ethernet port that you can connect to a primary or secondary network and multiple serial ports for connecting to the managed servers. The remote management client connects to the terminal concentrator through the Ethernet port and the managed servers connect to the terminal concentrator with null modem cables.

**VT-UTF8**
A character set for protocols evolving beyond the use of ASCII. The UTF-8 protocol provides for support of extended ASCII characters and translation of UCS-2, an international 16-bit Unicode character set. UTF-8 enables a far greater range of names than can be achieved using ASCII or extended ASCII encoding for character data.

**unattend.txt and Winnt.sif**
The Unicode-aware terminal type, based off of a VT-100 terminal type, that is used for transmitting data over an EMS connection.

**Universal Asynchronous Receiver/Transmitter (UART)**
An integrated circuit (silicon chip) that is commonly used in microcomputers to provide asynchronous communication. The UART provides parallel-to-serial conversion of data to be transmitted and serial-to-parallel conversion of data received.

**universal serial bus (USB)**
An external bus that supports Plug and Play installation. Using USB, you can connect and disconnect devices without shutting down or restarting your computer. You can use a single USB port to connect up to 127 peripheral devices, including speakers, telephones, CD-ROM drives, joysticks, tape drives, keyboards, scanners, and cameras. A USB port is usually located on the back of your computer near the serial port or parallel port.

**Emergency Management Services Architecture and Interfaces**
The following table describes the three components of Emergency Management Services.

### Emergency Management Services Components

| Component | Description |
|---|---|
| Special Administration Console (SAC) | The primary Emergency Management Services command-line environment hosted by Windows Server 2003 operating systems. It is separate from the Windows Server 2003 command-line environment and provides different functionality. |
| !Special Administration Console (!SAC) | An auxiliary Emergency Management Services command-line environment that is hosted by Windows Server 2003 operating systems. Like SAC it accepts input and sends output through the out-of-band port. !SAC is a separate entity from both SAC and the Windows Server 2003 command-line environment. |
| Special Administration Console Helper service (Sacsvr) | A user-mode service you can use to create Windows command-prompt channels when you type cmd at the SAC prompt. With the command-prompt channels, you can use in-band tools on a remotely administered server when an in-band connection is not available. |

**Emergency Management Services Physical Structures**
This section describes the types of hardware and software you might choose to implement Emergency Management Services on a remote server.

**Out-of-Band Components**
Depending on the out-of-band management tasks you must perform, you might need to use Emergency Management Services in conjunction with out-of-band hardware components. You can manage nearly every operating system state by using only Emergency Management Services and a serial port. However, if you need to manage many servers or need to manage servers in situations when the operating system is not functioning, you need supporting firmware and hardware components. These components can support situations ranging from power up to operating system initialization to unresponsive servers.

You might need any combination of the following components.

#### Out-of-Band Ports

Serial ports are the most common out-of-band hardware interface, but service processors sometimes provide alternative methods. For example, some service processors provide an RJ-45 Ethernet port for out-of-band connections. In addition, advances in technology are opening up new possibilities for out-of-band ports. For more information about types of out-of-band ports, see "Service Processors" later in this section.

To be compatible with Emergency Management Services, out-of-band ports must meet the following requirements.

- **Exclusive access.** The Windows Server 2003 operating system must have exclusive access to the out-of-band port. Instead of requesting input and output operations from the Windows I/O Manager, Emergency Management Services writes information directly to Universal Asynchronous/Receive Transmit (UART) hardware.

- **Single out-of-band port.** Emergency Management Services supports only one out-of-band management port. Windows Server 2003 does not support a configuration in which one out-of-band port is used to send data and another one is used to receive incoming data.

- **Continuous availability.** Emergency Management Services requires that the out-of-band port be available at all times, including when the Windows loader is running, the operating system is fully loaded, and when a Stop error occurs. Furthermore, the device must not be powered off while the system is running.

#### Serial Ports

The serial port, which is also referred to as a COM port, is the default out-of-band device for Emergency Management Services. This is because serial ports have the following characteristics.

- **Universality.** At least one serial port exists on most computers.

- **Simplicity and cost effectiveness.** Traditional serial ports use common 16550 or 16450 UART integrated circuits. UART interfaces are standard equipment on most motherboards. Hardware manufacturers can also incorporate inexpensive 16550 or 16450 UART interfaces into add-on adapters that provide out-of-band ports.

- **Hardware flexibility.** UARTs can be logically located at I/O addresses other than those traditionally reserved for COM1 or COM2 (provided that Emergency Management Services is properly configured to use the corresponding hardware settings). Serial ports enable external connectivity to other serial devices such as terminal concentrators, which act as network interfaces to out-of-band hardware.

- **Interpretability.** Several well-defined serial port communication standards exist, enabling interoperability with terminal hardware and software running on operating systems other than Windows, such as UNIX. The computer's firmware initializes serial ports early in the startup process and serial ports are detected and usable before Windows Server 2003 starts.

### Note

- When you use Emergency Management Services with a serial port, use null mode cables that support the Carrier Detect (CD) signal. Cables with the CD pin directly connected to the Request to Send pin also function correctly.

#### Requirements for Serial Port Compatibility

In addition to the general requirements described earlier in this section, serial ports must meet a number of other requirements to be compatible with Emergency Management Services.

- **UART device standards.** The UART control register must function as a standard 16450 or 16550 UART device. Before using a UART device for Emergency Management Services, Windows Server 2003 tests for this compliance.

- **UART device availability.** The UART device must be available before the Windows loader starts. As a rule, out-of-band devices must be configured by the firmware as part of the POST process.

- **UART device I/O address.** The UART device I/O address must not change. Emergency Management Services does not support Plug and Play. If you change UART hardware resource settings without making corresponding changes to

Emergency Management Services settings, data might be written to an invalid system address.

**Technology Trends for Out-of-Band Ports**

A recent industry trend is the movement towards legacy-free computers, that is, those that do not use super I/O chips or serial ports located on the Industry Standard Architecture (ISA) bus. (A super I/O chip is a single chip that contains integrated drive electronics (IDE) controllers, a floppy controller, serial ports, and a parallel port). The PC 99 and PC 2001 System Design Guides strongly recommend alternatives to super I/O chips for such legacy-free designs. In these systems, a UART placed on a Peripheral Component Interconnect (PCI) adapter is the preferred mechanism for implementing out-of-band ports.

Additionally, hardware manufacturers might develop proprietary out-of-band solutions that combine custom hardware and software solutions. Other possibilities for out-of-band external interfaces include connectivity based on industry standard Universal Serial Bus (USB), IEEE1394 Firewire ports, or other proprietary connections. Contact your hardware vendor for more information about technologies compatible with Emergency Management Services.

**Service Processors**

Emergency Management Services requires that the Windows loader or kernel be at least partially functioning. If you need to communicate with a server when this is not the case — such as when the computer is completely unresponsive due to a severe error — you might need a remote management channel that is independent of the operating system. Service processors can fill this need.

Service processors are micro controllers that operate independently of the computer processor(s) and operating system and use their own custom firmware. Service processors are typically integrated into the motherboard or a PCI adapter.

You can communicate directly with a service processor by using an out-of-band connection, regardless of the state of the computer. Depending on the manufacturer, a service processor might use any of a variety of out-of-band communication channels. The most common out-of-band channels are serial ports and RJ-45 Ethernet ports. However, if the out-of-band communication channel is a serial port, you can use only one tool at a time — either Emergency Management Services or the service processor.

**Serial port connections to service processors**

When a service processor uses a serial port for out-of-band connections, it passively monitors the traffic between the UART interface and the serial port. This behavior is sometimes referred to as pass-through mode. When the service processor detects information in the data stream that applies to it, it takes control of the out-of-band port. The service processor then presents a remote management user interface. The service processor must release control of the serial port when either of the following occurs:

- The service processor detects control sequences in the serial data stream instructing it to immediately release control of the out-of-band port.
- The firmware POST process completes and the Windows Server 2003 loader starts.

The following figure illustrates how Emergency Management Services, the UART, a service processor, and a serial port fit together.

**Serial Port Null Modem and Pass-Through Service Processor Configuration**

**Ethernet port connections to service processors**

Some service processors include an integrated RJ-45 Ethernet port that is dedicated for out-of-band use. These network-

enabled service processors typically use an Internet Protocol (IP) address different from the host computer and can be connected to a secondary management network for added security and redundancy.

**Service processor features**
Manufacturers vary in the management tools, features, and client interfaces they provide. Management tools and client interfaces range from simple Telnet consoles to complex Web browser environments. Some service processors also include their own power supplies to enhance reliability. Service processor features that you might want to use with Emergency Management Services include the following:

- Remote reset
- Console redirection
- Remote power on
- Remote power off

**Firmware Console Redirection**
Firmware console redirection works with Emergency Management Services to provide out-of-band support for any operating state. If you do not have firmware console redirection — or a service processor that provides console redirection — you cannot manage your server's remotely until Windows Server 2003 begins loading.

For a seamless transition from firmware console redirection to Emergency Management Services console redirection, the firmware or service processor must completely release control of the out-of-band port when the Windows loader starts. For best results, terminal software running on the client computer needs to use serial port and terminal definition settings that are compatible with firmware console redirection and Emergency Management Services console redirection.

**Terminal Concentrators**
A terminal concentrator is a network-capable management device that consolidates serial access to multiple servers. Terminal concentrators have at least one Ethernet port that you can connect to a primary or secondary network and multiple serial ports for connecting to the managed servers. The remote management client connects to the terminal concentrator through the Ethernet port and the managed servers connect to the terminal concentrator with null modem cables.

By using a terminal concentrator, you can establish an in-band connection from a remote management computer, typically by using the Telnet protocol, to monitor many servers simultaneously. By sending specific commands to the terminal concentrator, you can switch from one serial port to another, and therefore from one server to another.

Although the in-band connection from the management client eliminates physical security concerns, it does introduce logical security concerns. Some terminal concentrators provide authentication and encryption security for the in-band connection. For example, some terminal concentrators support Secure Shell (SSH), which is a secure alternative to Telnet. Because security features for terminal concentrators are not standardized, however, you might need to provide your own logical security. For example, you might set up a secondary private management network or use a secure router. It is important to ensure that only authorized users can access a terminal concentrator, because it provides access to the credentials for multiple servers.

**Intelligent Uninterruptible Power Supplies and Intelligent Power Switches**
An Uninterruptible Power Supply (UPS) is an optional component that provides a backup power source to a server in the event of a power failure. Some UPS units, known as intelligent UPSs, enable you to remotely cycle power, providing rudimentary remote management. For Emergency Management Services systems with firmware redirection enabled, an intelligent UPS can enhance remote management capabilities by responding to remote commands sent to it.

When used with Emergency Management Services, an intelligent UPS must passively monitor the serial port traffic and support the key sequences that apply to it and must not affect communication between the managing client and the server running Windows Server 2003. If you also use a service processor, the intelligent UPS must be able to differentiate the key sequences directed to itself, the service processor, and Emergency Management Services. The UPS must also be able to inform the system of a planned power shutdown.

An intelligent power switch is an alternative to an intelligent UPS. An intelligent power switch can provide features similar to an intelligent UPS, except that it does not provide a backup source of power.

### Note

- To take full advantage of intelligent UPS or intelligent power switch capabilities, you need to configure servers to automatically start up when power is applied. Your servers firmware might provide an option to enable this feature.

**Emergency Management Services Processes and Interactions**
The following section describes certain tasks that you can perform using Emergency Management Services.

**Remote Tasks Supported During Normal Operation**
With Emergency Management Services console redirection, you can perform the following remote management tasks when the operating system is functioning normally.

**Verify that Windows has started**
When the Windows loader starts, it displays the following message by using the out-of-band port:

```
Windows is now starting
```

The preceding message indicates that the Windows Server 2003 startup process has begun.

When the Windows kernel is initialized, it displays the following prompt by using the out-of-band port, indicating that Emergency Management Services is enabled:

```
SAC>
```

**Choose an item on the operating system boot menu (forx86-based computers)**
For multiple-boot systems that have Windows Server 2003 installed along with Recovery Console or another Microsoft operating system, the Windows loader (Ntldr) automatically displays an operating boot menu, both to the local display and to the out-of-band port. By using this operating system boot menu, you can start the Windows Server 2003 operating system or Recovery Console. You also have the option of viewing the Windows Advanced Options Menu by pressing the F8 key. The following is a typical operating system boot menu.

```
Please select the operating system to start:

Microsoft Windows Server 2003
Recovery Console

Use the up and down arrow keys to move the highlight to your choice.
Press Enter to choose.
Seconds until highlighted choice will be started automatically: 29

For troubleshooting and advanced startup options for Windows, press F8.
```

**Monitor the progress of Windows Server 2003 text-mode setup**
The text-mode setup phase displays character-based information, which supports Windows Emergency Management Services console redirection. Therefore, you can remotely view and respond to text-mode setup prompts.

**View and respond to PXE environment prompts**
If the server's firmware supports the Pre-Boot eXecution Environment (PXE) standard but does not support firmware console redirection, an alternate version of the Startrom.com file provides Emergency Management Services console redirection.

**Remote Tasks Supported for Problem Resolution**
With Emergency Management Services console redirection, you can perform the following remote management tasks to troubleshoot problems.

**Use Last Known Good Configuration to troubleshoot problems**
Last Known Good Configuration is a troubleshooting option you can use when a driver or application installation problem prevents a computer from starting in normal mode. By using Last Known Good Configuration, you can recover from a problem by reversing the driver and registry changes made since you last started Windows Server 2003. You can invoke Last Known Good Configuration from the Windows Advanced Options Menu. You can display the Windows Advanced Options Menu by pressing F8 during system startup or at the operating system boot menu, if it appears.

**Use Recovery Console to troubleshoot problems**
Recovery Console is a command-line environment that you can use to remotely perform advanced troubleshooting operations, such as manually replacing system files. You can invoke Recovery Console by installing it on your computer and then selecting it from the operating system boot menu or by starting it from the Windows Server 2003 installation CD.

**Ports Used by Emergency Management Services**
Emergency Management Services redirects text through an out-of-band connection, typically a serial port connection. Serial ports are also known as COM ports. The following table lists the COM ports used by Emergency Management Services and their settings.

**Typical Serial Port Resource Settings**

| Friendly Name | Typical Hexadecimal I/O Address | Interrupt Request (IRQ) Value |
|---|---|---|
| **COM1** | Emergency Management Services supports the industry standard 3F8 (this is typically the firmware default or AUTO value for COM1). Values of 2F8, 3F8, On, and Off might also be available. | 4 (this is typically the default or AUTO value) |
| **COM2** | Emergency Management Services supports the industry standard 2F8 (this is typically the firmware default or AUTO value for COM2). Values of 2F8, 3F8, On, and Off might also be available. | 3 (this is typically the default or AUTO value) |

**Note**

- It is important to realize that EMS does not use both COM1 and COM2 at the same time: it uses one or the other. In addition, it can use a non-legacy serial port address provided the system designer builds an EMS-aware design.

**Related Information**

The following resources contain additional information that is relevant to this section.

# Emergency Management Services Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Emergency Management Services Tools and Settings**

**In this section**

- Emergency Management Services Tools
- Emergency Management Services Registry Entries
- Emergency Management Services Group Policy Settings
- Emergency Management Services WMI Classes
- Ports Used by Emergency Management Services
- Related Information

Emergency Management Services is a new technology in Windows Server 2003 that administrators can use to remotely manage and recover servers that are not accessible through an in-band connection.

An in-band connection is a connection between two computers that relies on standard network connectivity, such as a local area network (LAN) or the Internet, and on standard remote administration tools, such as Remote Desktop or Telnet. You can use this type of connection to remotely manage computers only if both the local and remote computers are in a functional state and accessible on the network.

Emergency Management Services uses a nonstandard or out-of-band connection, such as a serial port connection, to connect two computers. This arrangement is useful when you are managing a particular computer that cannot access the network or is not fully operational and, as a result, must rely on the other computer for critical management functionality. In order to provide this functionality, Emergency Management Services makes available three tools: console redirection, Special Administration Console (SAC), and !Special Administration Console (!SAC).

Emergency Management Services also supports remotely administered serversthat do not have a locally attached keyboard, video, or mouse (also referred to as *headless* servers). Emergency Management Services also supports server configurations that have no keyboard controller or video controller, if the system firmware supports this. Using servers that do not have a locally attached keyboard, video or mouse in, for example, a datacenter or similar facility has several benefits. It can result in a significant savings in space, energy consumption, and hardware costs.

Emergency Management Services is only enabled by default if the Advanced Configuration and Power Interface (ACPI) Serial Port Console Redirection (SPCR) table in the system BIOS is set to indicate the out-of-band connecting settings. Otherwise, Emergency Management Services is not enabled by default, but can be enabled at any of the following times:

- During a new Windows Server 2003 installation (including RIS-based and image-based setups)
- During a Windows Server 2003 upgrade (for x86-based systems only)
- After you complete a Windows Server 2003 installation

Emergency Management Services functionality is built into Windows Server 2003. It is not necessary to copy additional files from the Windows Server 2003 installation CD.

**Note**

- The SPCR table, found on some computers that are equipped with ACPI-compliant firmware, provides information about how the system firmware and the service processor, if available, use the out-of-band management port. Emergency Management Services uses the information in the SPCR table to ensure a smooth transition between the output of the system firmware and the output of Emergency Management Services.

The purpose of Emergency Management Services is to help you return a server to a state where you can manage it using an in-band connection — the preferred way to manage a server. Unexpected events, however, can interrupt in-band connectivity. For example, a network adapter problem or system instability can cause a server to become unresponsive to management attempts from client computers that use an in-band connection. Because Emergency Management Services does not rely on operating system network drivers, client computers can communicate with servers through the out-of-band port in such situations and can attempt to bring the servers back into service remotely.

**Emergency Management Services Tools**
The following tools are associated with Emergency Management Services:

- Console redirection
- Special Administration Console (SAC)
- !Special Administration Console (!SAC)

Emergency Management Services console redirection is able to utilize a number of standard Windows features, such as Recovery Console, by redirecting text output from these features through the out-of-band port to a remote computer running terminal emulation software. This can be of vital importance when the remotely managed computer is not accessible, either locally or over the network, and the only means of communicating with the computer is through the out-of-band connection. Emergency Management Services console redirection is only available when the operating system is functioning normally.

SAC and !SAC are tools that are specific to Emergency Management Services. These tools are entirely separate from other Windows tools or features and provide their own functionality. Like Emergency Management Services console redirection, SAC is only available when the operating system is functioning normally. Unlike Emergency Management Services console redirection and SAC, !SAC only becomes available when the system is not functioning normally and SAC itself has failed to load or ceased to operate.

**Console Redirection**
**Category**
Windows Server 2003 operating system tool

**Version compatibility**
Supported on all Windows Server 2003 operating systems

Emergency Management Services console redirection enables you to use a number of standard Windows features, such as Recovery Console, even when the computer that you are managing is not otherwise accessible.

If Emergency Management Services is enabled when Windows Server 2003 starts, the operating system assumes responsibility for console redirection from the firmware. Up to this point, the firmware has provided a certain level of functionality independent of the operating system, and, in a manner similar to Emergency Management Services, has redirected text output through the out-of-band port. (Firmware is defined as software routines and low-level input/output instructions stored in read-only memory [ROM]. Unlike random access memory [RAM], read-only memory stays intact even in the absence of electrical power.)

The following table lists the Windows Server 2003 components and features that support Emergency Management Services console redirection after the operating system starts.

**Components That Work With Emergency Management Services Console Redirection**

| Windows Server 2003 Component or Feature | Description |
|---|---|
| Windows loader forx86-based computers (Ntldr) | The Windows Server 2003 operating system loader. When Ntldr is running, you can remotely view and select the Recovery Console or, on x86-based multiple-boot computers, which operating system to start. |

| | |
|---|---|
| Windows kernel (Ntoskrnl.exe) | The core (also called the kernel) of the Windows Server 2003 operating system. Code that runs as part of the kernel does so in privileged processor mode and therefore has direct access to system data and hardware.<br><br>The Windows kernel supports console redirection, which enables you to remotely view system information during normal operation, or remotely view Stop message text when a system problem occurs. |
| Recovery Console | A command-line environment that you can use to perform advanced troubleshooting and maintenance tasks, such as disabling a driver that you suspect is causing a startup problem. |
| Command Prompt (Cmd.exe) | A character-mode, command shell user interface that provides an environment for running commands and applications. |
| Text-mode Setup (including the CD-ROM Setup loader) | The initial portion of the Windows Server 2003 installation process when Setup displays character-mode prompts and status information text. During text-mode Setup, files are copied from the distribution folder to the local hard disk. |
| Startrom.com at 9600 baud for x86-based computers | Starts the x86-based Remote Installation Services (RIS) process. This file is downloaded and run by the RIS client to initiate the operating system installation procedure. Only special versions of Startrom.com that use 9600 baud support Emergency Management Services console redirection.<br><br>RIS includes software services that an administrator can use to set up new client computers remotely, without having to visit each client. The destination clients must support remote booting. |

Emergency Management Services does not provide console redirection for the components listed in the following table.

**Components That Do Not Work With Support Emergency Management Services Console Redirection**

| **Windows Server 2003 Component** | **Description** |
|---|---|
| The **Press Any Key to Boot from CD** prompt | This prompt appears when you start your system using the Windows Server 2003 operating system CD. |
| GUI-mode Setup | Emergency Management Services processes only character-mode input and output. Emergency Management Services cannot display GUI-mode graphics, such as windows and dialog boxes, or redirect mouse input. Using the Special Administration Console (SAC), you can, however, view Setup “channels” that allow you, in turn, to view Setup log files as they are created so that you can monitor the progress of Setup. |
| Startrom.com at baud rates greater than 9600 | Startrom.com supports Emergency Management Services console redirection only at 9600 baud. |
| Operating system boot menu for Itanium-based computers | For Itanium-based computers, the EFI boot manager (IA64ldr), not the Windows loader, displays the list of operating systems installed on the system. To remotely view and select boot manager menu items on Itanium-based systems, you must enable firmware console redirection. |

**Remote Management Tasks Supported by Console Redirection during Normal Operation**

With Emergency Management Services console redirection, you can perform the following remote management tasks when the operating system is functioning normally.

- **Verify that Windows has started**

  When the Windows loader starts, it displays the following message using the out-of-band port:

```
Windows is now starting
```

The preceding message indicates that the Windows Server 2003 startup process has begun.

When the Windows kernel initializes, it displays the following prompt by using the out-of-band port, indicating that Emergency Management Services is enabled:

```
SAC>
```

- **Choose an item on the operating system boot menu (for x86-based computers)**

  For multiple-boot systems that have Windows Server 2003 installed along with Recovery Console or another Microsoft operating system, Ntldr automatically displays an operating boot menu, both to the local display and to the out-of-band port. By using this operating system boot menu, you can start the Windows Server 2003 operating system or Recovery Console. You also have the option of viewing the Windows Advanced Options Menu by pressing the F8 key. The following is a typical operating system boot menu.

```
Please select the operating system to start:

Microsoft Windows Server 2003
Recovery Console

Use the up and down arrow keys to move the highlight to your choice.
Press Enter to choose.
Seconds until highlighted choice will be started automatically:  29

For troubleshooting and advanced startup options for Windows, press F8.
```

- **Monitor the progress of Windows Server 2003 text-mode Setup**

  The text-mode Setup phase displays character-based information, which supports Emergency Management Services console redirection. You can remotely view and respond to text-mode Setup prompts.

- **Monitor the progress of Windows Server 2003 GUI-mode Setup**

  Emergency Management Services processes only character-mode input and output. Emergency Management Services cannot display GUI-mode graphics, such as windows and dialog boxes, or redirect mouse input. Using Special Administration Console (SAC), you can, however, view Setup "channels" that allow you, in turn, to view Setup log files as they are created so that you can monitor the progress of Setup.

- **View and respond to Preboot Execution Environment (PXE) prompts**

  If the server firmware supports the PXE standard but does not support firmware console redirection, an alternate version of the Startrom.com file provides Emergency Management Services console redirection.

**Remote Management Tasks Supported by Console Redirection for Troubleshooting**

With Emergency Management Services console redirection, you can perform the following remote management tasks to troubleshoot problems.

- **Use Last Known Good Configuration to troubleshoot problems**

  Last Known Good Configuration is a startup option that you can use to troubleshoot when a driver or application installation problem prevents a computer from starting in normal mode. By using Last Known Good Configuration, you can recover from a problem by reversing the driver and registry changes that were made since you last started Windows Server 2003. You can access Last Known Good Configuration from the Windows Advanced Options Menu. The Windows Advanced Options Menu can be displayed by pressing F8 during system startup or at the operating system boot menu, if available.

- **Use Recovery Console to troubleshoot problems**

  Recovery Console is a command-line environment that you can use to remotely perform advanced troubleshooting operations, such as manually replacing system files. You can use Recovery Console by installing it on your computer and then selecting it from the operating system boot menu. You can also start it from the Windows Server 2003 installation CD.

**Sacdrv.sys: Special Administration Console**
**Category**
Windows Server 2003 operating system tool

**Version compatibility**
Supported on all Windows Server 2003 operating systems

Special Administration Console (SAC) is the primary Emergency Management Services command-line environment. You can access this console through an out-of-band remote management port, such as a COM port or the redirection port specified by the hardware platform, by using terminal software that supports VT-UTF8, or VT100. SAC is a kernel-mode component.

### Note

- Command-line functionality for Emergency Management Services requires mutual dependence across three components: Sacdrv.sys, Sacsvr.dll, and Sacsess.exe. The SAC driver provides the core channel functionality (as well as basic SAC> prompt features), while the SAC service and the SAC session register with the SAC driver to complete the functional loop. The service is responsible for responding to SAC driver requests to start sessions, and the session is responsible for creating a new SAC channel and routing **STDIO** between the channel and its child Cmd.exe process. At the same time, it is important to note that Sacdrv.sys was designed to allow Special Administration Console to continue to operate successfully, even if the system is in a state where Sacsvr.dll and Sacsess.exe cannot operate.

SAC is available early in the startup process, and you can use it to manage the server during normal system operation, Safe Mode, and the GUI phase of Windows Server 2003 Setup. When Emergency Management Services is enabled, SAC is always active as long as the kernel is running. SAC is a separate environment from the Windows Server 2003 command prompt (Cmd.exe). You can remotely monitor the status of a server or troubleshoot problems by using terminal software on a remote computer to access SAC.

**Remote Management Tasks Supported by SAC during Normal Operation**
You can use SAC to perform the following remote tasks when the operating system is functioning normally:

- Gather server information, such as computer name and IP address.
- Obtain a list of the services and applications that are running on the computer.
- Restart or shut down a server as part of planned maintenance.
- Change the system time and date.

**Remote Management Tasks Supported by SAC for Troubleshooting**
You can use SAC to perform the following troubleshooting tasks:

- Raise or lower the priority of a process, or end a process that is consuming excessive processor time or other system resources. By establishing an out-of-band connection to SAC, you can continue to manage a server even when low system resources have caused it to become unresponsive to management tools that rely on an in-band connection.
- Restart or shut down a server that has stopped responding to in-band commands and tools.
- View or change TCP/IP networking information for a server to resolve issues, such as problems caused by a duplicate IP address.
- Maintain communication with a server during network outages. For example, you might want to verify that a connectivity issue is caused by a problem that affects the primary network rather than a problem with the server hardware or a driver.

- Generate a list of drivers for diagnostic purposes.
- View Setup logs to determine the cause of a problem that prevents Windows Server 2003 installation from completing.

**Note**

- Use of SAC is not safeguarded by password and logon requirements. You must secure physical access to computers running Emergency Management Services by placing appropriate restrictions on all connecting terminals.

**Using SAC**

SAC is an operating system component that runs in kernel mode and displays the following prompt when you establish an out-of-band connection to a computer that is running Emergency Management Services:

```
SAC>
```

In addition to providing a variety of commands that support remote management, SAC provides access to the Windows command prompt and to Setup logs. When you use SAC, you can create multiple user sessions or *channels* and switch among them so that you can use SAC commands while concurrently running command-line commands or viewing Setup logs.

**SAC Commands**

The following table lists the commands that are available in the SAC environment. The commands are not case-sensitive. For some commands, you will have to specify a process identifier (PID)number. You can obtain PID numbers by using the **t** command, which causes SAC to list active processes and the PIDs that are assigned to them.

**Table 10.11 SAC Commands**

| SAC Command | Description |
|---|---|
| **?** or **help** | Lists the available SAC commands. |
| **ch** | Lists all available channels. See Table 10.12 for a complete list of channel management commands. |
| **cmd** | Creates a Windows command prompt channel once logon credentials are validated. |
| **Crashdump** | Manually generates a Stop message and forces a memory dump file to be created. |
| **D** | Dumps the current kernel log. |
| f | Switches the information output of the **tlist** command between showing processes only or showing both processes and threads. |
| I | Configures IP parameters by providing network number, IP address, and subnet information using the following format.<br><br>*<network#> <iPaddress> <subnet>*<br><br>If no parameters are passed, this command lists IP information.<br><br>**Note**<br>Please note that the IP address will be restored to the original value when the server is rebooted and any changes made by using this command will be lost. |
| **id** | Displays computer identification information. |
| **k** *<PID>* | Ends the process specified by its process ID (PID). |
| **l** *< PID>* | Lowers the priority of a process (and any associated child processes) to the lowest possible level. |
| **lock** | Locks access to command prompt channels. |

| | |
|---|---|
| **m** < *PID*> <*MB-allow*> | Limits the memory usage of a process (and any child processes) to the specified number of megabytes. |
| p | Causes **tlist** command output to pause after displaying one screen of information. |
| **r** < *PID*> | Raises the priority of a process and any associated child processes by one level. |
| **restart** | Restarts the computer immediately. |
| **s** | Displays the current date (using 24-hour clock format) if you provide no parameters.<br>Sets the system time if you provide the date and, optionally, the time in the following format:<br>*mm/dd/yyyy hh:mm* |
| **shutdown** | Shuts down the computer. |
| **t** | Lists the processes and threads that are currently running. The output is referred to as a *task list* or *tlist*. |

**Note**

- The SAC prompt (SAC>) might not immediately appear after a connection is established to a remote server running Emergency Management Services. If the SAC prompt does not appear, Press ENTER several times until the prompt does appear.

**SAC Channels**

SAC supports three types of channels: SAC, Windows command prompt, and Setup logs.

**SAC Channel**

The SAC channel, which is always active, is assigned a channel name of SAC and a channel number of 0 (zero).

**Windows Command Prompt Channels**

The Special Administration Console Helper service (Sacsvr) is a user-mode service that you can use to create command prompt channels when you type the **cmd** command from the SAC prompt. To use a Windows command prompt channel, you must log on to the server with administrative credentials. You must log on separately to each command prompt session. SAC assigns a name of "Cmd000*x*" to all command prompt channels, where *x* represents the next available channel number.

When using a Windows command prompt channel, you can run text-based tools as though you were logged on locally. These tools include command-shell commands, such as **dir**, and text-based console programs, such as the boot configuration tool (Bootcfg.exe).

As with other services, the Special Administration Console Helper service requires initialization time when Windows Server 2003 starts. Therefore, command prompt channels might not be immediately available, and you might have to wait until the operating system startup process is nearly complete.

**Note**

- The Windows command prompt might not be available or might become unavailable if system resources become low. In these situations, you can typically continue to manage the server by using SAC.

**Setup Log Channels**

You can access the Setup log channels only during the GUI-mode phase of Windows Server 2003 Setup. By viewing the following Setup log files, which contain the same information, you can monitor the installation process or diagnose problems that might cause Setup to stop or pause. These files are created automatically.

- **Setuplog.txt.** Provides information about files copied to your system by Windows Setup.
- **Setupact.log.** Provides information about actions performed by Windows Setup.
- **Setuperr.log.** Provides Setup-related warning and error information.

The following text shows output that is generated by the SAC **ch** command during the GUI-mode phase of Windows Server 2003 Setup.

```
SAC>ch
Channel List

(Use "ch -?" for information on using channels)

# Status  Channel Name
0 (AV)    SAC
1 (AR)    setuplog.txt
2 (AR)    setupact.log
3 (AR)    setuperr.log
```

**SAC Channel Commands**

You can create and switch among up to ten concurrent channels. The following table provides a list of channel commands.

**SAC Channel Commands**

| Channel Command | Description |
|---|---|
| **ch** | Lists all channels. |
| **ch -si** <#> | Switches to a channel by number. Press ENTER to confirm your channel selection. |
| **ch -sn** <*name*> | Switches to a channel by name. Press ENTER to confirm your channel selection. |
| **ch -ci** <#> | Closes a channel by number. Press ENTER to confirm your channel selection. |
| **ch -cn** <*name*> | Closes a channel by name. Press ENTER to confirm your channel selection. |
| **ESC** followed by **TAB** | Cycles through the available channels. Press ENTER to confirm your channel selection. |
| **ESC** then **TAB** followed by **0** | Returns to channel 0 (the SAC channel). Press ENTER to confirm your channel selection. |

SAC returns channel status information in the following format:

<*Channel #*> <*Two-character status*> <*Channel name*>

The following illustrates output generated by the SAC **ch** command:

```
SAC>ch
Channel List

(Use "ch -?" for information on using channels)

# Status  Channel Name
0 (AV)    SAC
1 (AV)    Cmd0001
2 (AV)    Cmd0002
```

To switch from SAC (Channel 0) to the next available channel (Channel 1), press ESC followed by TAB, and then press ENTER. To return to SAC, press ESC followed by TAB, type 0, and then press ENTER.

The following table describes the information provided by the two-character channel status code.

**SAC Channel Status Information**

| Status Code (AB) | Description |
|---|---|
| **A (First Character)** | Indicates channel status.<br><br>A = Active Channel, I = Inactive Channel |
| **B (Second Character)** | Channel terminal emulation type.<br><br>V = VT-UTF8, R = Raw (no emulation) |

**Note**

- Although you can create and use multiple channels to manage a computer running Windows Server 2003, you can only

access a single channel at a time. Therefore, access to SAC by multiple users is not possible.

**!Special Administration Console (resides in Ntoskrnl.exe)**
**Category**
Windows Server 2003 operating system tool

**Version compatibility**
Supported on all Windows Server 2003 operating systems

The !Special Administration Console (!SAC) is an auxiliary Emergency Management Services command-line environment that is hosted on Windows Server 2003. It also accepts input and sends output through the out-of-band port. !SAC is a separate entity from both SAC and Windows Server 2003 family command-line environments. After a specific failure point is reached, Emergency Management Services components determine when the shift should be made from SAC to !SAC. !SAC becomes available automatically if SAC fails to load or is not functioning.

!SAC provides a subset of SAC commands that you can use to restore system functionality during a failure. Its two primary functions are:

- To redirect Stop error message text.
- To restart the computer if SAC becomes unavailable.

**Using !SAC**
!SAC provides a command-line environment that you can use if a computer running Windows Server 2003 stops responding or SAC has failed to load or ceased to operate.

When !SAC becomes available, the following prompt appears:

```
!SAC>
```

The !SAC prompt might be preceded by a Stop message that contains information about the problem that caused the error condition to occur.

**!SAC Commands**
The following table lists available !SAC commands.

### !SAC Commands

| !SAC Command | Description |
|---|---|
| **?** or **help** | Lists available commands. |
| **D** | Displays all log entries (screen pauses at each page of information). |
| **Id** | Displays computer identification information. |
| **Restart** | Restarts the computer. |

Like SAC, it is not possible for multiple users to access !SAC simultaneously.

### Note

- The !SAC prompt might not immediately appear after you establish a connection to a remote server running Emergency Management Services. If the !SAC> prompt does not appear, press ENTER several times until it does appear.

**Preventing Automatic Restarts after a Stop Message**
An **Automatically reboot** setting in Control Panel controls whether your system restarts after a Stop message occurs. This option is enabled by default. It causes your computer to restart after a Stop message instead of enabling !SAC. To use !SAC after a Stop message occurs, you must disable the **Automatically reboot** setting. This setting might be important for troubleshooting, depending on the nature of the problem (for example, the computer is repeatedly failing after restart), because it gives you time to remotely view and record Stop message text for later reference while searching through technical resources, such as Microsoft Knowledge Base articles. In most cases, however, the **Automatically reboot** setting is preferred for computers in remote locations.

**Emergency Management Services Registry Entries**
The registry entries in this section are associated with Emergency Management Services.

The information here provided is a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

For more information about the Emergency Management Services registry entries, see the Registry Reference for Windows Server 2003.

**The following registry entries govern core Emergency Management Services Special Administration Console functionality, which includes the SAC command set as well as virtual channel support.**

**ComputerName**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\ComputerName\ComputerName\

**Version**
Windows Server 2003

Access required: Read

Function: Gets computer name for computer information.

**DisableCmdSessions**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\SacDrv\

**Version**
Windows Server 2003

Access required: Read

Function: Prevents the **cmd** command from starting a SAC session.

**PROCESSOR_ARCHITECTURE**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Session Manager\Environment\

**Version**
Windows Server 2003

Access required: Read

Function: Gets processor architecture for computer information.

**Start**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\SacSvr\

**Version**
Windows Server 2003

Access required: Write

Function: Forces the SAC service attribute to automatic if the mode is manual.

**SystemSetupInProgress**
**Registry path**
HKEY_LOCAL_MACHINE\System\Setup\

**Version**
Windows Server 2003

Access required: Read

Function: Determines if Setup is in progress. If Setup is in progress, then session locking is disabled – there is no password for

the administrator during GUI mode Setup

**The following registry entries govern Cmd.exe functionality by means of a SAC channel. That is, the session implements a SAC channel and routes Cmd.exe I/O to the channel so that it can be accessed by means of remote users.**

**BypassAuthentication**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Services\SacSvr\

**Version**
Windows Server 2003

Access required: Read

Function: Deliberately disables session authentication.

Who accesses the setting: Administrators

**LoadProfilesDisabled**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\SacSvr\Parameters\

**Version**
Windows Server 2003

Access required: Read

Function: Deliberately disables the loading of user profiles upon successful session authentication.

Who accesses the setting: Administrators

**Netsvcs**
**Registry path**
HKEY_LOCAL_MACHINE\ Software\Microsoft\Windows NT\CurrentVersion\Svchost

**Version**
Windows Server 2003

Access required: Read/Write

Function: States whether the SAC service is a member of the Netsvcs group. If it is not, it should be added.

What accesses the setting: Service Control Manager

**ServiceDll**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\SacSvr\Parameters\

**Version**
Windows Server 2003

Access required: Write/Create

Function: Specifies the location of the SAC service dll binary file.

What accesses the setting: Service Control Manager

**TimeOutDisabled**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\SacSvr\Parameters\

**Version**
Windows Server 2003

Access required: Read

Function: Deliberately disables the time-out (auto-session lock) feature.

Who accesses the setting: Administrators

**TimeOutInterval**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\SacSvr\Parameters\

**Version**
Windows Server 2003

Access required: Read

Function: Sets the time-out (auto-session lock) duration

Who accesses the setting: Administrators

**The following registry entries enable the Service Control Manager to successfully start the SAC service. The purpose of the SAC service (Special Administration Console Helper service) is to provide a mechanism for the SAC driver (sacdrv.sys) to start user-mode instances of SAC sessions (Sacsess.exe). Note that the Start value is set to offstate (4) when the service exits.**

**SacSvr**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\

**Version**
Windows Server 2003.

Access required: Read

Function: Populates the SAC service parameters so that the Service Control Manager is properly informed and can start the service correctly.

What accesses the setting: Service Control Manager

**Description**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\SacSvr\

**Version**
Windows Server 2003.

Access required: Read

Function: This value of the SacSvr key populates the SAC service parameters so that the Service Control Manager is properly informed and can start the service correctly.

What accesses the setting: Service Control Manager

**DisplayName**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\ SacSvr\

**Version**
Windows Server 2003.

Access required: Read

Function: This value of the SacSvr key populates the SAC service parameters so that the Service Control Manager is properly informed and can start the service correctly.

What accesses the setting: Service Control Manager

**ErrorControl**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\ SacSvr\

**Version**
Windows Server 2003.

Access required: Read

Function: This value of the SacSvr key populates the SAC service parameters so that the Service Control Manager is properly

informed and can start the service correctly.

What accesses the setting: Service Control Manager

**ImagePath**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\ SacSvr\

**Version**
Windows Server 2003.

Access required: Read

Function: This value of the SacSvr key populates the SAC service parameters so that the Service Control Manager is properly informed and can start the service correctly.

What accesses the setting? Service Control Manager

**ObjectName**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\ SacSvr\

**Version**
Windows Server 2003.

Access required: Read

Function: This value of the SacSvr key populates the SAC service parameters so that the Service Control Manager is properly informed and can start the service correctly.

What accesses the setting: Service Control Manager

**Start**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\ SacSvr\

**Version**
Windows Server 2003.

**Emergency Management Services Group Policy Settings**
There are no Group Policy settings associated with Emergency Management Services.

**Emergency Management Services WMI Classes**
There are no WMI classes associated with Emergency Management Services.

**Ports Used by Emergency Management Services**
**Network Ports**
As a technology that uses an out-of-band connection, Emergency Management Services does not directly utilize any network ports.

**Serial Ports**
Emergency Management Services redirects text output from certain tools and functions through an out-of-band connection, typically a serial port connection. However, this can also be a connection that is defined in the Serial Port Console Redirection (SPCR) table, if this table is supported by the system firmware. If Emergency Management Services is configured to use an SPCR table (including all Itanium-based systems), the following settings are available.

- Any COM port
- Any I/O port in memory mapped I/O space
- Other SPCR table information
- The serial port EFI console device path (Itanium-based systems only)

**Notes**

- The SPCR table is only available on computers with ACPI-compliant firmware. However, not all ACPI-compliant computers provide an SPCR table.
- The SPCR table is typically enabled if firmware console redirection is enabled or a service processor that supports Emergency Management Services is present. See your system documentation to determine whether your computer supports the SPCR table and whether you need to follow special requirements to enable it.

To find more information about the SPCR table, see MSDN and type the appropriate key words in the "Search for" text box.

Serial ports are also known as COM ports. The following table lists the COM ports used by Emergency Management Services and their settings. In older systems without firmware that supports the SPCR table, the user must configure these ports manually. However, it is important to emphasize that in order to achieve a higher degree of integration between Emergency Management Services and the system in general, it is preferable to define these connections in the SPCR table, if available.

**Typical Serial Port Resource Settings**

| Friendly Name | Typical Hexadecimal I/O Address | Interrupt Request (IRQ) Value |
|---|---|---|
| **COM1** | Emergency Management Services supports the industry standard 3F8 (this is typically the firmware default or AUTO value for COM1). Values of 2F8, 3F8, On, and Off might also be available. | N/A |
| **COM2** | Emergency Management Services supports the industry standard 2F8 (this is typically the firmware default or AUTO value for COM2). Values of 2F8, 3F8, On, and Off might also be available. | N/A |

**Notes**

- It is important to realize that Emergency Management Services does not use both COM1 and COM2 at the same time. It uses one port or the other. In addition, it can use a nonlegacy serial port address if a developer builds a feature or component that is written to the Emergency Management Services application programming interfaces (APIs) and specifies such an address.
- The Windows Server 2003 operating system must have exclusive access to the out-of-band port. Instead of requesting input and output operations from the Windows I/O Manager, Emergency Management Services writes information directly to Universal Asynchronous/Receive Transmit (UART) hardware. fallback

**Related Information**
The following resource contains additional information that is relevant to this section.

- For more information about Emergency Management Services, Group Policy and Telnet, click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection.

# Shutdown Event Tracker Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Shutdown Event Tracker Technical Reference**
Shutdown Event Tracker is a feature of the Microsoft Windows Server 2003 operating systems that provides a way for IT professionals to consistently track why users restart or shut down their computers. Shutdown Event Tracker captures the reasons users give for restarts and shutdowns to help create a comprehensive picture of an organization's system environment. It does not document why users choose other options, such as **Log off** and **Hibernate**.

In a more active sense, Shutdown Event Tracker also provides IT professionals with a specific tool, Remote Shutdown (Shutdown.exe), for restarting or shutting down both local and remote computers, while at the same time supplying reasons for doing so. In addition, users can employ Remote Shutdown to hibernate a local computer and abort delayed shutdowns.

Shutdown Event Tracker is enabled by default and is a routine part of the computer shutdown process.

**In this subject**

- What Is Shutdown Event Tracker?
- How Shutdown Event Tracker Works
- Shutdown Event Tracker Tools and Settings

# What Is Shutdown Event Tracker?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Shutdown Event Tracker?**

### In this section

- Common Scenarios for Shutdown Event Tracker
- Shutdown Event Tracker Dependencies on or Interactions with Other Technologies
- Shutdown Event Tracker Logical Diagrams
- How Shutdown Event Tracker Differs from Similar Technologies
- How Shutdown Event Tracker Works

Shutdown Event Tracker is a feature of the Microsoft Windows Server 2003 operating systems that provides a way for IT professionals to consistently track why users restart or shut down their computers. Shutdown Event Tracker captures the reasons users give for restarts and shutdowns to help create a comprehensive picture of an organization's system environment. It does not document why users choose other options, such as **Log off** and **Hibernate**.

In a more active sense, Shutdown Event Tracker also provides IT professionals with a specific tool, Remote Shutdown (Shutdown.exe), for restarting or shutting down both local and remote computers, while at the same time supplying reasons for doing so. In addition, users can employ Remote Shutdown to hibernate a local computer and cancel delayed shutdowns.

Shutdown Event Tracker is enabled by default and is a routine part of the computer shutdown process.

In first considering Shutdown Event Tracker, it is important to understand the difference between expected and unexpected restarts and shutdowns.

**Expected restarts and shutdowns**

Expected restarts and shutdowns can be either planned or unplanned.

A planned shutdown is one in which both the user and the computer fully anticipate the shutdown. For example, as a matter of either policy or habit, a user might shut down his or her computer at the end of each day. When a user has control over the timing of a restart or shutdown, the task is planned.

An unplanned shutdown is one in which the user does not anticipate the shutdown, but has time to perform the shutdown in a normal manner. For example, if an application becomes unresponsive, the user might be forced to restart or shut down the computer. When a user does not have control over the exact timing of a restart or shutdown, the task is unplanned.

### Note

- For the purpose of this topic, shutting down the system in a "normal manner" is defined as the user clicking **Start** and then **Shutdown**, or pressing CTRL+ALT+DELETE and then clicking **Shutdown**, or utilizing Shutdown.exe, a tool specific to Shutdown Event Tracker. These methods call the InitiateSystemShutdownEx application programming interface (API), which in turn spawns a number of related events. To find more information about these events, see "How Shutdown Event Tracker Works" in "How Shutdown Event Tracker Works."

**Unexpected restarts and shutdowns**

Unexpected shutdowns are shutdowns that the computer does not anticipate, and that the user may or may not anticipate. For example, the computer abruptly loses power and immediately shuts down. In this instance, neither the computer nor the user could have anticipated the shutdown. However, in another example, the user shuts down the computer by holding down the power button. In this instance, the user did, in fact, anticipate the shutdown but the computer, as in the first example, did not. It is important to understand that in both instances shutdown did not occur in a normal manner and that therefore the two shutdowns must be classified as "unexpected."

**Common Scenarios for Shutdown Event Tracker**

Shutdown Event Tracker is commonly used in the following scenarios:

**Expected restarts and shutdowns**
In this scenario, the user has complete control over the restart or shutdown process, and when the user performs the shutdown in a normal manner, the operating system has time to complete its usual shutdown routine. Moreover, because there is time, the user can provide a reason for the restart or shutdown in the dialog box presented to the user prior to shutdown.

In addition, it is important to understand that both planned and unplanned shutdowns form separate parts of the overall expected restarts and shutdowns scenario. They are described as follows:

**Planned restarts and shutdowns**
In this scenario, both the user and the computer fully anticipate the restart or shutdown: the user because he or she deliberately initiates the process, and the computer because the process is initiated in a normal manner, either by the user clicking **Start** and then **Shutdown**, or by pressing CTRL+ALT+DELETE and then clicking **Shutdown**,or by utilizing Shutdown.exe. When a restart or shutdown is planned, and shutdown occurs in a normal manner, the user is given the opportunity to provide a reason for the event at the time the event occurs.

**Unplanned restarts and shutdowns**
In this scenario, the user deliberately shuts down the computer, but in response to an unexpected event, such as an application failing to respond. The shutdown is therefore unplanned. If the user shuts down the computer in a normal manner, the operating system has time to execute the shutdown in a normal manner as well, and the user is given the opportunity to provide a reason for an "unplanned" shutdown. Conversely, if in response to the same unexpected event the user does not shut down the computer in a normal manner (for example, if the user unplugs the computer), the shutdown is no longer viewed as expected but unplanned, but as simply "unexpected."

**Unexpected restarts and shutdowns**
In this scenario, the user has no control over the restart or shutdown process, and the computer does not have time to complete its usual shutdown routine. For example, in the event of a power loss, the computer will immediately shut down unless there is an uninterruptible power supply (UPS) or other fault-tolerant strategy in place. As a result, the user will not be given the opportunity to provide a reason for the shutdown at the time the shutdown occurs. However, the **Shutdown Event Tracker** (unexpected shutdown) dialog box appears to the first person with the **Shutdown the system** user right or with administrative credentials who logs on to the computer after the event, and the user can, at that time, provide a reason for the shutdown.

### Note

- It is important to realize that a person with administrative credentials automatically has the **Shutdown the system** user right, but that it is possible for another person to have only this one right and not have administrative credentials.

Other reasons for unexpected shutdowns include (but are not limited to):

- A hardware failure
- A system error (also referred to as a bugcheck, system crash, fatal system error, or stop error)
- The user holding down the computer's power button for five seconds or longer
- The user pressing CTRL+ALT+DELETE and then holding down the CTRL key while clicking **Shutdown**

**Local restarts and shutdowns**
In this scenario, Remote Shutdown (Shutdown.exe) enables users to restart or shut down a local computer by either of two means: 1) the graphical user interface (GUI), invoked by typing **Shutdown /i** at the command prompt, or 2) the same **Shutdown** command used in combination with various *other* command-line parameters (for example, **Shutdown /s**, which causes the computer to shut down after a short interval).

**Remote restarts and shutdowns**
In this scenario, Remote Shutdown (Shutdown.exe) enables users to restart or shut down one or more remote computers by either of two means: 1) the graphical user interface (GUI), invoked by typing **Shutdown /i** at the command prompt, or 2) the same **Shutdown** command used in combination with various *other* command-line parameters (for example, **Shutdown -m** [*ComputerName*], which specifies the computer that the user wants to shut down).

### Note

- Although Remote Shutdown can be used to restart or shut down both local and remote computers, its primary purpose is to control the shutdown behavior of remote computers.

In addition, IT professionals can use this tool to perform remote bulk annotations of unexpected shutdowns, an alternative to the time-consuming task of logging on to each computer to record a reason for an unexpected shutdown. For example, a thousand computers in a datacenter all shut down at the same time because there is a catastrophic loss of power to the entire facility. In this circumstance, a user with administrative credentials can later record the same shutdown reason (power loss) in a single place (Remote Shutdown) for all one thousand computers, and is not required to log on to each computer to perform the same function over and over again.

To find more information about Shutdown Event Tracker command-line parameters, see Command Line References in Tools and Settings Collection.

**Shutdown Event Tracker Dependencies on or Interactions with Other Technologies**
Shutdown Event Tracker depends on, or interacts with, the following technologies:

- Windows Base Services
- Event log
- Registry
- Group Policy
- Custom Reason Editor
- System State Data feature
- System State Data Formatter (SSDFormat)
- Windows Error Reporting (WER)
- Poolmon

To find more information about this topic, see "How Shutdown Event Tracker Works" in "How Shutdown Event Tracker Works."

**Shutdown Event Tracker Logical Diagrams**
The following figures show the logical interactions between Shutdown Event Tracker components and between Shutdown Event Tracker and other Windows components.

**Shutdown Event Tracker Logical Diagram — Expected Shutdown**

**Shutdown Event Tracker Logical Diagram — Computer Startup After Expected or Unexpected Shutdown**

**Shutdown Event Tracker Logical Diagram — User Logon After Expected or Unexpected Shutdown**

To find more information about the terms used in these diagrams (for example, Savedump.exe and Event ID 6008), click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection. See also MSDN and type the appropriate key words in the "Search for" text box.

**How Shutdown Event Tracker Differs from Similar Technologies**

Other technologies, procedures, and actions in addition to Shutdown Event Tracker can be used to shut down Windows Server 2003. These include:

- Tssshutdn.exe
- Emergency Management Services (EMS)
- Windows Management Instrumentation (WMI)
- Computer Management MMC (Microsoft Management Console)
- Earlier versions of Shutdown.exe
- Pressing CTRL+ALT+DELETE, and then holding down the CTRL key while clicking Shutdown

**Note**

- This action may cause permanent data loss and should therefore be used with caution.

However, unlike Shutdown Event Tracker, none of these technologies enable the user to provide a reason for the shutdown.

**Related Information**

The following resources contain additional information that is relevant to this section.

- To find more information about Custom Reason Editor, click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection. After downloading Windows Resource Kit Tools, click **Start**, **All Programs**, **Windows Resource Kit Tools**, and then **Windows Resource Kit Tools Read Me**.

- To find more information about System State Formatter (SSDFormat), click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection.

- To find more information about Windows Error Reporting (WER), click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection.

- To find more information about Poolmon.exe, click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection.

- To find more information about InitiateSystemShutdown, InitiateSystemShutdownEx, and ExitWindowsEx (the shutdown APIs), see MSDN and type the appropriate key words in the "Search for" text box.

- To find more information about the terms used in the logical diagrams (for example, Savedump.exe and Event ID 6008), click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection.

- To find more information about Shutdown Event Tracker command-line parameters, see Command Line References in Tools and Settings Collection.

# How Shutdown Event Tracker Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Shutdown Event Tracker Works**

**In this section**

- Terms and Definitions
- Shutdown Event Tracker Architecture
- Shutdown Event Tracker Protocols
- Shutdown Event Tracker Interfaces
- Shutdown Event Tracker Processes and Interactions
- Network Ports Used by Shutdown Event Tracker
- Related Information

Shutdown Event Tracker is a feature of the Microsoft Windows Server 2003 operating systems that provides a way for IT professionals to consistently track why users restart or shut down their computers. Shutdown Event Tracker captures the reasons users give for restarts and shutdowns to help create a comprehensive picture of an organization's system environment. It does not document why users choose other options, such as **Log off** and **Hibernate**.

In a more active sense, Shutdown Event Tracker also provides IT professionals with a specific tool, Remote Shutdown (Shutdown.exe), for restarting or shutting down both local and remote computers, while at the same time supplying reasons for doing so. In addition, users can employ Remote Shutdown to hibernate a local computer and cancel delayed shutdowns.

Shutdown Event Tracker is enabled by default and is a routine part of the computer shutdown process.

The following sections provide an in-depth view of how Shutdown Event Tracker works in an optimal environment. An optimal environment for Shutdown Event Tracker is defined as follows:

- Windows Server 2003 is correctly installed and Shutdown Event Tracker is enabled.
- All other dependencies are in place, properly designed and deployed, and functioning normally.
- Server hardware is sized appropriately and there are no disk, CPU, memory, or network bottlenecks that affect the performance of the technology.

**Terms and Definitions**

The following terms are associated with Shutdown Event Tracker.

**Expected Restarts and Shutdowns**

Expected restarts and shutdowns can be either planned or unplanned. These shutdown types are explained as follows:

A *planned shutdown* is one in which both the user and the computer fully anticipate the shutdown. For example, as a matter of either policy or habit, a user might shut down his or her computer at the end of each day. When a user has control over the timing of a restart or shutdown, the task is planned.

An *unplanned shutdown* is one in which the user does not anticipate the shutdown, but has time to perform the shutdown in a normal manner. For example, if an application becomes unresponsive, the user might be forced to restart or shut down the computer. When a user does not have control over the exact timing of a restart or shutdown, the task is unplanned.

**Note**

- For the purpose of this topic, shutting down the system in a "normal manner" is defined as the user clicking **Start** and then **Shutdown**, or pressing CTRL+ALT+DELETE and then clicking **Shutdown**, or utilizing Remote Shutdown (Shutdown.exe), a tool specific to Shutdown Event Tracker. These methods call the InitiateSystemShutdownEx application programming interface (API), which in turn spawns a number of related events. To find more information about these events, see "Shutdown Event Tracker Architecture."

#### Unexpected Restarts and Shutdowns

Unexpected shutdowns are shutdowns that the computer does not anticipate, and that the user may or may not anticipate. For example, the computer abruptly loses power and immediately shuts down. In this instance, neither the computer nor the user could have anticipated the shutdown. However, in another example, the user shuts down the computer by holding down the power button. In this instance, the user did, in fact, anticipate the shutdown but the computer, as in the first example, did not. It is important to understand that in both instances shutdown did not occur in a normal manner and that therefore the two shutdowns must be classified as "unexpected."

#### Shut Down Windows (Expected Shutdown) Dialog Box

The **Shut Down Windows** (expected shutdown) dialog box appears when users restart or shut down the operating system in a normal manner. This dialog box differs from other Windows shutdown dialog boxes (for example, in earlier versions of Windows, or when Shutdown Event Tracker has been disabled) in that it prompts users to supply a reason and a comment to explain the action. In addition, since both planned and unplanned shutdowns are performed in a normal manner, the **Shut Down Windows** (expected shutdown) dialog box appears in either instance.

### Note

- Though titled as **Shut Down Windows**, this dialog box functions, in essence, as the expected shutdown dialog box.

#### Shutdown Event Tracker (Unexpected Shutdown) Dialog Box

When an unexpected shutdown occurs the user is not given the opportunity to perform the shutdown in a normal manner, and the **Shut Down Windows** (expected shutdown) dialog box does not appear at the time of shutdown. Instead, the **Shutdown Event Tracker** (unexpected shutdown) dialog box appears to the first person with the **Shutdown the system** user right or with administrative credentials who logs on to the computer after the restart or shutdown. Like the **Shut Down Windows** (expected shutdown) dialog box, it prompts this user to supply a reason and a comment for the shutdown.

### Notes

- Though titled as **Shutdown Event Tracker**, this dialog box functions, in essence, as the unexpected shutdown dialog box.

- It is important to realize that a person with administrative credentials automatically has **the Shutdown the system** user right, but that it is possible for another person to have only this one right and not have administrative credentials.

#### Shutdown Event Tracker Architecture

From an architectural standpoint, Shutdown Event Tracker is divided into three areas:

- The Shutdown Event Tracker interface (the expected shutdown dialog and the unexpected shutdown dialog)

- Other Windows technologies with which Shutdown Event Tracker interacts (Windows Base Services; Event Log; Registry; Group Policy; System State Data feature; Windows Error Reporting [WER]; Poolmon.exe or Memory Pool Monitor)

- Tools specific to Shutdown Event Tracker (Remote Shutdown [Shutdown.exe]; SSDFormat or System State Data Formatter; Custom Reason Editor)

The following figure shows the components within these three areas and how the areas and components interact.

### Shutdown Event Tracker Architectural Diagram

The following table lists the components in the first of the three areas described previously.

**Shutdown Event Tracker Components: Interface**

| Component | Description |
|---|---|
| Shut Down Windows (expected shutdown) dialog box | Appears at shutdown if shutdown occurs in a normal manner.<br><br>To find more information about the **Shut Down Windows** (expected shutdown) dialog box, see "Terms and Definitions" earlier in this section. |
| Shutdown Event Tracker (unexpected shutdown) dialog box | Appears at logon if DirtyShutdown key is present in the registry.<br><br>To find more information about the **Shutdown Event Tracker** (unexpected shutdown) dialog box, see "Terms and Definitions" earlier in this section. |

The following table lists the components in the second of the three areas described previously.

**Shutdown Event Tracker Components: Associated Windows Technologies**

| Technology | Description |
|---|---|

| | |
|---|---|
| Windows Base Services | The base services functions give applications access to the resources of the computer and the features of the underlying operating system, such as memory, file systems, devices, processes, and threads. An application uses these functions to manage and monitor the resources it needs to complete its work.<br><br>For Shutdown Event Tracker, Windows Base Services hosts components that log events to the event log; reads and interprets configuration information; and provides the public interface for initiating shutdowns. |
| Event log | The repository to which shutdown events are written by the expected shutdown dialog, the unexpected shutdown dialog, and Shutdown.exe. |
| Registry | Stores configuration data associated with Shutdown Event Tracker. Interacts with Custom Reason Editor, expected shutdown dialog (in providing custom reasons), unexpected shutdown dialog (in determining if a previous shutdown was unexpected), Shutdown.exe, and the System State Data feature. |
| Group Policy | Specifies configurations for groups of users and computers. These groups include software policies, scripts, user documents and configurations, application deployment, and security configurations.<br><br>To find more information about how Shutdown Event Tracker uses Group Policy, see "Shutdown Event Tracker Tools and Settings" in "Shutdown Event Tracker Tools and Settings." |
| System State Data feature | Gathers information for root-cause analysis of unplanned shutdowns. System state data is recorded in a log file when a user who has the **Shutdown the system** user right or administrative credentials specifies an unplanned reason for shutting down a computer. |
| Windows Error Reporting (WER) | WER is a set of technologies that captures product failure (also known as crash) data, enables end users to report failure information, and enables software and hardware vendors to analyze and respond to these problems.<br><br>WER is used by the System State Data feature to transmit shutdown data to Microsoft or other designated recipient.<br><br>To find more information about Windows Error Reporting, click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection. |
| Memory Pool Monitor (Poolmon.exe) | Displays data that the operating system collects about memory allocations from the system paged and nonpaged kernel pools. This information can be used to find kernel mode memory leaks.<br><br>Poolmon can also be used to confirm findings made by the System State Data feature that are suggestive of memory leaks.<br><br>To find more information about Poolmon.exe, see the Microsoft Knowledge Base. |

The following table lists the components in the third of the three areas described previously.

**Shutdown Event Tracker Components: Tools Specific to the Feature**

| Tool | Description |
|---|---|
| Remote Shutdown (Shutdown.exe) | Enables users to restart or shut down a local computer or one or more remote computers by either of two means: 1) the graphical user interface (GUI), invoked by typing **Shutdown /i** at the command prompt, or 2) the same **Shutdown** command used in combination with various other command-line parameters (for example, **Shutdown /s**, which causes the computer to shut down after a short interval).<br><br>Users can also employ Remote Shutdown to hibernate local computers and to cancel delayed shutdowns from the command prompt.<br><br>In addition, IT professionals can perform remote bulk annotations of unexpected shutdowns.<br><br>To find more information about Shutdown Event Tracker command-line parameters, see "Command Line References" in Tools and Settings Collection.<br><br>To find more information about bulk annotations, see, "Shutdown Event Tracker Processes and Interactions" later in this section. |

| | |
|---|---|
| System State Data Formatter (SSDFormat.exe) | A command-line tool that creates a formatted copy of a system state data log file. SSDFormat.exe opens a system state data log file, adds an XSL file header to format the data, fixes any characters from the original file that are not legitimate XML characters, and saves the changes to a new XML file. When the user opens the XML file created by SSDFormat in any XML-capable viewer, such as Microsoft Internet Explorer, the XSL style sheet formats the data into tabular form.<br><br>To find more information about SSDFormat, click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection. |
| Custom Reason Editor (CustomReasonEdit.exe) | A command-line and graphical user interface (GUI) tool that allows users to add, modify, and delete custom shutdown reasons for Shutdown Event Tracker.<br><br>To find more information about Custom Reason Editor, click "Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection." After downloading Windows Resource Kit Tools, click **Start**, **All Programs**, **Windows Resource Kit Tools**, and then **Windows Resource Kit Tools Read Me**. |

**Shutdown Event Tracker Protocols**

Shutdown Event Tracker uses the following protocols:

- RPC (remote procedure call), when communicating with a remote server
- HTTPS (Hypertext Transfer Protocol over Secure Sockets Layer), which is used by Windows Error Reporting (WER)

Both RPC and HTTPS reside at the application layer of the OSI (Open Systems Interconnection) model.

**Shutdown Event Tracker Interfaces**

The following APIs are associated with Shutdown Event Tracker.

### Shutdown Event Tracker APIs

| API Name | Description |
|---|---|
| InitiateSystemShutdown | Initiates a shutdown and optional restart of the specified computer. Does not support Shutdown Event Tracker and the use of shutdown reason options. Should not be used by a developer who wishes to utilize Shutdown Event Tracker functionality. |
| InitiateSystemShutdownEx | Initiates a shutdown and optional restart of the specified computer.<br><br>Supports Shutdown Event Tracker and the use of shutdown reason options. Should be used by a developer who wishes to utilize Shutdown Event Tracker functionality. |
| ExitWindowsEx | Either logs off the current user and shuts down the system, or shuts down and restarts the system. It sends the WM_QUERYENDSESSION message to all applications to determine if they can be terminated.<br><br>In the unlikely event that ExitWindowsEx fails to shut down the system, or the shutdown is cancelled by the user, it writes an event to the event log. |

To find more information about Shutdown Event Tracker interfaces, see MSDN and type the appropriate key words in the "Search for" text box.

**Shutdown Event Tracker Processes and Interactions**

The following is a general description of how Shutdown Event Tracker functions at a basic level.

As stated earlier, Shutdown Event Tracker provides a simple and standard mechanism for IT professionals to consistently document the reasons for shutting down or restarting computers. The information captured can then be used to analyze the root causes of shutdowns and to develop a more complete understanding of the system environment.

To record a restart or shutdown reason, users enter the reason into either the **Shut Down Windows** (expected shutdown) dialog box or the **Shutdown Event Tracker** (unexpected shutdown) dialog box. The **Shut Down Windows** dialog box is displayed when shutdown occurs in a normal manner (an expected shutdown); the **Shutdown Event Tracker** dialog box appears when shutdown does not occur in a normal manner (an unexpected shutdown). In each instance, Windows provides

users with a list of predefined shutdown reasons from which to choose. Users can also employ reason options that they have created using the Custom Reason Editor. The information that users provide is recorded in the system log in Event Viewer.

For these processes and interactions to work as described, Shutdown Event Tracker should reside in an optimal environment. An optimal environment for Shutdown Event Tracker is defined as follows:

- Windows Server 2003 is correctly installed and Shutdown Event Tracker is enabled.
- All other dependencies are in place, properly designed and deployed, and functioning normally.
- Server hardware is sized appropriately and there are no disk, CPU, memory, or network bottlenecks that affect the performance of the technology.

**Shutdown Event Tracker Technologies**

The following is a more detailed description of specific technologies that either form a part of, or are closely identified with, Shutdown Event Tracker.

**Remote Shutdown**

Remote Shutdown (Shutdown.exe) enables users to restart or shut down a local computer or one or more remote computers by either of two means: 1) the graphical user interface (GUI), invoked by typing **Shutdown /i** at the command prompt, or 2) the same **Shutdown** command used in combination with various other command-line parameters (for example, **Shutdown -m** [*ComputerName*], which specifies the computer that the user wants to shut down).

### Note

- Although Remote Shutdown can be used to restart or shut down both local and remote computers, its primary purpose is to control the shutdown behavior of remote computers.

IT professionals can also use this tool to perform remote bulk annotations of unexpected shutdowns, an alternative to the time-consuming task of logging on to each computer to record a reason for an unexpected shutdown. For example, a thousand computers in a datacenter all shut down at the same time because there is a catastrophic loss of power to the entire facility. In this circumstance, a user with administrative credentials can later record the same shutdown reason (power loss) in a single place (Remote Shutdown) for all one thousand computers, and is not required to log on to each computer to perform the same function over and over again.

In addition, users can employ Remote Shutdown to hibernate local computers and to cancel delayed shutdowns from the command prompt.

To find more information about Shutdown Event Tracker command-line parameters, see "Command Line References" in Tools and Settings Collection.

**System State Data feature**

The System State Data feature gathers information for root-cause analysis of expected but unplanned shutdowns, and of unexpected shutdowns.

System state data is written to a log file when a user who has the **Shutdown the system** user right or administrative credentials specifies an "unplanned" reason for shutting down the computer in the case of an expected, but unplanned, shutdown. This file is stored in the *%windir%\system32\LogFiles\Shutdown* directory. The first user with administrative credentials who logs on to the computer after the shutdown will see a dialog box notification that reads, "The system has restarted after an unplanned shutdown. A log of this event has been created." From this dialog box, the administrator can navigate to a more detailed description of the system state data file, its contents, and the Microsoft privacy policy for data collection on the Web. The administrator can choose whether to send the system state data file to Microsoft by clicking either the **Send Error Report** or **Don't Send** button.

**System State Data Formatter**

System State Data Formatter (SSDFormat.exe) is a command-line tool that creates a formatted copy of a system state data log file. SSDFormat.exe opens a system state data log file, adds an XSL file header to format the data, fixes any characters from the original file that are not legitimate XML characters, and saves the changes to a new XML file. When the user opens the XML file created by System State Data Formatter in any XML-capable viewer, such as Internet Explorer, the XSL style sheet formats the data into tabular form.

To find more information about System State Data Formatter, click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection.

**Custom Reason Editor**
Custom Reason Editor (CustReasonEdit.exe) is a command-line and GUI tool that enables users to add, modify, and delete custom shutdown reasons. Users can employ command-line functionality to perform basic importing and exporting of custom reasons to a registry file, or they can use the GUI to perform all other types of custom reason editing. CustReasonEdit includes a set of sample reasons as a guide to new users.

To find more information about Custom Reason Editor, click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection. After downloading Windows Resource Kit Tools, click **Start**, **All Programs**, **Windows Resource Kit Tools**, and then **Windows Resource Kit Tools Read Me**.

**Other Processes and Interactions**
The following is a brief description of other processes and interactions associated with Shutdown Event Tracker.

**Enabling or Disabling Shutdown Event Tracker**
The user can employ either Group Policy or the registry to enable or disable Shutdown Event Tracker on the user's system.

When Shutdown Event Tracker is enabled, the **Shut Down Windows** (expected shutdown) dialog box appears when the user clicks **Start** and then clicks **Shutdown**, or when the user presses CTRL+ALT+DELETE and then clicks **Shutdown**. If an unexpected restart or shutdown occurs, the **Shutdown Event Tracker** (unexpected shutdown) dialog box will appear to the first person with the **Shutdown the system** user right or with administrative credentials who logs on to the computer.

When Shutdown Event Tracker is disabled, the standard Windows shutdown dialog box appears. It provides a way to restart or shut down the users computer, although it does not provide a way to record whether or not the event is planned or unplanned, or a way to record a reason for it. If an unexpected restart or shutdown occurs under these circumstances, the **Shutdown Event Tracker** (unexpected shutdown) dialog box will *not* appear to the first person with the **Shutdown the system user** right who logs on to the computer.

To find more information about enabling or disabling "Shutdown Event Tracker, see "Shutdown Event Tracker Tools and Settings" in "Shutdown Event Tracker Tools and Settings." See also "Shutdown Event Tracker Tools and Settings" in "Shutdown Event Tracker Tools and Settings."

**Using Shutdown Event Tracker with Non-English Versions of Windows Server 2003**
Users can configure Shutdown Event Tracker to display standard and custom shutdown reasons in languages other than English by modifying the registry.

For example, to display the *standard* shutdown reasons in Romanian, the system version must be Romanian, and the user locale must be set to Romanian as well.

To display *custom* shutdown reasons in Romanian (or another language), users must employ the Custom Reason Editor, which writes custom shutdown reasons to the registry.

To find more information about Custom Reason Editor, click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection. After downloading Windows Resource Kit Tools, click **Start**, **All Programs**, **Windows Resource Kit Tools**, and then **Windows Resource Kit Tools Read Me**.

**Network Ports Used by Shutdown Event Tracker**
The following table lists the port assignments for transmitting data collected by Shutdown Event Tracker.

**Port Assignments for Shutdown Event Tracker**

| Service Name | User Datagram Protocol (UDP) | Transmission Control Protocol (TCP) |
|---|---|---|
| Windows Error Reporting (WER) | Not applicable | 443 |
| Remote Procedure Call (RPC) | Not applicable | 445 and 139 |

Windows Error Reporting (WER) is a set of technologies built into Windows Server 2003 that captures product failure (also know as crash) data, enables end users to report failure information, and enables software and hardware vendors to analyze and respond to these problems.

When the **Report unplanned shutdown events** policy setting is enabled, error reporting will include unplanned shutdown events. When this policy setting is disabled, unplanned shutdown events will not be included in error reporting.

If this policy setting is not configured, the user is able to control unplanned shutdown reporting using Control Panel, which is set to **upload unplanned shutdown events** by default.

The System State Data feature uses Windows Error Reporting to transmit shutdown data to Microsoft or other designated

recipient.

**Note**

- Data will not be submitted to the designated recipient unless users click **Send Report** when presented with the **Windows Error Reporting** dialog box.

**Related Information**

The following resources contain additional information that is relevant to this section.

- To find more information about Custom Reason Editor, click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection. After downloading Windows Resource Kit Tools, click **Start**, **All Programs**, **Windows Resource Kit Tools**, and then **Windows Resource Kit Tools Read Me**.

- To find more information about System State Formatter (SSDFormat), click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection.

- To find more information about Windows Error Reporting (WER), click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection.

- To find more information about Poolmon.exe, click "Windows Server 2003 Resource Kit Tools Help" in Tools and Settings Collection.

- To find more information about InitiateSystemShutdown, InitiateSystemShutdownEx, and ExitWindowsEx (the shutdown APIs), see MSDN and type the appropriate key words in the "Search for" text box.

- To find more information about Shutdown Event Tracker command-line parameters, see "Command Line References" in Tools and Settings Collection.

- To find more information about Shutdown Event Tracker Group Policy settings, click "Group Policy Settings Reference for Windows Server 2003" in Tools and Settings Collection.

# Shutdown Event Tracker Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Shutdown Event Tracker Tools and Settings**

### In this section

- Shutdown Event Tracker Tools
- Shutdown Event Tracker Registry Entries
- Shutdown Event Tracker Group Policy Settings
- Network Ports Used by Shutdown Event Tracker

Shutdown Event Tracker is a feature of the Microsoft Windows Server 2003 operating systems that provides a way for IT professionals to consistently track why users restart or shut down their computers. Shutdown Event Tracker captures the reasons users give for restarts and shutdowns to help create a comprehensive picture of an organization's system environment. It does not document why users choose other options, such as **Log off** and **Hibernate**.

In a more active sense, Shutdown Event Tracker also provides IT professionals with a specific tool, Remote Shutdown (Shutdown.exe), for restarting or shutting down both local and remote computers, while at the same time supplying reasons for doing so. In addition, users can employ Remote Shutdown to hibernate a local computer and cancel delayed shutdowns.

Shutdown Event Tracker is enabled by default and is a routine part of the computer shutdown process.

**Shutdown Event Tracker Tools**

The following tools are associated with Shutdown Event Tracker.

**Shutdown.exe: Remote Shutdown**

**Category**

Remote Shutdown (Shutdown.exe) is part of Windows Server 2003.

**Version compatibility**

Remote Shutdown can also be used to control restarts or shutdowns on computers running Windows NT 4.0 and Windows 2000.

Remote Shutdown (Shutdown.exe) enables users to restart or shut down a local computer or one or more remote computers by either of two means: 1) the graphical user interface (GUI), invoked by typing **Shutdown /i** at the command prompt, or 2) the same **Shutdown** command used in combination with various *other* command-line parameters (for example, **Shutdown /s**, which causes the computer to shut down after a short interval).

IT professionals can also use this tool to perform remote bulk annotations of unexpected shutdowns, an alternative to the time-consuming task of logging on to each computer to record a reason for an unexpected shutdown.

In addition, users can employ Remote Shutdown to hibernate local computers and to cancel delayed shutdowns from the command prompt.

### Note

- Although Remote Shutdown can be used to restart or shut down both local and remote computers, its primary purpose is to control the shutdown behavior of remote computers.

To find more information about Shutdown Event Tracker command-line parameters, see Command Line References in Tools and Settings Collection.

To find more information about bulk annotations, see "Shutdown Event Tracker Processes and Interactions" in "How Shutdown Event Tracker Works."

**System State Data: System State Data feature**

**Category**

The System State Data feature is part of Windows Server 2003.

**Version compatibility**
The System State Data feature runs on and targets all Windows Server 2003 operating systems.

System State Data gathers information for root-cause analysis of expected but unplanned shutdowns, and of unexpected shutdowns.

System state data is written to a log file when a user who has the **Shutdown the system** user right or administrative credentials specifies an "unplanned" reason for shutting down the computer. This file is stored in the *%windir%\system32\LogFiles\Shutdown* directory. The first user with administrative credentials who logs on to the computer after the shutdown will see a dialog box notification that reads: "The system has restarted after an unplanned shutdown. A log of this event has been created." From this dialog box, the administrator can navigate to a more detailed description of the system state data file, its contents, and the Microsoft privacy policy for data collection on the Web. The administrator can choose whether to send the system state data file to Microsoft by clicking either the **Send Error Report** or **Don't Send** button.

**Windows Error Reporting: WER**
**Category**
Windows Error Reporting is part of Windows Server 2003.

**Version compatibility**
Windows Error Reporting runs on and targets all Windows Server 2003 operating systems.

WER is a set of technologies that captures product failure (also known as crash) data, allows end users to report failure information, and allows software and hardware vendors to analyze and respond to these problems.

When the **Report unplanned shutdown events** policy setting is enabled, error reporting will include unplanned shutdown events. When this policy setting is disabled, unplanned shutdown events will not be included in error reporting.

If this setting is not configured, the user is able to control unplanned shutdown reporting using Control Panel, which is set to **upload unplanned shutdown events** by default.

The System State Data feature uses Windows Error Reporting to transmit shutdown data to Microsoft or to another designated recipient.

### Note

- Data will not be submitted to the designated recipient unless users click **Send Error Report** when presented with the **Windows Error Reporting** dialog box.

To find more information about Windows Error Reporting, click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection.

**SSDFormat.exe: System State Data Formatter**
**Category**
System State Data Formatter (SSDFormat.exe) is available in Resource Kit Tools in Tools and Settings Collection.

**Version compatibility**
System State Data Formatter runs on all Windows Server 2003 operating systems.

SSDFormat.exe is a command-line tool that creates a formatted copy of a system state data log file. SSDFormat.exe opens a system state data log file, adds an XSL file header to format the data, fixes any characters from the original file that are not legitimate XML characters, and saves the changes to a new XML file. When the user opens the XML file created by SSDFormat in any XML-capable viewer, such as Microsoft Internet Explorer, the XSL style sheet formats the data into tabular form.

To find more information about System State Data Formatter, click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection.

**CustReasonEdit.exe: Custom Reason Editor**
**Category**
Custom Reason Editor (CustomReasonEdit.exe) is available in Resource Kit Tools in Tools and Settings Collection. After downloading Windows Resource Kit Tools, click **Start**, **All Programs**, **Windows Resource Kit Tools**, and then **Windows Resource Kit Tools Read Me** to locate the tool.

**Version compatibility**
Custom Reason Editor runs on all Windows Server 2003 operating systems.

CustomReasonEdit.exe enables users to add, modify, and delete custom shutdown reasons for Shutdown Event Tracker.

Custom Reason Editor requires that the user have administrative credentials on the target system to function correctly. The tool has two interfaces: the command-line interface allows for basic importing and exporting functionality, and the graphical user interface allows for complete custom reason editing. Finally, a set of sample reasons is included in the package.

To find more information about Custom Reason Editor, click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection. After downloading Windows Resource Kit Tools, click **Start**, **All Programs**, **Windows Resource Kit Tools**, and then **Windows Resource Kit Tools Read Me**.

**Poolmon.exe: Memory Pool Monitor**
**Category**
Memory Pool Monitor (Poolmon.exe) is available in the Windows NT 4.0 Resource Kit and in the \Support\Tools folder of Windows 2000, and on the Windows XP and Windows Server 2003 CD-ROMs.

**Version compatibility**
Memory Pool Monitor runs on Windows NT 4.0, Windows 2000, Windows XP, and Windows Server 2003.

Poolmon.exe displays data that the operating system collects about memory allocations from the system paged and nonpaged kernel pools, and the memory pools used for Terminal Services sessions. The data is grouped by pool allocation tag. This information can be used by Microsoft Product Support Services to find kernel-mode memory leaks.

A memory leak is caused by an application or a process that allocates memory for use but does not free it up when finished. The result is that available memory is completely used over time, often causing the system to stop functioning properly.

Poolmon.exe is used to verify, or to further substantiate, memory usage information captured by the System State Data feature. In this sense, Memory Pool Monitor should be viewed as a non-interactive supplement to System State Data.

To find more information about Poolmon.exe, see MSDN and type the appropriate key words in the "Search for" text box.

**Shutdown Event Tracker Registry Entries**
Shutdown Event Tracker interacts with the registry in the following ways:

- The expected shutdown dialog reads custom shutdown reasons from the registry.
- Remote Shutdown (Shutdown.exe) reads custom shutdown reasons from the registry. It also writes bulk annotations to the registry and deletes keys from the registry.
- Custom Reason Editor (CustReasonEdit.exe) writes custom shutdown reasons to the registry.
- The unexpected shutdown dialog reads from the registry to determine if the previous shutdown was unexpected.
- The Event Log service writes the Shutdown Event Tracker heartbeat to the registry and then deletes it just before a normal shutdown occurs. On restart it verifies whether the heartbeat is present and, if so, writes the DirtyShutdown key to the registry.

### Note

- Used in this context, heartbeat is a defined as a time stamp interval, written once a minute, that tells the registry, and therefore the system, that Shutdown Event Tracker is still enabled.
- The System State Data feature reads system configuration information from the registry.

To find more information about these interactions, see How Shutdown Event Tracker Works.

The information here provided is a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following registry entries are associated with Shutdown Event Tracker.

**BugcheckString**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Reliability\

**Version**
Windows Server 2003.

This key contains the bug check string information that is used to fill in the unexpected shutdown dialog box comment field (which appears at logon after an unexpected shutdown) if the previous shutdown was caused by a system failure (also know as a system crash).

**DirtyShutdown**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Reliability\

**Version**
Windows Server 2003.

This key is set during event log startup. It indicates whether a previous shutdown was expected.

**LastAliveStamp**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Reliability\

**Version**
Windows Server 2003.

This key is cleared during shutdown. It indicates the date and time of the previous unexpected shutdown if it is present during startup.

**ReliabilityGUID**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Reliability\

**Version**
Windows Server 2003.

This key enables a GUID (globally unique identifier) to be written to the system state data file in order to uniquely identify the computer this file came from. It is not possible to physically identify the computer itself using this GUID, but it is possible to see how many different computers sent files and how many distinct reports were submitted by each computer. If the GUID is deleted from the registry, a new GUID is generated when a new system state data (.xml) file is created in the *%windir%\system32\LogFiles\Shutdown* directory at the time of an unplanned shutdown.

**ShutdownIgnorePredefinedReasons**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Reliability\

**Version**
Windows Server 2003.

This key prevents the predefined or built-in shutdown reasons from being displayed. If at least one custom reason is defined in the registry and this key is set to "1," the built-in reasons are not displayed.

**TimeStampInterval**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Reliability\

**Version**
Windows Server 2003 and Windows 2000.

This key defines how often LastAliveStamp (or heartbeat) is written to the registry. By default it is written every minute in Windows Server 2003 and every five minutes in Windows 2000.

**UserDefined**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Reliability\

**Version**
Windows Server 2003.

This key contains custom reasons stored as values. To add custom reasons, the user must define one key value for each reason. Each reason has a major and minor code that uniquely identifies the reason.

To find more information about Custom Reason Editor, click Windows Server 2003 Resource Kit Tools Help in Tools and Settings Collection. After downloading Windows Resource Kit Tools, click **Start**, **All Programs**, **Windows Resource Kit Tools**, and then **Windows Resource Kit Tools Read Me**.

**HKEY_LOCAL_MACHINE\SOFTWARE**
The following registry entries are located under HKEY_LOCAL_MACHINE\SOFTWARE\.

**ShutdownReasonUI**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\Windows NT\Reliability\

**Version**
Windows Server 2003.

This key is present if the **Display Shutdown Event Tracker** policy setting has been enabled.

**ShutdownReasonUI**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Reliability\

**Version**
Windows Server 2003.

Shutdown Event Tracker references the Group Policy key first (see the previous entry). If the Group Policy key is not present, then this key can be configured as “0” (off), or “1” (on). If the Group Policy key is not present and this key is invalid or missing, then Shutdown Event Tracker is off.

**Shutdown Event Tracker Group Policy Settings**
The following tables list and describe the Group Policy settings that are associated with Shutdown Event Tracker.

### Group Policy Settings Associated with Display Shutdown Event Tracker

| Group Policy Setting | Description |
|---|---|
| Not Configured | No choices are given. Specifies that no change is made to the registry for this setting. |
| Enabled | Shutdown Event Tracker is displayed. Specifies that the registry indicate that the policy setting applies to users or computers that are subject to this Group Policy object. |
| Disabled | Shutdown Event Tracker should not be displayed. Specifies that the registry indicate that the policy setting does not apply to users or computers that are subject to this Group Policy object. |

**Note**

- The path to Display Shutdown Event Tracker is Local Computer Policy \Computer Configuration\ Administrative Templates\System.

### Group Policy Settings Associated with Activate Shutdown Event Tracker System State Data Feature

| Group Policy Setting | Description |
|---|---|
| Not Configured | Specifies that no change is made to the registry for this policy setting. |
| Enabled | Specifies that the registry indicate that the policy setting applies to users or computers that are subject to this Group Policy object. |
| Disabled | Specifies that the registry indicate that the policy setting does not apply to users or computers that are subject to this Group Policy object. |

**Note**

- The path to Activate Shutdown Event Tracker System State Data feature is Local Computer Policy\Computer Configuration\Administrative Templates\System.

**Group Policy Settings Associated with Enable Persistent Time Stamp**

| Group Policy Setting | Description |
|---|---|
| Not Configured | Specifies that no change is made to the registry for this policy setting. |
| Enabled | Specifies that the registry indicate that the policy setting applies to users or computers that are subject to this Group Policy object.<br><br>The policy setting enables the user to customize how often the Persistent System Time Stamp is written to disk. The range is from 1 through 86400 seconds (1 day). |
| Disabled | Specifies that the registry indicate that the policy setting does not apply to users or computers that are subject to this Group Policy object. |

**Note**

- The path to Enable Persistent Time Stamp is Local Computer Policy\Computer Configuration\Administrative Templates\System.

**Group Policy Settings Associated with Report Unplanned Shutdown Events**

| Group Policy Setting | Description |
|---|---|
| Not Configured | Specifies that no change is made to the registry for this policy setting. |
| Enabled | Specifies that the registry indicate that the policy setting applies to users or computers that are subject to this Group Policy object.<br><br>When this policy setting is enabled, error reporting will include unplanned shutdown events. |
| Disabled | Specifies that the registry indicate that the policy setting does not apply to users or computers that are subject to this Group Policy object.<br><br>When this policy setting is disabled, unplanned shutdown events will not be included in error reporting. |

**Note**

- The path to Report unplanned shutdown events is Local Computer Policy \Computer Configuration\Administrative Templates\System\Error Reporting\Advanced Error Reporting settings.

To find more information about these Group Policy settings, click Group Policy Settings Reference for Windows Server 2003 in Tools and Settings Collection.

**Network Ports Used by Shutdown Event Tracker**

The following table lists the port assignments for transmitting data collected by Shutdown Event Tracker.

**Port Assignments for Shutdown Event Tracker**

| Service Name | User Datagram Protocol (UDP) | Transmission Control Protocol (TCP) |
|---|---|---|
| Windows Error Reporting (WER) | Not applicable | 443 |
| Remote Procedure Call (RPC) | Not applicable | 445 and 139 |

Windows Error Reporting (WER) is a set of technologies built into Windows Server 2003 that captures failure (also known as crash) data, enables end users to report failure information, and enables software and hardware vendors to analyze and respond to these problems.

When the **Report unplanned shutdown events** policy setting is enabled, error reporting will include unplanned shutdown events. When this policy setting is disabled, unplanned shutdown events will not be included in error reporting.

If this policy setting is not configured, the user is able to control unplanned shutdown reporting using Control Panel, which is set to **upload unplanned shutdown events** by default.

The System State Data feature uses Windows Error Reporting to transmit shutdown data to Microsoft or other designated recipient.

### Note

- Data will not be submitted to the designated recipient unless users click **Send Report** when presented with the **Windows Error Reporting** dialog box.

# Backup Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Backup Technical Reference**
The Backup utility in the Microsoft Windows Server 2003 operating systems helps you protect your data if your hard disk fails or if files are accidentally erased due to hardware or storage media failure. By using Backup, you can create a duplicate copy of the data on your hard disk and then archive it on another storage device, such as a hard disk or a tape.

If the original data on your hard disk is accidentally erased or overwritten, or becomes inaccessible because of a hard-disk malfunction, you can easily restore it from the disk or archived copy.

# What Is Backup?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Backup?**
The Backup utility in the Microsoft Windows Server 2003 operating systems helps you protect your data if your hard disk fails or files are accidentally erased due to hardware or storage media failure. By using Backup, you can create a duplicate copy of the data on your hard disk and then archive it on another storage device, such as a hard disk or a tape.

If the original data on your hard disk is accidentally erased or overwritten, or becomes inaccessible because of a hard-disk malfunction, you can easily restore it from the disk or archived copy.

Backup uses the Volume Shadow Copy service to create an accurate copy of the contents of your hard drive, including any open files or files that are being used by the system. Users can continue to access the system while Backup is running, without risking loss of data. For more information about the Volume Shadow Copy service, see "Volume Shadow Copy Service Technical Reference."

Using Backup, you can:

- Archive selected files and folders on your hard disk.
- Restore the archived files and folders to your hard disk or any other disk you can access.
- Make a copy of your computer's System State data.
- Use Automated System Recovery (ASR) to create a backup set that contains the System State data, system services, and all disks associated with the operating system components. ASR also creates a floppy boot disk that contains information about the backup, the disk configurations (including basic and dynamic volumes), and how to restore your system.
- Make a copy of any Remote Storage data and any data stored in mounted drives.
- Create a log of what files were backed up and when the backup was performed.
- Make a copy of your computer's system partition, boot partition, and the files needed to start up your system in case of a computer or network failure.
- Schedule regular backups to keep your archived data up-to-date.

Backup also performs simple media management functions such as formatting. You can perform more advanced management tasks such as mounting and dismounting a tape or disk by using Removable Storage, which is a feature in Windows Server 2003.

# How Backup Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Backup Works**

**In this section**

- Types of Backup
- Volume Shadow Copy Service
- Files Skipped During Backup
- System State Data
- Permissions and User Rights Required to Back Up
- Automated System Recovery
- Restoring File Security Settings
- Restoring Distributed Services
- Related Information

The Backup utility in Windows Server 2003, which uses the Volume Shadow Copy service, helps you protect your data if your hard disk fails or files are accidentally erased due to hardware or storage media failure. By using Backup, you can create a duplicate copy of the data on your hard disk and then archive it on another storage device, such as a hard disk or a tape.

If the original data on your hard disk is accidentally erased or overwritten, or becomes inaccessible because of a hard-disk malfunction, you can easily restore it from the disk or archived copy.

**Types of Backup**

The Backup utility supports five methods of backing up data on your computer: a copy backup, daily backup, differential backup, incremental backup, and normal backup.

**Types of Backup**

| Type | Description |
|---|---|
| Copy backup | Copies all the files that you select, but does not mark each file as having been backed up (in other words, the archive attribute is not cleared). Copying is useful if you want to back up files between normal and incremental backups because copying does not affect these other backup operations. |
| Daily backup | Copies all the files that you select that have been modified on the day that the daily backup is performed. The backed-up files are not marked as having been backed up (in other words, the archive attribute is not cleared). |
| Differential backup | Copies files that have been created or changed since the last normal or incremental backup. It does not mark files as having been backed up (in other words, the archive attribute is not cleared). If you are performing a combination of normal and differential backups, you must have the last normal as well as the last differential backup to restore files and folders. |
| Incremental backup | Backs up only those files that have been created or changed since the last normal or incremental backup. It marks files as having been backed up (in other words, the archive attribute is cleared). If you use a combination of normal and incremental backups, you will need to have the last normal backup set as well as all incremental backup sets to restore your data. |

| | |
|---|---|
| Normal backup | Copies all the files that you select and marks each file as having been backed up (in other words, the archive attribute is cleared). With normal backups, you only need the most recent copy of the backup file or tape to restore all of the files. You usually perform a normal backup the first time you create a backup set. |

If you want the quickest backup method that requires the least amount of storage space, you should back up your data using a combination of normal backups and incremental backups. However, recovering files from this combination of backups can be time-consuming and difficult because the backup set might be stored on several disks or tapes.

If you want to restore your data more easily, you should back up your data using a combination of normal backups and differential backups. This backup set is usually stored on only a few disks or tapes. However, this combination of backups is more time-consuming.

**Volume Shadow Copy Service**

Backup uses the Volume Shadow Copy service to create a volume shadow copy, which is an accurate copy of the contents of your hard drive, including any open files, files that are being used by the system, and databases that are held open exclusively.

Backup uses the Volume Shadow Copy service to ensure that:

- Applications can continue to write data to the volume during a backup.
- Files that are open are no longer omitted during a backup.
- Backups can be performed at any time, without locking out users.

If you choose to disable the volume shadow copy using advanced options or if the service fails, Backup will revert to creating a backup without the Volume Shadow Copy service technology. If this occurs, Backup skips files that are open or in use by other applications at the time of the backup.

**Note**

- Some applications manage storage consistency differently while files are open, which can affect the consistency of the files in a backup. For critical applications, consult the application documentation or your provider for information about the recommended backup method. When in doubt, close the application before performing a backup.

For more information, see "Volume Shadow Copy Service Technical Reference."

**Files Skipped During Backup**

Backup skips certain files by default, including files in the following categories:

- **Files that the person performing the backup does not have permission to read.** Only users with backup rights can copy files that they do not own. Members of the Backup Operators and Administrators groups have these permissions by default.
- **Temporary files.** For example, Pagefile.sys, Hiberfil.sys, Win386.swp, 386spart.par, Backup.log, and Restore.log. These files are not backed up or restored by Backup. The list of skipped temporary files is embedded into Backup and cannot be changed.
- **Registry files on remote computers.** Windows Server 2003 backs up only local registry files.

**System State Data**

With Backup, you can back up the System State data for your computer. System State data includes the registry, the COM+ Class Registration database, files under Windows File Protection, and system boot files. Depending on the configuration of the server, other data might be included in the System State data. For example, if the server is a certificate server, the System State data also contains the Certificate Services database. If the server is a domain controller, the Active Directory directory service database and the SYSVOL directory are included in the System State data.

With Backup, the following system components might be included in a backup of the System State:

| Component | When this component is included in System State? |
|---|---|

| | |
|---|---|
| Registry | Always |
| COM+ Class Registration database | Always |
| Boot files, including the system files | Always |
| Certificate Services database | If it is a Certificate Services server |
| Active Directory database | If it is a domain |
| SYSVOL directory | Only if it is a domain controller |
| Cluster service information | If it is within a cluster |
| IIS Metadirectory | If it is installed |
| System files that are under Windows File Protection | Always |

When you choose to back up or restore the System State data, all of the System State data that is relevant to your computer is backed up or restored. You cannot choose to back up or restore individual components of the System State data because of dependencies among the System State components. However, you can restore the System State data to an alternate location. If you do this, only the registry files, SYSVOL directory files, cluster database information files, and system boot files are restored to the alternate location. The Active Directory database, Certificate Services database, and COM+ Class Registration database are not restored if you designate an alternate location when you restore the System State data.

**Files Under Windows File Protection**

Backup works together with the catalog file for the Windows File Protection service when backing up and restoring boot and system files. System files are backed up and restored as a single entity. The Windows File Protection service catalog file, located in the folder *systemroot*\system32\catroot\{F750E6C3-38EE-11D1-85E5-00C04FC295EE}, is backed up with the system files.

In Windows NT 4.0 and earlier, backup programs could selectively back up and restore operating system files. However, Windows 2000 Server and Windows Server 2003 do not allow incremental restores of operating system files.

There is an Advanced Backup option that automatically backs up protected system files with the System State data. All of the system files that are in the *systemroot*\ directory and the startup files that are included with the System State data are backed up when you use this option.

**Permissions and User Rights Required to Back Up**

You must have certain permissions and user rights to back up files and folders using Backup. If you are an administrator or a backup operator in a local group, you can back up any file and folder on the local computer to which the local group applies. Similarly, if you are an administrator or backup operator on a domain controller, you can back up any file and folder locally on any computer in the domain or any computer on a domain with which you have a two-way trust relationship. However, if you are not an administrator or a backup operator and you want to back up files, then you must be the owner of the files and folders that you want to back up, or you must have one or more of the following permissions for the files and folders you want to back up: Read, Read and Execute, Modify, and Full Control.

You must also be certain that there are no disk-quota restrictions that might restrict your access to a hard disk. These restrictions make it impossible for you to back up data. You can check whether you have any disk-quota restrictions by right-clicking the disk you want to save data to, clicking **Properties**, and then clicking the **Quota** tab.

You can also restrict access to a backup file by selecting **Allow only the owner and the Administrator access to the backup data** in the **Backup Job Information** dialog box. If you select this option, only an administrator or the person who created the backup file will be able to restore the files and folders.

**Automated System Recovery**

Automated System Recovery (ASR) is a part of Backup that you can use to recover a system that will not start. With ASR, you can create ASR sets on a regular basis as part of an overall plan for system recovery in case of system failure. You should use ASR as a last resort in system recovery, only after you have exhausted other options such as the startup options Safe Mode and Last Known Good Configuration.

ASR is a recovery option that has two parts: ASR backup and ASR restore. You can access the backup portion through the **Automated System Recovery Preparation Wizard** located in Backup. The **Automated System Recovery Preparation Wizard** creates an ASR set, which is a backup of the System State data, system services, and all disks associated with the operating system components. It also creates a floppy disk, which contains information about the backup, the disk

configurations (including basic and dynamic volumes), and how to restore your system.

You can access the restore part of ASR by pressing **F2** when prompted in the text mode portion of Setup. ASR reads the disk configurations from the floppy disk and restores all of the disk signatures, volumes and partitions on the disks that are required to start your computer (at a minimum). It will attempt to restore all of the disk configurations, but under some circumstances it might not be able to. ASR then installs a simple installation of Windows and automatically starts to restore from backup using the backup ASR set.

**Note**

- ASR does not include data files. You should back up data files separately on a regular basis and restore them after the system is working.
- ASR only supports FAT16 volumes up to 2.1 gigabytes (GB). ASR does not support 4-GB FAT16 partitions that use a cluster size of 64 K. If your system contains 4-GB FAT16 partitions, convert them from FAT16 to NTFS before using ASR.

**Restoring File Security Settings**

Backup preserves permissions, ownership, and audit flags on files restored to NTFS volumes, but not on files restored to FAT volumes. It is not possible to secure data on FAT volumes.

When you restore files to a new computer or hard disk, you do not have to restore security information. The files inherit the permissions of the directory in which they are placed. If the directory has no permissions, the file retains its previous permissions, including ownership.

**Restoring Distributed Services**

In Backup, you can restore distributed services data that is part of the System State data, such as the Active Directory database, using one of three restore methods:

- Primary restore
- Normal (nonauthoritative) restore
- Authoritative restore

To understand how each restore method works, it is important to understand how the Backup utility backs up data for distributed services. When you back up the System State data on a domain controller, you are backing up all Active Directory data that exists on that server (along with other system components such as the SYSVOL directory and the registry). To restore these distributed services to that server, you must restore the System State data. However, the number and configuration of domain controllers in your system will dictate the type of restore method you choose.

For example, if you need to roll back replicated Active Directory changes, but have more than one domain controller in your organization, you will need to perform an authoritative restore to ensure that your restored data gets replicated to all of your servers. However, if you need to restore Active Directory data on a stand-alone domain controller or on the first of several domain controllers, you will need to perform a primary restore. If you need to restore Active Directory data on just one domain controller in a system where Active Directory data is replicated across several domain controllers, you can use a normal restore if your restored data does not have to be replicated to all your servers.

**Primary restore**

Use this type of restore when the server you are trying to restore is the only running server of a replicated data set (for example, the SYSVOL and File Replication service are replicated data sets). Select primary restore only when restoring the first replica set to the network. Do not use a primary restore if one or more replica sets have already been restored. Typically, perform a primary restore only when all the domain controllers in the domain have failed, and you are trying to rebuild the domain from backup.

| Distributed Data | Reason for Using Primary Restore of System State Data |
|---|---|
| Active Directory | Restoring a stand-alone domain controller.<br><br>Restoring the first of several domain controllers. |

| | |
|---|---|
| SYSVOL | Restoring a stand-alone domain controller.<br><br>Restoring the first of several domain controllers |
| Replica sets | Restoring the first replica set. |

**Normal restore**

During a normal restore operation, Backup operates in nonauthoritative restore mode. That is, any data that you restore, including Active Directory objects, will have their original update sequence number. The Active Directory replication system uses this number to detect and propagate Active Directory changes among the servers in your organization. Because of this, any data that is restored nonauthoritatively will appear to the Active Directory replication system as though it is old, which means the data will never get replicated to your other servers. Instead, if newer data is available from your other servers, the Active Directory replication system will use this to update the restored data. To replicate the restored data to the other servers, you must use an authoritative restore.

| Distributed Data | Reason for Using Normal Restore of System State Data |
|---|---|
| Active Directory | Restoring a single domain controller in a replicated environment. |
| SYSVOL | Restoring a single domain controller in a replicated environment. |
| Replica sets | Restoring all but the first replica sets (that is, sets 2 through n, for n replica sets). |

**Authoritative restore**

To authoritatively restore Active Directory data, you need to run the Ntdsutil utility after you have restored the System State data but before you restart the server. The Ntdsutil utility lets you mark Active Directory objects for authoritative restore. When an object is marked for authoritative restore its update sequence number is changed so that it is higher than any other update sequence number in the Active Directory replication system. This will ensure that any replicated or distributed data that you restore is properly replicated or distributed throughout your organization.

For example, if you inadvertently delete or modify objects stored in Active Directory, and those objects are replicated or distributed to other servers, you will need to authoritatively restore those objects so they are replicated or distributed to the other servers. If you do not authoritatively restore the objects, they will never get replicated or distributed to your other servers because they will appear to be older than the objects currently on your other servers. Using the Ntdsutil utility to mark objects for authoritative restore ensures that the data you want to restore gets replicated or distributed throughout your organization. On the other hand, if your system disk has failed or the Active Directory database is corrupted, then you can simply restore the data nonauthoritatively without using the Ntdsutil utility.

You can run the Ntdsutil command-line utility from the command prompt. Help for the Ntdsutil utility is available through the command prompt by typing **ntdsutil /?**.

| Distributed Data | Reason for Using Authoritative Restore of System State Data |
|---|---|
| Active Directory | Rolling back or undoing changes |
| SYSVOL | Resetting data |
| Replica sets | Rolling back or undoing changes |

# Backup Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Backup Tools and Settings**
**In this section**

- Backup Tools
- Backup Registry Entries
- Related Information

**Backup Tools**
The following tools are associated with Backup.

**Ntbackup.exe: Backup**
**Category**
Windows Server 2003 operating system tool

**Version compatibility**
Runs on computers running the Windows XP or Windows Server 2003 operating systems.

Performs backup operations at a command prompt or through a batch file.

For more information about Ntbackup.exe, see the Windows Server 2003 online Help.

**VSSadmin.exe: Volume Shadow Copy Service Administrative Tool**
**Category**
Windows Server 2003 operating system tool

**Version compatibility**
Runs on computers running the Windows XP or Windows Server 2003 operating systems.

Displays current volume shadow copies and all installed shadow copy writers and providers in the command window. The Windows Server 2003 version of this command contains more parameters than the one that is in Windows XP.

To find more information about VSSadmin.exe, see “Command Line References” in the Tools and Settings Collection.

**Backup Registry Entries**
The following registry entries are associated with Backup.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**Control**
The following registry entry is located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control.

**BackupRestore**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\BackupRestore

**Version**
Windows Server 2003

Contains subkeys that determine which files the system does not back up and which registry subkeys and entries the system does not restore.

**Control**

The following registry entry is located under HKEY_CURRENT_USER\SYSTEM\CurrentControlSet\Control.

**BackupRestore**
**Registry path**
HKEY_CURRENT_USER\SYSTEM\CurrentControlSet\Control\BackupRestore

**Version**
Windows Server 2003

Lists the files that are owned by the current user that should not be backed up.

**Microsoft**
The following registry entry is located under HKEY_CURRENT_USER\Software\Microsoft.

**Ntbackup**
**Registry path**
HKEY_CURRENT_USER\Software\Microsoft\Ntbackup

**Version**
Windows Server 2003

Contains subkeys that store configuration data for Windows Backup.

**Related Information**

# What Is Shadow Copies for Shared Folders?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Shadow Copies for Shared Folders?**

Shadow Copies for Shared Folders is a new file-storage technology in the Microsoft Windows Server 2003 operating systems. Shadow Copies for Shared Folders uses the Volume Shadow Copy service to provide point-in-time copies of files that are located on a shared network resource, such as a file server. With the Previous Versions client for Shadow Copies for Shared Folders, users can view shared files and folders as they existed at points of time in the past, without administrator assistance. Accessing previous versions of files, or shadow copies, is useful because users can:

- **Recover files that were accidentally deleted**. If users accidentally delete a file, they can open a previous version and copy it to a safe location.
- **Recover from accidentally overwriting a file**. If users accidentally overwrite a file, they can recover a previous version of the file.
- **Compare different versions of a file while working**. Users can use previous versions when they want to check what has changed between two versions of a file.

A common scenario for recovering lost or corrupted files occurs when an end user submits an urgent request to the IT help desk to find an archived version of a file. If the organization has an archiving system in place, this request usually requires a costly and time-intensive search of archived media, which in many instances is a tape backup. This situation creates several problems:

- Potential loss of business if the lost document is time-sensitive or labor-intensive to replace
- Decreased productivity for the end user
- Increased cost to help-desk and IT-support services

Because end users can access previous versions of files by themselves, using Shadow Copies of Shared Files for routine file recovery scenarios can help to:

- Reduce demand on busy administrators, for example, by reducing requests to restore files from tape.
- Reduce the cost of recovering single or multiple files.

### Note

- Shadow copies do not eliminate the need to perform regular backups or provide protection from media failure. In addition, shadow copies are not permanent. As new shadow copies are taken, old shadow copies are deleted when the storage limit is reached, when you run out of disk space, or when the number of shadow copies reaches 64, whichever occurs first. Therefore, shadow copies might not be present for as long as end users expect them to be.

# How Shadow Copies for Shared Folders Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Shadow Copies for Shared Folders Works**

**In this section**

- Shadow Copies for Shared Folders Architecture
- Source Volume
- Storage Volume
- Previous Versions Clients
- File Permissions
- Related Information

Shadow Copies for Shared Folders is a new file-storage technology in Microsoft Windows Server 2003. Shadow Copies for Shared Folders provides point-in-time copies of files that are located on shared network resources, such as a file server. With the Previous Versions client for Shadow Copies for Shared Folders, users can view shared files and folders as they existed at points of time in the past. Accessing previous versions of your files, or shadow copies, is useful because users can:

- **Recover files that were accidentally deleted**. If users accidentally delete a file, they can open a previous version and copy it to a safe location.
- **Recover from accidentally overwriting a file**. If users accidentally overwrite a file, they can recover a previous version of the file.
- **Compare different versions of a file while working**. Users can use previous versions when they want to check what has changed between two versions of a file.

**Shadow Copies for Shared Folders Architecture**

There are three main components that make up Shadow Copies for Shared Folders: the source volume, the storage volume, and the Previous Versions Client.

**Shadow Copies for Shared Folders Components**

| Component | Description |
|---|---|
| Source volume | The volume that is being copied. This volume is located on a server running Windows Server 2003 and has Shadow Copies for Shared Folders enabled. This volume contains several folders that are shared on the network. This is typically a volume on a file server. |
| Storage volume | The volume where shadow copies are stored. |
| Previous Versions Client | The interface that is used to view shadow copies. The client is available for Windows Server 2003, Windows XP, and Windows 2000 operating systems. For more information, see "Previous Versions Clients." |

The following diagram shows the main components of Shadow Copies for Shared Folders and how they interact.

**Shadow Copies for Shared Folders Architecture**

**Source Volume**
The source volume is the volume that is being copied, typically a volume on a file server. Shadow Copies for Shared Folders is enabled on a per-volume basis. That is, you can only make shadow copies of an entire volume. You cannot select specific shared folders and files on a volume to be copied.

The volume must reside on a server running Windows Server 2003 and must be formatted using the NTFS file system. Shadow Copies for Shared Folders is built upon the Volume Shadow Copy service technology, which provides a way to make copies of open files. For more information, see "Volume Shadow Copy Service Technical Reference."

The mounted drive will not be included when shadow copies are taken. You should enable shadow copies only on volumes without mount points or only when you do not want the shared resources on the mounted volume to be copied.

You can access the server portion of Shadow Copies for Shared Folders through the **Shadow Copies** tab of the **Local Disk Properties** dialog box.

### Note

- When you enable Shadow Copies for Shared Folders on a volume, a default scheduled task is also created. The default schedule for copies is twice a day at 7:00 A.M. and 12:00 noon, Monday through Friday.

**Storage Volume**
The storage volume is where shadow copies are stored. Shadow copies can be stored on any NTFS-formatted volume that is available to the server, including mounted volumes. Because of the high I\O involved in creating the copies, we recommend that you store the shadow copies on a volume on a separate disk from the disk that contains the source volume.

If you use Shadow Copies for Shared Folders on mounted volumes in a cluster, do not place the storage volume on a volume that is mounted to the source volume. In addition, do not mount the source volume to the storage volume. Otherwise, the cluster dependency between the Physical Disk resources of the mount point volume and the volume it is mounted to will interfere with the cluster dependency that is introduced by VSS between the source and storage volumes.

Shadow Copies for Shared Folders works by making a block-level copy of any changes that have occurred to a file since the last shadow copy was created. The file changes are copied and stored as blocks, or units of data. Generally, the entire file is not copied. Only the previous values of the changed blocks are copied to the storage area. As a result, previous versions of files do not usually take up as much disk space as the current file.

However, the amount of disk space that is used for changes can vary, depending on the application that changed the file. For example, some applications rewrite the entire file when a change is made, but other applications add changes to the existing file. If the entire file is rewritten to disk when a change is made, then the shadow copy contains the entire file.

The minimum amount of storage space that you can specify to be used for storing shadow copies on the storage volume is approximately 100 megabytes (MB) for computers running Windows XP with Service Pack 2 or Windows Server 2003. It is approximately 300 MB for Windows Server 2003 with hotfix 833167 applied. The default storage size is 10% of the source volume (the volume being copied). When the storage limit is reached, older versions of the shadow copies will be deleted and cannot be restored. There is also a limit of 64 shadow copies per volume that can be stored. When this limit is reached, the oldest shadow copy will be deleted and cannot be retrieved.

### Note

- Shadow copies are read-only. You cannot edit the contents of a shadow copy.

**Previous Versions Clients**

There are two clients for Shadow Copies for Shared Folders:

- **Previous Versions Client for Windows XP and Windows Server 2003.** This client can be installed on Windows XP from the Windows Server 2003 installation media or it can be installed using the .msi package that is available at the Microsoft Download Center. Previous Versions Client is installed by default on Windows Server 2003 and is included when you install Windows XP Service Pack 2.

- **Previous Versions Client for Windows 2000.** This client is only available from the .msi package available at the Microsoft Download Center. In order for Windows 2000 clients to view shadow copies, a registry key must be set on the computer running Windows Server 2003 that enables access by Windows 2000 clients. The .msi package that contains the Windows 2000 client also contains an installation package for the server that will set this registry key.

You can access the client view of shadow copies through the **Previous Versions** tab of the **Properties** dialog box of the shared file or folder.

You cannot view previous versions of files on a local shared resource. You must have a working network connection and be viewing the volume as a shared network resource. On a computer running Windows Server 2003, in order to view shadow copies of a local shared folder, you must create a connection to the shared resource on your local computer as if it were in another location on the network. For example: To view previous versions of files in the shared folder ***\Documents***on the local computer ***\\Server1***, you need to create a network connection to ***\\Server1\Documents*** and access the previous versions as if they were on a remote computer.

**File Permissions**
When you restore a file to a previous version, the file permissions will not be changed. File permissions remain the same as they were before the file was restored. When you recover a file that was accidentally deleted, the file permissions are set to the default permissions for the directory the file is in. This directory might have different permissions than the file.

**Shadow Copies for Shared Folders Tools**

The following tools are associated with Shadow Copies for Shared Folders.

**VSSadmin.exe: Volume Shadow Copy Service Administrative Tool**

**Category**

Windows Server 2003 operating system tool

**Version compatibility**

Runs on computers running the Windows XP or Windows Server 2003 operating systems.

Displays current volume shadow copies and all installed shadow copy writers and providers in the command window. The Windows Server 2003 version of this command contains more parameters than the one that is in Windows XP.

To find more information about VSSadmin.exe, see "Command Line References" in the Tools and Settings Collection.

**VolPerf.exe: Shadow Copy Performance Counters**

**Category**

Windows Server 2003 Resource Kit tool

**Version compatibility**

Runs on computers running any of the Windows Server 2003 operating systems.

Enables administrators to use System Monitor to monitor their shadow copies.

To find more information about Volperf.exe, see "Resource Kit Tools" in the Tools and Settings Collection.

**VolRest.exe: Shadow Copies for Shared Folders Restore Tool**

**Category**

Windows Server 2003 Resource Kit tool

**Version compatibility**

Runs on computers running the Windows XP or Windows Server 2003 operating systems.

Searches for and restores previous file versions from shared folders that are protected by the Shadow Copies for Shared Folders feature. With VolRest, administrators can browse or restore previous versions of one or multiple files that are stored on a server where Shadow Copies for Shared Folders has been enabled.

To find more information about Volrest.exe, see "Resource Kit Tools" in the Tools and Settings Collection.

**Shadow Copies for Shared Folders Registry Entries**

The following registry entries are associated with Shadow Copies for Shared Folders.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This

can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**Parameters**
The following registry entry is located under \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\LanmanServer\Parameters.

**DisableDownLevelTimewarp**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\LanmanServer\Parameters\DisableDownLevelTimewarp

**Version**
Runs on computers running the Windows Server 2003 operating system.

This registry entry enables or disables support for Shadow Copies for Shared Folders on clients running the Windows 2000 operating system.

Set the value of the DisableDownLevelTimewarp registry key to 0 (zero) to enable Shadow Copies for Shared Folders from clients running Windows 2000. Set the value of the DisableDownLevelTimewarp registry key to 1 (one), the default, to disable Shadow Copies for Shared Folders from clients running Windows 2000.

**VOLSNAP**
The following registry entry is located under \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\VOLSNAP.

**MinDiffAreaFileSize**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\VOLSNAP\MinDiffAreaFileSize

**Version**
Windows Server 2003

Controls the initial size of the shadow copy storage area for each shadow copy. The MinDiffAreaFileSize registry key uses the REG_DWORD data type.

The MinDiffAreaFileSize registry key specifies the minimum size of the shadow copy storage area. The default size of the shadow copy storage area is 300 MB, and the maximum size is 3 gigabytes (GB). For an accurate setting, specify a value that is a multiple of 300 MB. Otherwise, the next multiple of 300 MB will be used. A value of 300 is equal to 300 MB, and a value of 3,000 is equal to 3 GB.

Shadow copies might not function correctly if the value of the MinDiffAreaFileSize registry key is larger than the maximum size of the shadow copy storage area. Before you change this registry entry, run the **vssadmin list shadowstorage** command. Make sure that the shadow copy storage area is larger than 300 MB or that the shadow copy storage area is larger than the value that is set in the registry. Also, make sure that you have at least 300 MB of free space on the shadow copy storage volume.

**Shadow Copies for Shared Folders WMI Classes**
The following table lists and describes the WMI classes that are associated with Shadow Copies for Shared Folders.

### WMI Classes Associated with Shadow Copies for Shared Folders

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_ShadowBy | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowContext | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowCopy | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowDiffVolumeSupport | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowFor | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowOn | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowStorage | \root\cimv2 | Windows Server 2003 family |

| | | |
|---|---|---|
| Win32_ShadowVolumeSupport | \root\cimv2 | Windows Server 2003 family |
| Win32_Volume | \root\cimv2 | Windows Server 2003 family |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by Shadow Copies for Shared Folders**

Shadow Copies for Shared Folders uses the following network ports.

**Network Ports Used by Shadow Copies for Shared Folders**

| Service Name | Description | Port Used |
|---|---|---|
| Server Message Block (SMB) | Required for Shadow Copies for Shared Folders | TCP 138, 139, 445 |
| DCOM/Remote Procedure Call (RPC) | Required for remote management using WMI. | TCP 135, dynamic |

**What Is Volume Shadow Copy Service?**

**In this section**

- Volume Shadow Copy Service Scenarios
- Related Information

The Volume Shadow Copy Service provides the backup infrastructure for the Microsoft Windows XP and Microsoft Windows Server 2003 operating systems, as well as a mechanism for creating consistent point-in-time copies of data known as shadow copies.

Previous to the Volume Shadow Copy Service and its standard set of extensible application programming interfaces (APIs), there was no standard way to produce "clean" (uncorrupted) snapshots of a volume. Snapshots often contained corruptions due to "torn writes" that required the use of utilities such as Chkdsk.exe to repair. Torn writes occur when an unplanned event (such as a power failure) prevents the system from completely writing a block of data to disk. The Volume Shadow Copy Service APIs prevent torn writes by enabling applications to flush partially committed data from memory.

The Volume Shadow Copy Service has native support for creating consistent shadow copies across multiple volumes, regardless of the snapshot technology or application. The Volume Shadow Copy Service can produce consistent shadow copies by coordinating with business applications, file-system services, backup applications, fast recovery solutions, and storage hardware. Several features in the Windows Server 2003 operating systems use the Volume Shadow Copy Service, including Shadow Copies for Shared Folders and Backup.

**Volume Shadow Copy Service Scenarios**

Shadow copies can be used for a number of purposes such as:

- Creating consistent backups of open files and applications
- Creating shadow copies for shared folders
- Creating transportable shadow copies using a hardware provider — for backup, testing and data mining scenarios
- Quickly recovering and restoring files and data

The Volume Shadow Copy Service is commonly used in the following scenarios.

**Consistent backups of open files and applications**

Applications that are running often keep their files open continuously. For backup, this can present a problem because this prevents backup applications from accessing and copying these files to backup media. Even if an application does not have its files open, it is possible—because of the finite time needed to open, back up, and close a file—that files copied to the backup media might not all reflect the same application state at the same point in time.

Additionally, backing up servers that are running critical applications such as databases or messaging services presents a unique challenge. These applications run in a volatile state as a result of extensive optimizations that deal with huge flows of transactions and messages. Because these applications keep their data in a constant flux between memory and disk, it is difficult to pinpoint the data that needs to be archived. The most straightforward solution is to interrupt the application during backup, which puts the data into a stable state, but might result in unacceptable amounts of downtime, particularly if the applications are large.

For both problems, the Volume Shadow Copy Service provides a solution by enabling a snapshot of the data at a given point in time, while minimizing the interruption to applications. This can involve cooperation from the applications, so that they can notify the operating system that they are briefly quiescing their data for archival. During quiescence, applications make data on the disk consistent. For example, an application might flush its buffers to disk or write out in-memory data to disk.

The Volume Shadow Copy Service provides interfaces for storage-management applications (called requestors), business

applications (called writers) and storage devices (with components called providers) to ensure that volume shadow copies are in a consistent state.

**Shadow Copies for Shared Folders**
Shadow Copies for Shared Folders uses the Volume Shadow Copy Service to provide point-in-time copies of files that are located on a shared network resource, such as a file server. With Shadow Copies for Shared Folders, users can quickly recover deleted or changed files that are stored on the network without administrator assistance, which can increase productivity and reduce administrative costs.

For more information about Shadow Copies for Shared Folders, see "Shadow Copies for Shared Folders Technical Reference."

**Shadow Copy Transport**
With a hardware provider that is designed for use with the Volume Shadow Copy Service, you can create transportable shadow copies that can be imported onto servers within the same subsystem (for example, a storage area network (SAN)). While multiple servers can access the same storage array, they do not share access to the same storage unit or LUN. For servers to share the same data, the traditional solution is to first copy the data on one server and then restore it to a second server. This process can be quite lengthy.

With the Volume Shadow Copy Service and a storage array with a hardware provider designed for use with the Volume Shadow Copy Service, it is possible to create a shadow copy of the source data volume on one server and then to import the shadow copy onto another server (or back to the same server). This process is accomplished in a few minutes, regardless of the size of the data. The transport process is accomplished through a series of steps using a shadow copy requestor (storage-management application) that supports transportable shadow copies. The following is a generalized version of those steps:

1. Create a transportable shadow copy of the source data on a server.

2. Import the shadow copy to a server connected to the SAN (you can import to a different server or the same server).

3. The data is now ready to be used.

Note that shadow copies are read-only. If you want to convert a shadow copy to a read/write LUN, you can use a storage-management application (including some requestors) that is compatible with the Virtual Disk Service, in addition to the Volume Shadow Copy Service. Using this application, you can remove the shadow copy from Volume Shadow Copy Service management and convert it to a read/write LUN.

Volume Shadow Copy Service transport is an advanced solution on computers running Windows Server 2003, Enterprise Edition or Windows Server?2003, Datacenter Edition that works only if there is a hardware provider on the storage array. Shadow copy transport can be used for a number of purposes, including tape backups, data mining, and testing.

**Transport for Tape Backups**
Backing up data to tape is perhaps the most I/O intensive operation that an application can perform. On a production local area network (LAN), this is problematic because the data must travel across two systems: from the storage on the server across to the network to the backup system, and from the backup system to the tape device. This high traffic process can result in considerable congestion on the production network, degrading application performance.

One way to alleviate this problem is to transport shadow copies from the production server onto a backup server, where the shadow copy volumes can be backed up to tape. This option removes backup traffic from the production server. While some backup applications might be designed with the hardware provider software that enables transport, others are not. The administrator should determine whether or not this functionality is included in the backup application.

**Transport for Data Mining**
The data in use by a particular production server is often useful to different groups or departments within an organization. Rather than add additional load to the production server, a shadow copy of the data can be made available through transport to another server. The shadow copy can then be processed for different purposes, without any performance impact on the original server.

**Transport for Testing**
Shadow copies can be particularly useful for software developers, who often need data against which to test new versions of an application. Developers can make a shadow copy of the source data and transport it to a different server in order to test an application. If an application corrupts the shadow copy of the data, there is no impact on the original data.

**Fast Recovery**
Fast recovery uses shadow copies as a complement to traditional tape-based recovery solutions. Using point-in-time shadow copies with Active Directory and Exchange Server configurations, for example, helps you to quickly recover from a number of

specific system problems, including:

- Hardware failure
- Storage failure
- Software corruption

Because this mirroring (or "cloning") process is fast and nondisruptive to system performance, shadow copies can be made more frequently than tape backups. Shadow copies that are kept locally on a storage area network can be quickly accessed. With the appropriate hardware provider, they can be transported to a backup server, backed up to tape, and sent to off-site storage for archiving.

With the Volume Shadow Copy Service and the Virtual Disk Service, Windows Server 2003 contains the functionality to enable fast data restores that only take a few minutes — compared to the hours it can take with tape backups.

As with tape-based recovery of data, recovery using the Volume Shadow Copy Service and Virtual Disk Service requires planning well ahead of the potential server failure. The difference is that the data recovery from tape is far slower and more labor intensive than when using Windows Server 2003 technology and storage area networks.

**Mechanisms Underlying Fast Recovery**
The following sections briefly outline the conceptual aspects of each of these fast recovery solution components.

**Shadow Copy Creation**
The process of creating shadow copies begins when the backup application (requestor) contacts the Volume Shadow Copy Service to request a shadow copy. The Volume Shadow Copy Service, acting as a coordinator, notifies each of the writers to prepare for shadow copy creation. Once the writers indicate they are prepared, the requestor instructs the Volume Shadow Copy Service to create the shadow copy. The Volume Shadow Copy Service informs the writers to quiesce their stores and briefly freeze (stop) writes to disk for the few seconds it takes the provider to create the point-in-time shadow copies of the volumes.

Once a shadow copy of one or more volumes is made, the Volume Shadow Copy Service informs the writers they can thaw (resume writing to disk) and the original data continues to be used in production. At this point, the read-only shadow copy resides in the storage array until a need arises.

**Fast Recovery Process**
After a failure event, a management application using both the Volume Shadow Copy Service and the Virtual Disk Service can remove the failed LUNs from the system. The shadow copies of the LUNs can be converted from read-only to read/write. The LUNs can then be assigned to another server.

A generalized example of shadow copy creation and transport between two servers is shown in the following diagram. A single point-in-time shadow copy is made of the three LUNs assigned to Server 1. This shadow copy set can be accessed by Server 2 through the process of first unmasking, then mounting the LUNs. The complete process is called "shadow copy transport."

**Shadow Copy Creation and Transport Between Two Servers**

Note that this is a general example of transporting shadow copies of LUNs between two servers.

# How Volume Shadow Copy Service Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Volume Shadow Copy Service Works**

**In this section**

- Methods for Creating Shadow Copies
- Volume Shadow Copy Service Architecture
- Components Used for Creating Shadow Copies
- How Shadow Copies Are Created
- Related Information

The Volume Shadow Copy Service provides the backup infrastructure for the Microsoft Windows XP and Microsoft Windows Server 2003 operating systems, as well as a mechanism for creating consistent point-in-time copies of data known as shadow copies.

The Volume Shadow Copy Service can produce consistent shadow copies by coordinating with business applications, file-system services, backup applications, fast-recovery solutions, and storage hardware. Several features in the Windows Server 2003 operating systems use the Volume Shadow Copy Service, including Shadow Copies for Shared Folders and Backup.

**Methods for Creating Shadow Copies**

There are two methods for creating shadow copies: making either a complete copy (a full copy or clone) or copying only the changes to the volume (a differential copy or copy-on-write). Each method results in two data images — the original volume and the shadow copy volume. The functional difference between the two is that the original volume maintains full read/write capabilities, whereas the shadow copy volume is read-only. This read-only status ensures that the shadow copy volume remains a point-in-time copy until its status is changed by the administrator for a specific purpose.

**Clone (Full Copy/Split Mirror):**

A clone is a full copy of the original data on a volume. You can create a clone through either software or hardware mirroring. Clones remain synchronized until the mirror connection is broken for the shadow copy. From this point forward, the source data and the shadow copy volume are independent. The original volume continues to take application changes, while the shadow copy volume remains an exact read-only copy of the original data at the time of the break.

Hardware vendors offer different hardware-based implementations (sometimes called split mirrors, snapshot mirrors, or clones) for creating identical images of volumes that can be used for online backup, application development, and testing.

**Copy-on-Write (Differential Copy)**

The copy-on-write method creates shadow copies that are differential rather than full copies of the original data. Like the clone method of creating shadow copies, the copy-on-write method can produce shadow copies using either software or hardware solutions. This method makes a copy of the original data before it is overwritten with new changes, as shown in the following table. When a change to the original volume occurs, but before it is written to disk, the block about to be modified is read and then written to a "differences area", which preserves a copy of the data block before it is overwritten with the change. Using the blocks in the differences area and unchanged blocks in the original volume, a shadow copy can be logically constructed that represents the shadow copy at the point in time in which it was created.

**The Copy-on-Write Method of Creating Shadow Copies**

| Time | Source Data | Contents | Shadow Copy | Contents |
|---|---|---|---|---|
| T0 | Original data | 1 2 3 4 5 | No copy | — |
| T1 | Original data overwritten | 1 2 3 4 5 | Differences and index stored on shadow copy | 3 |

The advantage of the copy-on-write method is that it creates shadow copies very rapidly because it is only writing the changes

to disk. The disadvantage is that in order to fully restore the data, the original data must still be available. Without the original data, the shadow copy is incomplete and cannot be used. Another disadvantage is that the performance of copy-on-write implementations can affect the performance of the original volume.

**Volume Shadow Copy Service Architecture**

The following diagram and table describe how the Volume Shadow Copy Service coordinates with various components to create a shadow copy of a volume.

**Volume Shadow Copy Service Architecture Diagram**

**Volume Shadow Copy Service Components**

| Component | Description |
|---|---|
| Volume Shadow Copy Service | A service that coordinates various components to create consistent shadow copies of one or more volumes. |
| Requestor | An application that requests that a volume shadow copy be taken. A backup application is an example. |
| Writer | A component of an application that stores persistent information on one or more volumes that participate in shadow copy synchronization. Typically, this is a database application like SQL Server or Exchange Server, or a system service like Active Directory. |
| Provider | A component that creates and maintains the shadow copies. Examples are the system provider included with the operating system and the hardware providers included with storage arrays. |
| Source volume | The volume that contains the data to be shadow copied. |
| Storage volume | The volume that holds the shadow copy storage files for the system copy-on-write software provider. |

**Components Used for Creating Shadow Copies**

This section outlines the requestors, writers, and providers that are necessary for creating consistent shadow copies. The Volume Shadow Copy Service provides coordination among these components.

**Requestors: Initiating Shadow Copy Creation**

The Volume Shadow Copy Service is invoked by the requestor, which is typically a backup application that creates shadow copy volumes to back up data while the source volume continues to operate in production. Requestors can also be management applications that manage shadow copy creation and usage, or fast recovery solutions which are specific products that reduce service level agreement (SLA) times for specific applications.

The requestor also communicates with the writers to gather information about what should be backed up and how it should be backed up.

**Writers: Preventing Data Inconsistencies**

Writers are software that is included in applications and services that help provide consistent shadow copies. Writers serve two main purposes:

- When applications and services are running, the writer responds to signals provided by the Volume Shadow Copy Service interface to allow applications to prepare and quiesce their data stores for shadow copy creation and to ensure that no writes occur on the volume while the shadow copy is being created. (During quiescence, applications make data on the disk consistent. For example, an application might flush its buffers to disk or write out in-memory data to disk.)

- The writer also provides information about the application name, icons, files to include or exclude, and a strategy to

restore the files.

If an application or service is not running, and the writer cannot respond to the requesting backup application, it is assumed that all data on the volume is consistent, the databases are closed, and no additional effort is required to perform the backup.

A writer is associated with one or more components. A component is a group of files that must be backed up as a unit. For example, a database and set of log files. For a backup to be successful, all files associated with the component must be backed up. Writers also provide information about restoring the data on a component-by-components basis.

If an application has no writer, the shadow copy will still occur and all of the data, in whatever form it is in at the time of the copy, will be included in the shadow copy. This means that there might be inconsistent data that is now contained in the shadow copy. This data inconsistency is caused by incomplete writes, data buffered in the application that is not written, or open files that are in the middle of a write operation. Even though the file system flushes all buffers prior to creating a shadow copy, the data on the disk can only be guaranteed to be crash-consistent if the application has completed all transactions and has written all of the data to the disk. (Data on disk is "crash-consistent" if it is the same as it would be after a system failure or power outage.)

Under this design, the responsibility for data consistency has been shifted from the requestor application to the production application. The advantage of this approach is that application developers — those most knowledgeable about their applications — can ensure, through development of their own writers, the maximum effectiveness of the shadow copy creation process.

**Applications that are not shadow copy–enabled**
If the computer has no applications that are enabled for the Volume Shadow Copy Service, the data in a shadow copy is considered to be in a "crash consistent" state. All files that were open will still exist, but are not guaranteed to be free of incomplete I/O operations or data corruption.

While the crash-consistent state does not fully deal with all the issues associated with defining a stable backup set, it has several advantages over the backup set that conventional backup operations would have to use.

- For example, a shadow copy of a volume, even in crash-consistent state, still contains all files. A backup set created without a shadow copy would not contain all files open exclusively at the time of the backup. Files held open at the time of the backup operation are excluded from the backup.

The shadow copy of the volume is created at a single point in time and is synchronized across the whole volume set. In order to avoid inconsistencies, shadow copies are not taken file by file.

**Providers: Creating Shadow Copies**
In the context of shadow copy creation, a provider is a component that serves as an interface to the point-in-time imaging capabilities — either on the storage array (hardware-based) or in the operating system (software based). Providers manage running volumes and create shadow copies of them on demand. In response to a request from a requestor, the Volume Shadow Copy Service signals applications that a shadow copy is about to be created, then signals the provider to create and maintain that shadow copy until it is no longer needed. Hardware providers are implemented as a user-mode component which communicates with the hardware that will expose the shadow copy data. Windows Server 2003 includes a system software provider with shadow copy functionality.

Alternatively, other hardware and software vendors can develop their own hardware or software providers to provide point-in-time imaging functionality. Windows Server 2003 supports multiple hardware and software providers that can be used in combination to solve many different IT operational scenarios.

The Volume Shadow Copy Service uses the following hierarchy to select the provider to use during shadow copy creation:

1. Hardware provider

2. Software provider

3. System software provider.

However, if a specific IT operational problem requires it, the requestor can override this hierarchy.

**Hardware-based Providers**
Hardware-based shadow copy providers act as an interface between the Volume Shadow Copy Service and the hardware level

by working in conjunction with a hardware storage adapter or controller. The work of creating the shadow copy is performed by a host adapter, storage appliance, or RAID controller outside of the operating system.

Hardware providers always take the shadow copy of an entire LUN, but the Volume Shadow Copy Service will only expose the shadow copy of the volume or volumes that were requested.

While a hardware-based shadow copy provider makes use of the Volume Shadow Copy Service functionality that defines the point in time, allows data synchronization, manages the shadow copy, and provides a common interface with backup applications, the Volume Shadow Copy Service does not specify the underlying mechanism by which the hardware-based provider produces and maintains shadow copies.

**Software-based Providers**
Software-based shadow copy providers typically intercept and process I/O requests in a software layer between the file system and the volume manager software.

These providers are implemented as a user-mode DLL component and at least one kernel-mode device driver, typically a storage filter driver. The work of creating these shadow copies is done in software.

A software-based shadow copy provider must maintain a "point-in-time" view of a volume by having access to a data set that can be used to recreate volume status prior to the shadow copy. An example of this is the copy-on-write technique of the system provider. However, the Volume Shadow Copy Service places no restrictions on what technique software-based providers use to create and maintain shadow copies.

A software provider will be applicable to a wider range of storage platforms than a hardware-based provider and should be able to work with basic disks or logical volumes equally well.

This implementation sacrifices the performance that might be available by implementing shadow copies in hardware and does not make use of any vendor-specific features.

**System Provider**
One shadow copy provider, the system provider, is supplied as a default part of the Windows Server 2003 operating system. While a default provider is supplied as part of Windows, other vendors are free to supply their own implementations that are optimized for their own storage hardware and software applications.

To maintain the "point in time" view of a volume contained in a shadow copy, the system provider uses a copy-on-write technique. Copies of the blocks on volume that have been modified since the beginning of the shadow copy creation are stored in a shadow copy storage area.

The system provider can expose the production volume, which can be written to and read from normally. When the shadow copy is needed, it logically applies the differences to data on the production volume to expose the complete shadow copy.

For the system provider, the shadow copy storage area must be on an NTFS volume. The volume to be shadow copied does not need to be an NTFS volume, but at least one volume mounted on the system must be an NTFS volume.

**How Shadow Copies Are Created**
The various roles of the requestor, writer and provider are put into context in this section, which lists the steps that need to be taken to create a shadow copy. Overall coordination of the requestor, writer, and provider is controlled by the Volume Shadow Copy Service, as shown in the following diagram.

**Shadow Copy Creation Process**

1. The requestor asks the Volume Shadow Copy Service to enumerate the writers, gather the writer metadata, and prepare

for shadow copy creation.

2. The writer creates an XML description of the backup components to the Volume Shadow Copy Service, and defines the restore method. The Volume Shadow Copy Service notifies the application-specific writer to prepare its data for making a shadow copy.

3. The writer prepares the data in whatever way is appropriate, such as completing all open transactions, rolling transaction logs, and flushing caches. When the data is prepared for shadow copy creation, the writer notifies the Volume Shadow Copy Service.

4. The Volume Shadow Copy Service initiates the "commit" shadow copy phase.

5. The Volume Shadow Copy Service tells the writers to quiesce their data and temporarily freeze requestor (application) I/O write requests (I/O read requests are still possible) for the several seconds required to create the shadow copy of the volume or volumes. The application freeze is not allowed to take longer than 60 seconds. The Volume Shadow Copy Service flushes the file system buffer and then freezes the file system, which ensures that file system metadata is written and that the data is written in a consistent order.

6. The Volume Shadow Copy Service tells the provider to create the shadow copy (a maximum of 10 seconds).

7. The Volume Shadow Copy Service thaws the file system. After the shadow copy is created, the Volume Shadow Copy Service releases the writers from their temporary inactive phase and all queued write I/Os are completed.

8. The Volume Shadow Copy Service queries the writers to confirm that write I/Os were successfully held during shadow copy creation.

9. If the writes were not successfully held (meaning that the shadow copy data is potentially inconsistent), the shadow copy is deleted and the requestor is notified.

10. The requestor can retry the process (go back to step 1) or notify the administrator to retry at a later time.

11. If the copy is successful, the Volume Shadow Copy Service gives the location information for the shadow copy back to the requestor.

# Volume Shadow Copy Service Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Volume Shadow Copy Service Tools and Settings**

**In this section**

- Volume Shadow Copy Service Tools
- Volume Shadow Copy Service Registry Entries
- Volume Shadow Copy Service WMI Classes
- Related Information

**Volume Shadow Copy Service Tools**

The following tools are associated with the Volume Shadow Copy Service.

**DiskRaid.exe: RAID Configuration Tool**

**Category**

Windows Server 2003 Resource Kit tool

**Version compatibility**

Runs on computers running the Windows Server 2003 operating systems.

Enables configuration and management of redundant array of independent (or inexpensive) disks (RAID) storage subsystems.

To find more information about DiskRaid.exe, see "Resource Kit Tools" in the Tools and Settings Collection.

**VSSadmin.exe: Volume Shadow Copy Service Administrative Tool**

**Category**

Windows Server 2003 operating system tool

**Version compatibility**

Runs on computers running the Windows XP or Windows Server 2003 operating systems.

Displays current volume shadow copies and all installed shadow copy writers and providers in the command window. The Windows Server 2003 version of this command contains more parameters than the one that is in Windows XP.

To find more information about VSSadmin.exe, see "Command Line References" in the Tools and Settings Collection.

**VolPerf.exe: Shadow Copy Performance Counters**

**Category**

Windows Server 2003 Resource Kit tool

**Version compatibility**

Runs on computers running any of the Windows Server 2003 operating systems.

Enables administrators to use System Monitor to monitor their shadow copies.

To find more information about Volperf.exe, see "Resource Kit Tools" in the Tools and Settings Collection.

**VolRest.exe: Shadow Copies for Shared Folders Restore Tool**

**Category**

Windows Server 2003 Resource Kit tool

**Version compatibility**

Runs on computers running the Windows XP or Windows Server 2003 operating systems.

Searches for and restores previous file versions from shared folders that are protected by the Shadow Copies for Shared Folders feature. With VolRest, administrators can browse or restore previous versions of one or multiple files that are stored on a server where Shadow Copies for Shared Folders has been enabled.

To find more information about Volrest.exe, see “Resource Kit Tools” in the Tools and Settings Collection.

**Vrfydsk.exe: Verify Disk**
**Category**
Windows Server 2003 Resource Kit tool

**Version compatibility**
Runs on computers running Windows Server 2003 operating systems.

Checks the consistency and integrity of the file system (FAT or NTFS) on a specified volume. It creates and displays a status report for the volume based on the file system and also lists the errors on that volume, if any. However, if any errors are discovered, VrfyDsk cannot correct them. To correct these errors, run Chkdsk in fix mode.

To find more information about Vrfydsk.exe, see “Resource Kit Tools” in the Tools and Settings Collection.

**Volume Shadow Copy Service Registry Entries**
The following registry entries are associated with Volume Shadow Copy Service.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**VSS**
The following registry entry is located under \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\VSS.

**VssAccessControl**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\VSS\VssAccessControl

**Version**
Windows Server 2003

Enables or prevents a writer from using a specific user account.

In order for any writer to use the VSS infrastructure, the writer must run under an account that is a member of the local Administrators or Backup Operators group on the local computer. For example, a writer running under the Local System account meets this requirement. This is true for the vast majority of writers.

You can, however, enable a writer to use a specific user account by adding the appropriate registry entry. You can also prevent a writer from using a specific user account.

To enable a writer to use a specific user account, add a REG_DWORD entry with the name equal with the user name. Set the value of the registry entry to 1 (one).

To prevent a writer from using a specific user account, add a REG_DWORD entry with the name equal with the user name. Set the value of the registry entry to 0 (zero).

**VOLSNAP**
The following registry entry is located under \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\VOLSNAP.

**MinDiffAreaFileSize**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\VOLSNAP\MinDiffAreaFileSize

**Version**
Windows Server 2003

Controls the initial size of the shadow copy storage area for each snapshot. The MinDiffAreaFileSize registry key uses the REG_DWORD data type.

The MinDiffAreaFileSize registry key specifies the minimum size of the shadow copy storage area. The default size of the shadow copy storage area is 300 MB, and the maximum size is 3 gigabytes (GB). For an accurate setting, specify a value that is a multiple of 300 MB. Otherwise, the next multiple of 300 MB will be used. A value of 300 is equal to 300 MB, and a value of 3,000 is equal to 3 GB.

Shadow copies might not function correctly if the value of the MinDiffAreaFileSize registry key is larger than the maximum size

of the shadow copy storage area. Before you change this registry entry, run the **vssadmin list shadowstorage** command. Make sure that the shadow copy storage area is larger than 300 MB or that the shadow copy storage area is larger than the value that is set in the registry. Also, make sure that you have at least 300 MB of free space on the shadow copy storage volume.

**Volume Shadow Copy Service WMI Classes**

The following table lists and describes the WMI classes that are associated with the Volume Shadow Copy Service.

**WMI Classes Associated with Volume Shadow Copy Service**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_ShadowBy | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowContext | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowCopy | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowDiffVolumeSupport | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowFor | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowOn | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowProvider | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowStorage | \root\cimv2 | Windows Server 2003 family |
| Win32_ShadowVolumeSupport | \root\cimv2 | Windows Server 2003 family |
| Win32_Volume | \root\cimv2 | Windows Server 2003 family |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

# Scalability Factors for Shadow Copies

Applies To: Windows Server 2003, Windows Server 2003 R2

With the increased adoption of the Volume Shadow Copy Service (VSS), we have had several requests from partners and customers for guidance on provisioning server and storage resources in their deployments. This document is intended to provide general information that a partner or customer needs to make appropriate choices for scalability when deploying Shadow Copies of Shared Folders.

This information refers to VSS deployments on Windows Server® 2003 with Service Pack 1 and Windows Server 2003 R2. There are three significant parameters to consider when planning for scalability: availability of paged pool memory, nonpaged pool memory, and system virtual memory.

**Paged pool memory and snapshot limitations**
The NTFS file system requires 1 to 2 MB of paged pool memory per million files for snapshots and volumes mounted on the system. The usage is independent of actual number of snapshots on the system. This is an approximation—the actual usage would vary depending on the file access patterns.

**Example:** Mounting 64 snapshots of a volume with 2 million files is equivalent to mounting 8 snapshots of a volume with 16 million files.

**Impact of file access patterns on paged pool memory usage**
NTFS maps file records in 64-MB chunks. Each 64-MB mapping of file records consumes 64 KB of paged pool memory. Each 64-MB mapping of file records represents 65,536 files, where each file is represented by a 1-KB file record. NTFS maps a new 64-MB range of its file records whenever one of those file records is accessed. If all the file records are mapped, this translates to 1 MB of paged pool memory used for every 1 million files. Besides the file records, there are many other NTFS disk data structures that need to be mapped—and those mappings also consume paged pool memory. That is why we estimate the paged pool memory usage as being between 1 MB and 2 MB per million files.

**Mitigation:**

- Split the volumes among more servers.
- Install the KB 891957 update described in the Microsoft Knowledge Base article 913648 (http://go.microsoft.com/fwlink/?LinkId=89811).

  Based on heuristics, this update dismounts all mounted shadow copies if:

  - More than 128 MB of paged pool memory is being used by the mounted shadow copies.

    Or

  - The available paged pool memory drops below 50 MB.

VSS attempts to estimate the amount of paged pool memory actually being used by the snapshots by monitoring the change in paged pool memory allocation whenever a snapshot is deleted or dismounted. The dismounts occur during shadow copy creation.

**Scope:**
This limitation is significant only on 32-bit systems, which may have a maximum paged pool memory of 650 MB. 64-bit systems support 128 GB of paged pool memory.

**Event:**
A lack of paged pool memory leads to events such as Event 2020.

**System virtual memory limitation**
For every 16 KB of diff area on a system, VSS consumes about 40 bytes of virtual memory on the system. However, optimizations used by VSS can reduce the usage of virtual memory, so a production system will most likely have better usage.

The total diff area on a system is configured by the shadow copy storage space setting and is often set at 10% of the volume to be shadow copied.

**Example:** To snapshot a 10 TB volume, we prescribe a 1 TB diff area, which requires about 2 GB of virtual memory after accounting for the optimizations used by VSS.

**Scope**
This limitation is significant only on 32-bit systems which have 2 GB of addressable space. 64-bit systems have 8 TB of virtual address space.

**Event**
A lack of virtual memory leads to Event 6.

**Nonpaged pool memory limitation**
The amount of nonpaged pool memory in the system is proportional to the amount of physical memory, but the amount of nonpaged pool memory on a 32-bit system is never greater than 256 MB—regardless of the amount of physical memory available. VSS consumes 1 bit (16 KB) of the volume to be shadow copied.

**Example:** A 1-TB volume that is shadow copied consumes 8 MB of nonpaged pool memory.

**Snapshot creation:**
VSS consumes 5 bits per volume to be shadow copied only during snapshot creation. This usage is pruned once the snapshot is created.

**Example:** A 5-TB volume consumes 200 MB of nonpaged pool memory during the snapshot creation phase and then drops to using 40 MB after that.

**Scope**
While this limitation applies to both 32-bit and 64-bit systems, it is less significant on 64-bit systems. On 64-bit systems, nonpaged pool memory is capped at 7/8th of physical memory and can never exceed 128 GB. 32-bit systems are limited to 256 MB of nonpaged pool memory, and 128 MB of nonpaged pool memory if the system is booted with the **/3GB** switch.

**Event:**
A lack of nonpaged pool memory usually results in Event 5.

**Additional resources**
For memory limits for specific Windows releases, see http://go.microsoft.com/fwlink/?LinkId=89378.

# Device Management Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this subject**

- Device Management Architecture
- Device Management Components
- Device Management Scenarios
- New Storage Device Drivers in Windows Server 2003

Device management provides a way for Microsoft Windows Server 2003 to uniformly notify all applications and system components of changes that may affect their operation or access to resources.

Applications and system components use and process device messages between the operating system and devices to take advantage of new resources when they become available and to prevent loss of data when existing resources become unavailable. Device messages notify applications of device change events, such as the removal of a hardware device; power messages notify applications of power management events. Applications and device drivers can also define and use custom messages to enable notification of other types of events.

Windows Server 2003 uses the Device Manager snap-in to dynamically track and manage devices and drivers on a system. For example, you can view device status and set device properties through Device Manager. If you request to update a driver, Device Manager calls the Hardware Update wizard.

Device Manager displays all devices installed in the system, as illustrated in the following figure.

**Device Manager**

The Device Manager display represents the computer's hardware configuration. The Device Manager display is recreated each time the computer is started and whenever a dynamic change to the computer configuration occurs, such as the addition of a new device while the system is running.

Device Manager allows you to do the following:

- Determine whether the hardware on your computer is working properly

- Change hardware configuration settings
- Identify the device drivers that are loaded for each device and obtain information about each device driver
- Change advanced settings and properties for devices
- Install updated device drivers
- Disable, enable, and uninstall devices
- Roll back to the previous version of a driver
- Print a summary of the devices that are installed on the computer
- Change resources, such as interrupt requests (IRQs), assigned to devices

Device Manager can be used to check the hardware status and update device drivers on a computer. Device Manager cannot be used to change resource allocation settings; resources are automatically allocated by the system during hardware setup. In order to manage device drivers through Device Manager, you must be a member of the Administrators group.

Some hardware cannot handle dynamic resource assignments. However, these resource assignments can be assigned through Device Manager.

Device Manager manages devices on a local computer only. On a remote computer, Device Manager works only in read-only mode.

The following table lists some of the major device classes that Device Manager tracks. Each of these classes has a corresponding class GUID value in the Windows registry.

**Device Manager Class**

| Class | Description |
|---|---|
| Battery Devices | Batteries and UPS devices. |
| Biometeric Device | Biometric-based personal identification devices. |
| Bluetooth Devices | Bluetooth devices. |
| CD-ROM Drives | CD-ROM drives, including SCSI CD-ROM drives. |
| Disk Drives | Hard disk drives. |
| Display Adapters | Video adapters installed on the system. |
| DVD/CD-ROM drives | CD-ROM drives, including SCSI CD-ROM drives, and DVD drives. |
| Floppy Disk Controllers | Floppy disk drive controllers. |
| Floppy Disk Drives | Floppy disk drives. |
| Hard Disk Controllers | Hard disk controllers, including ATA/ATAPI controllers (not SCSI or RAID disk controllers, which have their own Class). |

| | |
|---|---|
| Human Interface Devices | Interactive input devices not operated by the system-supplied HID class driver, which includes USB devices that comply with USB HID Standard and non-USB devices that use a HID minidriver. |
| Imaging Device | Still-image-capture devices, digital cameras, and scanners. |
| IrDA Devices | Infrared devices, including Serial-IR and Fast-IR NDIS miniports. The Network Adapter class displays other NDIS NIC miniports. |
| Keyboards | Keyboard device. |
| Media Changers | SCSI media changer devices. |
| Memory Technology Driver | Memory devices, such as flash memory cards. |
| Monitors | Each of the monitors. Specifies the features of a particular monitor to be stored in the registry for use by drivers of video adapters. |
| Mouse | Mouse devices and other pointing devices, such as trackballs. |
| Multifunction Devices | Combination cards, such as a PCMCIA modem and network card adapter. |
| Multimedia | Audio and DVD multimedia devices, joystick ports, and full-motion video capture devices. |
| Network Adapters | Network adapters, including NDIS NIC miniport drivers, excluding Fast-IR miniport drivers, NDIS intermediate drivers (of virtual adapters), and CoNDIS MCM miniport drivers. |
| PCMCIA Adapters | PCMCIA and CardBus host controllers, but not PCMCIA or CardBus peripherals. |
| Ports (COM & LPT) | Serial and parallel ports. |
| Printers | All printers. |
| Processors | Processor types. |
| SCSI and RAID controllers | SCSI HBAs (Host Bus Adapters) and disk-array controllers. |
| Smart Card Readers | Smart card readers. |
| Storage Volumes | Storage volumes defined by the system-supplied logical volume manager and class drivers that create device objects to represent storage volumes, such as the system disk class driver. |
| System Devices | HALs, system buses, system bridges, the system ACPI driver, and the system volume manager driver. |
| USB | USB host controllers and USB hubs, but not USB peripherals. |
| Windows CE USB ActiveSync Devices | Windows CE ActiveSync devices. |

For a complete list of the system-supplied device setup classes, along with their class GUID entries in the registry, see "Microsoft Windows Driver Development Kits" on the Microsoft Web site.

**Device Management Architecture**

The following diagram shows an overview of how device drivers and device management components are organized on a system.

**Device Management Architecture**

**Device Management Components**

The following table describes the components used for managing devices.

**Device Management Architecture Components**

| Component | Description |
|---|---|
| Hardware Abstraction Layer (HAL) | A component based on the Windows NT operating system that provides platform-specific support for the Windows NT kernel, I/O Manager, kernel-mode debuggers, and the lowest-level device drivers. The HAL exports routines that abstract platform-specific hardware details about caches, I/O buses, interrupts, and so forth. The HAL provides an interface between the platform's hardware and the system software. For example, the HAL implements a routine to map each device driver's bus-relative device interrupt vector to a system-assigned vector with a corresponding platform-specific hardware priority (DIRQL). The HAL also provides several routines that provide DMA transfer support. |
| Device Drivers | Files used to communicate between devices and Windows Server 2003. Drivers are structured under the Windows Device Model (WDM). The three WDM driver types are bus driver, function driver, and filter driver. |
| I/O Manager | Subsystem that controls and interacts with all devices on the system and provides routines that drivers can call to have the I/O Manager insert IRPs into the associated device queue. |
| Plug and Play Manager | Component responsible for determining the hardware resources requested by each device (for example, input/output ports [I/O], interrupt requests [IRQs], direct memory access [DMA] channels, and memory locations) and assigning hardware resources appropriately. Plug and Play Manager reconfigures resource assignments when necessary, such as when a new device added to the system requires resources already in use. |
| Power Manager | Component responsible for managing power usage for the system. Power Manager administers the system-wide power policy and tracks the path of power IRPs through the system. |
| Device Manager | Interface displaying the computer's hardware configuration information. The Device Manager display is recreated each time the computer is started or whenever a dynamic change to the computer configuration occurs, such as addition of a new device while the system is running. Device Manager is used to enable or disable devices, troubleshoot devices, update drivers, use driver rollback, and change resources such as interrupt requests (IRQs) assigned to devices. |

**Device Management Scenarios**

This section contains descriptions of some common scenarios for device management.

**Viewing system devices**

Device Manager provides a quick view of a system and all the hardware devices installed. Device Manager also provides information about the version of the driver installed, the provider, and digital signature, if any.

**Troubleshooting driver problems**

Device Manager automatically flags the status of a device so that you can readily detect where hardware problems or conflicts occur.

**Updating device drivers**

Device Manager allows you to manage the devices on your system by allowing you to check a specific location, such as Windows Update or a CD, for updated device drivers. Updated device drivers are then automatically installed and resources reallocated.

**New Storage Device Drivers in Windows Server 2003**
New and updated storage device drivers are available for Windows Server 2003, including drivers for iSCSI and Multipath I/O (MPIO) technologies. Windows Server 2003 also includes a new port driver model, Storport.

### Note

- The Microsoft Storage Server 2003 Web site has the most recent information about storage devices and drivers, as well as storage architecture.

Storage architecture consists of a series of layered drivers, as shown in the following figure. When a storage device is added, each layer is responsible for ensuring that the disk is functional.

### Windows Storage Stacks

The following table describes the components of the previous diagram.

### Windows Storage Stacks Components

| Component | Description |
|---|---|
| I/O Subsystem | Sends I/O requests to the file system. |
| File System | Structure of a disk, either FAT or NTFS. File systems access and manage all data on the disk, including information about the structure of the disk itself. |
| Volume Snapshot | Manages software snapshots. |
| Volume Manager | Presents volumes to users; supports basic and dynamic disks. |
| Partition Manager | Manages disk partitions. |
| Class | Manages specific devices types, such as disks and tapes. |
| Port | Manages specific transports, such as SCSIport or Storport. |
| Miniport | Vendor-supplied functionality linked to a specific port driver. Manages hardware-specific details. |
| Disk Subsystem | Disk processes such as read/write. |
| Device Stack | Stack layers that manage storage devices. |

| | |
|---|---|
| Driver Stack | Chain of drivers that support the operations of a device. |

**Storport**

The Storport driver is new to Windows Server 2003. Storport implements an architecture designed for better performance for RAID systems and in Storage Area Network (SAN) environments. Storport delivers higher I/O throughput, enhanced manageability, and an improved miniport interface. Storport better utilizes faster adapters through the use of reduced Delay Procedure Call (DPC) and improved queue management.

**iSCSI**

Internet Small Computer System Interface (iSCSI) is an alternative to Fibre Channel protocols. iSCSI is used to transfer data storage over long distances, making it a key contributor to the advancement and growth of storage area networks (SANs). iSCSI is also used to transmit data over local area networks (LANs), wide area networks (WANs), or the Internet.

Microsoft released the Microsoft iSCSI Software Initiator in June 2003 for Windows 2000, Windows XP, and Windows Server 2003. The Microsoft iSCSI Software Initiator is not included with Windows Server 2003, but you can download the driver from the Microsoft Download site. Customers should ensure that the hardware included in their iSCSI solution has passed the Designed for Windows Logo Program qualification tests.

**Multipath I/O**

Microsoft Multipath I/O architecture allows hardware manufacturers to develop highly available storage devices that can be added easily to a computer running Windows 2000 or Windows Server 2003. The Multipath I/O (MPIO) DDK consists of three standard drivers plus a fourth, device-specific driver that a storage vendor will use to create a Microsoft MPIO solution that works with the specific storage array it supports.

Microsoft MPIO enables the use of multiple physical paths from a server to a storage device. A physical path includes adapters, cables, and switches that connect the storage device to the server. In the event that one of the components in a path fails, all subsequent I/O is routed over an alternate path, providing applications uninterrupted access to the data on the storage device. In addition, Microsoft MPIO can be used to balance I/O operations over these paths using methods and algorithms defined by the storage vendor.

# Device Driver Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft Windows Server 2003 uses device drivers to interact with hardware devices, such as displays and keyboards. Rather than access devices directly, Windows loads device drivers and calls functions in the drivers to carry out actions on the devices. Each device driver exports a set of functions; Windows calls these functions to complete an action, such as drawing a circle on a display or translating a keyboard scan code. The driver functions contain the device-specific code needed to carry out actions on the device.

Windows requires device drivers for the display, keyboard, and communication ports. Other drivers may also be required if the user adds optional devices to the system.

# What Is a Device Driver?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is a Device Driver?**

**In this section**

- Device Driver Dependencies and Interactions
- Related Information

A device driver is a component that Windows uses to provide I/O services for and interact with an underlying device, such as a modem or network adapter. Rather than access the device directly, Windows loads device drivers and calls functions in the drivers to carry out actions on the device. The driver functions contain the device-specific code needed to carry out actions on the device. Device drivers for Windows Server 2003 are usually library files with .sys filename extensions.

Windows Server 2003 installs and configures device drivers automatically. This saves you from needing to allocate resources manually or check for conflicts in devices.

Windows Server 2003 checks for a digital signature during device driver installation and issues a message if the driver is not signed. Windows Server 2003 checks a database of known problem drivers when a computer is started or when a device driver is loaded; if a driver is located in the database of known problem drivers, that driver cannot be loaded, installed, or used on the computer.

**Device Driver Dependencies and Interactions**

**Plug and Play**

For automatic configuration of device drivers to occur, the system should have a BIOS compatible with Plug and Play. Plug and Play technology provides software and hardware support that enables the Windows operating system to detect and configure the hardware with little or no user involvement. This makes it easier to add and configure hardware on a computer running Windows Server 2003 without needing special knowledge about hardware configurations.

**Power Management**

Windows Server 2003 offers enhanced power-management features for desktop and mobile computers. The operating system supports the Advanced Configuration and Power Interface (ACPI) specification, which provides reliable power management and system configuration features. Devices and drivers designed in compliance with the ACPI specification work with the operating system to respond to or request changes in the system power state.

The following illustration shows a system-wide overview of how device drivers interact with other components of a system running Windows Server 2003.

**Device Drivers**

The following table describes the components used for installing and managing devices and drivers.

**Device Driver Components**

| Component | Description |
|---|---|

| | |
|---|---|
| Hardware Abstraction Layer (HAL) | A component based on the Windows NT operating system that provides platform-specific support for the Windows NT kernel, I/O Manager, kernel-mode debuggers, and the lowest-level device drivers. The HAL exports routines that abstract platform-specific hardware details about caches, I/O buses, interrupts, and so forth. The HAL provides an interface between the platform's hardware and the system software. For example, the HAL implements a routine to map each device driver's bus-relative device interrupt vector to a system-assigned vector with a corresponding platform-specific hardware priority (DIRQL). The HAL also provides several routines that provide DMA transfer support. |
| Device Drivers | Files used to communicate between devices and Windows Server 2003. Drivers are structured under the Windows Device Model (WDM). The three WDM driver types are bus driver, function driver, and filter driver. |
| I/O Manager | Subsystem that controls and interacts with all devices on the system and provides routines that drivers can call to have I/O Manager insert IRPs into the associated device queue. |
| Plug and Play Manager | Component responsible for determining the hardware resources requested by each device (for example, input/output ports [I/O], interrupt requests [IRQs], direct memory access [DMA] channels, and memory locations) and assigning hardware resources appropriately. Plug and Play Manager reconfigures resource assignments when necessary, such as when a new device added to the system requires resources already in use. |
| Power Manager | Component responsible for managing power usage for the system. Power Manager administers the system-wide power policy and tracks the path of power IRPs through the system. |
| Device Manager | Interface displaying the computer's hardware configuration information. The Device Manager display is recreated each time the computer is started or whenever a dynamic change to the computer configuration occurs, such as addition of a new device while the system is running. Device Manager is used to enable or disable devices, troubleshoot devices, update drivers, use driver rollback, and change resources such as interrupt requests (IRQs) assigned to devices. |

# How Device Drivers Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Device Drivers Work**

**In this section**

- Device Driver Architecture
- Device Driver Physical Structure
- Device Driver Processes and Interactions
- Related Information

A device driver is a component that Windows uses to interact with a hardware device, such as a modem or network adapter. Rather than access the device directly, Windows loads device drivers and calls functions in the drivers to carry out actions on the device. Each device driver exports a set of functions; Windows calls these functions. The driver functions contain the device-specific code needed to carry out actions on the device.

**Driver Signing and Digital Signatures**

Windows Server 2003 includes many features that help to ensure that the device drivers installed on a computer are reliable and up to date.

Drivers are signed by Microsoft after they pass a series of tests for functionality and reliability. For a driver to earn this certification, it must pass a series of tests administered by the Windows Hardware Quality Labs (WHQL). Due to stringent WHQL standards, using signed drivers typically results in a more stable system. Microsoft digitally signs drivers that pass the WHQL tests and Windows Server 2003 performs signature detection for signed drivers for various device types, which include the following:

- Keyboards
- Hard disk controllers
- Modems
- Mouse devices
- Multimedia devices
- Network adapters
- Printers
- SCSI adapters
- Smart card readers
- Video adapters

**Note**

- During installation of some hardware devices, you may be prompted to choose **Ignore** on the driver signing dialog box. This indicates that the driver has not gone through digital signing.

A digital signature indicates that a driver file is an original, unaltered system file that Microsoft has approved for use with Windows Server 2003.

Windows Server 2003 checks for a digital signature during device driver installation and issues a message if the driver is not signed. Windows Server 2003 checks a database of known problem drivers when a computer is started or when a device driver is loaded; if a driver is located in the database of known problem drivers, that driver cannot be loaded, installed, or used on the computer.

Updated versions of signed drivers are available for download from the Windows Update Web site.

**Device Driver Architecture**
The Windows Server 2003 I/O system provides a layered architecture for serial device drivers, consisting of the drivers and their corresponding device objects.

**Plug and Play Drivers**
Plug and Play supports three types of drivers:

- Function drivers, which drive individual devices
- Filter drivers, which filter I/O requests for devices, classes of devices, and buses
- Bus drivers, which service bus controllers, adapters, and bridges

The most common bus driver types are PCI, PnP ISA, SCSI, and USB. During enumeration, a bus driver identifies the devices on its bus and creates device objects for them.

**Device Objects**
A driver creates a device object (DO) for each device it controls; the device object represents the device to the driver. Plug and Play recognizes three types of device objects:

- Physical device objects (PDOs), which represent individual devices on a bus to a bus driver
- Functional device objects (FDOs), which represent individual devices to a function driver
- Filter device objects (filter DOs), which represent individual devices to a filter driver

The following figure shows a chain of attached device objects and drivers for a Plug and Play device.

**Device Objects in a Device Stack**

The device stack includes a device object for each driver involved in handling the I/O to a particular device.

**Components for Device Objects in a Device Stack**

| Component | Description |
|---|---|
| Lower-level filter driver | Optional filter driver, loaded after the bus driver and any bus driver filters. There are two types of filters, device-specific and per-class. A lower-level device-specific filter monitors and/or modifies I/O requests to a particular device; typically, such filters redefine hardware behavior to match specifications. A lower-level per-class filter monitors and/or modifies I/O requests for a class of devices; for example, a lower-level class filter driver for mouse devices could provide acceleration, performing a nonlinear conversion of mouse movement data. |

| | |
|---|---|
| Upper-level filter driver | Optional filter driver, loaded after the function driver, which attaches its device object above the FDO. There are two types of upper-level filters, device-specific and per-class. An upper-level device filter driver adds value for a particular device; for example, an upper-level device filter for a keyboard could enforce additional security checks. An upper-level per-class filter adds value for all devices of a particular class. |

For Plug and Play devices, the device object at the bottom of the device stack is the PDO created by the underlying bus driver. The FDO is created by the function driver for the device. Filter DOs are attached above and below the FDO.

The PDO is created by the underlying bus driver when it enumerates the device. The FDO and filter DOs are created by FDOs or filter DOs for devices enumerated by the Plug and Play Manager

**Device Driver Physical Structure**

The following figure shows how device drivers operate in both kernel mode and user mode.

**Device Driver Physical Structure**

The following table describes the components of the preceding Device Driver Physical Structure diagram.

**Components for Device Drivers**

| Component | Description |
|---|---|
| Win32 API | 32-bit application programming interface for Windows operating systems that initiates I/O operations through Ntdll |
| Ntdll | Function library that exposes stubs that invoke Windows system calls (like NtReadFile below) as exported functions |
| NtReadFile | I/O Manager system call that creates an I/O request packet and directs it to the appropriate driver |
| I/O Manager | Subsystem that controls and interacts with all devices on the system and provides routines that drivers can call to have the I/O Manager insert IRPs into the associated device queue |
| IRP | I/O Request Packet sent by I/O Manager to request services from a driver |
| IoCallDriver | Routine that sends an IRP to the driver associated with a specified device object |

Once the request has been processed, the outcome is one of three results:

**Queue for later process**

The device driver defers the request processing to a later time; for example, when necessary resources are available, or the device is not busy.

**Send to hardware port**
The device driver programs the hardware to perform the operation specified in the request.

**Send to another device driver**
The device driver sends the request to another device driver; for example, if the request parameters change.

**Device Driver Processes and Interactions**
This section describes device driver processes and interactions for computers running Windows Server 2003.

**How Windows Server 2003 Installs Device Drivers**
Windows Server 2003 automatically configures a device so that it will work properly with other devices that are installed on the computer. As part of the configuration process, Windows assigns a unique set of system resources to each device so that it can function with little or no user input.

Windows Server 2003 device drivers included on the Setup CD are stored in a single cabinet file, Driver.cab. This file is used by Setup and other system components as a driver file source. Information files (.inf files) are searched when Windows Server 2003 starts or new hardware is detected. These text files provide the names and locations of driver-related files and the initial settings required for new devices to work. During setup, Driver.cab is copied from the installation CD to the WINNT\Driver Cache*platform* directory of the local hard disk. The variable *platform* here is a placeholder for a specific value that reflects the architecture of the system: for example, i386.

Device drivers are installed with no user intervention if certain conditions are met:

- Installing the driver does not require showing a user interface.
- The driver package contains all files needed to complete the installation.
- The driver package is available on the system in the Driver.cab file or was previously installed.
- The driver package is digitally signed.
- No errors occur during installation.

If any of the conditions is not met, the device installation restarts and the user might need to respond to dialog boxes or messages. Manual installation of a driver requires that the person installing the driver be a member of the Administrators group.

Windows Server 2003 determines which device driver to load for a device using the following criteria.

- Driver ranking schemes
- Driver search location policies
- Windows Driver Protection
- Windows Update

To facilitate device installation, devices that are set up and configured in the same way are grouped into a device setup class. For example, SCSI media changer devices are grouped into the MediumChanger device setup class.

**How Device Drivers Are Processed**
Microsoft uses a multistage process to test device drivers. Drivers are subjected to compatibility, reliability, and functionality tests administered by the Windows Hardware Quality Lab (WHQL). Drivers that successfully complete the process are digitally signed. Because of this testing, signed drivers are typically more robust and reliable. Once a driver is digitally signed, Windows Server 2003 recognizes it when it is loaded. Windows Server 2003 will notify a user if a driver is not signed or if a driver file has been changed since its inclusion on the Microsoft Hardware Compatibility List (HCL).

The digital signature is associated with an individual driver version and certifies that the driver provided with the device is identical to the driver that was tested.

**Driver Signature Checking**

Driver Signature Checking enables you to detect unsigned drivers before you install them. You can set verification levels for driver signature checking to ensure that Windows Server 2003 inspects files for digital signatures whenever you install or update drivers.

Signature Checking Levels are set to one of three categories, as described in the following table. These levels apply to processing both signed and unsigned drivers.

**Signature Checking Levels**

| Level | Description |
|---|---|
| Level 0 (Ignore) | Disables digital signature checking. Setup silently checks the signature on the driver, logs any unsigned driver files to a log file, and allows installation of the driver even if the driver is unsigned. |
| Level 1 (Warn) | Checks the signature on the driver before installation by checking whether the driver has passed WHQL testing. A message appears whenever a user tries to install a driver that fails a signature check. The driver can still be installed; however, this is not recommended. |
| Level 2 (Block) | Blocks installation of a driver that fails a signature check. The user is notified that Windows Server 2003 cannot install the unsigned driver. |

**Note**

- Warn is the default setting. You can change the signature-checking policy for a user without administrator permissions, but you must have administrator permissions to change the driver-signing policy for a computer.

**Verifying File Signatures**

The File Signature Verification Tool (Sigverif.exe) detects signed files and allows you to do the following:

- View the certificate of a signed files to verify that the file has not been tampered with after being digitally signed
- Search for signed files in a specific location
- Search for unsigned files in a specific location

**How Drivers are Ranked**

Windows Server 2003 uses driver ranking schemes to determine which driver to load when multiple drivers are available for a device. Drivers are ranked by whether they are signed and how closely their Plug and Play ID matches the device's Plug and Play ID. The Plug and Play ID of a driver or device consists of hardware IDs and compatible IDs. If the hardware ID of the driver exactly matches one of the hardware IDs of the device, there is a hardware match. If some other match occurs (for example, device compatible ID to driver compatible ID) there is a compatible match. Driver rank also depends on whether the device information file (.inf file) for the device includes information specifically for installations in a Windows Server 2003 environment. If multiple drivers for a device exist, the lowest ranking driver — the driver with the highest chance of optimum functionality — is installed.

The following table summarizes the driver ranking scheme for Windows Server 2003 from lowest (best match) to highest.

**Windows Server 2003 Driver Ranking Scheme**

| Rank | Description |
|---|---|
| 1 | Signed driver with a hardware match to a device |
| 2 | Signed driver with a compatible match to a device |
| 3 | Unsigned driver with a hardware match to the device, with Windows Server 2003 targeted in the INF section |
| 4 | Unsigned driver with a compatible match to the device, with Windows Server 2003 targeted in the INF section |
| 5 | Unsigned driver with a hardware match to the device, without Windows Server 2003 targeted in the INF section |

| | |
|---|---|
| 6 | Unsigned driver with a compatible match to the device, without Windows Server 2003 targeted in the INF section |

**How Driver Protection Affects Applications**

Windows Driver Protection prevents the installation of drivers known to cause instabilities when installed under Windows Server 2003. Windows Server 2003 includes a list of such drivers, known as the Driver Protection List, which is checked at the following times.

- During installation of Windows Server 2003
- Each time the system is rebooted
- Each time a device or application is installed

Driver Protection compares each driver that attempts to load under Windows Server 2003 against the Driver Protection List before loading that driver. The comparison and matching happen using the criteria in the following table.

**File Attributes Matched by Driver Protection**

| Key | Meaning |
|---|---|
| SYS_NAME | File name of the driver file. |
| BIN_PRODUCT_VERSION | Product version of the driver file. |
| UPTO_BIN_PRODUCT_VERSION | Superset of the BIN_PRODUCT_VERSION. Represents all product versions of the driver file that are less than or equal to the version specified. |
| LINK_DATE | Link date of the driver file. LINK_DATE appears to the operating system as a more accurate and consistent value than BIN_PRODUCT_VERSION, primarily due to the various ways versioning information can be stored. LINK_DATE is consistently set by the linker. |
| UPTO_LINK_DATE | Superset of LINK_DATE. Represents all link dates of the driver file that are less than or equal to the date specified. |

If Driver Protection finds a match for a driver in the Driver Protection List, the following occurs:

- The driver is not loaded under Windows Server 2003.
- The operating system logs an event in the Event Log.
- A notification is displayed to the user.

Windows Driver Protection is a low-level kernel feature that was designed to be the last resort for protecting a Windows Server 2003 system from errant drivers. Driver Protection will block known problem drivers from loading, but it does not block any associated applications that might depend on those drivers. Therefore, the behavior of applications that depend on blocked drivers will vary depending on the implementation of the application.

Some applications — such as antivirus programs — install drivers in order to provide their core functionality. Other applications — such as CD-burning applications — use drivers for portions of their feature sets. If a driver does not load, the former category of application might not work at all, while the latter might work for features that do not depend on the driver. Because Microsoft works closely with the driver and application vendors to implement fixes, in most cases the application vendor will have an updated version compatible with Windows Server 2003 available on the vendor's Web site for download.

Most applications that ship drivers on the Driver Protection List will already be in the Windows Server 2003 application compatibility database. Users will get warnings whenever these applications are installed or run. However, because many drivers are sublicensed to multiple application vendors, Microsoft may not have information about every application that includes the driver. Therefore, for some applications, only the Driver Protection warning will appear.

The Driver Protection List database is updated through Microsoft Windows Update. Drivers are added to the Driver Protection List based upon feedback from users about problems that can be reproduced and confirmed by Microsoft. Whenever a system connects to the Windows Update Web site, the system's driver protection list is updated. If a driver on the list was previously installed, the driver will be disabled and the user will be told how to obtain a new driver.

**How Drivers are Located**
Driver search location policies are Group Policies that specify where to search for new or updated device drivers. Group Policy can be configured to search a local machine and/or Windows Update, as well as turning off this policy.

**Windows Update**
The Windows Update Web site provides a central location for product enhancements, such as device drivers.
Windows Server 2003 users can install or update drivers from the Windows Update Web site. When a user accesses the Windows Update Web site, Windows Update compares the drivers installed on a user's system with the latest updates available. If newer drivers are found, Windows Update offers the list of applicable drivers to the user.

Drivers are included on Windows Update only if they are digitally signed, they have passed the testing requirements for the Windows Logo Program, and the vendor has given Microsoft redistribution rights for those drivers. This helps to ensure that the drivers offered from Windows Update are of high quality and reliability.

Devices each have a hardware ID that uniquely identifies the device, which is identified in the .inf file for the driver. Drivers that have a hardware or compatible match with the device, such as a device hardware ID to driver hardware ID, are candidates for download and installation. If a hardware or compatible match exists, Windows Update determines whether the driver on Windows Update is newer than the installed one. If the driver on Windows Update is newer, the driver is presented to the user for potential download. Also, if the hardware ID for the driver on Windows Update is a better match than the installed one, Windows Update offers that driver to the user. If the user chooses to install the offered driver, the file is downloaded, and the Windows Update ActiveX control points Device Manager to the .inf file for installation.

# Device Driver Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Device Driver Tools and Settings**

**In this section**

- Device Driver Tools
- Device Driver Registry Entries
- Device Driver Group Policy Settings
- Device Driver WMI Classes
- Related Information

This section describes tools, registry entries, Group Policy settings, and Windows Management Instrumentation (WMI) classes associated with device drivers.

**Device Driver Tools**

The following tools are associated with device drivers.

**ChkINF.exe: INF File Syntax Checker**

**Category**

ChkINF.exe ships with the Windows Driver Development Kit.

**Version compatibility**

Windows 2000, Windows XP, and Windows Server 2003

ChkINF checks the structure and syntax of Windows Server 2003 driver .inf files. Results are presented in HTML format and include a list of the errors and warnings detected in each .inf file, with each error and warning shown next to the errant .inf file entry.

**DevCon.exe: Device Console**

**Category**

Device Console ships with the Windows Driver Development Kit.

**Version compatibility**

Windows 2000, Windows XP, and Windows Server 2003

Device Console (Devcon) is a command-line tool that displays detailed information about devices and lets you search for and manipulate devices from the command line. Devcon enables, disables, installs, configures, and removes devices on the local computer and displays detailed information about devices on local and remote computers.

For more information about Devcon.exe and the syntax used to carry out commands, see the Windows Driver Development Kit.

**GenINF.exe: INF File Creation Wizard**

**Category**

GenINF ships with the Windows Driver Development Kit.

**Version compatibility**

GenINF generates .inf files for Windows 2000, Windows XP, and Windows Server 2003.

GenINF is a GUI-based tool that guides users through the process of creating device driver .inf files. GenINF does not generate fully valid .inf files. However, the skeleton .inf files that it generates should help developers complete their device driver .inf files.

GenINF is located in the \Tools subdirectory of the DDK installation directory. Because GenINF is GUI-based, you can execute it from within the Windows Server 2003 user interface or from the command prompt. The command to start GenINF takes no arguments. GenINF supports all device classes but includes specific support for only certain device classes. For a list of these classes, see the Geninf.htm file located in the Tools\geninf subdirectory of the DDK.

For more information about GenINF.exe, see the Windows Driver Development Kit.

**SigVerif.exe: File Signature Verification**
**Category**
Operating system tool

**Version compatibility**
Windows XP, Windows 2000, and Windows Server 2003

File Signature Verification checks to see which system files and device driver files are digitally signed and displays its findings. If you have enabled logging, the search results are also written to a log file.

**Device Driver Registry Entries**
The following registry entries are associated with device drivers.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools — such as Microsoft Management Console (MMC), Device Manager, or the software that accompanies a device — to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

### Note

- Because many of the device driver subkeys and registry entries are hardware-specific, the following section contains only a partial list of registry keys and entries.

**Enum**
This registry key is located at HKEY_LOCAL_MACHINE\SOFTWARE\Enum.

This class key stores the enumeration information for Plug and Play devices. Under Enum, each enumerator gets its own branch, with one child under the enumerator for each device it has ever enumerated and set up. There is a special enumerator branch, Enum\Root; this branch contains registry entries for legacy hardware that is not Plug and Play for which there is no enumerator but that can be detected using other means. Device Installer creates new registry entries when an enumerator detects a device for which there is no registry entry.

**Class**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Class.

The Class subkey stores configuration data for classes of hardware devices displayed in Device Manager.

Each subkey in the Class subkey represents a device class and is named by the globally unique identifier (GUID) for the class: a 16-byte value generated from the unique identifier on a device, the current date and time, and a sequence number. A GUID is used to identify a particular device or component.

**{Class-GUID}**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Class

**Version**
Microsoft Windows NT 4.0 Server and Windows NT 4.0 Workstation and later

The {*Class-GUID*} subkey represents the component associated with the class-GUID.

Each {*Class-GUID*} subkey in the Class subkey represents a device class and is named by the GUID for the class, which is a 16-byte value generated from the unique identifier on a device, the current date and time, and a sequence number. A GUID identifies a particular device or component.

It appears as a 16-digit alphanumeric string within curly braces. These {*Class-GUID*} subkeys store configuration data that apply to the entire class of devices, such as the class of all modems.

Within the {*Class-GUID*} subkeys are 4-digit numbered subkeys, which represent particular devices that are instances of the class. These subkeys store data that apply only to that device.

Because the Class subkey is hardware-specific, its contents vary widely and it is dependent upon the devices installed on a system.

**Services**
This registry key is located at HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services.

Services registry keys and entries define background operations by device drivers or other tasks. The Services key includes a number of subkeys for such services as ACPI or Plug and Play. Registry entries for each subkey vary, but each subkey may include some of the following registry entries.

**Description**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services*Subkey*

**Version**
Windows XP, Windows 2000, Windows Server 2003

Text field that displays the description of the service.

**DisplayName**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services*Subkey*

**Version**
Windows XP, Windows 2000, Windows Server 2003

Text field that displays the default service name.

**ErrorControl**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services*Subkey*

**Version**
Windows XP, Windows 2000, Windows Server 2003

Tells the system how to boot if a device driver fails. The following table lists the accepted values for this registry entry.

### ErrorControl Values

| Value | Description |
|---|---|
| 00 | Ignore. If the driver fails to load or initialize, then startup continues as normal and no warning message appears. |
| 01 | Normal. If the driver fails to load or initialize, then startup proceeds, but a warning message appears. |
| 02 | Severe. If the driver fails to load or initialize, then startup is declared to have failed and restarts by using the LastKnownGood control set. If startup is already using the LastKnownGood control set, then startup continues |
| 03 | Critical. If the driver fails to load or initialize, then startup is declared to have failed and restarts by using the LastKnownGood control set. If startup is already using the LastKnownGood control set, then startup stops and enters Debugging Mode. |

**Group**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services*Subkey*

**Version**
Windows XP, Windows 2000, Windows Server 2003

Specifies which group the service belongs to when a service is started

**ImagePath**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services*Subkey*

**Version**
Windows XP, Windows 2000, Windows Server 2003

Location of Services Control Manager, which uses the information located in the subkeys to initialize the services. The default path is %SystemRoot%\system32\services.exe.

**Start**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services*Subkey*

**Version**
Windows XP, Windows 2000, Windows Server 2003

Determines when a service should be started on a system. The following table lists the accepted values for this registry entry.

### Start Values

| Value | Description |
|---|---|
| 00 | Boot. Starts the service during the boot sequence. |
| 01 | System. Starts the service when loaded by the I/O subsystem in the kernel. |
| 02 | Automatic. Starts the service automatically. |
| 03 | Manual. Starts the service when a user initiates it from the control panel or a command line. |
| 04 | Disable. Loads the service, but neither the system nor a user can start it. |

**Type**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services*Subkey*

**Version**
Windows XP, Windows 2000, Windows Server 2003

Identifies the type of service. The following table lists the accepted values for this registry entry.

### Type Values

| Value | Description |
|---|---|
| 01 | Kernel-mode device driver |
| 02 | File system driver |
| 04 | Network adapter |
| 10 | Win32 service that can run as a standalone process |
| 20 | Win32 service that shares address space with other services at the same time |

**Device Driver Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with device drivers.

### Group Policy Settings Associated with Device Drivers

| Group Policy Setting | Description |
|---|---|
| Administrator_Power_Policy | Defines limits to certain power policy values that are applied globally to all users' power schemes. |
| Global_Machine_Power_Policy | Contains global computer power policy settings that apply to all power schemes for all users. |
| Global_Power_Policy | Contains global power policy settings that apply to all power schemes. |
| Global_User_Power_Policy | Contains global user power policy settings that apply to all power schemes. |
| Machine_Power_Policy | Contains computer power policy settings that are unique to each power scheme on the computer. |

| | |
|---|---|
| Machine_Processor_Power_Policy | Contains processor power policy settings that apply while the system is running on AC power or battery power. |
| Power_Action_Policy | Contains information used to set the system power state. |
| Power_Policy | Contains power policy settings that are unique to each power scheme. |
| Processor_Power_Policy | Contains information about processor performance control. |
| Remove Computer from Docking Station | Determines whether a user can undock a portable computer from its docking station without logging on. If this policy is set, the user must log on before removing the portable computer from its docking station. If this policy is not set, the user can remove the portable computer from its docking station without logging on. |
| Allow undock without having to log on | Determines whether a user must log on to request that a portable computer be removed from a docking station. If this policy is not set, the user must log on to request an undock, at which time the user must have been granted the Remove Computer from Docking Station privilege. If this policy is set, a user can request an undock by pressing the portable computer's physical eject button. |
| Allowed to format and eject removable media | Determines who is allowed to format and eject removable NTFS media. This capability can be given to Administrators, Administrators and Power Users, or Administrators and Interactive Users. |
| Prevent users from installing printer drivers | Determines who is allowed to install a printer driver as part of adding a network printer. For a computer to print to a network printer, the driver for that network printer must be installed on the local computer. If this policy is set, only Administrators and Power Users can install a printer driver as part of adding a network printer. If this policy is not set, any user can install a printer driver as part of adding a network printer. You can use this setting to prevent unprivileged users from downloading and installing an untrusted printer driver. |
| Restrict CD-ROM access to locally logged-on user | Determines whether a CD-ROM is accessible to both local and remote users simultaneously. If this policy is set, it allows only the interactively logged-on user to access removable CD-ROM media. If this policy is set and no one is logged on interactively, the CD-ROM can be accessed over the network. |
| Restrict floppy access to locally logged-on user only | Determines whether removable floppy media are accessible to both local and remote users simultaneously. If this policy is set, it allows only the interactively logged-on user to access removable floppy media. If this policy is set and no one is logged on interactively, the floppy can be accessed over the network. |
| Unsigned driver installation behavior | Determines what happens when an attempt is made to install a device driver (by means of Setup API) that has not been certified by the Windows Hardware Quality Lab (WHQL). |

**Device Driver WMI Classes**

The Windows Server 2003 Driver Development Kit (DDK) covers WMI classes that are associated with device drivers. For more information about the Windows Server 2003 device driver classes, see "Microsoft Windows Driver Development Kits" on the Microsoft Web site.

### WMI Classes Associated with Device Drivers

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| WMIBinaryMofResource | \root\wmi | Windows XP, Windows 2000 Professional, Windows Server 2000, Windows NT Server 4.0 SP4 and later, Windows Server 2003 |

# Plug and Play Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Plug and Play technology provides a combination of hardware and software support that enables applications and the system to recognize and adapt to changes in hardware configuration. With Plug and Play in Microsoft Windows Server 2003, you can add devices while the system is in use and leave the job of configuring and starting the hardware to the operating system.

In order to use Plug and Play to install new devices without user intervention, the computer hardware, the device drivers, and the BIOS must be compliant with Plug and Play specifications. If any of these components are not designed to support Plug and Play, devices can still be added to a computer, but they must be manually configured to work properly.

# What Is Plug and Play?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Plug and Play?**

**In this section**

- Common Plug and Play Scenarios
- Technologies Related to Plug and Play
- Related Information

Plug and Play technology provides a combination of software and hardware support that enables the Windows operating system to detect and configure hardware with little or no user involvement. Plug and Play makes it easier to add and configure hardware on a computer running Microsoft Windows Server 2003 without the user needing special knowledge about hardware configurations. Plug and Play in Windows Server 2003 supports a wide range of device types.

The Plug and Play framework defines several base components that can be implemented in any environment. Buses, devices, and resources are abstracted from the base components via hardware-specific enumerators, arbitrators, and device drivers. This ensures that the framework is extensible not only to other environments but to future bus and device architectures.

In Windows Server 2003, Plug and Play provides the following services.

- Detection of a Plug and Play device
- Determination of hardware resource requirements
- Determination of device identification number
- Allocation of hardware resources
- Dynamic loading, initialization, and unloading of drivers
- Notification to other drivers and applications when a new device is available
- Coordination with power management components to install and remove devices

Some bus types, such as Peripheral Component Interconnect (PCI) and USB, take full advantage of Plug and Play. Older bus types, such as ISA, do not take full advantage of Plug and Play and require more user interaction to ensure that devices are correctly installed.

After Windows Server 2003 detects a Plug and Play device, the device driver is configured and loaded dynamically, typically without requiring user input.

The following diagram shows the Plug and Play states of a device after initialization.

**Plug and Play Device States**

The following table describes the Plug and Play states for a device.

**Plug and Play Device States**

| State | Description |
|---|---|
| Start State | After it has assigned all necessary hardware resources to the device, the Plug and Play Manager sends an I/O request packet (IRP) indicating that all drivers for the device have performed their start operations. The device may have been recently enumerated and is being started for the first time, or the device may be restarting after being stopped for resource rebalancing. |
| Remove-Pending State | The Plug and Play Manager sends a requests to the drivers to remove a device's software representation (device objects, and so forth). The Plug and Play Manager sends this IRP when a device has been removed in an orderly fashion (for example, initiated by a user in the Unplug or Eject Hardware program), when a device has been removed by surprise (a user pulls the device from its slot without prior warning), or when the user makes a request to update drivers. |
| Surprised-Removed State | The Plug and Play Manager sends a request to notify drivers that a device is no longer available for I/O operations and has probably been unexpectedly removed from the machine. In response to this request, the drivers power off the device and perform additional removal processing. |
| Stop-Pending State | The Plug and Play Manager sends a request asking whether the drivers for a device can stop the device. If all the drivers in the device stack return a confirmation, the drivers put the device into a stop-pending state, from which the device can be stopped quickly. |
| Stopped State | Plug and Play Manager requests that drivers for a device driver hold IRPs that require access to the device. |

**Common Plug and Play Scenarios**

Plug and Play works automatically by default on computers running Windows Server 2003. The following are the most common scenarios in which Plug and Play is used.

**Adding new hardware to a computer**

In Windows Server 2003, Plug and Play installs most hardware devices that can be loaded at a time other than during the system startup process. If the hardware is compliant with Plug and Play, Windows Server 2003 will automatically detect and configure the new hardware once it is connected to the system. Plug and Play devices are capable of identifying themselves and declaring their services and resource requirements to the operating system. This information enables Windows Server 2003 to determine and set a working configuration, then load the appropriate device drivers without user intervention.

**Docking a mobile computer**

The Plug and Play framework allows docking of mobile computers and insertion of devices while the computers are running. When such a connection occurs, Windows Server 2003 will recognize that a device is connected, recognize the services and requirements, and load the necessary drivers. Applications are notified about dynamic events so that they can take advantage of new functionality or start using available devices.

**Technologies Related to Plug and Play**

In Windows Server 2003, Plug and Play support is optimized for computers that include an Advanced Configuration and Power Interface (ACPI) BIOS. ACPI devices are defined by the Advanced Configuration and Power Interface (ACPI) Specification, a hardware and software interface specification that combines and enhances the Plug and Play and Advanced Power Management (APM) standards. ACPI devices include low-level system devices such as batteries, thermal zones, and other devices defined in a system's *ACPI namespace,* a hierarchical namespace that an ACPI BIOS uses to reference objects. ACPI shifts many power management tasks to the operating system and provides the following features.

- Automatic and dynamic recognition of installed hardware
- Hardware resource allocation and reallocation
- Loading of appropriate drivers
- Interface for driver interaction with the Plug and Play system
- Dynamic handling of device management and power management events

### Note

- For all Plug and Play features to work, a system must include an ACPI-compliant BIOS that works with the ACPI to provide reliable power management and system configuration.

# How Plug and Play Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Plug and Play Works**

**In this section**

- Plug and Play Architecture
- Plug and Play Processes and Interactions
- Network Ports Used by Plug and Play
- Related Information

With Plug and Play under Microsoft Windows Server 2003, you can connect a hardware device to your system and leave the job of configuring and starting the device to the operating system. If the device and drivers are not designed to take advantage of Plug and Play, Windows Server 2003 will not be able to automatically configure and start the device. Plug and Play in Windows Server 2003 supports a wide range of devices.

In Windows Server 2003, Plug and Play support is optimized for computers that include an Advanced Configuration and Power Interface (ACPI) BIOS. ACPI devices are defined by the Advanced Configuration and Power Interface (ACPI) Specification, a hardware and software interface specification that combines and enhances the Plug and Play and Advanced Power Management (APM) standards. ACPI devices include low-level system devices such as batteries and thermal zones.

On x86-based computers, the interaction between the BIOS and Plug and Play is dependent on whether the system BIOS or the operating system configures the hardware.

The following table describes the recommended BIOS settings on x86-based systems.

**Recommended Plug and Play BIOS Settings on x86-based Systems**

| Condition | Recommended BIOS Setting |
|---|---|
| Fully compliant ACPI system (ACPI BIOS is present; ACPI Hardware Abstraction Layer (HAL) is installed.) | Windows Server 2003 assigns device resources and ignores BIOS settings. This includes assigning IRQ, DMA, and I/O resources and arbitrating conflicts for all PCI devices. |
| Non-compliant ACPI system (ACPI BIOS is present; compliance problems prevented ACPI HAL installation.) | The system BIOS assigns device resources prior to loading of the operating system, and the Plug and Play BIOS settings must be set to **No/Disabled**. If your devices have a static configuration, you must turn the computer off before removing or attaching these devices. |
| Non-ACPI systems | The system BIOS assigns device resources prior to the loading of the operating system, and the Plug and Play BIOS setting must be set to **No/Disabled**. If your devices have a static configuration, you must turn the computer off before removing or attaching these devices |
| Dual-boot Windows Server 2003, Windows Server 2003, and Microsoft Windows 98, or Windows Me operating systems | The Plug and Play BIOS setting must be set to **No/Disabled**. Disabling Plug and Play in the BIOS is the recommended method to prevent errors that may otherwise occur. For example, if the system check for Plug and Play on a Windows 98 ACPI system passes, the system check for Plug and Play might fail on a Windows Server 2003 system. |

Plug and Play detection runs with the logon process and relies on system firmware, hardware, device drivers, and operating system features to detect and enumerate new devices. ACPI firmware provides enhanced features, such as hardware resource sharing. When Plug and Play components are coordinated, Windows Server 2003 can detect new devices, allocate system resources, and install or request drivers with minimal user intervention.

**Plug and Play Architecture**

The following diagram shows the components that work together to support Plug and Play.

**Plug and Play Architecture**

The kernel-mode Plug and Play Manager maintains central control, directing bus drivers to perform enumeration and configuration and directing device drivers to add a device, start a device, and so on.

For example, Plug and Play Manager can send a request to determine whether a device can be safely paused or removed, and to give the device driver a chance to synchronize outstanding I/O requests to the incoming request. Plug and Play in kernel mode coordinates with Plug and Play in user mode to pause or remove devices that are available for such actions.

Drivers for Plug and Play devices do not assign resources; instead, the requested resources for a device are identified when the device is enumerated. When a device is enumerated, Plug and Play Manager retrieves the requirements for each device during resource allocation. Resources are not dynamically configurable for legacy devices, so Plug and Play Manager assigns resources to legacy devices first.

I/O Manager provides core services for device drivers. It is the kernel-mode component that translates user-mode read and write commands into read and write IRPs. I/O Manager manages all other main operating system IRPs.

The following table describes the components from the previous illustration, Plug and Play Architecture.

**Plug and Play Components**

| Component | Description |
|---|---|
| Hardware Abstraction Layer (HAL) | A component based on the Windows NT operating system that provides platform-specific support for the Windows NT kernel, the I/O Manager, kernel-mode debuggers, and the lowest-level device drivers. The HAL exports routines that abstract platform-specific hardware details about caches, I/O buses, interrupts, and so forth. The HAL provides an interface between the platform's hardware and the system software. For example, the HAL implements a routine to map each device driver's bus-relative device interrupt vector to a system-assigned vector with a corresponding platform-specific hardware priority (DIRQL). The HAL also provides several routines that provide DMA transfer support. |
| Windows Driver Model (WDM) | Driver files used to communicate between devices and Windows Server 2003 are structured under the Windows Device Model (WDM). The three WDM driver types are bus driver, function driver, and filter driver. WDM drivers must support Plug and Play, Power Management, and Windows Management Instrumentation (WMI). |

| | |
|---|---|
| Plug and Play Manager (Kernel) | Kernel-mode component responsible for determining the hardware resources requested by each device) and assigns resources appropriately. Reconfigures resource assignments when necessary, such as when a new device added to the system requires resources already in use.<br><br>The kernel-mode Plug and Play Manager interacts with the user-mode Plug and Play Manager by receiving control requests and notifying the user-mode Plug and Play Manager that a new device is present on the system that needs to be started. |
| I/O Manager | Subsystem that controls and interacts with all devices on the system and provides routines that drivers can call to have the I/O Manager insert IRPs into the associated device queue. |
| Power Manager | Component responsible for managing power usage for the system. Power Manager administers the system-wide power policy and tracks the path of power IRPs through the system. |
| Executive Components | The collection of kernel-mode operating system components. Executive components include executive support, the kernel, Memory Manager, Cache Manager, process structure, interprocess communication (LPC and RPC), Object Manager, I/O Manager, Configuration Manager, and Security Reference Monitor. Each executive component, with the exception of Cache Manager, supplies a specialized set of native system services. Every executive component also exports a set of kernel-mode support routines for use by other executive components. |
| Plug and Play Manager (User) | User-mode component that interacts with user-mode setup components, such as Class Installers, to configure and install devices, as well as interacting with applications to register notification of device changes or to notify the application when a device event occurs.<br><br>The user-mode Plug and Play Manager interacts with the kernel-mode Plug and Play Manager by sending control requests. |
| Win32 Services | Windows Server 2003 functionality that uses the Win32 API to manage resources on a computer. |

**Plug and Play Processes and Interactions**
The following section describes Plug and Play processes and interactions.

**How Plug and Play Detects and Installs a Device**
The following diagram shows how Plug and Play detects and installs a device.

**Plug and Play Driver Installation Process**

When a hardware device is connected — as when you plug a USB camera into a USB port — Plug and Play Manager goes through the following steps to install the device.

1. After receiving an insertion notification, Plug and Play Manager checks what hardware resources the device needs —

such as memory ranges, I/O ranges, and DMA channels. Plug and Play Manager then assigns those resources.

2. Plug and Play Manager checks the hardware identification number of the device. Plug and Play Manager then checks the hard drive, floppy drives, CD-ROM drives, and Windows Update for drivers that match the hardware identification number of the device.

3. If multiple drivers are found, Plug and Play Manager chooses the driver that is the best match by looking for the closest hardware ID or compatible ID match, driver signatures, and other driver features.

4. Plug and Play Manager then installs the best-match driver and the operating system starts the device.

When multiple drivers are available for a given device, Windows Server 2003 uses driver-ranking schemes to determine the best driver to load. Driver rank is established based on whether the driver is signed and how closely the driver's Plug and Play ID matches the device's Plug and Play ID.

If no driver is available on the computer, and the computer is connected to the Internet, then the operating system will use the Windows Update service to search for available drivers on the Windows Update site. If an appropriate driver is found, Windows Server 2003 copies it and installs it on the computer.

Device drivers included with or installed under Windows Server 2003 must meet the standards of the Windows Logo program. Device drivers that have passed the Windows Hardware Quality Lab (WHQL) compatibility tests are electronically signed, and Windows Server 2003 detects the digital signature. For system stability, it is recommended that you use only signed device drivers with Windows Server 2003. A message notifies the user if an unsigned driver is being installed.

The extent of Plug and Play support depends on both the hardware device and the device driver. If a driver does not support Plug and Play, its devices behave as devices that are not Plug and Play. This might result in the loss of some operating system functionality. For example, power management features such as hibernation might not work. Some bus types, such as Peripheral Component Interconnect (PCI) and Universal Serial Bus (USB) take full advantage of Plug and Play. Older bus types, such as Industry Standard Architecture (ISA), do not and require more user interaction to ensure that devices are correctly installed.

For more information about device ranking and device signing, see "Device Driver Technical Reference."

**Plug and Play in Managed Environments**
When you install a Plug and Play device and are connected to the Internet, Windows Server 2003 automatically accesses Windows Update to search for a device driver.

In order to install devices using the hardware wizards, you must be logged on as an administrator or a member of the Administrators group. You then use hardware wizards to search the Windows Update site for device drivers.

You can control how administrators update and install hardware devices by using Group Policy. For example, an IT administrator in a highly managed network environment can control the ability of administrators to install new hardware and to access the Internet automatically when Windows Server 2003 searches for device drivers. You can set a policy to disallow any access to Windows Update, preventing certain administrators from automatically accessing Windows Update. You can also set a policy for downloading the updates from the Windows Update Catalog and distributing through a corporate network as needed.

In a managed environment, you can control how Plug and Play operates by changing any or all of the following, including downloading updates from Windows Update:

**Specific information sent or received**
The Code Download Manager (CDM) calls Windows Update to find and download device drivers. The CDM also calls Help and Support Center, which logs Plug and Play IDs for devices for which Microsoft does not have drivers. Neither of these communications is under the direct control of Plug and Play. The CDM handles all of the communication between the computer and Windows Update. None of this communication between the computer and the Internet uniquely identifies the user.

**Default and recommended settings**
Plug and Play is enabled by default.

**Triggers**
A user controls whether to run Windows Update. If Automatic Updates is enabled following setup, it is triggered about once per day when there is an Internet connection.

**User notification**
When searching for a device driver, Windows Update sends a list of available drivers to the user's computer.

**Logging**
If you use a Plug and Play driver with a device that is not Plug and Play, any associated issues or problems are recorded in the event log.

**Encryption**
Data transfer is based on interaction with Windows Update. The data is transferred using HTTPS.

**Transmission protocol and ports**
The protocol for non-secure transmission is HTTP and the port used is 80; the protocol for secure transmission is HTTPS and the port used is 443.

**Ability to disable**
Plug and Play cannot be disabled, since system instability would result. You can disable access to Windows Update using Group Policy.

**Plug and Play Services**
Plug and Play in Windows Server 2003 provides the following services.

- Detection of a Plug and Play device
- Determination of hardware resource requirements
- Determination of device identification number
- Allocation of hardware resources
- Dynamic loading, initialization, and unloading of drivers
- Notification to other drivers and applications when a new device is available
- Coordination with power management components to install and remove devices

**How Plug and Play Detection Occurs on ACPI Systems**

1. The function driver for the bus detects a new device on the bus.
2. The bus driver notifies Plug and Play Manager that a set of devices has changed.
3. Plug and Play Manager queries the driver for the current list of devices on the bus.
4. When Plug and Play Manager obtains the current list of devices, it determines whether any devices have been added or removed.
5. Plug and Play Manager gathers information about the new device and begins configuring it.
6. Plug and Play Manager checks the registry to determine whether the device has been installed on the computer before; if not, Plug and Play Manager creates a registry key and any associated subkeys about the device in the registry.
7. Plug and Play Manager attempts to find and load the function drivers and filter drivers for the device.
8. Plug and Play Manager assigns resources to the device if needed and issues an I/O request packet (IRP) to start the device.

**Plug and Play Device States**
The following diagram shows how a device transitions through Plug and Play states as it is configured, started, and stopped.

### Plug and Play Device States

The process illustrated in the previous diagram begins when a device is first recognized as physically present. This is indicated in the diagram above by the box in the upper left labeled "Device is physically present". Before the a Plug and Play device is recognized as physically present, the device has not yet been identified by the system. This could be because the device has just been inserted into the system; however, the device could have been present at boot time and was not detected then for some reason.

Plug and Play Manager begins configuration of the device by enumerating it, then identifying and initializing the drivers for the device, and then creating and attaching the function driver objects and any optional filter driver objects.

Plug and Play Manager calls a routine to load each driver if the driver is not yet loaded. Once the driver is initialized, it must be ready to initialize the device. When a device receives a request from Plug and Play Manager, the driver starts the device and is ready to process I/O requests for the device.

Upon any changes in the device status, such as the device being physically removed from the system, Plug and Play Manager will reconfigure the hardware resources of the device. If a device is reconfigured, Plug and Play Manager directs the drivers to restart the device.

**Removing Devices While the System is Running**

Some Plug and Play devices can be installed or removed while the system is running. For example, USB, IEEE 1394, and PC Card devices can be added to and removed from a fully powered system. When such hardware is added or removed, the operating system automatically detects insertion or removal of the device and manages system and device configuration as required. If the device is not designed to be removed while the system is running, it is recommended that you notify the operating system in advance to avoid problems. The Safely Remove Hardware application notifies the operating system that a device will be removed.

The following table shows the different types of Plug and Play devices and whether or not they can be removed while the system is turned on.

**Plug and Play Device Connections and Installation Guidelines**

| Devices on These Buses or Connectors | Can Be Added to or Removed from a Running System? | System Must be Turned Off Before Device is Added to or Removed from System? |
|---|---|---|
| USB, IEEE 1394, PC Card devices, CardBus devices | Yes. Remove hardware by using the Safely Remove Hardware application if it appears in the notification area. | No. |
| PCI, ISA, EISA | No. | Yes. |
| Docking station | Varies among computer manufacturers; most support docking and undocking while the computer is running. | Varies among computer manufacturers; most support docking and undocking while the computer is running. |

Even when removing a device from a bus that supports the removal of devices while the system is running, it is best to use the Safely Remove Hardware application to ensure a safe removal of hardware from the system. The Safely Remove Hardware application informs Windows that the user intends to remove a device. This gives Windows an opportunity to prepare for the removal by taking steps such as halting data transfers to the device and unloading device drivers. If a device supports safe removal, a Safe Removal icon displays in the notification area next to the task bar. The icon displays a list of the Plug and Play

devices supporting safe removal currently attached to the system. If you do not see the icon, the device does not support this feature, and you cannot unplug or eject your device using Safe Removal.

When hardware is removed from a running system without using the Safely Remove Hardware application to notify the operating system in advance of the removal, it is referred to as surprise removal. Surprise removal is particularly a concern for storage devices for which write caching is enabled; when such devices are surprise-removed, data loss or data corruption might occur. To reduce the likelihood of data loss or data corruption due to surprise removal of consumer-oriented storage devices, Windows Server 2003 disables write caching by default for these devices (such as cameras that include IEEE 1394 or USB storage and small-form-factor storage devices such as compact flash). While write caching policy addresses this particular issue, it is recommended that you continue to use the Safely Remove Hardware application when it appears in the notification area. Also, disabling write caching might slow the performance of consumer storage devices.

Write caching is enabled by default for high-performance external storage devices such as IEEE 1394 hard drives and SCSI hard drives and for storage devices inside the computer that cannot be surprise-removed.

**How Plug and Play Interoperates with an ACPI BIOS**
In Windows Server 2003, Plug and Play support is optimized for computers that include an ACPI BIOS. ACPI devices are defined by the ACPI Specification, a hardware and software interface specification that combines and enhances the Plug and Play and Advanced Power Management (APM) standards. ACPI devices include low-level system devices such as batteries, thermal zones, and other devices defined in a system's *ACPI namespace,* a hierarchical namespace that an ACPI BIOS uses to reference objects. The ACPI BIOS is responsible for tasks such as describing hardware that is not visible to Plug and Play because the hardware is connected to a bus that does not directly support Plug and Play. For example, the ACPI BIOS describes and helps in configuring devices such as system timers and programmable interrupt controllers on the motherboard, which is not on a bus that supports Plug and Play.

For all Plug and Play features to work on a given system, it must include an ACPI BIOS and hardware devices and drivers that are compliant with Plug and Play. An Advanced Power Management (APM) BIOS or a Plug and Play BIOS does not enable all Plug and Play features and is not as robust as an ACPI BIOS.

**Network Ports Used by Plug and Play**
The following table describes the port used by Plug and Play when searching Windows Update for the most current device drivers.

### Port Assignments for Plug and Play

| Service Name | UDP | TCP |
|---|---|---|
| HTTP, IIS | None | 80 |
| HTTPS | None | 443 |

The following tools, registry entries, Group Policy settings, network ports, and Windows Management Instrumentation (WMI) classes are associated with Plug and Play.

**Plug and Play Tools**
The following tools are associated with Plug and Play.

**Devcon.exe: Device Console**
**Category**
Devcon ships with the Windows Driver Development Kit.

**Version compatibility**
Windows 2000, Windows XP, and Windows Server 2003

Device Console (Devcon) is a command-line tool that displays detailed information about devices and lets you search for and manipulate devices from the command line. Devcon enables, disables, installs, configures, and removes devices on the local computer and displays detailed information about devices on local and remote computers.

For more information about Devcon.exe and the syntax used to carry out commands, see the Windows Driver Development Kit.

**GenINF.exe: INF File Creation Wizard**
**Category**
GenINF ships with the Windows Driver Development Kit.

**Version compatibility**
GenINF generates .inf files for Windows 2000, Windows XP, and Windows Server 2003.

GenINF is a GUI-based tool that guides users through the process of creating device driver .inf files. GenINF does not generate fully valid .inf files. However, the skeleton .inf files it generates should help developers complete their device driver .inf files.

GenINF is located in the \Tools subdirectory of the DDK installation directory. Because GenINF is GUI-based, it can be executed from within the Windows Server 2003 User Interface or from the command prompt. GenINF takes no arguments. GenINF supports all device classes, but includes specific support for only certain device classes. For a list of these classes, see the Geninf.htm file that is located in the Tools\geninf subdirectory of the DDK.

For more information about GenINF.exe see the Windows Driver Development Kit.

**Net.exe: Net Start or Net Stop**
**Category**
Command-line tool that ships with Windows Server 2003

**Version compatibility**
Windows XP, Windows 200, and Windows Server 2003

Net.exe allows you to start and stop the Plug and Play service.

For more information about the syntax used with Net.exe, see the Windows Server 2003 help.

**SigVerif.exe: File Signature Verification**
**Category**
Operating system tool

**Version compatibility**
Windows XP, Windows 200, and Windows Server 2003

File Signature Verification checks to see which system files and device driver files are digitally signed and displays its findings. If you have enabled logging, the search results are also written to a log file.

**Svchost.exe: Service Host Process**
**Category**
Operating system tool

**Version compatibility**
Windows 2000, Windows XP, and Windows Server 2003

Generic host process name for services that are run from dynamic-link libraries (DLLs). At startup, Svchost.exe checks the services portion of the registry to construct a list of services that it needs to load. There can be multiple instances of Svchost.exe running at the same time. Each Svchost.exe session can contain a grouping of services, so that separate services can be run depending on how and where Svchost.exe is started.

**Plug and Play Registry Entries**
The following registry keys are associated with Plug and Play.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

For more information about registry entries, see "Registry Reference" in the Tools and Settings Collection.

**PnPManager**
**Registry path**
HKEY_LOCAL_MACHINE\HARDWARE\RESOURCEMAP\PnPManager

**Version**
Windows XP, Windows Server 2003

This key contains registry entries for each device installed on the system. Each of the subkeys and entries for this key are dependent upon the specific device installed on a system. Because of this, these subkeys and entries are not listed here.

**PlugPlay**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services

**Version**
Windows Server 2003

The Plug and Play registry key enables a computer to recognize and adapt to hardware changes with little or no user input. Stopping or disabling this service will result in system instability.

**Description**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay

**Version**
Windows XP, Windows 2000, Windows Server 2003

Text field that displays the description of the Plug and Play service.

**DisplayName**
**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay

**Version**
Windows XP, Windows 2000, Windows Server 2003

Text field that displays the default service name, Plug and Play.

**ErrorControl**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay

**Version**
Windows XP, Windows 2000, Windows Server 2003

Tells the system how to boot if a Plug and Play driver fails. The following table lists the accepted values for this registry entry.

### ErrorControl Values

| Value | Description |
|---|---|
| 00 | Ignore. If the driver fails to load or initialize, then startup continues as normal and no warning message appears. |
| 01 | Normal. If the driver fails to load or initialize, then startup proceeds, but a warning message appears. |
| 02 | Severe. If the driver fails to load or initialize, then startup is declared to have failed and restarts by using the LastKnownGood control set. If startup is already using the LastKnownGood control set, then startup continues |
| 03 | Critical. If the driver fails to load or initialize, then startup is declared to have failed and restarts by using the LastKnownGood control set. If startup is already using the LastKnownGood control set, then startup stops and enters Debugging Mode. |

**Group**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay

**Version**
Windows XP, Windows 2000, Windows Server 2003

Specifies which group the service belongs to when Plug and Play services are started

**ImagePath**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay

**Version**
Windows XP, Windows 2000, Windows Server 2003

Location of Services Control Manager, which uses the information located in the subkeys to initialize Plug and Play services. The default path is %SystemRoot%\system32\services.exe.

**ObjectName**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay

**Version**
Windows XP, Windows 2000, Windows Server 2003

Name of the account under which the Plug and Play service runs. The default value is LocalSystem, which sets the greatest privileges. In order to run as any other user, the service must provide a password for the user. If the service is a kernel driver, this specifies which kernel object loads it.

**Start**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay

**Version**
Windows XP, Windows 2000, Windows Server 2003

Determines when Plug and Play services should be started on a system. The following table lists the accepted values for this

registry entry.

**Start Values**

| Value | Description |
|---|---|
| 00 | Boot. Starts the service during the boot sequence. |
| 01 | System. Starts the service when loaded by the I/O subsystem in the kernel. |
| 02 | Automatic. Starts the service automatically. |
| 03 | Manual. Starts the service when a user initiates it from the control panel or a command line. |
| 04 | Disable. Loads the service, but neither the system nor a user can start it. |

**Type**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay

**Version**
Windows XP, Windows 2000, Windows Server 2003

Identifies the type of service. The following table lists the accepted values for this registry entry.

**Type Values**

| Value | Description |
|---|---|
| 01 | Kernel-mode device driver |
| 02 | File system driver |
| 04 | Network adapter |
| 10 | Win32 service that can run as a standalone process |
| 20 | Win32 service that shares address space with other services at the same time |

**Security**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay\Security.

**Security**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\PlugPlay

**Version**
Windows Server 2003

Holds the account policy information for the workstation or member server, as well as the security rights users have with the local Security Accounts Manager (SAM).

**Plug and Play Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with Plug and Play.

**Group Policy Settings Associated with Plug and Play**

| Group Policy Setting | Description |
|---|---|

| | |
|---|---|
| Remove Computer from Docking Station | Determines whether a user can undock a portable computer from its docking station without logging on. If this policy is set, the user must log on before removing the portable computer from its docking station. If this policy is not set, the user can remove the portable computer from its docking station without logging on. |
| Allow undock without having to log on | Determines whether a user must log on to request that a portable computer be removed from a docking station. If this setting is not set, the user must log on to request an undock, at which time the user must have been granted the Remove Computer from Docking Station privilege. If this setting is set, a user can request an undock by pressing the portable computer's physical eject button. |
| Allowed to format and eject removable media | Determines who is allowed to format and eject removable NTFS media. This capability can be given to Administrators, Administrators and Power Users, or Administrators and Interactive Users. |
| Prevent users from installing printer drivers | Determines who is allowed to install a printer driver as part of adding a network printer. For a computer to print to a network printer, the driver for that network printer must be installed on the local computer. If this setting is set, only Administrators and Power Users can install a printer driver as part of adding a network printer. If this setting is not set, any user can install a printer driver as part of adding a network printer. This setting can be used to prevent unprivileged users from downloading and installing an untrusted printer driver. |
| Restrict CD-ROM access to locally logged-on user | Determines whether a CD-ROM is accessible to both local and remote users simultaneously. If set, this policy allows only the interactively logged-on user to access removable CD-ROM media. If no one is logged on interactively, the CD-ROM can be shared over the network. If this policy is not set, then the local user and remote users can access the CD-ROM simultaneously. |
| Restrict floppy access to locally logged-on user only | Determines whether removable floppy media are accessible to both local and remote users simultaneously. If set, this policy allows only the interactively logged-on user to access removable floppy media. If no one is logged on interactively, the floppy media can be shared over the network. If this policy is not set, then the local user and remote users can access the floppy media simultaneously. |
| Unsigned driver installation behavior | Determines what happens when an attempt is made to install a device driver (by means of Setup API) that has not been certified by the Windows Hardware Quality Lab (WHQL). |

For more information about Group Policy settings, see "Group Policy Settings Reference" in the Tools and Settings Collection.

**Plug and Play WMI Classes**

The following table lists and describes the WMI (Windows Management Instrumentation) classes that are associated with Plug and Play.

### WMI Classes Associated with Plug and Play

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| WMIBinaryMofResource | \root\wmi\ | Windows XP, Windows 2000 Professional, Windows Server 2000, Windows NT Server 4.0 Service Pack 4 and later, Windows Server 2003 |
| Win32_DeviceSettings | \root\cimv2 | Windows XP, Windows 2000 Professional, Windows Server 2000, Windows NT Server 4.0 Service Pack 4 and later, Windows Server 2003 |
| Win32_PnP | \root\cimv2 | Windows XP, Windows 2000 Professional, Windows Server 2000, Windows NT Server 4.0 Service Pack 4 and later, Windows Server 2003 |

| | | |
|---|---|---|
| Win32_PnPAllocatedResource | \root\cimv2 | Windows XP, Windows 2000 Professional, Windows Server 2000, Windows NT Server 4.0 Service Pack 4 and later, Windows Server 2003 |
| Win32_PnPDevice | \root\cimv2 | Windows XP, Windows 2000 Professional, Windows Server 2000, Windows NT Server 4.0 Service Pack 4 and later, Windows Server 2003 |
| Win32_PnPEntity | \root\cimv2 | Windows XP, Windows 2000 Professional, Windows Server 2000, Windows NT Server 4.0 Service Pack 4 and later, Windows Server 2003 |
| Win32_PnPSignedDriver | \root\cimv2 | Windows XP, Windows 2000 Professional, Windows Server 2000, Windows NT Server 4.0 Service Pack 4 and later, Windows Server 2003 |
| Win32_PnPSignedDriverCIMDataFile | \root\cimv2 | Windows XP, Windows 2000 Professional, Windows Server 2000, Windows NT Server 4.0 Service Pack 4 and later, Windows Server 2003 |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by Plug and Play**

The following table describes the port used by Plug and Play when searching Windows Update for the most current device drivers.

### Port Assignments for Plug and Play

| Service Name | UDP | TCP |
|---|---|---|
| HTTP, IIS | None | 80 |
| HTTPS | None | 443 |

# Installation and Setup Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Microsoft Windows Server 2003 operating system provides several installation and setup technologies. You can use these technologies to perform an interactive setup, which prompts the user for configuration information, or an automated installation, which requires no user input.

Interactive setup technologies are used to install or upgrade an operating system on a single computer. Interactive setup technologies are typically used by small organizations that have few servers, or medium and large organizations that need to install the operating system on servers that have one-of-a-kind configuration settings.

Automated installation technologies are used to install or upgrade operating systems on numerous computers. Automated installation technologies include Remote Installation Services (RIS), the System Preparation (Sysprep) tool, and unattended installation answer files. Automated installation technologies are typically used by medium and large organizations during large-scale rollouts when it would be too slow and costly to have administrators or technicians interactively install the operating system on individual computers.

**Installation and Setup Components**
The installation and setup technologies include the following components.

**Interactive Setup**
Interactive setup relies on the Setup program in Windows Server 2003 and provides a method for carrying out an interactive installation or upgrade on a single computer. Interactive setup can be started by running Setup.exe, but also by running Winnt32.exe or Winnt.exe, both of which offer command-line options. The Setup program is also the basis for the automated installation technologies, including RIS, Sysprep, and unattended installation.

Running Setup interactively is a simple way to accomplish a server installation or upgrade. The installation or upgrade can be carried out from the CD drive or across the network (after you copy the installation files that are on the product CD to a shared folder). In addition, interactive setup requires little preparatory work compared to automated installation, and does not require supplemental tools or programs. Also, interactive setup can be used to install an operating system on a computer that is not connected to a network.

**Unattended Installation**
Unattended installation is an automated installation technology in Windows Server 2003 that you can use to install or upgrade an operating system with minimal user intervention. Unattended installation relies on the Setup program and an answer file to automate the setup process. An answer file is a simple text file that provides details about how to install and configure the operating system. To start an unattended installation, you run Winnt32.exe or Winnt.exe with a command-line parameter that specifies the answer file to use. Then, during the installation process, necessary information is obtained from instructions contained in the answer file instead of your responses to prompts.

**Sysprep**
Sysprep is an automated installation technology that you can use to install Windows Server 2003 and Microsoft Windows XP operating systems. The Sysprep tool is typically used in conjunction with a non-Microsoft disk imaging tool or Microsoft Windows Server 2003 Automated Deployment Services (ADS) to perform image-based installations. Image-based installation is a method of copying or cloning preconfigured operating systems (and, optionally, software applications) onto destination computers. After you set up a master installation — an installation with the operating system, software applications, and configuration settings that you want to install onto the destination computers in your organization, Sysprep prepares the master installation so that you can create a disk image; that is, a functionally identical replica of the disk containing the master installation, that can be copied onto multiple computers. Next, you use a disk-imaging program to create the disk image of the master installation. After you copy the disk image onto a destination computer and start the destination computer, a shortened version of the Setup program runs. The shortened version of Setup configures only user-specific and computer-specific settings, such as computer name, domain membership, and regional options. You can automate this last part of the setup process by using an answer file, a simple text file that instructs the Setup program how to configure the various operating system settings.

**Remote Installation Services**
RIS is an automated installation technology that can be used to install Windows Server 2003, Windows XP, and Microsoft Windows 2000 operating systems. RIS uses Pre-Boot Execution Environment (PXE) technology to enable client computers without an operating system to start up and connect remotely to a RIS server, which installs a supported operating system.

You can use RIS to perform either CD-based installations or image-based installations. To perform CD-based installations you

use the Remote Installation Services Setup (Risetup.exe) tool, which installs an operating system on a destination computer by using an answer file and the installation files that are on the product CD. To perform image-based installations you use the Remote Installation Preparation Wizard (Riprep.exe) tool, which is similar to the Sysprep tool and prepares a master installation for disk imaging.

**Installation and Setup Scenarios**
Although you can use the installation and setup technologies to create a wide range of interactive and automated deployment solutions, each technology has certain requirements and limitations that make it better suited to a specific deployment solution. The following describes optimum scenarios for each of the installation and setup technologies.

**Interactive Setup Scenarios**
Interactive setup is the most versatile and robust setup and installation technology. Interactive setup does not require network connectivity and it does not require any supplemental tools or programs. Because interactive setup has no limitations or restrictions, you can use it to install an operating system on any type of server or create any type of server configuration. However, the following installation scenarios are particularly well-suited for interactive setup.

**Installation in an organization that requires only a small number of servers**
Interactive setup is useful when you are installing a small number of servers, because you do not need to do any preparatory work related to creating answer files or images.

**One-of-a-kind server configuration**
Interactive setup is useful if you are installing an operating system on a server that requires unique configuration settings or contains unique hardware. For example, you might use interactive setup to create a file server that contains special redundant array of independent disks (RAID) hardware and therefore requires you to install special device drivers, or a bastion server or proxy server that requires special security settings.

**Master installations for image-based deployment technologies**
You can use interactive setup to create master installations for image-based installation technologies, such as image-based installation with Sysprep, or RIS when it is being used for image-based installation. For example, to use Sysprep, you need to create a master installation from which you create a disk image. You can create the master installation manually by running Setup.exe, and then manually configuring operating system settings and installing software.

**Upgrades**
You can use interactive setup to upgrade a Windows server operating system to Microsoft Windows Server 2003, Standard Edition; Microsoft Windows Server 2003, Enterprise Edition; or Microsoft Windows Server 2003, Web Edition operating systems. An upgrade is useful if you want to retain existing server settings (for example, user rights, groups, and permissions settings) and you do not want to reinstall applications and files.

**Unattended Installation Scenarios**
Unattended installation is the most versatile and robust automated installation technology, and can be used to roll out any type of server or any server configuration. However, the following installation scenarios are particularly well suited for unattended installation.

**Heterogeneous hardware**
Unattended installation is ideal if you are installing the same server configuration on computers that have dissimilar or heterogeneous hardware. In addition, unattended installation is equally adept at handling other hardware differences, including differences among network adapters, media devices (CD drives), and video adapter cards. In large part, this is because unattended installation is just an automated process that uses the standard Setup program. Therefore, whatever device Setup can detect or install, unattended installation can also detect or install.

**Upgrades**
You can use unattended installation to automate the upgrade of a Windows server operating system to Microsoft Windows Server 2003, Standard Edition; Microsoft Windows Server 2003, Enterprise Edition; or Microsoft Windows Server 2003, Web Edition operating systems. No other automated installation technology can perform upgrades. Unattended upgrade installations are useful if you want to retain existing server settings (for example, user rights, groups, and permissions settings) and you do not want to reinstall applications and files.

**Special server configurations**
Unattended installation is an ideal automated installation technology for deploying domain controllers, and member servers that run Certificate Services and Cluster service. Although you can use other automated installation technologies to deploy these types of servers, those technologies require you to use scripts or supplemental answer files after the automated installation is finished. With unattended installation, the answer file contains all of the necessary settings for installing these types of servers.

**Master installations for image-based deployment technologies**
You can use unattended installation to create master installations for image-based installation technologies, such as the

Sysprep tool, or RIS when it is being used for image-based installation. For example, to use Sysprep, you need to create a master installation from which you create a disk image. You can create the master installation by performing an unattended installation on the master computer.

**Sysprep Scenarios**

Image-based installation with Sysprep can only be used to perform clean installations of an operating system. Image-based installation with Sysprep also requires a disk imaging program and usually requires high-speed network connectivity among the destination computers you are deploying. Given these requirements, several installation scenarios are particularly well suited for image-based installations with Sysprep.

**Homogeneous hardware configurations**

If you are installing the same server configuration on computers that have similar or homogeneous hardware, you can customize hardware configurations on the disk image, thereby avoiding many post-installation configuration and installation tasks. For example, you can use image-based installation with Sysprep to rapidly roll out the same file server configuration to a group of computers that have similar processor configurations and similar storage configurations.

**Rapid rollouts**

If you need to install the operating system as rapidly as possible, you can copy a preconfigured disk image onto a destination computer much faster than you can perform an unattended installation or a Remote Installation Services (RIS) installation. For example, you can use image-based installation with Sysprep to quickly deploy critical servers in your organization or quickly reinstall an operating system on member servers after a hard disk failure or some other catastrophic event.

**Application deployment**

If you want to roll out applications at the same time that you roll out the operating system, you can include the applications on the disk image. For example, if your organization's standard computer configuration includes an antivirus program, an e-mail program, and an office suite, you can install and configure these programs on the master installation so that the disk image includes these programs.

**RIS Scenarios**

Like Sysprep, RIS can be used only to perform clean installations of an operating system. RIS also requires PXE-enabled network adapters and high-speed network connectivity among the destination computers you are deploying. In addition, RIS can be used as a CD-based or image-based deployment solution. Given these requirements and options, several installation scenarios are particularly well suited for RIS installation.

**Minimize user interaction**

You can configure RIS so that minimal user interaction is necessary to configure and install an operating system. In this scenario users can initiate a RIS installation on a destination computer by pressing the F12 key. After pressing the F12 key, all configuration and installation tasks are automated and cannot be altered.

**Application deployment**

Because you can use RIS as an image-based deployment solution, you can deploy preinstalled and preconfigured applications with the operating system. For example, if your organization's standard computer configuration includes an antivirus program, an e-mail program, and an office suite, you can install and configure these programs on the master installation so that the disk image includes these programs.

# Setup Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setup Technical Reference**

The Setup program in the Microsoft Windows Server 2003 operating systems provides a method for carrying out an interactive installation or upgrade on a single computer. The Setup program is also the basis for the following installation or upgrade methods that are not interactive: unattended installation, Remote Installation Services (RIS), and image-based installation with the System Preparation tool (Sysprep).

Interactive setup involves a simple repeating process in which Setup alternates between prompting for information and performing appropriate tasks, such as copying files, saving settings, and so on. In contrast, for installation methods that are not interactive, the input does not come from a person responding to prompts, but from another source, such as an answer file (for unattended installation or RIS) or an operating system image (for Sysprep or RIS).

# What Is Setup?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Setup?**

**In this section**

- Related Information

The Setup program in Windows Server 2003 provides a method for carrying out an interactive installation or upgrade on a single computer. The Setup program is also the basis for the following installation or upgrade methods that are not interactive: unattended installation, Remote Installation Services (RIS), and image-based installation with the System Preparation tool (Sysprep).

Running Setup interactively is a simple way to accomplish a server installation or upgrade. The installation or upgrade can be carried out from the CD drive or across the network (after you share the installation files that are on the product CD). No preparatory work related to creating answer files or images is necessary. In contrast, installation methods that are not interactive require preparatory work, but are more efficient in the context of a large-scale rollout. Installation methods that are not interactive are also useful for achieving consistency and precision in the configuration on each server.

**How Interactive Setup Differs from Installation Methods That Are Not Interactive**

Interactive Setup involves a simple repeating process in which Setup alternates between prompting for information and performing the appropriate tasks, such as copying files, saving settings, and so on. The following figure shows how the process repeats until the installation or upgrade is complete.

### Interactive Installation or Upgrade

In contrast, for installation methods that are not interactive, the input does not come from a person responding to prompts, but from another source, such as an answer file (for unattended installation or RIS) or an operating system image (for Sysprep or RIS).

# How Setup Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setup Architecture**

The Setup program contains components that start or restart the computer, gather information, copy files, and create or adjust settings. The components involved and the sequence of actions they perform are slightly different when Setup is started in different ways. The following figures and tables show the components and briefly describe their relationships for the two most common ways of performing an interactive setup:

- An upgrade when you insert the product CD while the computer is running the existing operating system and then wait for a display to appear.
- A clean installation when you insert the product CD and then restart the computer from the CD drive.

### Note

- Multiple methods are available for running Setup. This Technical Reference focuses on two methods, but it is not intended to provide guidance for choosing a method. For information about choosing a method, see "Related Information" later in the section.

**Setup Components Used During an Upgrade**

The following figure and corresponding table show the components that are involved when you perform an upgrade by starting the computer from the existing operating system, inserting the product CD in the CD drive, and then waiting for a display to appear.

The figure and table list both the components and the related information files for each stage of the upgrade. Setup components use information files to store information that is later retrieved. Note that information might be retrieved by a component different from the one that stored it. Information might also be retrieved after restarting the computer.

For more information about the operating systems from which you can start an upgrade, see "Setup Processes" later in this section.

### Setup Components Used During an Upgrade

The following table describes the Setup components used for each stage of an upgrade.

### Setup Components Used During an Upgrade

| Components and Descriptions Grouped by Stage | Corresponding Information Files |
|---|---|
| **Initial stage, also known as data-collection stage** | |
| **Setup.exe (autorun)**<br><br>Setup.exe runs automatically when you insert the product CD in the CD drive on a computer that is turned on and running an operating system that can be upgraded to Windows Server 2003. When this happens, Setup.exe offers options for viewing information about the product CD or for beginning the setup process. | None |
| **Winnt32.exe** and **Winnt32u.dll**<br><br>If Setup.exe is allowed to start as described in the previous line of this table, and you choose to begin the setup process, Setup.exe runs Winnt32.exe. | **For the compatibility report**: Ntcompat.inf in the \I386\compdata folder on the product CD<br><br>**For other actions**: Winnt.sif in $win_nt$.~bt folder<br><br>*.inf files in \I386\Winntupg folder and subfolders on product CD |
| **Intermediate stage, also known as text-mode stage** | |
| **$LDR$ file (copied and renamed from Setupldr.bin in \I386 folder on product CD)**<br><br>As part of the previous stage, Winnt32.exe causes the computer to restart with the Setup loader, instead of NTLDR, the loader that would otherwise be used when starting a server running Windows. | Winnt.sif in $win_nt$.~bt folder<br><br>Txtsetup.sif in $win_nt$.~bt folder and in root directory (of the boot disk on the computer)<br><br>Migrate.inf in $win_nt$.~bt folder (stores drive letter assignments)<br><br>For some computers that have a mass storage controller, Unsupdrv.inf will be created. For more information, see the paragraphs after this table. |
| **Setupdd.sys**<br><br>Setupdd.sys carries out most of the actions during text-mode stage. | Winnt.sif in $win_nt$.~bt folder<br><br>Txtsetup.sif in $win_nt$.~bt folder and in root directory (of the boot disk on the computer) |
| **Final stage, also known as GUI-mode stage** | |

| | |
|---|---|
| **Syssetup.dll, Setupapi.dll, Netshell.dll, and other DLLs**<br><br>For the final stage of an upgrade, Syssetup.dll coordinates most of the actions. The operating system running during this stage is very similar to the completely upgraded operating system, although only a small number of services are started. Syssetup.dll uses a variety of other DLLs for configuration tasks, for example, iesetup.dll for configuring Internet Explorer and Ocgen.dll for configuring certain operating system components such as Windows Management Instrumentation (WMI). | Syssetup.dll uses:<br><br>$Winnt$.inf in *systemroot*\system32<br><br>Syssetup.inf and Layout.inf in *systemroot*\inf<br><br>At this stage, the operating system is very similar to the completely upgraded operating system and uses many of the same .inf files (not listed here). |

The Unsupdrv.inf file mentioned in the preceding table is created to store settings for a mass storage driver in certain situations. If a mass storage driver is installed on the computer, Setup will copy the driver into the $win_nt$.~bt folder unless the product CD has an equivalent, updated driver or the existing driver is on a list of those that must be disabled for Windows Server 2003. When Setup copies the driver, it also adds the driver file to its list of files and stores the driver settings retrieved from the existing registry in Unsupdrv.inf.

When the computer first restarts after interactive setup, a few final user settings are applied, much like the process that happens at the beginning of any restart. The upgrade is then complete.

**Setup Components Used During a Clean Installation When You Start the Computer from the Product CD**

The following figure and corresponding table show the components that are involved in a clean installation when you start the computer from the product CD.

The figure and table list both the components and the related information files for each stage of Setup. Setup components use information files to store information that is later retrieved. Note that information might be retrieved by a component different from the one that stored it. Information might also be retrieved after restarting the computer.

### Note

- The following figure and table describe the contents of the I386 folder on the product CD. This folder contains the Setup components for installations on an x86-based computer. The Setup components on an Itanium architecture-based computer are located in the IA64 folder on the product CD.

### Setup Components Used During a Clean Installation When You Start the Computer from the Product CD

The following table describes the Setup components used for each stage of a clean installation.

**Setup Components Used During a Clean Installation When You Start the Computer from the Product CD**

| Components and Descriptions Grouped by Stage | Information File |
|---|---|
| **Initial stage, also known as data-collection stage and text-mode stage** | |

| | |
|---|---|
| **Setupldr.bin in the I386 folder on the product CD**<br><br>When the computer is started from the product CD, the boot sector on the CD initializes the setup loader instead of NTLDR, the loader normally used when starting a server running Windows. | Txtsetup.sif in the I386 folder on the product CD<br><br>Optionally, you can use the information file Winnt.sif. For more information, see the note after this table. |
| **Setupdd.sys**<br><br>Setupdd.sys carries out most of the actions during text-mode stage. | Txtsetup.sif in the I386 folder on the product CD<br><br>Optionally, you can use the information file Winnt.sif. For more information, see the note after this table. |
| **Final stage, also known as GUI-mode stage** | |
| **Syssetup.dll, Setupapi.dll, Netshell.dll, and other DLLs**<br><br>For the final stage of a clean installation, Syssetup.dll coordinates most of the actions. The operating system running during this stage is very similar to the complete Windows Server 2003 operating system, although only a small number of services are started. Syssetup.dll uses a variety of other DLLs for configuration tasks, for example, Iesetup.dll for configuring Internet Explorer and Ocgen.dll for configuring certain operating system components such as Windows Management Instrumentation (WMI). | Syssetup.dll uses:<br><br>$Winnt$.inf in *systemroot*\system32<br><br>Syssetup.inf and Layout.inf in *systemroot*\inf<br><br>At this stage, the operating system is very similar to the complete Windows Server 2003 operating system and uses many of the same .inf files (not listed here). |

When the computer first restarts after interactive setup, a few final user settings are applied, much like the process that happens at the beginning of any restart. The installation is then complete.

**Note**

- If you start the computer from the product CD and also insert a floppy disk containing an information file called Winnt.sif, Setup reads the copy of Winnt.sif on the floppy disk. For more information about Winnt.sif, see "Unattended Installation Technical Reference."

**Additional Setup Components Used in Other Installation or Upgrade Scenarios**

Some Setup components are called only if you start or restart Setup in a specific way. The following table lists and describes those components.

**Additional Setup Components Used in Other Installation or Upgrade Scenarios**

| Component | Installation or Upgrade Scenario |
|---|---|
| $Win_nt$.~ls folder<br><br>Dosnet.inf in the \I386 folder on the product CD | $Win_nt$.~ls is created when you perform an installation or upgrade by sharing Setup files in a network folder. During the initial stage of setup, all the folders and files needed for the new operating system are copied to the $Win_nt$.~ls folder on the local computer. This folder is also created when you run Winnt32.exe with the /makelocalsource option.<br><br>Dosnet.inf contains the list of files to copy to $Win_nt$.~ls. |
| Migrate.inf in $win_nt$.~bt folder | Migrate.inf stores the computer's drive letter assignments when you start either an upgrade or a clean installation on a computer running an earlier operating system such as Windows NT 4.0 or Windows 2000. |

| | |
|---|---|
| Sprestrt.exe and Undo_Guimode.txt | Sprestrt.exe, which runs at the start of GUI mode, determines if GUI mode ran previously and failed. If so, Undo_Guimode.txt is used to bring files back to the state appropriate for the beginning of GUI mode. |

**Log Files Created by Setup**
A number of log files are created during an installation or upgrade and are saved in the *systemroot* folder, for example, C:\Windows. The names and descriptions of the log files are as follows.

**Commonly Used Log Files**
**Setupapi.log**
Log file for Setupapi.dll, which processes .inf files during hardware installation and registration. This file can include entries that begin with #E, which indicates problems or errors.

**Setuperr.log**
Logs errors that occur during the setup process.

**Setuplog.txt**
Logs the overall setup process. This log includes information about the process of setup, the process of applying user settings after the computer's first restart into the new operating system, and the process of activation. The last line in this file shows the last action Setup was able to complete.

**Upgrade.txt**
Default name for the file that stores the compatibility report. (You can also save the report with a different name.) The compatibility report is created when you carry out any of the following:

- Insert the product CD in the CD drive, wait for the display to appear, and then click the appropriate options for checking system compatibility.
- Begin an upgrade of the existing operating system.
- Run Winnt32.exe with the /checkupgradeonly option.

**Other Log Files**
**Setupact.log**
Records some file copying and many actions related to hardware, for example, the detection of devices in the system. For upgrades, this file can contain some information about whether the computer hardware is compatible with Windows Server 2003.

**Winnt32.log**
Logs details about the initial stage of Setup, sometimes called the data-collection stage. If you attempted to upgrade to a product version that is not on the upgrade path from the existing operating system (for example, an upgrade to an English version of Windows Server 2003 from a non-English version of Windows 2000 Server), details will be logged in this file. This file is only created when you start Setup while the previous operating system is running, not when you start the computer from the product CD.

**Wsdu.log**
Logs Dynamic Update actions, if Dynamic Update is run.

**Logs created by other components**
During the last stage of Setup (also known as GUI-mode stage), the Windows Server 2003 operating system installation or upgrade is nearly complete, and therefore operating system components begin to create logs. The file name often indicates the component that created the log.

**Setup Processes**
An interactive setup can be started using a variety of methods. This Setup Technical Reference provides detailed descriptions of two of the most common methods for starting Setup:

- An upgrade when the computer is started from the operating system to be upgraded.
- A clean installation when the computer is started from the product CD.

The following information defines these two methods as well as other methods used for starting Setup. You can use almost all methods either for a clean installation or an upgrade. The exception is when you start the computer from the product CD, which is used for clean installations only.

**Note**

- Multiple methods are available for running Setup. This Technical Reference focuses on two methods, but it is not intended to provide guidance for choosing a method. For information about choosing a method, see "Related Information" later in this section.

**Methods for Starting Setup When the Computer is Started from the Product CD**

If you insert the product CD in the computer's CD drive and then start the computer from that drive, Setup starts automatically. This method for starting Setup differs from the other methods in the following ways:

- This is usually the most straightforward way to begin a clean installation. With this method, you can change the partitions on the hard disk and format partitions as needed. With other methods, you can make changes to the partitions or format the hard disk during installation only if those changes do not affect files that Setup must store on the hard disk while it is running.

- You must use the basic input/output system (BIOS) or Extensible Firmware Interface (EFI) to configure the computer so that you can start it from the CD drive.

- This method is used only for a clean installation (not an upgrade).

- You cannot use Dynamic Update if you start the computer from the product CD because the computer will not have network or Internet connectivity.

**Methods for Starting Setup When the Computer is Running MS-DOS**

If you start Setup from a computer that is running MS-DOS, you must use Winnt.exe; you cannot run Setup.exe or Winnt32.exe. Starting Setup from MS-DOS is the least preferred method; it does not offer all the options available with the other methods.

**Methods for Starting Setup When the Computer is Running Any 32-bit or 64-bit Windows Operating System**

The following table describes different methods for starting Setup from a computer that is running any 32-bit or 64-bit Windows operating system.

| **Medium and Method for Starting Setup** | **Notes** |
|---|---|
| **Medium:** Windows Server 2003 product CD<br><br>**Method:** Insert CD in local CD drive and wait for display to appear. | If the operating system already on the computer is one from which you can upgrade, this is the most straightforward way to begin an upgrade.<br><br>Allowing the display to appear after the CD is inserted in the drive is the same as running Setup.exe (in the root directory on the CD).<br><br>You can also start an installation or upgrade by changing to the I386 folder on the product CD and running Winnt32.exe. (For Itanium architecture-based computers, the folder is the IA64 folder on the product CD.) Winnt32.exe is described later in this table. |
| **Medium:** Windows Server 2003 product CD<br><br>**Method:** Insert CD in remote CD drive that has been shared on the network. On the local computer, run Setup.exe from the remote CD drive. | With this method, you do not have to keep track of a product CD or carry it from computer to computer.<br><br>Running Setup across the network requires slightly more free space on the local hard disk during Setup than if it is run locally. |
| **Medium:** A shared folder in which you place files from the Windows Server 2003 product CD.<br><br>**Method:** Run Setup.exe across the network. | With this method, you do not have to keep track of a product CD or carry it from computer to computer.<br><br>Running Setup across the network requires slightly more free space on the local hard disk during Setup than if it is run locally. |

| | |
|---|---|
| **Medium:** A shared folder in which you place files from the Windows Server 2003 product CD as well as other files. **Method:** From the I386 subfolder in the shared folder, run Winnt32.exe across the network, using appropriate options. (For Itanium architecture-based computers, run Winnt32.exe from the IA64 folder on the product CD.) | With this method and with appropriate preparation of the shared installation folder or subfolders, you can specify options with Winnt32.exe to change the installation process slightly. For example, you can create a shared subfolder with additional drivers, and have the subfolder installed at the same time as the operating system. As another example, you can have Dynamic Update use updated Setup files that you have downloaded to your shared installation folder. You download these files from the Windows Update Web site. For more information about Winnt32.exe, see "Command line reference A-Z" on the Microsoft TechNet Web site.<br><br>Running Winnt32.exe across the network requires slightly more free space on the local hard disk during installation than if Winnt32.exe is run locally.<br><br>Winnt32.exe can also be used for unattended installation. For more information, see "Unattended Installation Technical Reference." |

**Note**

- When you run Setup from an existing operating system, you have the option of installing a new operating system while leaving the old one in place. This results in a computer with multiple operating systems installed. For information about using the NTFS file system on such a computer, see "NTFS Technical Reference."

**Supported Upgrade Paths**

The operating systems from which you can upgrade depend on the specific product in the Windows Server 2003 family that you have purchased:

**Supported Upgrade Paths in Windows Server 2003**

| | **Standard Edition** | **Enterprise Edition** | **Datacenter Edition** | **Web Edition** | **Windows Small Business Server 2003** |
|---|---|---|---|---|---|
| Windows NT 4.0* Server | ● | ● | | | |
| Windows NT 4.0* Terminal Server Edition | ● | ● | | | |
| Windows NT 4.0* Enterprise Edition | | ● | | | |
| Windows 2000 Server | ● | ● | | | ● |
| Windows 2000 Advanced Server | | ● | | | |
| Windows 2000 Datacenter Server | | | ● | | |
| Windows Server 2003 Standard Edition | ● | ● | | | ● |
| Windows Server 2003 Enterprise Edition | | ● | | | |
| Windows Server 2003 Datacenter Edition | | | ● | | |
| Windows Server 2003 Web Edition | | | | ● | |
| Windows Server 2003** Beta3/RC1/RC2 | ● | ● | ● | ● | *** |
| Small Business Server 2000 | | | | | ● |

| | | | | | |
|---|---|---|---|---|---|
| Windows Small Business Server 2003 | | | | | • |

* Windows NT 4.0 upgrade is supported by Service Pack 5 (SP5) or later. If an earlier version of the service pack is installed, the upgrade is not possible.

** Interim releases of Windows Server 2003 will upgrade to the release to manufacturer (RTM) code of the same edition. For example, RC1 Standard Edition upgrades to RTM Standard Edition.

*** Release candidate (RC) to RTM code for Windows Small Business Server 2003 is supported.

**How Setup Performs an Upgrade**

In the process of performing an upgrade, Setup goes through several stages, carrying out specific actions in an orderly way during each stage. The Setup stages and actions are defined as follows:

- **Initial stage, also known as data-collection stage:** You start Setup from the existing operating system. Setup prompts you for items such as the product key and your decision about whether to run Dynamic Update. Setup also performs a compatibility check (with a report) during this stage. Finally, Setup copies the files necessary for starting the computer in the next stage and then restarts.

- **Intermediate stage, also known as text-mode stage:** Setup copies most of the files that will become the new operating system and then restarts.

- **Final stage, also known as GUI-mode stage:** Setup loads appropriate device drivers, applies network settings, copies additional files necessary for the operating system, installs Start menu items, and makes changes to the registry. At the end of this stage, Setup removes temporary files it used and then restarts the computer into the newly upgraded operating system.

The following numbered list shows the sequence of actions in each stage of an upgrade.

**Upgrade: Initial Stage (Also Known as Data-Collection Stage)**

1. You start Setup, typically by inserting the product CD in the CD drive and waiting for a display to appear. Setup examines the computer to determine which operating system exists on it, and offers the following options:

   - Installing the operating system

   - Performing additional tasks, that is, setting up a Remote Desktop Connection, browsing the CD, or viewing setup instructions and release notes

   - Checking system compatibility

   If the operating system that exists on the computer is in the Windows Server 2003 family, the display also offers the option to install optional Windows components (such as Certificate Service or Terminal Server).

   You can start Setup from an existing operating system in other ways. For more information, see "Setup Processes" earlier in this section. For some of these options, the display described in step 2 is the first display you see.

2. If you choose the first option in step 1, Setup asks you whether you want to perform an upgrade or a new installation.

3. Setup confirms that you agree with the product license.

4. Setup prompts you to type the product key.

   The 25-character product key is printed on a sticker on the back of your Windows Server 2003 product CD case.

5. Setup checks that the amount of memory and the space on the hard disk are adequate for the version of the product to which you are upgrading.

6. Setup asks whether to use Dynamic Update to get updated Setup files from the Microsoft Windows Update Web site. If you agree, Setup performs Dynamic Update (actions are recorded in Wsdu.log), and then checks that the space on the hard disk is still adequate for the upgrade.

7. Setup checks your system for compatibility, and displays a report if there are incompatibilities. For many types of incompatibilities, you can continue the upgrade. If, however, an incompatibility exists that is known to prevent Setup from completing, you cannot continue the upgrade. The report is saved with a default file name of Upgrade.txt, and actions are recorded in Winnt32.log.

8. Setup copies files to the hard disk. These files are necessary for starting the computer in the next stage.

9. Setup restarts the computer.

**Upgrade: Intermediate Stage (Also Known as Text-Mode Stage)**

1. Setup rechecks that the space on the hard disk is adequate, and then copies most of the files that will become the new operating system, replacing previous versions of the files where they exist.

2. Setup restarts the computer again.

**Upgrade: Final Stage (Also Known as GUI-Mode Stage)**

1. Using Plug and Play technology, Setup loads appropriate device drivers for the attached devices.

2. Setup configures settings using the existing registry as a baseline.

3. Setup copies files to the hard disk for operating system components that have not yet been installed.

4. Setup installs Start menu items and makes changes to the registry.

5. Setup sets file and folder permissions to protect the new operating system, for example, for files in the root directory, the system root folder, and the registry.

6. Setup runs Windows File Protection to ensure that all upgraded files are valid.

7. Setup removes any temporary files used during the installation process.

8. Setup restarts the computer. A few final user settings are applied after this restart, much like the process that happens at the beginning of any restart. The upgrade is then complete.

**How Setup Performs a Clean Installation when the Computer is Started from the Product CD**

In the process of performing a clean installation, Setup goes through several stages, carrying out specific actions in an orderly way during each stage. This Setup stages and actions are defined as follows:

- **Initial stage, also known as data-collection stage and text-mode stage:** You start Setup, typically by starting the computer from the product CD. Setup displays a character-oriented window during this stage. It collects information, mainly about what partitions to create or delete and what file system to use on an unformatted partition. Setup carries out your instructions for creating, deleting, and formatting partitions, then copies files and restarts.

- **Final stage, also known as GUI-mode stage:** Setup displays a graphical user interface (GUI) during this stage. It loads appropriate device drivers, then prompts for the following information:

    - Regional and language preferences

    - Your name and the name of the organization

- Product key
- Licensing mode
- Computer name and Administrator account password
- Date and time settings
- Network settings

Also during the final stage, Setup applies the network settings you specified, copies the files, installs Start menu items, and makes changes to the registry. At the end of this stage, Setup removes temporary files it used and then restarts the computer into the newly installed operating system.

The following numbered list shows the sequence of actions in each stage of a clean installation where the computer has been started from the product CD.

**Clean Installation: Initial Stage (Also Known as Data-Collection Stage and Text-Mode Stage)**

1. You turn the computer on and start it from the product CD.

   In order to start the computer from a CD, either you must press a key at the appropriate prompt, or you must prepare the computer ahead of time by configuring the BIOS or EFI to specify a boot sequence that will cause the computer to start from the CD drive. For more information, see the manufacturer's instructions for your computer.

2. Setup gives you the opportunity to load a mass storage driver (press F6). At this time, you can also press F5 to load a Hardware Abstraction Layer (HAL) file.

3. Setup gives you the opportunity to run Automated System Recovery (press F2).

4. If you continue with installation (not Automated System Recovery), Setup loads a set of generic device drivers.

5. Setup displays a welcome screen and gives you the opportunity to start the Recovery Console (press R).

6. Setup confirms that you agree with the product license.

7. Setup searches the hard disks for an existing installation of the product that you are installing. If an existing installation is found, Setup gives you the opportunity to repair that installation (press R).

8. Setup checks that the amount of memory and the hard disk size are adequate for the version of the product that you are installing.

9. Setup gives you the opportunity to delete or create partitions on the hard disk. If you create a partition and specify it as the installation partition, you must specify a file system (NTFS or FAT) and specify whether to use quick format (integrity of sectors is not verified) or full format (bad sectors are identified and tracked).

10. After carrying out the specified partition and file system changes, Setup checks that the partition you selected contains enough space to hold the installation, and then copies files to the partition. The files are most of those that will become the new operating system.

11. Setup restarts the computer.

**Clean Installation: Final Stage (Also Known as GUI-Mode Stage)**

1. Using Plug and Play technology, Setup loads appropriate device drivers for the attached devices.

2. Setup requests information about the following items:

    - Regional and language options
    - Your name and the name of the organization (the name of the organization can be left blank)
    - Product key

      The 25-character product key is printed on a sticker on the back of your Windows Server 2003 product CD case.
    - The licensing mode
    - Computer name and administrator password
    - Date and time settings

3. Setup installs a basic set of network components to begin the process of establishing network connectivity.
4. Setup requests information about the following items:

    - Networking settings
    - Workgroup or computer domain

5. Setup configures the settings that were specified.
6. Setup copies files to the hard disk for operating system components that have not yet been installed.
7. Setup installs Start menu items and makes changes to the registry.
8. Setup sets file and folder permissions to protect the new operating system, for example, for files in the root directory, the systemroot folder, and the registry.
9. Setup runs Windows File Protection to ensure that all installed files are valid.
10. Setup removes any temporary files used during the installation process.
11. Setup restarts the computer. A few final user settings are applied after this restart, much like the process that happens at the beginning of any restart. The installation is then complete.

**Configuration Elements That You Can Change After Setup**

In Windows Server 2003, most of what you specify during Setup can be changed at a later time. The following table specifies what you can change after Setup.

**Configuration Elements That You Can Change After Setup**

| Configuration Elements Specified During Setup | Configuration Elements You Can Change After Setup |
|---|---|
| **Partitions:** Arrangement, order, or format of partitions on the hard disk | You can use Disk Manager to change various aspects of the partitions. However, unless you reinstall, you cannot perform actions that involve deleting, moving, or changing the letter of the boot partition (also called the boot volume) or the system partition (also called the system volume). |

| | |
|---|---|
| **Components:** Installed components of the operating system | You can use Add or Remove Programs in Control Panel to add or remove Windows components after installation, for example, the Remote Storage component. To add components, you will need access to the product CD or a network share containing files from the product CD. |
| **Regional and language options Support for East Asian languages:** These languages include Chinese, Japanese, or Korean, or the complex script and right-to-left languages, which include Arabic, Armenian, Georgian, Hebrew, the Indic languages, Thai, or Vietnamese. | You can use Regional and Language Options in Control Panel to change most of these options after installation. However, to add support for East Asian languages after installation, you will need access to the product CD or a shared network folder containing files from the product CD. |
| **Name** entered by the person who installed the computer (in Personalize Your Software) | You can change this setting by changing the following registry key: \HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft \Windows NT\CurrentVersion\RegisteredOwner |
| **Other options** | You can change other settings after installation, usually through Control Panel or through Administrative Tools (in Control Panel). |

**Note**

- Incorrectly editing the registry might severely damage your system. Before making changes to the registry, you should back up any valued data on the computer

# Setup Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Setup Tools
- Related Information

This section describes the Winnt32.exe and Winnt.exe commands.

**Setup Tools**
The following tools are associated with Setup.

**Winnt32.exe**
Winnt32.exe is on the Windows Server 2003 product CD in the I386 folder. For Itanium architecture-based computers, Winnt32.exe is located in the IA64 folder on the product CD.

**Version Compatibility**
Winnt32.exe can be run on a computer running Windows 95, Windows 98, Windows Millennium Edition, Windows NT, Windows 2000, Windows XP, or a product in the Windows Server 2003 family. If you run Winnt32.exe on a computer running Windows NT 4.0, you must first apply Service Pack 5 or later.

To install Windows Server 2003, use the version of Winnt32.exe on your Windows Server 2003 product CD, not the version of Winnt32.exe that exists on a CD for a different product.

**Description**
Winnt32.exe provides some ways to run Setup that contrast with starting the computer from the product CD or starting Setup by inserting the product CD and waiting for a display to appear automatically. With options available with Winnt32.exe, you can make slight changes to the interactive installation process, or you can run unattended installation (by using an answer file).

The typical way you would use Winnt32.exe with interactive installations is by creating a shared network folder containing files from the Windows Server 2003 product CD. You would then prepare the folder to work with specific Winnt32.exe options and run Winnt32.exe across the network using those options. For example, you can create a shared subfolder with additional drivers and have the subfolder installed at the same time as the operating system. As another example, you can perform an installation in which you use Dynamic Update files that you have downloaded and prepared in a special shared folder. (When you use the correct options with Winnt32.exe, the files are downloaded from the Windows Update Web site.)

For more information about Winnt32.exe, see “Command line reference A-Z” on the Microsoft TechNet Web site. For more information about using Winnt32.exe for unattended installation, see “Unattended Installation Technical Reference.”

**Winnt.exe**
**Category**
Winnt.exe is on the Windows Server 2003 product CD in the I386 folder.

**Version Compatibility**
Winnt.exe can be run on a computer running MS-DOS. To install Windows Server 2003, use the version of Winnt.exe on your Windows Server 2003 product CD, not the version of Winnt.exe that exists on the CD for a different product.

**Description**
Winnt.exe is a command-line interface for starting an installation or upgrade on a computer running MS-DOS.

Winnt.exe provides some ways to run Setup that contrast with starting the computer from the product CD or starting Setup by inserting the product CD and waiting for a display to appear automatically. With options available with Winnt.exe, you can make slight changes to the interactive installation process, or you can run unattended installation (by using an answer file).

The typical way you would use Winnt.exe with interactive installations is by creating a shared network folder containing files from the Windows Server 2003 product CD. You would then prepare the folder to work with specific Winnt.exe options and run Winnt.exe across the network using those options. For example, you can create a shared subfolder with additional drivers and have the subfolder installed at the same time as the operating system.

For more information about Winnt.exe, see “Command line reference A-Z” on the Microsoft TechNet Web site. For more

information about using Winnt.exe for unattended installation, see "Unattended Installation Technical Reference."

# Unattended Installation Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Unattended Installation Technical Reference**
Unattended installation is an automated installation technology in Microsoft Windows Server 2003 that you can use to install or upgrade an operating system with minimal user intervention. Unattended installation uses an answer file to automatically answer the questions that the Windows Setup program asks during the Windows setup process. Unattended installation is typically used during large-scale rollouts when it would be too slow and costly to have administrators or technicians interactively install the operating system on individual computers.

**In this subject**

# What Is Unattended Installation?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Unattended Installation?**

**In this section**

- Common Unattended Installation Scenarios
- Unattended Installation Dependencies
- Technologies Related to Unattended Installation
- Related Information

Unattended installation is an automated installation technology in Microsoft Windows Server 2003 that you can use to install or upgrade an operating system with minimal user intervention. Unattended installation is typically used during large-scale rollouts when it would be too slow and costly to have administrators or technicians interactively install the operating system on individual computers.

One of the essential components of an unattended installation is an answer file. An answer file is a simple text file that instructs the Windows Setup program how to install and configure the operating system. To perform an unattended installation, you run Setup with a special command-line parameter that instructs Setup to read the answer file. Then, during the setup process, instead of prompting you for installation and configuration information interactively, Setup follows the instructions contained in the answer file.

The following figure shows how an unattended installation differs from an interactive setup.

**Comparison of Unattended Installation and Interactive Setup**

Like all automated installation technologies, unattended installation has many benefits that standard interactive setup does not.

**Fewer errors during installation**

Because unattended installation uses an answer file to install and configure the operating system, there is minimal interaction by administrators or technicians during the setup process. This reduces the number of errors that are introduced during the setup process.

**Greater consistency during a rollout**
By using the same answer file to install and configure the operating system, you can ensure that all of the computers in your organization are set up exactly the same way.

**Shorter installation times**
Unattended installation is faster than interactive setup because Setup does not have to prompt administrators or technicians for configuration information and wait for them to enter it; instead, Setup reads configuration settings from an answer file.

**Lower support costs**
By minimizing errors during the setup process, increasing the consistency of the computers in your organization, and reducing the amount of time a technician needs to spend setting up a computer, you can reduce the overall support costs in your organization.

Unattended installation is a suitable automated installation technology if you need to:

- Upgrade a Windows operating system to Microsoft Windows XP Professional, Microsoft Windows Server 2003, Standard Edition; or Microsoft Windows Server 2003, Enterprise Edition operating systems.
- Perform clean, automated installations on computers that have heterogeneous hardware configurations.
- Perform clean, automated installations on specific types of servers, such as domain controllers, remote access servers, and servers that run Certificate Services or the Cluster service.
- Configure a wide range of operating system settings during an automated installation without using batch files and scripts.

**Common Unattended Installation Scenarios**
Although unattended installation is a robust installation technology, and can be used to roll out many types of server configurations, some installation scenarios are particularly well suited for unattended installation.

**Heterogeneous Hardware**
Unattended installation is ideal if you are installing the same server configuration on computers that have dissimilar or heterogeneous hardware. For example, you can use unattended installation to roll out the same file server configuration to a group of computers that have different processor configurations and different storage configurations because an unattended installation can detect and install the appropriate hardware abstraction layer (HAL) and the appropriate hard disk controller during the installation process. Other automated installation technologies — particularly image-based technologies — have a limited ability to detect and install different HALs and hard disk controllers during the installation process.

In addition, unattended installation is equally adept at handling other hardware differences, including differences among network adapters, media devices (CD drives), and video adapter cards. In large part, this is because unattended installation is just an automated process that uses the standard Setup program. Therefore, whatever device Setup can detect or install, unattended installation can also detect or install.

**Upgrades**
You can use unattended installation to upgrade a Windows server operating system to Microsoft Windows Server 2003, Standard Edition or Microsoft Windows Server 2003, Enterprise Edition operating systems. You cannot use unattended installation to upgrade a Windows operating system to Windows Server 2003, Web Edition. No other automated installation technology can perform upgrades.

Unattended upgrade installations are commonly performed by small organizations that have only a limited number of servers and a limited number of IT professionals to perform installations. An unattended upgrade installation is preferred in this situation because existing server settings are retained during an upgrade (for example, user rights, groups, and permissions settings), and applications and files do not need to be reinstalled.

The following table shows the types of upgrades that you can perform by using unattended installation.

**Types of Upgrades by Using Unattended Installation of Windows Server 2003**

| Existing Operating System | Upgrade to Windows Server 2003, Standard Edition | Upgrade to Windows Server 2003, Enterprise Edition |
|---|---|---|
| Microsoft Windows NT Server 3.51 | | |
| Microsoft Windows NT Server version 4.0 (with Service Pack 5) | ● | ● |
| Microsoft Windows NT version 4.0, Terminal Server Edition | ● | ● |
| Microsoft Windows NT version 4.0, Enterprise Edition | | ● |
| Microsoft Windows 2000 Server | ● | ● |
| Microsoft Windows 2000 Advanced Server | | ● |
| Microsoft Windows Server 2003, Standard Edition | | ● |

There are three exceptions to the upgrades listed in the previous table:

- You cannot upgrade from one localized version of a Windows operating system to another localized version of a Windows operating system. For example, you cannot upgrade from the Japanese version of Windows 2000 Server to the English version of Windows Server 2003, Standard Edition.

- You cannot upgrade the operating system of a computer that has the Multilingual User Interface Pack (MUI Pack) except to the English version of the operating system.

- You cannot upgrade the operating system from Windows NT 4.0 unless you have Service Pack 5 or later installed. It is not possible to upgrade from Windows NT 4.0 with Service Pack 4 or earlier.

**Note**

- You cannot use unattended installation to install or upgrade to Windows Server 2003, Datacenter Edition.

**Domain Controllers and Servers Running Certificate Services and Cluster Service**

Unattended installation is an ideal automated installation technology for deploying domain controllers, and member servers that run Certificate Services and Cluster service. Although you can use other automated installation technologies to deploy these types of servers, those technologies require you to use scripts or supplemental answer files after the automated installation is finished. With unattended installation, the answer file contains all of the necessary settings for installing these types of servers.

**Master Installations for Image-based Deployment Technologies**

You can use unattended installation to create master installations for image-based installation technologies, such as the System Preparation (Sysprep) tool, or Remote Installation Services (RIS) when it is being used for image-based installation. For example, to use Sysprep, you need to create a master installation from which you create a disk image. You can create the master installation manually by running Setup, and then manually configuring operating system settings and installing software, or you can automate the creation of the master installation by performing an unattended installation on the master computer.

By using unattended installation to create master installations you:

- Introduce fewer installation errors because unattended installation relies on an answer file for configuration settings.

- Enhance consistency among all of your master installations because you can use the same answer file as a basis for each of your master installations.

- Decrease the amount of time it takes to modify and create a master installation because unattended installation is much simpler and quicker than manual installation.

- Maintain a record of each of your master installations because the settings are all recorded in an answer file (with the exception of password and product key information).

**Unattended Installation Dependencies**
To perform an unattended installation, you need the following:

- Answer file
- Operating system files, including the Windows Setup program

Because an unattended installation is an automated way of using Setup, you can perform an unattended installation only by running one of the two Windows Setup programs, Winnt.exe or Winnt32.exe. Winnt.exe is a 16-bit Setup program that you can use to perform an unattended installation by starting a destination computer with a 16-bit operating systems such as MS-DOS. Winnt32.exe is a 32-bit Setup program that you can use to perform an unattended installation by starting a destination computer with a 32-bit operating system such as Windows 95, Windows 98, Windows NT, Windows 2000, Windows XP, or Windows Server 2003. You can also perform an unattended installation on an Itanium architecture-based computer by running Winnt32.exe from the command prompt on the following: Windows XP 64-Bit Edition; the 64-bit version of Windows Server 2003, Enterprise Edition; or the 64-bit version of Windows Server 2003, Datacenter Edition.

An answer file can be created in two ways: by using a text editor such as Notepad, or by using Setup Manager (Setupmgr.exe). Setup Manager is a wizard-like tool that prompts you for a series of configuration parameters, and then writes your responses to an answer file.

You also need a Windows Server 2003 product CD, or a shared distribution folder ("distribution share") that contains the Windows Server 2003 installation files. If you store the installation files on a distribution share, each of your destination computers needs a high-speed network connection and appropriate permissions to access the server on which the distribution share resides.

**Technologies Related to Unattended Installation**
Unattended installation is similar to two other automated installation technologies: image-based installation with the Sysprep tool and Remote Installation Services (RIS) installation. Like unattended installation, these technologies are designed specifically as mass roll-out or deployment solutions. Although you can use these technologies to automate the installation of Windows Server 2003, each of these technologies is based on a different installation process, and relies on a different set of programs and tools.

**Image-based installation with Sysprep**
Image-based installation with the Sysprep tool is a method of copying, also known as *cloning*, preconfigured operating systems and software applications to servers.

Image-based installation with Sysprep is a suitable automated installation technology if you need to:

- Install identical operating systems and software configurations on multiple computers.
- Install an operating system and software configuration as quickly as possible.
- Eliminate administrator and technician interaction during the setup process.
- Minimize post-installation tasks.
- Perform clean installations of an operating system, rather than upgrade existing installations.
- Install operating systems on computers that have similar hardware and a compatible HAL.

You need two tools to perform an image-based installation with Sysprep: Sysprep, which can be found on any Windows Server 2003 product CD; and a disk-imaging program. Usually, you use a non-Microsoft disk-imaging program, which you must purchase from a vendor. However, you can instead perform an image-based installation with Sysprep by using Windows Server 2003 Automated Deployment Services (ADS). ADS is part of the Dynamic Systems Initiative (DSI), and can be used to rapidly deploy Windows server operating systems.

Image-based installation with Sysprep requires substantial planning and design, but it is the fastest method of installing

operating systems and applications. You cannot use it to perform operating system upgrades.

**RIS installation**
RIS installation is a method of cleanly installing an operating system and applications over a network with minimal administrator or technician interaction. RIS uses Pre-Boot Execution Environment (PXE) technology to enable client computers without an operating system to start up from a PXE-enabled network adapter and connect remotely to a RIS server, which installs a supported operating system.

RIS is a suitable automated installation technology if you need to:

- Eliminate administrator and technician interaction during the setup process.
- Minimize post-installation tasks.
- Perform clean installations of an operating system, rather than upgrade existing installations.

RIS installation is more complex and requires more upfront configuration and planning than image-based installation and unattended installation. However, RIS installation is an efficient deployment technology if you have a high-speed network and you need to perform clean installations of operating systems and preconfigured applications on a large number of computers.

# How Unattended Installation Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Unattended Installation Architecture
- Unattended Installation Physical Structures
- Unattended Installation Processes and Interactions
- Related Information

Unattended installation is an automated installation technology that you can use to install an operating system with minimal administrator or technician intervention. Unattended installation is typically used during large-scale rollouts when it would be too slow and costly to have administrators or technicians interactively install the operating system on individual computers. It can also be used to upgrade operating systems.

One of the essential components of an unattended installation is an answer file that you create. An answer file is a simple text file that instructs the Windows Setup program how to install and configure the operating system. To perform an unattended installation, you run Setup by using a special command-line parameter that instructs Setup to read the answer file, or you start the destination computer with the product CD and then insert a floppy disk that contains an answer file. Then, during the setup process, instead of prompting you for installation and configuration information interactively, Setup follows the instructions contained in the answer file.

The following sections provide an in-depth view of how unattended installation works in an optimal environment. An optimal environment for unattended installation contains the following elements:

- Plug and Play hardware that is compatible with Windows Server 2003.
- High-bandwidth network connectivity between the computer on which the unattended installation is being performed (destination computer) and any installation file that resides in a shared folder (distribution share).
- Physical access to the destination computer.
- BIOS and hardware configured so that you can start the computer from the product CD.
- BIOS and hardware configured so that you can start the computer from the floppy disk.

**Unattended Installation Architecture**

Unattended installation relies on the same setup components as an interactive setup. These components are used in three distinct setup stages, including the initial stage (also known as data-collection stage), the intermediate stage (also known as text-mode stage), and the final stage (also known as GUI-mode stage). These three stages culminate with a final restart, after which a user logs onto the computer for the first time. In addition, unattended installation relies on several answer files and optional components, such as a distribution share, a product CD, and a renaming answer file to rename long file and folder names. How these components interact is illustrated in the following figure.

**Unattended Installation Architecture**

The following are descriptions of the primary unattended installation components.

**$ldr$**

The Setup loader, similar to Ntldr, which starts the destination computer in a special setup state during which the intermediate stage of unattended installation occurs. This file is named Setupldr.bin on the product CD. Setupldr.bin is renamed $ldr$ and copied to the destination computer's hard disk when you do not start the destination computer from the product CD.

**$win_nt$.~ls**

Temporary installation folder created on the hard disk of the destination computer that contains the files and folders that are copied from the I386 folder in the distribution share.

**$win_nt$.~bt**

Temporary installation folder created on the hard disk of the destination computer that contains temporary startup files. The startup files are used to restart the computer into a special setup state that allows the intermediate stage of unattended installation to occur.

**$Winnt$.inf**

Final version of the unattended installation answer file that Setup creates and saves in the *systemroot*\System32 folder on the destination computer. Setup makes this a hidden file and names it $winnt$.inf, regardless of what the name of the original answer file is.

**$$Rename.txt**

A file that lists all files contained in a particular folder that need to be renamed from an 8.3 format name to a long file name during the setup process. All file names must be in 8.3 format if you run Setup by using Winnt.exe, or if you copy a set of files from one computer to another using MS-DOS.

**Cmdlines.txt**

A configurable text file that you use to customize an unattended installation. Cmdlines.txt contains a list of commands that run synchronously after Setup finishes, but before a computer restarts.

**Destination computer**

Computer on which you are installing an operating system. During a large-scale rollout, there can be typically hundreds or thousands of destination computers.

**Distribution share (I386\)**

Hierarchical folder structure that is stored in a shared folder on a remote computer (usually a server). The distribution share contains all of the Windows Server 2003 installation files that are necessary to perform an unattended installation. You can use Setupmgr.exe to create a distribution folder, or you can create one manually by using Windows Explorer.

**[GUIRunOnce]**

A section in an unattended installation answer file that contains a list of commands, programs, scripts, or batch files that run the first time a user logs on to the computer after the operating system is installed.

**Setupapi.dll**

Dynamic-link library that is responsible for installing hardware.

**Setupdd.sys**
System file responsible for performing tasks during the intermediate stage of unattended installation, such as creating or modifying the system folder (usually, C:\Windows or C:\Winnt), copying system files and folders from the temporary folder or the product CD to the system folder, and building the registry. It is also responsible for creating partitions and formatting disks.

**Setupldr.bin**
The Setup loader, similar to Ntldr, which starts the destination computer in a special setup state during which the intermediate stage of unattended installation occurs. Setupldr.bin is renamed $ldr$ and copied to the destination computer's hard disk if you do not start the destination computer from the product CD.

**Syssetup.dll**
Dynamic-link library that performs installation and configuration tasks during the final stage of unattended installation. This component might have to access the CD in order to install optional components.

**Technician computer**
Computer used by an administrator or technician to use Setup Manager or Notepad to create and modify answer files, such as Unattend.txt or Cmdlines.txt.

**Txtsetup.sif**
System information file that Setup uses during the setup process. Txtsetup.sif defines the names of installation files and folders, where files and folders are copied, and how to process existing files and folders (for example, delete or overwrite). Txtsetup.sif is saved in the I386 folder of the distribution share and resides in the I386 folder of every product CD.

**Unattend.txt**
Default name for an unattended installation answer file. You can name an answer file anything you want, but Unattend.txt is the name that Setupmgr.exe uses when you first create an answer file.

**Winlogon.exe**
A component of the Windows operating system that provides interactive logon support. Winlogon is designed around an interactive logon model that consists of three components: the Winlogon executable, a Graphical Identification and Authentication dynamic-link library (DLL) referred to as the GINA, and many network providers.

**Winnt32.exe**
The 32-bit and 64-bit Setup program. You can run the 32-bit version of this program on Windows 95, Windows 98, Windows Millennium Edition, Windows NT, Windows 2000, Windows XP, or a product in the Windows Server 2003 family. The 32-bit version of this program can be found in the I386 folder on any 32-bit Windows operating system product CD. You can run the 64-bit version of this program on Windows XP 64-bit Edition, the 64-bit version of Windows Server 2003, Enterprise Edition, and the 64-bit version of Windows Server 2003, Datacenter Edition. The 64-bit version of this program can be found in the IA64 folder on any 64-bit operating system product CD.

**Winnt32u.dll**
Dynamic-link libraries that perform installation tasks during the initial stage of unattended installation. These include assessing the current operating system that is installed on the destination computer, copying installation files and folders from the distribution share to the temporary folders, parsing the answer file, and creating intermediate information files that are used by the intermediate stage of unattended installation.

**Winnt.exe**
The 16-bit Setup program. You can use this program to start an unattended installation from any 16-bit operating system, such as MS-DOS.

**Winnt.sif**
Name you must use for the answer file if you are performing an unattended installation by starting a destination computer from the Windows Server 2003 product CD. Winnt.sif is also the name of an intermediate information file that Setup creates after the initial stage of unattended installation. This intermediate file contains all of the information that is in the answer file (regardless what the name of the answer file is), as well as information about the destination computer and the type of installation you are performing.

**Unattended Installation Physical Structures**
Two physical structures are essential to an unattended installation: the distribution share and the answer file. You can create these structures by using Setup Manager (Setupmgr.exe) or you can create them manually by using Windows Explorer and a text editor, such as Notepad. These structures are illustrated in the following figure and are described in the sections that follow.

### Unattended Installation Physical Structures

**Distribution Share Structure**

A distribution share consists of a single, top-level folder named I386 and several subfolders. The following figure shows the structure of a distribution share.

**Distribution Share Structure**

**Distribution Share Folders**

The following sections describe the folders that can exist in a distribution folder.

**I386**

This is the distribution share. You create it at the root of the distribution server (the server on which the distribution share is located). This folder must be named I386 if it contains installation files for a 32-bit operating system; it must be called IA64 if it contains installation files for a 64-bit operating system. You can create this folder manually by copying the I386 folder that is on a Windows Server 2003 or Windows XP Professional product CD to your distribution server. You can also use Setup Manager to create this folder.

**$OEM$**

You create the $OEM$ subfolder directly beneath the I386 folder. During the setup process, you can automatically copy folders, standard 8.3 format files, and any tools needed for your automated installation process to the $OEM$ subfolder. However, the contents of this folder are copied only when you include the following setting in your answer file:

```
[Unattended]
OemPreInstall = Yes
```

If you want to create the $OEM$ subfolder in a different location than the distribution share, you can use the OemFilesPath parameter in the answer file to specify a different location.

The $OEM$ subfolder can contain the optional file Cmdlines.txt, which contains a list of commands to be run at the end of the final stage of unattended installation. These commands can be used to install additional services or applications that you want to include with your installation.

As long as Setup finds the $OEM$ subfolder in the root of the distribution share, Setup copies all the files found in this folder

to a temporary folder that is created during the initial stage of unattended installation on the destination computer.

**$OEM$\Textmode**
The $OEM$\Textmode subfolder contains new or updated files for installing mass storage device drivers and hardware abstraction layers (HALs). These files can include an OEM HAL, drivers for a small computer system interface (SCSI) device, and a Txtsetup.oem file, which directs the loading and installing of these components. Be sure to include the Txtsetup.oem file in this folder: most device drivers cannot be installed without a Txtsetup.oem file. All files placed in the $OEM$\Textmode subfolder (HALs, drivers, and Txtsetup.oem) must be listed in the [OEMBootFiles] section of the answer file.

**$OEM$\$$**
The $OEM$\$$ subfolder is equivalent to the systemroot or windir environment variable. The subfolder contains additional files that need to be copied to the various subfolders of the Windows Server 2003 or Windows XP Professional installation directory. The structure of this subfolder must match the structure of a standard Windows Server 2003 or Windows XP Professional installation, where $OEM$\$$ matches systemroot or windir (for example, C:\Windows), $OEM$\$$\Fonts matches *systemroot*\Fonts, and so on. Each subfolder must contain the files that need to be copied to the corresponding system folder on the destination computer.

**$OEM$\$$\Help**
A subfolder that contains the OEM Help files to be copied to the *systemroot*\Help folder during the setup process.

**$OEM$\$$\System32**
A subfolder that contains files to be copied to the *systemroot*\System32 folder during the setup process.

**$OEM$\$1**
This folder points to the drive on which Windows Server 2003 or Windows XP Professional is installed; $1 is equivalent to the systemdrive environment variable. For example, if you are installing Windows Server 2003 on drive D, $OEM$\$1 points to drive D.

**$OEM$\$1\Pnpdrvrs**
You can use the $OEM$\$1\Pnpdrvrs subfolder to place new or updated Plug and Play device drivers in your distribution shares. These folders are copied to the *systemdrive*\Pnpdrvrs location on the destination computer. Adding the OemPnPDriversPath parameter to your answer file directs Windows Server 2003 or Windows XP Professional to look (both during and after the setup process) for new or updated Plug and Play drivers in the folders that you created, in addition to those originally included with the system. Note that you can replace the file name Pnpdrvrs with any name that is eight or fewer characters long.

**$OEM$\$1\Sysprep**
The $OEM$\$1\Sysprep subfolder is optional. This subfolder contains the files that you need to run the System Preparation (Sysprep.exe) tool.

**$OEM$\drive_letter**
During the intermediate stage of unattended installation, the structure and contents of each $OEM$*drive_letter* subfolder are copied to the root of the corresponding drive on the destination computer. For example, files that you place in the $OEM$\D subfolder are copied to the root of drive D. You can also create subfolders within these subfolders. For example, $OEM$\E\Misc causes Setup to create a subfolder called Misc on drive E.

**Converting Short File Names to Long File Names by Using $$Rename.txt**
If you are using Winnt.exe to perform an unattended installation, your distribution share can contain only files and folders that have short file names. This is because Winnt.exe runs only on MS-DOS, and MS-DOS can process only files and folders that use the 8.3 naming convention. The 8.3 naming convention allows only eight characters to the left of the decimal point and three characters to the right of the decimal point. Because of the short file name limitation, you need to shorten the names of files and folders so that you can put them into your distribution share. You can convert these short file and folder names back to long file and folder names during the setup process by using the $$Rename.txt file.

$$Rename.txt lists all of the files and folders that need to be renamed. You need only one $$Rename.txt file to rename files in an entire distribution share. If you are using Winn32.exe to perform an unattended installation, short file names are automatically converted to long file names during the setup process.

To use $$Rename.txt, put the file in the $1 folder in your distribution share. Saving the $$Rename.txt file in this location will ensure that the $$Rename.txt file is copied to the systemdrive on the destination computer. Setup automatically looks for $$Rename.txt; if it finds a $$Rename.txt file, Setup renames the files and folders that are in your distribution share. The syntax for $$Rename.txt is:

```
[
section_name_1
]
```

```
short_name_2 = long_name_2short_name_1 = long_name_1short_name_x= "long_name_x"
.
.
.
[section_name_2]
short_name_1 = long_name_1short_name_2 = long_name_2short_name_x= "long_name_x"
.
.
.
```

Where:

- *section_name_x* is the path to the folder that contains the files and folders. A section does not need to be named; it can have a backslash (\) as a name, which indicates that the section contains the names of the files or subfolders that are in the root of the drive.

- *short_name_x* is the name of the file or folder within this named folder that needs to be renamed. The name *must not* be enclosed in quotation marks.

- *long_name_x* is the new name of the file or folder. If the name contains spaces or commas, it *must* be enclosed in quotation marks.

**Answer File Structure**

The answer file for unattended installations of Windows Server 2003 is usually named Unattend.txt, but you can name it anything you want. However, if you start a destination computer from a product CD and the answer file is on a floppy disk, you must name the answer file Winnt.sif. Setup will then detect the answer file on the disk without user input.

The answer file supplies Setup with answers to all the questions that an administrator or technician would be asked during a standard, interactive setup. The answer file also contains information about your installation and configuration requirements. In addition, an answer file tells Setup how to interact with the distribution shares and files that you have created (or the installation files on the product CD).

An answer file contains multiple sections — some mandatory and some optional — that you can modify. Section names are always enclosed in square brackets (for example, [Unattended]).

Every section has one or more entries that contain installation and configuration information. Entries are usually composed of an entry name, an equal sign, and a value (for example, `ComputerName = Computer1`). The entry name represents a specific computer setting or action; the value represents the unique way you want the setting configured or the action performed. In some cases, entries do not have an entry name. In these cases, a value or a list of values (usually commands) appear in the answer file below a section name. The following example shows a section that contains only values and does not have entry names.

```
[GUIRunOnce]
dcpromo /answer:a:\installdc.txt
%systemroot%\cluster\cluster.exe
```

Use the following guidelines when you create or modify an answer file:

- Sections do not have to be any particular order.

- Sections and entries are not case sensitive.

- Entries must have valid values. For example, “on” is not equivalent to “enable,” and “off” is not equivalent to “disable.” Invalid sections and entries can generate errors, or cause Setup to fail.

- Each entry must have a value.

- Each section and entry must appear on a separate line.

- Comments must begin with a semi-colon (;). Do not use “REM” to specify a comment.

**Note**

- Do not modify undocumented sections or entries in an answer file; doing so can cause unpredictable results.

The following table lists all of the valid sections that can appear in an answer file for an unattended installation.

**Answer File Sections for Unattended Installation**

| Section | Description |
|---|---|
| [*adapter_specific_protocol_section*] | Contains an entry for specifying a network component. Must be used in conjunction with the [Networking] section. |
| [Branding] | Contains entries for branding Microsoft Internet Explorer during an unattended installation. If you do not specify this section, Setup uses the default for Windows Server 2003. |
| [CertSrv_Client] | Contains entries for the Web client component of Certificate Services. You do not need to include this section in the answer file to install the Web client component of Certificate Services on the computer. Enabling Certificate Services in the [Components] section of the answer file installs the necessary files. |
| [CertSrv_Server] | Contains entries for specifying the server components of Certificate Services. The entries in this section are supported only for the Windows Server 2003. |
| [Components] | Contains entries for installing the optional components of Windows XP Professional and Windows Server 2003. |
| [Data] | Contains entries for starting directly from the Windows Server 2003 product CD when performing an unattended installation. |
| [DCInstall] | Contains entries for installing a domain controller after the initial setup of the operating system finishes. |
| [Display] | Contains entries for specifying display settings for graphics devices. |
| [FavoritesEx] | Contains the default Favorites settings for the Windows browser. If not present, Setup uses the default Uniform Resource Locator (URL) for Windows XP or Windows Server 2003. |
| [Fax] | Contains entries for specifying custom installation information for the Fax service. |
| [GuiRunOnce] | Contains commands that run the first time a user logs on to the computer after final (GUI-mode) stage of Setup completes. |
| [GuiUnattended] | Contains entries for preparing the graphical user interface (GUI) for unattended installation. |
| [Homenet] | Contains entries for installing Home Networking settings for network adapters, Internet Connection Sharing (ICS), and Internet Connection Firewall (ICF). |
| [Identification] | Contains entries for specifying the network identification of a computer. If these entries are not present, Setup adds the computer to the default workgroup. If there is not enough information for this entry, Setup prompts the user to provide this information. |
| [IEHardening] | Contains entries for configuring Web content zones. |
| [InternetServer] | Contains entries for configuring the installation folder for Internet Information Services (IIS) components. |
| [LicenseFilePrintData] | Contains entries for installing licensing information for Windows Server 2003. |

| | |
|---|---|
| [MassStorageDrivers] | Contains an entry for loading retail or original equipment manufacturer (OEM) small computer system interface (SCSI) drivers in the Setup Loader during the intermediate (text-mode) stage of Setup |
| [*MS_AppleTalk parameters*] | Contains entries for configuring AppleTalk. |
| [*MS_ATMArps parameters*] | Contains no entries. |
| [*MS_ATMLANE parameters*] | Contains no entries. |
| [*MS_ATMUni parameters*] | Contains no entries. |
| [*MS_L2TP parameters*] | Contains entries for the Layer 2 Tunneling Protocol (L2TP). |
| [*MS_MSClient parameters*] | Contains entries for Client for Microsoft Networks. |
| [*MS_NetMon parameters*] | Contains no entries. |
| [*MS_NWClient parameters*] | Contains entries for Client Service for NetWare. |
| [*MS_NWIPX parameters*] | Contains entries for the Internetwork Packet Exchange (IPX) protocol. Its parameters are network adapter–independent. |
| [*MS_NwSapAgent parameters*] | Contains no entries. |
| [*MS_PPTP parameters*] | Contains entries for the Point-to-Point Tunneling Protocol (PPTP). |
| [*MS_Psched parameters*] | Contains no entries. |
| [*MS_RAS parameters*] | Contains entries for the Routing and Remote Access service. |
| [*MS_RasSrv parameters*] | Contains entries for the Routing and Remote Access service for remote access servers. |
| [*MS_Server parameters*] | Contains entries for the File and Print Service. |
| [*MS_TCPIP parameters*] | Contains entries for configuring the TCP/IP protocol. |
| [*MS_WLBS parameters*] | Contains entries for configuring Network Load Balancing (formerly, Windows Load Balancing Service, or WLBS) and binding Network Load Balancing to multiple network adapters. |
| [NetAdapters] | Contains entries for network adapters that you want to install. |
| [NetBindings] | Contains entries for disabling, enabling, and demoting binding rules for network components such as services, protocols, and adapters. |
| [NetClients] | Contains an entry for specifying the network clients to install. |
| [NetOptionalComponents] | Contains entries for installing optional network components. |
| [NetProtocols] | Contains an entry for installing the network protocols. |
| [NetServices] | Contains entries for installing network services. |
| [Networking] | Contains no entries. However, to configure network protocols in unattended installation, you must include the [Networking] section name in your answer file. |
| [OEMBootFiles] | Contains entries for specifying OEM-supplied boot files. |
| [*params.adapter_instance*] | Contains entries for specifying an adapter's instance on a computer by using either PCI location information or a Plug and Play device ID. |
| [PCHealth] | Contains entries for configuring error reporting, Remote Assistance, and Help and Support Center. |

| | |
|---|---|
| [*protocol_parameters_section*] | Contains an entry for specifying network protocol parameters that are also specified in the [NetProtocols] section. |
| [Proxy] | Contains entries for specifying proxy server settings for the Windows XP or Windows Server 2003 browser. |
| [RegionalSettings] | Contains entries for installing regional options during the setup process. |
| [SetupMgr] | Contains entries for specifying the server and folder in which the distribution share resides and the name of the distribution share. This section is used only by Setup Manager when an existing distribution share is edited. It is not used by Setup during an unattended installation. |
| [SetupParams] | Contains an entry for running an additional post-Setup command. |
| [Shell] | Contains entries for specifying the visual style of the user interface. |
| [SNMP] | Contains entries for specifying the Simple Network Management Protocol (SNMP) service. |
| [SystemFileProtection] | Contains entries for specifying Windows File Protection (WFP) settings. |
| [SystemRestore] | Contains entries for specifying the System Restore feature. |
| [TapiLocation] | Contains entries for specifying the telephony API (TAPI). It is valid only if a modem is present on the computer. |
| [TerminalServices] | Contains entries for configuring Terminal Services features (Terminal Server and Remote Desktop). |
| [Unattended] | Contains entries for running Setup. |
| [Uninstall] | Contains entries for allowing users who upgrade to Microsoft Windows XP to remove the operating system if they encounter problems. |
| [URL] | Contains entries for specifying default Uniform Resource Locator (URL) settings for the browser available in Windows XP or Windows Server 2003. |
| [UserData] | Contains entries for specifying user settings during the setup process. |
| [WindowsFirewall] | This section must be included in your answer file to configure firewall sections and entries in unattended installations. To configure Windows Firewall settings, you must include the [WindowsFirewall] section along with one or more of the other Windows Firewall settings sections. |
| [WindowsFirewall.*profile_name*] | Contains entries for specifying a domain type of profile, a standard type, or a profile that applies to both domain and standard. |
| [WindowsFirewall.*program_name*] | Contains entries for adding programs to the Windows Firewall Exceptions list. |
| [WindowsFirewall.*service_name*] | Contains entries for adding services to the Windows Firewall Exceptions list. |
| [WindowsFirewall.*portopening_name*] | Contains entries for adding static ports to the Windows Firewall Exceptions list. |
| [WindowsFirewall.*icmpsetting_name*] | The default configuration for Windows Firewall blocks all Internet Control Message Protocol (ICMP) message types, the entries in this section allows you to modify this behavior. |
| [Win9xUpg] | Contains entries for specifying an unattended upgrade from Windows 98, Windows 98 Second Edition, or Windows Millennium Edition to either Windows XP Home Edition or Windows XP Professional. |

You do not need to add every possible section and entry to an answer file. Most sections and entries are optional, and Setup ignores optional sections and entries that are not present in an answer file.

**Entries for Fully-Automated Unattended Installation**
If you want to perform a fully-automated unattended installation, you must configure the following sections and entries in your answer file. If you do not provide values for these entries in your answer file, Setup will display a prompt asking for the values.

**[GuiUnattended]**
You must specify values for the AdminPassword and TimeZone entries. The value for AdminPassword cannot begin with an asterisk (*). Using a password that begins with an asterisk can cause the password to be set to a null value, which can be a security risk.

**[Identification]**
You must specify values for the JoinDomain, DomainAdmin, and DomainAdminPassword entries. However, if you are concerned about security you might want to leave the DomainAdminPassword blank because this entry cannot be encrypted in the answer file. If you leave the DomainAdminPassword entry blank, you will be prompted for the password during the unattended installation.

**[LicenseFilePrintData]**
You must specify values for the AutoMode and AutoUsers entries if you are installing Windows Server 2003.

**[Networking]**
If your destination computer requires network connectivity, you must specify values for various network protocol entries.

**[Unattended]**
You must specify values for the UnattendMode and TargetPath entries.

**[UserData]**
You must specify values for the FullName and ComputerName entries.

**Entries for Unattended Upgrade**
If you are performing an unattended upgrade, you can use only the following answer file sections and entries. All other sections and entries are ignored during an unattended upgrade.

**[Unattended]**
You must specify values for either the NtUpgrade or the Win9xUpgrade entry. You must use the entry `OEMPreinstall = No`, which will prevent the files and folders in the $OEM$ folder in your distribution share from being copied to the destination computer. You can also set values for the AutoActivate, DUDisable, DUShare, and DUStopOnError entries.

**[UserData]**
You can set a value for the ProductKey entry. If you do not, the administrator or technician will be prompted for a product key.

In addition, your answer file must reside on a floppy disk and you must use the product CD instead of a distribution share.

For more information about answer file sections, including descriptions and examples of entries and values, see "Unattended Installation Tools and Settings."

**Unattended Installation Processes and Interactions**
Because there are numerous different ways to perform an unattended installation, it is impractical to describe all of the processes and interactions that occur for each method and variation. Therefore, this section describes the processes and interactions that occur during the two most commonly used methods of performing an unattended installation: a fully-automated unattended installation when you start the destination computer from a 32-bit operating system, and a fully-automated unattended installation when you start the destination computer from the product CD.

In addition, this section describes log file interactions that occur during an unattended installation as well as the processes that occur when you perform post-installation tasks by using a Cmdlines.txt file or the [GUIRunOnce] section of an answer file.

**Unattended Installation When You Start the Computer from a 32-bit Operating System**
The following figure shows the processes and interactions that occur during a fully-automated unattended installation of Windows Server 2003 when you start the destination computer from a 32-bit operating system and you copy the installation files from a distribution share. The 32-bit operating system can be any of the following: Windows XP, Windows NT, Windows 2000, and Windows Server 2003. The distribution share can be saved on any accessible server that you can secure with file and folder permissions.

### Note

- You can also copy the installation files from the product CD; however, it is more common to use a distribution share when you start the destination computer from a 32-bit operating system.

**Unattended Installation from a 32-bit Operating System Using a Distribution Share**

This figure is based on the following requirements:

- The destination computer is running Windows 2000 Server (or an equivalent 32-bit Windows operating system).
- The distribution share is named Win2003_Std and is saved in the OS_Shares folder on the distribution server.
- The answer file is named Unattend.txt and is saved in the distribution share.
- All of the installation files, including Winnt32.exe, are saved in the I386 folder in the distribution share.
- The unattended installation is a clean installation of the operating system (not an upgrade).
- The unattended installation is started from the existing Windows 2000 Server operating system by running Winnt32.exe at the command line.

In addition, the following answer file is used to perform this installation:

```
 [Unattended]
    UnattendMode=FullUnattended
    OemSkipEula=Yes
    OemPreinstall=Yes
    FileSystem = LeaveAlone
    TargetPath= *

[GuiUnattended]
    AdminPassword=ca8d43d0eae56d1019ac6cc7a3608820ae698f3d8ce553674c94fb185
    EncryptedAdminPassword=Yes
    OEMSkipRegional=1
    TimeZone=004
    OemSkipWelcome=1

[UserData]
    ProductKey=#####-#####-#####-#####-#####
    FullName="My Name"
    OrgName="Microsoft Corporation"
    ComputerName=Server2

[Display]
    BitsPerPel=24
    Xresolution=800
    YResolution=600
    Vrefresh=70

[LicenseFilePrintData]
    AutoMode=PerServer
    AutoUsers=5

[TapiLocation]
    CountryCode=1
```

```
    Dialing=Tone
    AreaCode=425
    LongDistanceAccess="9"

[SetupMgr]
    DistFolder=\\Server1\OS_Shares
    DistShare=Win2003_Std

[Identification]
    JoinDomain=MyDomain
    DomainAdmin=MyAdmin
    DomainAdminPassword=MyPassword

[Networking]
    InstallDefaultComponents=Yes
```

**Starting the Unattended Installation**
The processes and interactions described in this section are valid only when you start the installation by mapping a network drive to the distribution share from the destination computer, navigating to the distribution share, and running Winnt32.exe with the `/unattend` parameter. You need to map a network drive to the distribution share because all of the installation files, including Winnt32.exe, and the answer file, Unattend.txt, are saved in the distribution share.

**Initial Stage**
After you start an unattended installation from a 32-bit operating system, the initial stage (also known as data-collection stage) of unattended installation begins. The following actions occur during the initial stage of an unattended installation:

**Assess current operating system**
The current operating system configuration is assessed, including operating system version, available disk space, hardware, and installed components.

**Process answer file**
The answer file is parsed and the results are saved in a new file named Winnt.sif. This file contains all of the settings that are in the answer file as well as other information that was gathered during the system assessment.

**Begin Welcome to Windows Setup**
The Welcome to Windows Setup dialog boxes appear briefly and then close. During an interactive setup this sequence of dialog boxes prompts you for several configuration settings, including installation type (upgrade or clean installation), product key, acceptance of the End-User License Agreement (EULA), installation folder, location of installation files, language options, accessibility options, and dynamic update options. Because this information is specified in the answer file, the introductory dialog box stays open for only a few seconds and then closes; other dialog boxes are not displayed.

**Copy files to temporary folders**
During the initial stage, Setup creates two temporary folders on the destination computer's hard disk — $win_nt$.~ls and $win_nt$.~bt. The $win_nt$.~ls folder (known as the local source folder) contains the installation files, which are copied from the $OEM$ folder in the distribution share.

The $win_nt.~bt folder (known as the boot folder) contains all of the files that are necessary for starting the computer and initiating the setup process after all of the installation files are copied to the destination computer's hard disk. These files are copied from the distribution share and include basic device drivers, such as mouse, keyboard, mass storage, and video drivers. The $win_nt.~bt folder also contains Txtsetup.sif and Winnt.sif. Txtsetup.sif contains definitions and processing instructions for the files and folders that are installed during the setup process. Winnt.sif contains all of the answer file settings as well as other information that was gathered during system assessment.

A file known as $ldr$ is also created during the initial stage. This file is similar to Ntldr and is used to start the computer in a special setup state during which the intermediate stage of unattended installation occurs (this stage is also known as the text-mode stage).

**Load boot sector and change boot.ini**
The partition boot sector is changed so that it contains the master boot code for starting the computer with $ldr$. The Boot.ini file is also modified so that the computer uses the startup files in the $Win_nt$.~bt folder, which start the computer in a special setup state during which the intermediate stage of Setup occurs.

At the end of initial stage, when all of the installation files have been copied to the destination computer's hard disk, the destination computer restarts and the intermediate stage of the unattended installation begins.

**Intermediate Stage**
The following actions occur during the intermediate stage (also known as the text-mode stage) of an unattended installation from a 32-bit operating system:

**Start the Computer in a Special Setup State**
The computer starts by running $ldr$ and the files that are in $Win_nt$.~bt. During this stage of an interactive setup you would be prompted for information about partitions, file system formats, and system folder name and location. Because it is not possible to configure partitions or file formats when you start an installation from an existing operating system, and all other configuration information is contained in the answer file, these prompts do not appear.

**Build directory structure**
Setup creates the system folder structure and copies files from the temporary installation folder ($win_nt$.~ls) to the system folders. For example, for a default installation, Setup creates the Windows folder and all subfolders (Inf, Help, System, System32, and so forth). The Txtsetup.sif file defines which folders are created and which files are copied to which folders. In addition, Winnt.sif, the file that contains the original answer file settings and other operating system information, is renamed $winnt$.inf and saved in the *systemroot*\System32 folder. Finally, the default registry hive files are created in the *systemroot*\System32\Config folder.

### Note

- Not all files are copied from the temporary installation folders to the system folders during the intermediate stage of the installation. Many of the files for optional components are installed during the final stage of Setup instead. This makes the installation process more efficient.

Load boot sector and change boot.ini

The partition boot sector is changed again so that it contains the master boot code for starting the computer with Ntldr instead of $ldr$. The Boot.ini file is also modified so that the computer uses the Windows Server 2003 startup files instead of the startup files in the $Win_nt$.~bt folder.

At the end of the intermediate stage, when all of the installation files have been copied from the temporary folders to the system folders, the destination computer restarts and the final stage of the unattended installation begins.

**Final Stage**
The following actions occur during the final stage (also known as the GUI-mode stage) of an unattended installation from a 32-bit operating system:

**Start Windows Server 2003**
The destination computer starts by using the Windows Server 2003 startup files and device drivers instead of the temporary startup files in $Win_nt$.~bt. For example, the computer uses Ntldr instead of $ldr$, and the computer uses the startup files and device drivers in the systemroot folder instead of the startup files and device drivers in the $Win_nt$.~bt folder. As with an interactive setup, the hardware detection and installation process also occurs.

**Install and configure optional components and settings**
Optional components are installed (or not installed) and optional settings are configured based on the settings in the answer file. Examples of optional components and settings include regional and language options, text services and input languages, user name, company name, licensing mode, computer name, administrator account password, time zone settings, network adapter settings, protocol settings, and file and printer sharing. During an interactive setup you would be prompted for the installation information and the configuration settings, but these dialog boxes do not appear during a fully-automated unattended installation.

**Copy files from temporary folders**
Based on the answer file settings for the final stage of the installation process, additional files might need to be copied from the temporary installation folders to the system folders. As with an interactive setup, a dialog box shows the progress of this file-copy process; however, no administrator or technician interaction is necessary or possible.

**Complete the installation**
Windows performs the final configuration tasks. This includes configuring start menu items, registering components, deleting temporary installation folders, and running any commands specified in the Cmdlines.txt file.

At the end of the final stage, all of the required installation tasks have been completed and the destination computer is ready to run Windows Server 2003. If the answer file contains any instructions for performing post-installation tasks, Windows then restarts the destination computer, logs on with the Administrator account, and performs the post-installation tasks that are specified in the answer file.

**Unattended Installation When You Start the Computer from a Product CD**
The following figure shows the processes and interactions that occur during a fully-automated unattended installation when you start the destination computer from a product CD.

**Unattended Installation from a Product CD**

This figure is based on the following requirements:

- The destination computer is running Windows 2000 Server.
- The answer file is named Winnt.sif and is saved on a floppy disk.
- The unattended installation is a clean installation of the operating system (not an upgrade).
- The primary partition on the hard disk is reformatted during the unattended installation.
- The unattended installation is started by starting the destination computer from the product CD.
- The unattended installation is fully automated (no administrator or technician interaction required).

In addition, the following answer file is used to perform this installation:

```
 [Data]
    AutoPartition=1
    MsDosInitiated="0"
    UnattendedInstall="Yes"

[Unattended]
    UnattendMode=FullUnattended
    OemSkipEula=Yes
    OemPreinstall=No
    TargetPath=\WINDOWS
    Repartition = Yes

[GuiUnattended]
    AdminPassword=ca8d43d0eae56d10197a3608820ae698fa3254ef3d8ce553674c94fb185
    EncryptedAdminPassword=Yes
    OEMSkipRegional=1
    TimeZone=4
    OemSkipWelcome=1

[UserData]
    ProductKey=#####-#####-#####-#####-#####
    FullName="MyName"
    OrgName="MyCompany"
    ComputerName=MyComputer

[Display]
    BitsPerPel=24
    Xresolution=800
    YResolution=600
    Vrefresh=70

[LicenseFilePrintData]
    AutoMode=PerServer
    AutoUsers=5
```

```
[TapiLocation]
    CountryCode=1
    Dialing=Tone
    AreaCode=425
    LongDistanceAccess="9"

[Identification]
    JoinDomain=MyDomain
    DomainAdmin=MyAdmin
    DomainAdminPassword=MyPassword

[Networking]
    InstallDefaultComponents=Yes
```

**Starting the Unattended Installation from the Product CD**
The processes and interactions described in this section are valid only when you start the destination computer from the product CD and quickly insert the floppy disk on which you saved your answer file into the floppy disk drive. You must insert the floppy disk immediately after the destination computer starts from the product CD because the Setup program immediately searches the floppy disk drive for a Winnt.sif file. If the Setup program does not find a floppy disk in the floppy disk drive, it assumes you are performing an interactive setup. When Setup finds a Winnt.sif file, Setup reads the Winnt.sif and initiates an unattended installation.

**Initial and Intermediate Stages**
After you start an unattended installation from the product CD, the initial and intermediate stages of unattended installation begin (these stages are also known as the data-collection and text-mode stages). Unlike in most installations, the initial and intermediate stages are not separate processes during an unattended installation from the product CD. Instead, these stages are combined into a single process and the destination computer does not restart between them.

The following actions occur during the initial and intermediate stages of an unattended installation from a product CD:

**Begin the setup process**
Setup loads the files that are necessary to start the computer from the product CD. During this process a text-based Setup dialog box provides information about the Setup files that are loading. This is the same dialog box that appears at the beginning of an interactive setup. Usually, during an interactive setup from a product CD, several text-based dialog boxes appear after this initial Setup dialog box. For example, these dialog boxes ask you whether you are repairing an existing installation, whether you want to overwrite an existing operating system, and whether you want to use an existing partition or create a new partition. Because all of this information is contained in the answer file, these dialog boxes do not appear during an unattended installation from the product CD.

### Note

- The Dynamic Update feature cannot be used during an unattended installation from the product CD because there is no network connectivity when you start a computer from the product CD.

**Process answer file**
After the Setup files are loaded, the answer file is parsed and the results are saved in a new file named Winnt.sif. This file contains all of the settings that are in the answer file. A dialog box notifies you when the answer file is being processed, but it requires no administrator or technician interaction because you are performing a fully-automated unattended installation.

**Format and repartition**
The primary partition is deleted and a new partition is created and formatted based on the information in the answer file. A dialog box notifies you when the partition is being created and the status of the formatting process, but the dialog box requires no administrator or technician interaction because you are performing a fully-automated unattended installation.

**Load boot sector**
The partition boot sector is changed so that it contains the master boot code for Windows Server 2003. This small executable code initiates the startup process and instructs the computer where to find Ntldr.

Build directory structure

Setup creates the system folder structure on the hard disk. For example, for a default installation, Setup creates the Windows folder and all subfolders (Inf, Help, System, System32, and so on). The Txtsetup.sif file defines which folders are created.

**Copy files to system folders**
During the file-copy process Setup copies files from the I386 folder on the product CD to the system folders on the hard disk. The Txtsetup.sif file contains definitions and processing instructions for the files and folders that are copied. In addition,

Winnt.sif, the file that contains the original answer file settings, is renamed $winnt$.inf and saved in the *systemroot*\System32 folder.

At the end of initial and intermediate stage, when all of the installation files have been copied to the destination computer's hard disk, the destination computer restarts and the final stage of the unattended installation begins.

**Final Stage**
The following actions occur during the final stage (also known as the GUI-mode stage) of an unattended installation from a product CD:

**Start Windows Server 2003**
Windows Server 2003 starts by using the Ntldr file (not Setupldr.bin) and all of the necessary startup files and device drivers that are in the system folder. As with an interactive setup, the hardware detection and installation process occurs.

**Install and configure optional components and settings**
Optional components are installed (or not installed) and optional settings are configured based on the settings in the answer file. Examples of optional components and settings include regional and language options, text services and input languages, user name, company name, licensing mode, computer name, administrator account password, time zone settings, network adapter settings, protocol settings, and file and printer sharing. During an interactive setup you would be prompted for the installation information and the configuration settings, but these dialog boxes do not appear during a fully-automated unattended installation.

**Copy files from the product CD**
Based on the answer file settings for the final stage of the installation process, additional files might need to be copied from the product CD to the system folders. As with an interactive setup, a dialog box shows the progress of this file-copy process; however, no administrator or technician interaction is necessary or possible.

**Complete the installation**
Setup performs the final configuration tasks. This includes configuring start menu items, registering components, deleting temporary files, and running any commands specified in the Cmdlines.txt file.

At the end of the final stage, all of the required installation tasks have been completed and the destination computer is ready to run Windows Server 2003. If the answer file contains any instructions for performing post-installation tasks, Setup then restarts the destination computer, logs on with the Administrator account, and performs the post-installation tasks that are specified in the answer file.

**Post Installation Processes**
Several unattended installation processes can occur after an operating system is installed on a destination computer. These processes occur when you automate post-installation configuration tasks. Examples of post-installation configuration tasks include running command-line programs to configure system services, running scripts to configure Group Policy settings, and installing software programs. The most commonly used mechanisms for automating post-installation tasks is the Cmdlines.txt file, the `winnt32` command with the `/cmd` parameter, and the [GUIRunOnce] and [SetupParams] sections of the unattended installation answer file.

### Note

- Several answer file sections contain entries that are not configured during the intermediate or final stages of an unattended installation. These settings are configured after the operating system is installed on the destination computer and the destination computer has restarted. The answer file sections include [DCInstall], [CertSrv_Client], and [CertSrv_Server].

**Cmdlines.txt Processes and Interactions**
A Cmdlines.txt file contains a list of commands, programs, scripts, or batch files that run just after the final stage of Setup finishes but before the destination computer restarts. By default, Cmdlines.txt does not exist, so you must manually create the file with a text editor, such as Notepad.

The syntax for Cmdlines.txt is as follows:

```
              [Commands]
command_1command_2
     .
     .
command x
```

Where *command_1*, *command_2*, and *command_x* refer to the commands, programs, scripts, or batch files that you want to

run when final stage of Setup is complete. Note that all commands must be enclosed in quotation marks. Also, if you are using the command window (Cmd.exe) to run commands, programs, scripts, or batch files, then you need to use the `/c` parameter with the `cmd` command. For example, to create a new folder named Test on drive C, you type:

```
cmd /c mkdir c:\Test
```

In addition, to use a Cmdlines.txt file, you need to:

- Add the following section, entry, and value to your answer file:

```
[Unattended]
OemPreinstall = Yes
```

- Copy all of the programs, scripts, and batch files that are listed in your Cmdlines.txt file to the $OEM$ folder in your distribution share.

- Save the Cmdlines.txt file in the $OEM$ folder in your distribution share.

When you use the entry `OemPreinstall = Yes` in the [Unattended] section of your answer file, Setup searches the $OEM$ folder in your distribution share for a Cmdlines.txt file. If Setup finds a Cmdlines.txt file, then the current path is changed to c:\$win_nt$.~ls\$OEM$. This is why you need to put all programs, scripts, or batch files that are listed in Cmdlines.txt into the $OEM$ folder in your distribution share.

You can only have one Cmdlines.txt file, but you can use it to run multiple commands, programs, scripts, or batch files. When these commands, programs, scripts, or batch files run, the following processes and interactions occur:

- The commands, programs, scripts, and batch files run synchronously, which means each command, program, script, or batch file runs to completion before the next one starts running.

- All commands, programs, scripts, and batch files specified in a Cmdlines.txt run under the Local System security account.

- Network connectivity is not available when the commands, programs, scripts, and batch files listed in a Cmdlines.txt file run.

- Windows Installer packages (.msi files) cannot be run from a Cmdlines.txt file.

**Note**

- You cannot use Cmdlines.txt if you are using a product CD and a Winnt.sif file to perform an unattended installation. You can use Cmdlines.txt only if you are installing from a distribution share.

**[GuiRunOnce] Processes and Interactions**

The [GuiRunOnce] section of an answer file contains a list of commands, programs, scripts, or batch files that run the first time an administrator or technician logs on to the computer after the operating system is installed. Because the [GuiRunOnce] section does not exist in a default answer file built by Setup Manager, you must add it manually by editing the answer file with a text editor, such as Notepad.

The syntax for [GuiRunOnce] is:

```
[GuiRunOnce]
command_1command_2
      .
      .
command_x
```

Where *command_1*, *command_2*, and *command_x* refer to the commands, programs, scripts, or batch files that you want to run after the operating system is installed and the administrator or technician logs on. Note that all commands must be

enclosed in quotation marks.

The commands that are listed in the [GuiRunOnce] section are stored in the following registry location:

HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Runonce

When an administrator or technician logs onto the destination computer for the first time after the unattended installation is complete, Windows Server 2003 reads and then runs the commands that are listed in this registry location. When these commands, programs, scripts, or batch files run, the following processes and interactions occur:

- The commands, programs, scripts, and batch files run synchronously, which means each command, program, script, or batch file runs to completion before the next one starts running.
- The commands, programs, scripts, and batch files listed in the [GuiRunOnce] section run under the security account of the user who logged onto the destination computer (usually an administrator or a technician).
- Network connectivity is available when the commands, programs, scripts, and batch files run.
- You can use Windows Installer packages (.msi files) to install applications (unlike Cmdlines.txt).
- You can run commands, programs, scripts, and batch files from hard disk drives, CD drives, shared folders on the network, or other storage devices (unlike Cmdlines.txt, which runs everything from the $OEM$ folder in your distribution share).

In addition, there are some interactions and processes that you might need to control if you run certain commands, programs, scripts, and batch files with the [GuiRunOnce] section.

**Prevent restarts**
You can run commands, programs, scripts, and batch files only if you can prevent the command, program, script, or batch file from restarting the computer. When a computer restarts, all remaining entries in the [GuiRunOnce] section are lost because the Runonce registry entry is deleted. If the system restarts before completing entries listed in the [GuiRunOnce] section, the remaining items will not run. Therefore, you need to suppress restarts. If you cannot suppress a restart within a command, program, script, or batch file, you can try to repackage the command, program, script, or batch file into a Windows Installer package.

**Do not rely on the Windows Explorer shell**
The Windows Explorer shell is not loaded when the operating system starts running commands, programs, scripts, or batch files that are listed in the [GuiRunOnce] section of an answer file. In some cases, you can get an updated installer program from the application vendor that does not rely on the Windows Explorer shell. If you cannot, you might be able to repackage the command, program, script, or batch file as a Windows Installer package (.msi file).

**Control the processes by using the /wait parameter**
Commands, programs, scripts, and batch files often start and stop several different processes. In some cases, when you are running multiple programs — especially installation programs — this can inadvertently cause the next program listed in the [GuiRunOnce] section to start before the previous program is finished running. When this occurs, the second program usually fails. To prevent this, you can run the programs from batch files by using the `start` command with the `/wait` parameter. This forces each program to run to completion before the next command listed in [GuiRunOnce] runs.

**Other Post-Installation Processes and Interactions**
In addition to the Cmdlines.txt file and the [GuiRunOnce] section of an answer file, two other mechanisms can create post-installation processes and interactions during an unattended installation. These mechanisms are the [SetupParams] section of an answer file, and the `winnt32` command with the `/cmd` parameter.

**[SetupParams]**
The [SetupParams] section of an answer file contains a single command, program, script, or batch file that runs immediately after the commands, programs, scripts, or batch files listed in the Cmdlines.txt file run. You typically use this answer file section and entry to perform a post-installation task on only a few computers without changing the Cmdlines.txt file. Because the [SetupParams] section does not exist in a default answer file built by Setup Manager, you must add it manually by editing the answer file with a text editor, such as Notepad.

The syntax for the [SetupParams] section is:

```
[SetupParams]
```

```
UserExecute =path_and_file_name_or_command
```

Where *path_and_file_name_or_command* refers to the command, program, script, or batch file that you want to run. Note that the *path_and_file_name_or_command* must be enclosed in quotation marks. Also, you can omit the path portion of *path_and_file_name_or_command* only if the application is in the systemroot or *systemroot*\System32 folder or search path.

**Winnt32 /cmd**

The `winnt32` command with the `/cmd` parameter specifies a single command, program, script, or batch file that runs immediately after the commands, programs, scripts, or batch files listed in the Cmdlines.txt file run. You typically use this answer file section and entry to perform a post-installation task on only a few computers without changing the Cmdlines.txt file.

The syntax for the `winnt32` command with the `/cmd` parameter is:

```
Winnt32 /cmd:
path_and_file_name_or_command
```

Where *path_and_file_name_or_command* refers to the command, program, script, or batch file that you want to run.

**Log File Interactions During an Unattended Installation**

Several log files are created during an unattended installation and saved in the systemroot folder. The following table provides the names, locations, and descriptions of the Setup log files. The descriptions provide a summary of the contents of each log file when the logging level is set to its default state. You can increase the logging level (increase log file details) for the Winnt32.log and Setupact.log files by using the `winnt32` command with the `/debug` parameter. By default, the logging level is set to 2, which means severe errors, common errors, and warnings are included in the log files. By increasing the logging level you can include basic setup information and detailed debugging information in the Winnt32.log and Setupact.log log files.

**Setup Log Files for an Unattended Installation**

| Log File Name | Location | Description |
|---|---|---|
| Setupact.log | Systemroot | Log file for the initial (data-collection) and final ( GUI-mode) stage of unattended installation. Contains information about detected hardware, installation requirements, and a list of device driver files that are copied from the product CD or $Win_nt$.~ls to various system folders. |
| Setupapi.log | Systemroot | Log file for Setupapi.dll, which processes .inf files during hardware installation and registration. |
| Setuperr.lot | Systemroot | Log file for errors that occur during the initial (data -collection) and final (GUI-mode) stages of unattended installation. This log file consolidates Setup errors; the errors that appear in this log file also appear in other log files. |
| Setuplog.txt | Systemroot | Log file for the initial (data-collection) and final (GUI-mode) stages of unattended installation, as well as some post-installation tasks that occur after Setup completes and the destination computer restarts. Contains information about the files that are copied and deleted, the settings that are configured, and the security settings that are applied to the destination computer. |
| Winnt32.log | Systemroot | Log file for the initial (data-collection) stage of the setup process. Contains information about the existing operating system, hard disk size, Boot.ini configuration, and a list of the files that are copied to the temporary installation folders $Win_nt$.~bt and $Win_nt$.~ls. |

Setupapi.log and Setuplog.txt are not overwritten if you restart the unattended installation process: that is, information is appended to the log file each time you prematurely interrupt and restart the unattended installation process. All of the other log files are overwritten every time the unattended installation process is prematurely interrupted and restarted.

**Note**

- No log files are generated during the intermediate (text-mode) stage of Setup.

In addition to these log files, three other log files contain relevant information about the unattended installation process. The following table provides the names, locations, and descriptions of these log files.

**Supplemental Log Files for an Unattended Installation**

| Log File Name | Location | Description |
|---|---|---|
| Wsdu.log | Systemroot | Log file for Dynamic Update. This is generated only if you use Dynamic Update during an unattended installation, which you can only do if you are performing an unattended installation from an existing 32-bit operating system such as Windows NT, Windows 2000, or Windows Server 2003. |
| Dberr.txt | *systemroot*\System32\CatRoot2 | Log file for catalog file registrations. Contains information about catalog files that are not registered, and exists only if any nonregistered catalogs are identified during unattended installation. If a catalog is not registered, then the files in the catalog file are considered unsigned and will generate errors in Setuperr.log. |
| Scesetup.log | *systemroot*\security\logs | Log file for security settings. |

# Unattended Installation Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Unattended Installation Tools
- Unattended Installation Answer File Settings

The following tools and answer file settings are associated with unattended installations. You use the tools and answer file settings to perform unattended installations.

**Unattended Installation Tools**
The following tools are associated with unattended installations.

**Winnt.exe: Windows Setup program for 16-bit operating systems**
**Category**
Windows setup and installation tool available on every Windows Server 2003 product CD.

**Version compatibility**
Runs on MS-DOS and Windows for Workgroups.

You can use this tool to perform an unattended installation from the 16-bit MS-DOS and Windows for Workgroups operating systems. Typically, you use Winnt.exe to perform an unattended installation on a computer that does not have an operating system and you start the computer with an MS-DOS startup floppy disk. You cannot perform an upgrade with Winnt.exe; you can only perform clean installations with Winnt.exe.

For more information about Winnt.exe, see "Command Line References" in the Tools and Settings Collection.

**Winnt32exe: Windows Setup program for 32-bit and 64-bit operating systems**
**Category**
Windows setup and installation tool available on every Windows Server 2003 product CD.

**Version compatibility**
Runs on Windows Server 2003, Windows XP, Windows 2000, Windows NT, Windows Millennium Edition (Me), Windows 98, and Windows 95.

You can use this tool to perform an unattended installation or upgrade from a Windows 32-bit operating system by using the 32-bit version of Winnt32.exe and from 64-bit operating systems by using the 64-bit version of Winnt32.exe. Typically, you use Winnt32.exe to perform an unattended installation or upgrade on a computer that has an operating system; you start the computer from the existing operating system and then run Winnt32.exe from the command line.

For more information about Winnt32.exe, see "Command Line References" in the Tools and Settings Collection.

**Setupmgr.exe: Setup Manager**
**Category**
Windows deployment tool available on the Windows Server 2003 product CD.

**Version compatibility**
Runs on the 32-bit versions of Windows Server 2003 and Windows XP.

Setup Manager is a wizard-like program that helps you configure distribution shares and answer files that can be used to perform automated installations, including unattended installation, image-based installation with Sysprep, and Remote Installation Services (RIS) installations. Setup Manager prompts you for information in a series of dialog boxes. Setup Manager configures answer file settings and distribution shares based on the information you provide in these dialog boxes.

Usually, you run Setup Manager on the administrator or technician computer. Setup Manager does not affect the system files of the technician computer on which the tool runs and does not actually run Setup. Also, you do not need to specify all of your customizations with Setup Manager. Instead, you can create an answer file in Setup Manager and then manually edit the file with Notepad. If you later open the answer file in Setup Manager, the tool displays your changed settings.

Setup Manager is not installed when you install Windows XP or Windows Server 2003. You must manually install Setup Manager on the administrator or technician computer.

**To install Setup Manager**

1. Insert a Windows XP or Windows Server 2003 product CD into your CD drive and open the \Support\Tools folder.

2. Double-click **Deploy.cab**.

3. Right-click the file named **Setupmgr.exe** and click **Extract**.

4. In the **Select a Destination** dialog box, select a location on your hard drive where you want to save Setup Manager, and then click **Extract**.

You can run Setup Manager from the graphical user interface by double-clicking the Setupmgr.exe file that you saved to your hard disk, or from the command line by typing `setupmgr`.

**Note**

- If you use Setup Manager to create or modify a distribution share that is not on the local computer, be sure you run Setup Manager under a user account that has the minimum user rights to connect to the remote computer. This is because Setup Manager sends the user name and the password across the network in plaintext when it connects to a remote distribution share.

The following sections provide information about each Setup Manager dialog box. The section names correspond to the dialog box name that you see in Setup Manager.

**New or Existing Answer File**
Enables you to create a new answer file or edit an existing one.

Answer file sections and entries configured:

- None

**Type of Setup**
Provides three Setup options: Unattended, Sysprep, or Remote Installation Services (RIS).

Answer file sections and entries configured:

- None

**Product**
Prompts you to select the Windows product that you want to install.

Answer file sections and entries configured:

- None

**User Interaction**
Prompts you to select the level of user interaction you want. This dialog box is not used if you are configuring a Sysprep or RIS installation.

Answer file sections and entries configured:

- [Unattended]

- UnattendMode

**Distribution Share**
Enables you to create a new distribution share, modify an existing one, or set up Windows from a product CD.

Answer file sections and entries configured:

- None

**Location of Setup Files**
Prompts you for the location of the Setup files you want to copy.

Answer file sections and entries configured:

- None

**Distribution Share**
Prompts you for the location of the distribution share you want to create or modify. This section is used only by Setup Manager when an existing distribution share is edited. It is not used by Setup during an unattended installation.

Answer file sections and entries configured:

- [SetupMgr]
- DistFolder
- DistShare

**Name and Organization**
Enables you to provide a default user name and organization name.

Answer file sections and entries configured:

- [UserData]
- FullName
- OrgName

**Display Settings**
Enables you to change the change settings for colors, screen area, and refresh frequency.

Answer file sections and entries configured:

- [Display]
- BitsPerPel
- XResolution
- YResolution
- VRefresh

**Time Zone**
Prompts you to select a default time zone.

Answer file sections and entries configured:

- [GuiUnattended]
- TimeZone

**Product Key**
Prompts you to provide a Product Key to identify your copy of Windows.

Answer file sections and entries configured:

- [UserData]
- ProductKey

**Computer Names**
Prompts you to provide names for the destination computers.

Answer file sections and entries configured:

- [UserData]
- ComputerName

**Administrator Password**
Enables you to specify a password for the Administrator account on all destination computers.

Answer file sections and entries configured:

- [GuiUnattended]
- AdminPassword
- EncryptedAdminPassword

**Networking Computers**
Enables you to choose typical or custom network settings.

Answer file sections and entries configured:

- [Networking]
- [NetAdapters] (if custom settings are configured)
- [NetClients] (if custom settings are configured)
- [NetProtocols] (if custom settings are configured)

**Workgroup or Domain**
Prompts you to specify how the destination computers will participate in a network.

Answer file sections and entries configured:

- [Identification]

**Windows Components**
Enables you to install commonly used Windows components.

Answer file sections and entries configured:

- [Components]

**Telephony**
Enables you to provide telephony information for the user.

Answer file sections and entries configured:

- [TapiLocation]

**Regional Settings**
Enables you to customize Windows for different regions and languages.

Answer file sections and entries configured:

- [RegionalSettings]

**Languages**
Prompts you to select the language groups you want to use.

Answer file sections and entries configured:

- [RegionalSettings]
- Language

**Browser and Shell Settings**
Enables you to customize the browser and shell settings for Windows.

Answer file sections and entries configured:

- [FavoritesEx]

**Installation Folder**
Enables you to specify the name of the Windows folder.

Answer file sections and entries configured:

- [Unattended]
- TargetPath

**Install Printers**
Enables you to install network printers on the destination computers.

Answer file sections and entries configured:

- [GuiRunOnce]

**Run Once**
Enables you to automatically run a command the first time the user logs on.

Answer file sections and entries configured:

- [GuiRunOnce]

**Additional Commands**
Enables you to add commands to run at the end of unattended installation. Settings from this page are saved only if you choose to create a new distribution share or modify an existing one. If you choose to set up from a product CD, anything entered on this page is ignored.

Answer file sections and entries configured:

- [Commands] (in the Cmdlines.txt file)

**Unattended Installation Answer File Settings**

This section describes the settings that you can configure in an unattended installation answer file. For more information about how to structure an answer file, see "Unattended Installation Physical Structures" in How Unattended Installation Works.

The following table lists all of the valid sections that can appear in an answer file for an unattended installation.

**Answer File Sections for Unattended Installation**

| Section | Description |
|---|---|
| [adapter_specific_protocol_section] | Contains an entry for specifying a network component. Must be used in conjunction with the [Networking] section. |
| [Branding] | Contains entries for branding Microsoft Internet Explorer during an unattended installation. If you do not specify this section, Setup uses the default for Windows Server 2003. |
| [CertSrv_Client] | Contains entries for the Web client component of Certificate Services. You do not need to include this section in the answer file to install the Web client component of Certificate Services on the computer. Enabling Certificate Services in the [Components] section of the answer file installs the necessary files. |
| [CertSrv_Server] | Contains entries for specifying the server components of Certificate Services. The entries in this section are supported only for the Windows Server 2003. |
| [Components] | Contains entries for installing the optional components of Windows XP Professional and Windows Server 2003. |
| [Data] | Contains entries for starting directly from the Windows Server 2003 product CD when performing an unattended installation. |
| [DCInstall] | Contains entries for installing a domain controller after the initial setup of the operating system finishes. |
| [Display] | Contains entries for specifying display settings for graphics devices. |
| [FavoritesEx] | Contains the default Favorites settings for the Windows browser. If not present, Setup uses the default Uniform Resource Locator (URL) for Windows XP or Windows Server 2003. |
| [Fax] | Contains entries for specifying custom installation information for the Fax service. |
| [GuiRunOnce] | Contains commands that run the first time a user logs on to the computer after final (GUI-mode) stage of Setup completes. |
| [GuiUnattended] | Contains entries for preparing the graphical user interface (GUI) for unattended installation. |
| [Homenet] | Contains entries for installing Home Networking settings for network adapters, Internet Connection Sharing (ICS), and Internet Connection Firewall (ICF). |
| [Identification] | Contains entries for specifying the network identification of a computer. If these entries are not present, Setup adds the computer to the default workgroup. If there is not enough information for this entry, Setup prompts the user to provide this information. |
| [IEHardening] | Contains entries for configuring Web content zones. |
| [InternetServer] | Contains entries for configuring the installation folder for Internet Information Services (IIS) components. |
| [LicenseFilePrintData] | Contains entries for installing licensing information for Windows Server 2003. |

| | |
|---|---|
| [MassStorageDrivers] | Contains an entry for loading retail or original equipment manufacturer (OEM) small computer system interface (SCSI) drivers in the Setup Loader during the intermediate (text-mode) stage of Setup |
| [MS_AppleTalk parameters] | Contains entries for configuring AppleTalk. |
| [MS_ATMArps parameters] | Contains no entries. |
| [MS_ATMLANE parameters] | Contains no entries. |
| [MS_ATMUni parameters] | Contains no entries. |
| [MS_L2TP parameters] | Contains entries for the Layer 2 Tunneling Protocol (L2TP). |
| [MS_MSClient parameters] | Contains entries for Client for Microsoft Networks. |
| [MS_NetMon parameters] | Contains no entries. |
| [MS_NWClient parameters] | Contains entries for Client Service for NetWare. |
| [MS_NWIPX parameters] | Contains entries for the Internetwork Packet Exchange (IPX) protocol. Its parameters are network adapter–independent. |
| [MS_NwSapAgent parameters] | Contains no entries. |
| [MS_PPTP parameters] | Contains entries for the Point-to-Point Tunneling Protocol (PPTP). |
| [MS_Psched parameters] | Contains no entries. |
| [MS_RAS parameters] | Contains entries for the Routing and Remote Access service. |
| [MS_RasSrv parameters] | Contains entries for the Routing and Remote Access service for remote access servers. |
| [MS_Server parameters] | Contains entries for the File and Print Service. |
| [MS_TCPIP parameters] | Contains entries for configuring the TCP/IP protocol. |
| [MS_WLBS parameters] | Contains entries for configuring Network Load Balancing (formerly, Windows Load Balancing Service, or WLBS) and binding Network Load Balancing to multiple network adapters. |
| [NetAdapters] | Contains entries for network adapters that you want to install. |
| [NetBindings] | Contains entries for disabling, enabling, and demoting binding rules for network components such as services, protocols, and adapters. |
| [NetClients] | Contains an entry for specifying the network clients to install. |
| [NetOptionalComponents] | Contains entries for installing optional network components. |
| [NetProtocols] | Contains an entry for installing the network protocols. |
| [NetServices] | Contains entries for installing network services. |
| [Networking] | Contains no entries. However, to configure network protocols in unattended installation, you must include the [Networking] section name in your answer file. |
| [OEMBootFiles] | Contains entries for specifying OEM-supplied boot files. |
| [params.adapter_instance] | Contains entries for specifying an adapter's instance on a computer by using either PCI location information or a Plug and Play device ID. |
| [PCHealth] | Contains entries for configuring error reporting, Remote Assistance, and Help and Support Center. |

| | |
|---|---|
| [protocol_parameters_section] | Contains an entry for specifying network protocol parameters that are also specified in the [NetProtocols] section. |
| [Proxy] | Contains entries for specifying proxy server settings for the Windows XP or Windows Server 2003 browser. |
| [RegionalSettings] | Contains entries for installing regional options during the setup process. |
| [SetupData] | Contains the OSLoadOptionsVar entry, which is used to modify the /NoExecute option in Boot.ini used by Data Execution Prevention (DEP). |
| [SetupMgr] | Contains entries for specifying the server and folder in which the distribution share resides and the name of the distribution share. This section is used only by Setup Manager when an existing distribution share is edited. It is not used by Setup during an unattended installation. |
| [SetupParams] | Contains an entry for running an additional post-Setup command. |
| [Shell] | Contains entries for specifying the visual style of the user interface. |
| [SNMP] | Contains entries for specifying the Simple Network Management Protocol (SNMP) service. |
| [SystemFileProtection] | Contains entries for specifying Windows File Protection (WFP) settings. |
| [SystemRestore] | Contains entries for specifying the System Restore feature. |
| [TapiLocation] | Contains entries for specifying the telephony API (TAPI). It is valid only if a modem is present on the computer. |
| [TerminalServices] | Contains entries for configuring Terminal Services features (Terminal Server and Remote Desktop). |
| [UDDIDatabase] | Contains entries for configuring the optional Universal Description, Discovery and Integration (UDDI) Database feature. |
| [UDDIWeb] | Contains entries for configuring the optional Universal Description, Discovery and Integration (UDDI) Web services feature. |
| [Unattended] | Contains entries for running Setup. |
| [Uninstall] | Contains entries for allowing users who upgrade to Microsoft Windows XP to remove the operating system if they encounter problems. |
| [URL] | Contains entries for specifying default Uniform Resource Locator (URL) settings for the browser available in Windows XP or Windows Server 2003. |
| [UserData] | Contains entries for specifying user settings during the setup process. |
| [WindowsFirewall] | This section must be included in your answer file to configure firewall sections and entries in unattended installations. To configure Windows Firewall settings, you must include the [WindowsFirewall] section along with one or more of the other Windows Firewall settings sections. |
| [WindowsFirewall.profile_name] | Contains entries for specifying a domain type of profile, a standard type, or a profile that applies to both domain and standard. |
| [WindowsFirewall.program_name] | Contains entries for adding programs to the Windows Firewall Exceptions list. |
| [WindowsFirewall.service_name] | Contains entries for adding services to the Windows Firewall Exceptions list. |
| [WindowsFirewall.portopening_name] | Contains entries for adding static ports to the Windows Firewall Exceptions list. |

| | |
|---|---|
| [WindowsFirewall.icmpsetting_name] | The default configuration for Windows Firewall blocks all Internet Control Message Protocol (ICMP) message types, the entries in this section allows you to modify this behavior. |
| [Win9xUpg] | Contains entries for specifying an unattended upgrade from Windows 98, Windows 98 Second Edition, or Windows Millennium Edition to either Windows XP Home Edition or Windows XP Professional. |

# Sysprep Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sysprep Technical Reference**
The System Preparation tool (Sysprep) is a technology that you can use with other deployment tools to install Microsoft Windows operating systems with minimal administrator or technician intervention. You typically use the Sysprep tool in conjunction with a non-Microsoft disk imaging tool or Microsoft Windows Server 2003 Automated Deployment Services (ADS) to perform image-based installations. Image-based installations are ideal for large-scale rollouts when it would be too slow and costly to have administrators or technicians interactively install the operating system on individual computers.

# What Is Sysprep?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Sysprep?**

**In this section**

- Common Sysprep Scenarios
- Sysprep Limitations
- Sysprep Dependencies
- Technologies Related to Sysprep
- Related Information

The System Preparation tool (Sysprep) is a technology that you can use with other deployment tools to install Microsoft Windows operating systems with minimal intervention by an administrator or technician. Sysprep is typically used during large-scale rollouts when it would be too slow and costly to have administrators or technicians interactively install the operating system on individual computers.

You typically use the Sysprep tool in conjunction with a non-Microsoft disk imaging tool or Microsoft Windows Server 2003 Automated Deployment Services (ADS) to perform image-based installations. Image-based installation is a method of copying or cloning preconfigured operating systems (and, optionally, software applications) onto destination computers. After you set up a master installation — an installation with the operating system, software applications, and configuration settings that you want to install onto the destination computers in your organization, Sysprep prepares the master installation so that you can create a disk image; that is, a functionally identical replica of the disk containing the master installation, that can be copied onto multiple computers. The disk-imaging program creates the disk image of the master installation. After the disk image is copied onto a destination computer, and you start the destination computer, a shortened version of the Windows Setup program runs. The shortened version of Setup configures only user-specific and computer-specific settings, such as computer name, domain membership, and regional options. You can automate this last part of the setup process by using an answer file, a simple text file that instructs the Setup program how to configure the various operating system settings.

The following figure shows how an image-based installation differs from an interactive setup.

**Comparison of Image-based Installation and Interactive Setup**

Like all automated installation technologies, imaged-based installation with Sysprep has many benefits that standard interactive setup does not.

**Fewer errors during installation**

Because image-based installation with Sysprep uses preconfigured disk images and answer files to install and configure the operating system, there is minimal administrator or technician interaction during the setup process. This reduces the number of errors that are introduced during the setup process.

**Greater consistency**

By using the same disk image and answer file to install and configure operating systems, you can ensure that all of the computers in your organization are set up exactly the same way.

**Shortest installation times**

Image-based installation with Sysprep is faster than interactive setup because the operating system and applications are preinstalled and preconfigured on the disk image and require only minimal configuration after the disk image is copied to a destination computer. In addition, you can speed up the installation process by using an answer file. Instead of prompting administrators or technicians for configuration information, Setup reads configuration settings from an answer file.

**Lower support costs**

By minimizing errors during the setup process, increasing the consistency of the computers in your organization, and reducing the amount of time a technician needs to spend setting up a computer, you can reduce the overall support costs in your organization.

**Common Sysprep Scenarios**

Several installation scenarios are particularly well suited for image-based installations with Sysprep.

**Homogeneous hardware configurations**

If you are installing the same server configuration on computers that have similar or homogeneous hardware, you can customize hardware configurations on the disk image, thereby avoiding many post-installation configuration and installation tasks. For example, you can use image-based installation with Sysprep to rapidly roll out the same file server configuration to a group of computers that have similar processor configurations and similar storage configurations.

**Rapid rollout scenarios**

If you need to install the operating system as rapidly as possible, you can copy a preconfigured disk image onto a destination computer much faster than you can perform an unattended installation or a Remote Installation Services (RIS) installation. For example, you can use image-based installation with Sysprep to quickly deploy critical servers in your organization or quickly reinstall an operating system on member servers after a hard disk failure or some other catastrophic event. .

**Application deployment**

If you want to roll out applications at the same time that you roll out the operating system, you can include the applications on

the disk image. For example, if your organization's standard computer configuration includes an antivirus program, an e-mail program, and an office suite, you could install and configure these programs on the master installation so that the disk image includes these programs.

**Sysprep Limitations**
You can use Sysprep and image-based installation to deploy operating systems and software applications onto many types of servers. However, image-based installation has several significant limitations and can be used only when certain conditions are met.

**Clean installation only**
You can use image-based installation with Sysprep only to install a clean version of the operating system and clean versions of software applications. You cannot use image-based installation to upgrade an operating system or software configuration.

**Limited server configuration**
Some server components must be installed and configured after an image-based installation with Sysprep is complete. These components include Certificate Services, Cluster service, and any software that is dependent on the Active Directory directory service. They also include any application or service that stores the computer name or the computer SID and cannot recover if the computer name or SID changes.

**HAL compatibility**
You can perform an image-based installation with Sysprep only if the hardware abstraction layer (HAL) on the disk image is compatible with the hardware on the destination computer. In some cases, Windows Server 2003 automatically upgrades the HAL that is on a disk image to suit the HAL requirements of a destination computer, but this upgrade can occur only if the master installation is built on an APIC uniprocessor-system (UP) computer and the image of that master installation is copied to a compatible multiprocessor-system destination computer.

**Special domain controller installation process**
You cannot deploy preconfigured domain controllers by using image-based installation with Sysprep. However, you can configure a domain controller by first deploying a member server and then automatically running a script that runs Dcpromo.exe, the Active Directory Installation Wizard.

**Limited configuration of some security settings**
You cannot use image-based installation with Sysprep to deploy computers that contain any files that are encrypted by using Encrypting File System (EFS). In addition, you cannot use image-based installation to deploy systems that have already been configured with NTFS security settings, such as file and folder permissions, unless the disk-imaging program supports the NTFS file system. However, you can use a script to configure these settings after the image-based installation is complete.

### Note

- You can use Sysprep only to prepare a master installation that is installed on the master computer's drive C.

**Sysprep Dependencies**
You need two tools to perform an image-based installation: Sysprep, which can be found on any Microsoft Windows XP Professional or Windows Server 2003 product CD; and a disk-imaging program. Setup Manager can also be a useful tool for performing image-based installations with Sysprep, but it is not required.

**Sysprep**
The Sysprep tool consists of three separate programs: Sysprep.exe, Setupcl.exe, and Factory.exe. However, you run only Sysprep.exe; Setupcl.exe and Factory.exe are secondary programs that Sysprep.exe runs as needed. Sysprep is found in the Support\Tools folder on any Windows XP Professional or Windows Server 2003 product CD, under Deploy.cab.

You run Sysprep on the master computer before you create an image of the master computer's hard disk. Sysprep configures various operating system settings on the master computer to ensure that every copy of the master computer's disk image is unique when you distribute it to a destination computer. Specifically, Sysprep configures a master installation so that unique security identifiers (SIDs) are generated on each destination computer. Sysprep also configures the master computer's disk image so that every destination computer starts in a special setup mode known as Mini-Setup. After you copy a disk image onto a destination computer, Mini-Setup runs the first time you start the destination computer.

**Disk-imaging program**
You can use either a non-Microsoft disk-imaging program or ADS to create an image of the master computer's hard disk. You also use the disk-imaging program to copy the disk image from the master computer onto a shared folder or a CD, and from the shared folder or CD onto a destination computer.

### Note

- You can perform an image-based installation with Sysprep without purchasing a non-Microsoft disk-imaging program by using Windows Server 2003 Automated Deployment Services (ADS). ADS is an early deliverable of the Dynamic Systems Initiative (DSI), and can be used to rapidly deploy Windows server operating systems.

If you are not using ADS to create disk images, you need to purchase a non-Microsoft disk imaging program.

**Setup Manager**
In addition to Sysprep and a disk imaging program, there is an optional tool called Setup Manager that you can use to create an answer file for image-based installations with Sysprep. You can also create an answer file manually by using a text editor such as Notepad. Usually, you use Setup Manager to create a basic answer file, and then you use Notepad to customize the answer file.

**Technologies Related to Sysprep**
Image-based installation with Sysprep is similar to two other automated installation technologies: unattended installation and Remote Installation Services (RIS) installation. Like image-based installation with Sysprep, these technologies are designed specifically as mass roll-out or deployment solutions. Although you can use all of these technologies to automate the installation of Windows Server 2003, each of these technologies is based on a different set of installation processes, and relies on a different set of programs and tools.

**Unattended Installation**
Unattended installation is a method of automating clean installations and upgrades with minimal administrator or technician interaction. It relies on an answer file that you create and can be performed from the product CD or from a shared distribution folder.

Unattended installations are particularly useful if you need to:

- Perform automated installations on computers that have heterogeneous hardware configurations.
- Perform automated installations on specific types of servers, such as domain controllers, remote access servers, and servers that run Certificate Services or the Cluster service.
- Upgrade Windows-based servers to Microsoft Windows Server 2003, Standard Edition or Microsoft Windows Server 2003, Enterprise Edition operating systems.
- Configure a wide range of operating system settings during an automated installation without using batch files and scripts.

In addition to these deployment solutions, unattended installation is a useful method of creating master installations for image-based and RIS installations.

Unattended installation requires some upfront planning and design, but it is the most flexible and robust automated installation technology.

**RIS Installation**
RIS installation is a method of cleanly installing an operating system and applications over a network with minimal administrator or technician interaction. RIS uses Pre-Boot Execution Environment (PXE) technology to enable client computers without an operating system to start up and connect remotely to a RIS server, which installs a supported operating system.

You can use RIS to perform either CD-based installations or image-based installations. To perform CD-based installations you use the Remote Installation Services Setup (Risetup.exe) tool, which installs an operating system on a destination computer by using an answer file and the installation files that are on the product CD. To perform image-based installations you use the Remote Installation Preparation Wizard (Riprep.exe) tool, which is similar to the Sysprep tool and prepares a master installation for disk imaging.

RIS is a suitable automated installation technology if you need to:

- Install operating systems on computers that have similar hardware and a compatible HAL.
- Eliminate administrator or technician interaction during the setup process.
- Minimize post-installation tasks.

- Perform clean installations of an operating system, rather than upgrade existing installations.
- Install software applications with the operating system.

RIS installation is more complex and requires more upfront configuration and planning than image-based installation and unattended installation. However, RIS installation is an efficient deployment technology if you have a high-speed network and you need to perform clean installations of operating systems and preconfigured applications on a large number of computers.

# How Sysprep Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Sysprep Works**

**In this section**

- Sysprep Architecture
- Sysprep Physical Structures
- Sysprep Processes and Interactions
- Related Information

The System Preparation tool (Sysprep) is a technology that you can use when performing an image-based installation. Image-based installation is a method of copying or cloning preconfigured operating systems and software applications onto destination computers. Image-based installation is the fastest method of installing an operating system and applications, and is typically used during large-scale rollouts when it would be too slow and costly to have administrators or technicians interactively install the operating system on individual computers.

These sections provide an in-depth view of how Sysprep works in an optimal environment. An optimal environment for Syprep contains the following:

- Plug and Play hardware that is compatible with Windows Server 2003.
- High-bandwidth network connectivity between the destination computers and the computer on which the disk images are stored.
- Physical access to the destination computers.
- BIOS and hardware that support starting from the floppy drive and the CD drive.
- Disk-imaging software, such as a non-Microsoft disk-imaging program that is compatible with Microsoft Windows Server 2003 or Windows Server 2003 Automated Deployment Services (ADS).

**Sysprep Architecture**

Sysprep relies on several components, including three executable programs and several answer files. How these components interact with each other at the various stages of an image-based installation is illustrated in the following figure.

**Sysprep Architecture**

The Sysprep tool consists of three components: Sysprep.exe, Setupcl.exe, and Factory.exe. These components run on both the master computer — the computer on which you are creating your master installation — and the destination computer — the computer on which you are installing a disk image. The answer files (Cmdlines.txt, Sysprep.inf, and Winbom.ini) are created on a technician or administrator computer, and are used on the master computer and the destination computer when Sysprep and its associated components run. The disk imaging tool runs on the master computer, where it is used to create a disk image, and on the destination computer, where it is used to copy a disk image from a CD or a remote server onto the destination computer's hard disk.

The following are components used in an image-based installation with Sysprep.

**Cmdlines.txt**
A configurable text file that you use to perform installation and configuration tasks at the end of the Mini-Setup stage. Cmdlines.txt contains a list of commands that run synchronously after the Mini-Setup stage finishes, but before a computer restarts.

**Destination computer**
Computer on which you are installing an operating system. For image-based installations, this is the computer to which you are copying a disk image. During a large-scale rollout, there can be typically hundreds or thousands of destination computers.

**Disk image**
Functionally identical replica of a hard disk that can be copied onto multiple computers. You need a disk imaging tool to create a disk image.

**Disk-imaging tool**
Program that creates and manages disk images. You use the disk-imaging tool on the master computer to create a disk image and save the disk image to a CD, DVD, or a remote server. You use the disk-imaging tool on the destination computer to copy the disk image from a CD, DVD, or remote server to the destination computer's hard drive. You can purchase a non-Microsoft disk-imaging program to perform an image-based installation with Sysprep, but you can also use ADS.

**Distribution server**
Computer that contains the disk images you want to copy onto destination computers.

**Factory.exe**
Sysprep component that controls the Factory-mode stage of an image-based installation with Sysprep. You can configure Sysprep so that a destination computer starts in Factory mode. Factory mode puts a destination computer into a network-enabled state that allows you to perform installation and configuration tasks before you prepare the destination computer for final delivery to a user. Factory.exe must exist in the same folder on the master computer as Setupcl.exe and Sysprep.exe, which is typically the *systemdrive*\Sysprep folder.

**Master computer**
Computer from which a disk image is derived. A master computer contains a master installation, which is the system disk on which you have installed and configured the operating system and software applications that you want to install onto the

destination computers in your organization.

**Mini-Setup**
A wizard that is a subset of Setup. Mini-Setup runs automatically after a disk image is copied to a destination computer and the destination computer is started. Mini-Setup provides prompts for user-specific information, configures operating system settings, and detects new hardware. You can automate the Mini-Setup stage by using Sysprep.inf.

**Registry**
Repository where Sysprep stores configuration and setup information prior to the disk imaging process. Sysprep reads the configuration and setup information from this repository the first time a destination computer starts after delivery to a user.

**Setupcl.exe**
Sysprep component that resets security identifiers (SIDs) on the master computer prior to running a disk imaging tool and creating a disk image of the master computer's system disk. Setupcl.exe can also run at the end of the Factory-mode stage if you run Sysprep with the Factory mode option. Setupcl.exe must exist in the same folder on the master computer as Factory.exe and Sysprep.exe, which is typically the *systemdrive*\Sysprep folder.

**Setup Manager**
Deployment tool that creates a basic Sysprep.inf answer file. You use Setup Manager on the administrator or technician computer, and then transfer the answer file to the master computer prior to creating the disk image.

**Sysprep.exe**
Primary Sysprep component. You run Sysprep.exe on the master computer prior to running a disk-imaging tool to create a disk image. Sysprep.exe also runs automatically after you copy a disk image to a destination computer and then start the destination computer for the first time. Sysprep.exe can be run from the command line or it can be run in the Windows graphical user interface (GUI). Sysprep.exe must exist in the same folder on the master computer as Setupcl.exe and Factory.exe, which is typically the *systemdrive*\Sysprep folder.

**Sysprep.inf**
An answer file that can be used to automate the Mini-Setup stage.

**Syssetup.dll**
Dynamic-link library that performs installation and configuration tasks during the Factory mode stage and the Mini-Setup stage of an image-based installation with Sysprep.

**Technician computer**
Computer used by an administrator or technician to use Setup Manager or Notepad to create and modify answer files, such as Sysprep.inf and Winbom.ini.

**Winbom.ini**
An answer file that you can use to automate installation tasks when a computer is started in Factory mode. Factory mode is useful for updating drivers, running Plug and Play enumeration, installing applications, testing, configuring the computer with customer data, or making other configuration changes before you deliver a computer to an end user.

**Winlogon.exe**
A component of the Windows operating system that provides interactive logon support. Winlogon is designed around an interactive logon model that consists of three components: the Winlogon executable, a Graphical Identification and Authentication dynamic-link library (DLL) referred to as the GINA, and many network providers.

**Sysprep Physical Structures**
The structures of two files are essential to an image-based installation with Sysprep: the Sysprep.inf answer file, which automates the Mini-Setup stage of an image-based installation, and the Winbom.ini answer file, which automates the Factory-mode stage of an image-based installation. You can create the Sysprep.inf answer file by using Setup Manager (Setupmgr.exe) or you can create it manually by using a text editor, such as Notepad. You must create the Winbom.ini answer file manually by using a text editor, such as Notepad.

As with most answer files, Sysprep.inf and Winbom.ini contain multiple predefined sections — some mandatory and some optional — that you can modify. Section names are always enclosed in square brackets (for example, [Unattended]).

Every section has one or more entries that contain installation and configuration information. Entries are usually composed of an entry name, an equal sign, and a value (for example, `ComputerName = Computer1`). The entry name represents a specific computer setting or action; the value represents the unique way you want the setting configured or the action performed. In some cases, entries do not have an entry name. In these cases, a value or a list of values (usually commands) appear in the answer file below a section name. The following example shows a section that contains only values and does not have entry names.

```
[GUIRunOnce]
```

```
dcpromo /answer:a:\installdc.txt
%systemroot%\cluster\cluster.exe
```

Use the following guidelines when you create or modify an answer file:

- Sections do not have to be any particular order.
- Sections and entries are not case sensitive.
- Entries must have valid values. For example, “on” is not equivalent to “enable,” and “off” is not equivalent to “disable.” Invalid sections and entries can generate errors, or cause Setup to fail.
- Each entry must have a value.
- Each section and entry must appear on a separate line.
- Comments must begin with a semi-colon (;).Do not use “REM” to specify a comment.

**Note**

- Do not modify undocumented sections or entries in an answer file; doing so can cause unpredictable results.

**Sysprep.inf Structure**

You can use Sysprep.inf to automate the Mini-Setup stage of an image-based installation. This corresponds to the final stage, or GUI-mode stage, of an interactive setup. The following table lists all of the valid sections that can appear in a Sysprep.inf file.

**Answer File Sections for Sysprep.inf**

| Section | Description |
|---|---|
| [*adapter_specific_protocol_section*] | Contains an entry for specifying a network component. Used in conjunction with the [Networking] section. |
| [Display] | Contains entries for specifying display settings for graphics devices. |
| [GuiRunOnce] | Contains commands to run the first time a user logs on to the computer after the Mini-Setup stage completes and the destination computer restarts. |
| [GuiUnattended] | Contains entries for configuring the way the Mini-Setup stage runs as well as time and date settings. . |
| [Identification] | Contains entries for specifying the network identification of a computer. If these entries are not present, Setup adds the computer to the default workgroup. If there is not enough information for this entry, Setup prompts the user to provide this information. |
| [IEHardening] | Contains entries for configuring Web content zones. |
| [LicenseFilePrintData] | Contains entries for installing licensing information for Windows Server 2003. |
| [*MS_AppleTalk parameters*] | Contains entries for configuring AppleTalk. |
| [*MS_ATMArps parameters*] | Contains no entries. |
| [*MS_ATMLANE parameters*] | Contains no entries. |
| [*MS_ATMUni parameters*] | Contains no entries. |
| [*MS_L2TP parameters*] | Contains entries for the Layer 2 Tunneling Protocol (L2TP). |
| [*MS_MSClient parameters*] | Contains entries for Client for Microsoft Networks. |

| | |
|---|---|
| [*MS_NetMon parameters*] | Contains no entries. |
| [*MS_NWClient parameters*] | Contains entries for Client Service for NetWare. |
| [*MS_NWIPX parameters*] | Contains entries for the Internetwork Packet Exchange (IPX) protocol. Its parameters are network adapter–independent. |
| [*MS_NwSapAgent parameters*] | Contains no entries. |
| [*MS_PPTP parameters*] | Contains entries for the Point-to-Point Tunneling Protocol (PPTP). |
| [*MS_Psched parameters*] | Contains no entries. |
| [*MS_RAS parameters*] | Contains entries for the Routing and Remote Access service. |
| [*MS_RasSrv parameters*] | Contains entries for the Routing and Remote Access service for remote access servers. |
| [*MS_Server parameters*] | Contains entries for the File and Print Service. |
| [*MS_TCPIP parameters*] | Contains entries for configuring the TCP/IP protocol. |
| [*MS_WLBS parameters*] | Contains parameters for configuring Network Load Balancing (formerly, Windows Load Balancing Service, or WLBS) and binding Network Load Balancing to multiple network adapters. |
| [NetAdapters] | Contains entries that specify network adapters. |
| [NetBindings] | Contains entries for disabling, enabling, and demoting binding rules for network components such as services, protocols, and adapters. |
| [NetClients] | Contains an entry for specifying the network clients to install. |
| [NetOptionalComponents] | Contains entries for installing optional network components. |
| [NetProtocols] | Contains an entry for installing the network protocols. |
| [NetServices] | Contains entries for installing network services. |
| [Networking] | Contains no entries. However, to configure network protocols, you must include the [Networking] section name in your answer file. |
| [*params.adapter_instance*] | Contains entries for specifying an adapter's instance on a computer. |
| [*protocol_parameters_section*] | Contains an entry for specifying network protocol parameters that are also specified in the [NetProtocols] section. |
| [RegionalSettings] | Contains entries for installing regional options during the setup process. |
| [Sysprep] | Contains an entry for automatically generating the entries in the pre-existing [SysprepMassStorage] section and then installing those mass-storage controllers. |
| [SysprepMassStorage] | Contains entries for identifying the different mass-storage controllers that you want to install on each destination computer. |
| [TapiLocation] | Contains entries for specifying the telephony API (TAPI). It is valid only if a modem is present on the computer. |
| [Unattended] | Contains entries that control the Mini-Setup stage. |
| [UserData] | Contains entries for specifying user settings during the setup process. |

You do not need to add every possible section and entry to the Sysprep.inf file. Most sections and entries are optional, and Mini-Setup ignores optional sections and entries that are not present in the answer file.

If you want to fully automate the Mini-Setup stage, you must configure the following sections and entries in Sysprep.inf. If you

do not provide values for these entries in Sysprep.inf, a prompt will appear during the Mini-Setup stage asking for the values.

**[GuiUnattended]**
You must provide values for the AdminPassword, EncryptedAdminPassword, and TimeZone entries. The value for AdminPassword cannot begin with an asterisk (*). Using a password that begins with an asterisk can cause the password to be set to a null value, which can be a security risk. You must also include the following entries and values: `OEMSkipWelcome = 1` and `OEMSkipRegional = 1`.

**[Identification]**
You must specify values for either the JoinWorkgroup entry or the JoinDomain entry. If you choose the latter, you must also provide values for the DomainAdmin and DomainAdminPassword entries. However, if you are concerned about security you might want to leave the DomainAdminPassword blank because this entry cannot be encrypted in the answer file. If you leave the DomainAdminPassword entry blank, you will be prompted for the password during the Mini-Setup stage.

**[LicenseFilePrintData]**
You must specify values for the AutoMode and AutoUsers entries if you are installing Windows Server 2003. This section does not apply to Windows XP.

**[Networking]**
At a minimum you must set `InstallDefaultComponents=Yes`.

**[Unattended]**
You must accept the End User License Agreement (EULA) by setting `OEMSkipEula = Yes`. You must also provide a value for the InstallFilesPath entry, which specifies the location of any files that are necessary during the Mini-Setup stage, such as language files.

**[UserData]**
You must specify values for the ComputerName, FullName, and OrgName entries. You must also specify a value for the ProductKey entry.

**Winbom.ini Structure**
You can use Winbom.ini to automate the Factory-mode stage of an image-based installation with Sysprep. The following table lists all of the valid sections that can appear in a Winbom.ini file.

### Answer File Sections for Winbom.ini

| Section | Description |
|---|---|
| [Components] | Contains entries for installing the components of Windows XP Professional and Windows Server 2003. |
| [ComputerSettings] | Contains entries for configuring user settings on the destination computer. |
| [DesktopShortcutsFolder] | Contains an entry for specifying a shortcuts folder on the desktop. |
| [DiskConfig] | Contains entries for configuring and partitioning one or more physical hard disks when Factory.exe runs in the Windows Preinstallation Environment (Windows PE) |
| [*description*.config] | Contains entries for configuring partitions located on a physical disk. |
| [Factory] | Contains entries for managing the actions of Factory.exe. |
| [NetCards] | Contains an entry for configuring the network adapter on the destination computer, if Setup requires a network connection. |
| [OEMLink] | Contains entries for adding graphics and text to the Start menu so that users have easy access to an OEM's customized folder, .htm file, or .exe file for a tour. |
| [OEMRun] | Enables you to run external applications and command-line scripts when auditing the computer in Factory mode, by using the `Sysprep -factory` command. |
| [OEMRunOnce] | Enables you to control how and when external applications and command shell scripts run when auditing the computer in Factory mode, by using the `Sysprep -factory` command. |
| [*section_name*] | Contains entries for configuring the preinstallation of applications during the Factory-mode stage of Sysprep. This section can be used only with the [OEMRunOnce] section. |

| | |
|---|---|
| [PnPDrivers] | Lists all the updated drivers to copy onto the destination computer. |
| [PnPDriverUpdate] | Contains entries for specifying optional user credentials and a source location of drivers to place on an installed image. |
| [SetupHomenet] | Contains an entry for setting up a firewall on a computer with a preconfigured Internet connection. |
| [Shell] | Contains entries for specifying the visual style of the user interface. |
| [StartMenuMFUList] | Contains entries for installing shortcut links in the Start menu. |
| [UpdateSystem] | Contains entries, called directives, for performing registry or file system updates. |
| [UserAccounts] | Contains entries for controlling the creation of user accounts on the destination computer. |
| [UserDefined] | Contains branding information or any other data that other processes might need to access. |
| [WinPE] | Contains entries for identifying the configuration set and Windows operating system that you install. |
| [WinPE.Net] | Contains entries for controlling the settings that Windows Preinstallation Environment (Windows PE) uses to connect to a network. |

You do not need to add every possible section and entry to the Winbom.ini file. All sections and entries are optional, and Factory.exe ignores optional sections and entries that are not present in the answer file.

For more information about answer file sections, including descriptions and examples of entries and values, see "Sysprep Tools and Settings".

**Sysprep Processes and Interactions**

Sysprep configures various operating system settings on the master computer to ensure that every copy of the master computer's disk image is unique when you distribute it to a destination computer. Specifically, Sysprep configures a master installation (and hence, the disk image of that master installation) so that a unique computer *security identifier* (SID) is generated on each destination computer. A SID is a variable length data structure that identifies a user, a group, or a computer. Internal processes in Windows refer to the SID instead of the computer name or user name or group name. Sysprep resets SIDs by running *Setupcl.exe*, which is a Sysprep component.

You can also use Sysprep to configure the master computer's disk image so that every destination computer starts in a special setup mode known as *Mini-Setup*. Mini-Setup is the first-run experience on Windows Server 2003 and Windows XP, however, you can also configure Sysprep so that Windows Welcome is the first-run experience on Windows XP.

After you copy a disk image onto a destination computer, Mini-Setup runs the first time you start the destination computer. Mini-Setup provides the administrator, technician, or user the opportunity to configure operating system settings that are unique to the user or the computer. For example, computer name, regional options, time zone, and display settings. The Mini-Setup stage is a shortened version of the final stage of an interactive setup.

You can also use Sysprep to configure the master computer's disk image so that every destination computer starts in a special intermediate setup mode known as *Factory mode*. Factory mode is controlled by *Factory.exe* and is commonly used in a manufacturing environment where every computer requires some customization prior to final delivery; however, it is also useful for some corporate deployments. You can use Factory mode if you want to customize individual computers or groups of computers after you have copied a disk image onto a destination computer but before Mini-Setup runs. For example, Factory mode gives you the ability to update drivers, run Plug and Play enumeration, install applications, test hardware and software, and configure computer settings. Factory mode is an extension of Mini-Setup and encompasses many of the same installation and configuration tasks as the final (GUI-mode) stage of an interactive setup.

In addition to preparing a master computer for disk duplication, you can configure Sysprep so that the Mini-Setup and Factory-mode stages are automated. You use an answer file known as *Sysprep.inf* to automate the Mini-Setup stage of an image-based installation; you use an answer file known as *Winbom.ini* to automate the Factory-mode stage of an image-based installation. You can also use an answer file known as *Cmdlines.txt* to automate installation and configuration tasks at the end of the Mini-Setup stage. Cmdlines.txt does not contain any predefined, structured entries like Sysprep.inf and Winbom.ini. Instead, Cmdlines.txt contains command-line instructions similar to a batch file. You can use Cmdlines.txt to perform customized installation and configuration tasks such as installing software programs and running command-line programs.

This section describes the primary processes and interactions that occur when you:

- Run the Sysprep tool to prepare a master installation for disk imaging.
- Run a destination computer in Factory mode.
- Run Mini-Setup to perform final installation and configuration tasks.
- Perform post-installation tasks with Cmdlines.txt and the [GuiRunOnce] section.

This section does not discuss all of the processes and interactions that occur during an image-based installation: this section discusses only the processes and interactions that occur when you run the Sysprep tool. For example, the disk-imaging process and the image-copying process are not discussed in this section because these processes vary according to the disk-imaging program that you use.

**Tasks Performed by Sysprep**
You can use the Sysprep tool to perform four tasks.

**Prepare a master installation for final delivery**
This is the primary purpose of the Sysprep tool. To do this you run the `Sysprep -reseal` command, or click the **Reseal** button in the Sysprep interface.

**Configure a destination computer for Factory mode**
This task is performed primarily in manufacturing environments where every computer requires some customization prior to final delivery. However, it is also useful for some corporate deployments. To do this you run the `Sysprep -factory` command, or click the **Factory** button in the Sysprep interface.

**Configure a destination computer for auditing**
This task is performed to audit a destination computer before Mini-Setup runs. To do this you run the `Sysprep -audit` command, or click the **Audit** button in the Sysprep interface.

**Remove hidden mass storage devices**
This task is performed to remove references to devices that were present on the master computer but are not present on the destination computer. To do this you run the `Sysprep -clean`, `Sysprep -factory`, or `Sysprep -reseal` command, or click **Factory** or **Reseal** in the Sysprep interface.

The following sections describe the processes and interactions that occur when you use the four main parameters of Sysprep. The processes and interactions are presented in the approximate order in which they occur. It is not possible to describe these processes and interactions in precise order because the order might vary slightly depending on the way you perform the image-based installation and the options you choose when you run the Sysprep tool.

**Running Sysprep -reseal**
There are three types of processes and interactions that occur when you run the `Sysprep -reseal` command: verification and data gathering, configuration, and cleanup.

**Verification and Data Gathering**
Before any configuration settings are changed on the master installation, Sysprep checks various configuration settings and gathers information about the master installation. The main verification and data gathering processes include:

- Verifying that no other instance of Sysprep is running on the master installation. If there is another version of Sysprep running, Sysprep generates an error message.
- Verifying command-line syntax. For example, several command-line parameters must be used exclusively, such as `-bmsd`, `-clean`, `-audit`, `-factory`, and `-reseal`. If these parameters are used with other parameters, Sysprep generates an error.
- Verifying that the user is a member of the local Administrators group. If not, Sysprep generates an error and exits.
- Verifying that the user has sufficient privileges to run Sysprep. Users must have the following privileges: back up files and directories, modify firmware environment variables, restore files and directories, and shut down the system.
- Verifying that Setupcl.exe is present in the current directory (usually, *systemroot*\Sysprep). If the file is present, Sysprep copies it to *systemroot*\System32. If the file is not present, Sysprep checks for it in *systemroot*\System32. If it is not present there, Sysprep generates an error message and exits. This process is skipped if you use the `-nosidgen` parameter.

- Displaying a dialog box that describes the Sysprep tool. Users must verify that they have read this message. This process is skipped if you use the `-quiet` parameter.

- Verifying that that master computer is not joined to a domain. If it is, Sysprep removes the computer from the domain.

- Verifying that the screensaver is not enabled. If it is, Sysprep disables it and saves the settings so it can be enabled and reconfigured during the Mini-Setup stage.

**Configuration**
After the verification and data gathering processes are complete, Sysprep configures the master installation. The main configuration processes and interactions include:

- Checking the operating system version to be sure it is either Windows XP or Windows Server 2003. If you are not running Sysprep on either operating system, Sysprep generates an error and exits.

- Finding Sysprep.inf and saving the path information.

- Checking whether the master computer is a member of a domain, and if it is, disjoining it from the domain.

- Adding the information string to the registry if you specified a value for the OEMDuplicatorString entry in the [GuiUnattended] section of Sysprep.inf.

- Configuring the registry so that Setupcl.exe either runs or does not run the first time a destination computer is started. This is depends on whether you use the `-nosidgen` parameter. Setupcl.exe is responsible for resetting SIDs.

- Removing mass storage devices from the critical device database that were included in the [SysprepMassStorage] section but are not present on the destination computer.

- Saving network configuration settings so that they can be reapplied the first time the destination computer is started, and uninstalling all network adapters so that they will be detected the first time a destination computer is started.

**Cleanup**
After the configuration processes complete, Sysprep cleans up user-specific and computer-specific settings and data that you don't want copied to a destination computer. The main cleanup processes include:

- Deleting Systems Management Server settings.

- Deleting the event logs.

- Deleting per-user settings, such as user settings for Windows Media Player and Internet Connection Wizard.

- Deleting the list of most recently used documents, applications, and Web sites.

- Modifying device paths in the registry if you specified a path in the InstallFilesPath entry or the OemPnPDriversPath in the [Unattended] section of Sysprep.inf.

After these processes run, the master computer either shuts down or restarts depending on whether you use the `-reboot` or `-noreboot` parameters with Sysprep.

**Running Sysprep -factory**
There are two types of processes and interactions that occur when you run the `Sysprep -factory` command: configuration and cleanup.

**Configuration**
The main configuration processes and interactions that occur when you run the `Sysprep -factory` command include:

- Renaming Winbom.ini so that the file is not used again in the event that the computer is restarted during the Factory-mode stage.

- Checking to see if Factory.exe exists and saving the path information.
- Verifying that Factory.exe and Sysprep.exe are on the same drive and in the same location on the drive.
- Making various registry modifications so that the destination computer starts in factory mode the first time it is started.
- Making sure the user has privileges to update the registry.
- Checking whether the master computer is a member of a domain, and if it is, disjoining it from the domain.
- Configuring the registry so that Setupcl.exe runs the first time a destination computer is started.
- Building the [SysprepMassStorage] section in Sysprep.inf if the BuildMassStorageSection entry is present in the [Sysprep] section of Sysprep.inf or you used the `-bmsd` parameter with Sysprep.
- Saving network configuraton settings so they can be reapplied the first time the destination computer is started, and uninstalling all network adapters (except legacy network adapters) so they will be detected the first time a destination computer is started.

**Cleanup Processes**
After the configuration processes complete, Sysprep cleans up user-specific and computer-specific settings and data that you don't want to appear on a destination computer. The main cleanup processes include:

- Deleting per-user settings, such as user settings for Windows Media Player and Internet Connection Wizard.
- Deleting the list of most recently used documents, applications, and Web sites.
- Modifying device paths in the registry if you specified a path in the InstallFilesPath entry or the OemPnPDriversPath in the [Unattended] section of Sysprep.inf.
- Deleting the event logs.

After these processes run, the master computer shuts down.

**Running Sysprep -audit**
When you use Sysprep to configure a destination computer for auditing, Sysprep changes the registry so that the destination computer starts in an audit mode the next time it is started. When the technician or administrator is finished performing auditing tasks, Sysprep must be run again with the `-factory` parameter or the `-reseal` parameter, or by clicking **Factory** or **Reseal** in the Sysprep interface.

**Running Sysprep -clean**
When you use Sysprep to remove hidden mass storage devices, Sysprep does two things:

- Finds Sysprep.inf and removes the BuildMassStorageSection entry, if it exists.
- Removes mass storage devices from the critical device database that were included in the [SysprepMassStorage] section but are not present on the destination computer.

After the command `Sysprep -clean` is run, the computer is typically shut down and is ready for delivery to its final destination.

**Factory Mode Processes and Interactions**
You can use Factory mode to perform configuration and installation tasks on a destination computer. It is most often used to perform configuration and installation tasks that you could not perform on the master installation. This includes such tasks as configuring operating system settings, installing additional device drivers, and installing applications. When you use Factory mode, every destination computer starts in a network-enabled state without starting Mini-Setup. In this state, Factory.exe processes its answer file, Winbom.ini, and performs these actions:

- Copies drivers from a network source to the computer.
- Starts Plug and Play enumeration.
- Stages, installs, and uninstalls applications on the computer from source files located on either the computer or a network source.
- Performs configuration tasks specified in the Winbom.ini file.

**Locating a Winbom.ini File**
Sysprep searches these locations in this order for a Winbom.ini file:

- The path and file name specified by the registry key HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Factory\Winbom.
- The root of all removable media drives that are not CD drives, such as a floppy disk drive.
- The root of all CD drives.
- The location of Factory.exe, usually the %systemdrive%\Sysprep folder.
- The root of %systemdrive%.

After locating a Winbom.ini file, Sysprep reads the value of the WinbomType entry in the [Factory] section. If the value of WinbomType is not appropriate (for example, you use the entry `WinbomType = WinPE` but the computer is not running WinPE), the Winbom.ini file is ignored and Sysprep continues searching for a Winbom.ini file. If the value of the WinbomType entry is appropriate, Sysprep reads the value of the NewWinbom entry in the [Factory] section. If a value is specified for NewWinbom, and a Winbom.ini file is located at that location, Sysprep examines that Winbom.ini file for a NewWinbom entry.

This cycle continues until Sysprep locates a Winbom.ini file of the correct type that does not contain a NewWinbom entry or for a maximum of ten times, whichever occurs first. Sysprep then continues to run in Factory mode, performing the tasks that are specified in the Winbom.ini file.

When you run Sysprep in Factory mode, the NewWinbom entry is processed only once at each start.

**Processing Winbom.ini**
Factory.exe processes Winbom.ini entries in different ways, depending on the value of the WinbomType entry in the [Factory] section of the Winbom.ini file.

- If you use the entry `WinbomType = WinPE`, you can start a computer by using the Windows Preinstallation Environment (Windows PE) as the operating system, and run the command `factory -winpe` to preinstall Windows from a configuration set specified in the Winbom.ini file.
- If you use the entry `WinbomType = Factory`, the Winbom.ini file can be used to control Sysprep in factory mode, which you run by using the command `Sysprep -factory`.
- If you use the entry `WinbomType = OOBE`, you can use the Winbom.ini file to configure Windows XP during Windows Welcome. After you run the command `Sysprep -reseal`, Windows Welcome runs the next time you start the computer.

A state is the smallest group of Winbom.ini sections and entries that is logged as a single unit. For each value of the WinbomType entry, the states are listed in the order in which Factory.exe processes them. States always restart the computer, meaning that if the computer restarts either programmatically or unexpectedly, Factory.exe resumes by processing its last state, along with any states that are processed on every restart of the computer for that value of WinbomType.

Specific states can apply to more than one value of the WinbomType entry, and Factory.exe might process the same state multiple times during a particular instance of running the tool.

The following sections contain information about the states that occur during each type of Winbom.ini processing. The information for each state is listed in a table formatted as follows:

| | |
|---|---|
| State | Name of the state as it appears in the user interface and/or the log file. This name is localized and can be different in each language build of Factory.exe. |
| Winbom.ini | List of the Winbom.ini sections and entries processed in this state.<br>• If only a section is listed, then all entries in the section are processed.<br>• If the value for an entry is not specified, the entry can have any value that is syntactically correct. |
| Default | Specifies the default value if the entry is omitted or blank.<br>• "Nothing" means that the state does nothing if the entry is not specified.<br>• Otherwise, the values listed are used as specified, even when the entries are not present |
| Executes | Specifies if this state is processed once or on every boot of the computer.<br>• "Once" means that after the state completes, Factory.exe does not process that state again until you run either `Sysprep -factory` or `Sysprep -reseal`. Any entries read in those states are not read again from that state if you run `Sysprep -audit`.<br>• "Always" means that the state is processed on every start. If the computer restarts in the middle of processing the Winbom.ini file or if you manually restart the computer while auditing the installation, all of the "Always" states are processed again. However, each state is processed only once per start, unless otherwise noted. |
| Variables | Specifies if the entries processed in this state support environment variables.<br>• If No, then none of the entries support them.<br>• If Yes, then all the entries listed (or the whole section) support them.<br>• Otherwise, the individual Winbom.ini entries that support environment variables are listed.<br><br>If the state occurs before a user account logs on to the system or during Windows Welcome, then that state supports only system environment variables, not per user-defined environment variables, because the state is processed in the system context. |
| Comments | Additional comments, if any. |

**Winbom.ini Processing When Preinstalling Windows from Windows PE**

The states in this section contain the Winbom.ini entries that are processed when you start a computer by using Windows PE as the operating system, and run the command `factory -winpe` to preinstall Windows from a configuration set specified in the Winbom.ini file. WinbomType, located in the [Factory] section of the Winbom.ini file, must include the value WinPE.

The following tables describe the states in the order in which they are processed.

| State | Setting display resolution |
|---|---|
| Winbom.ini | [ComputerSettings]<br>DisplayResolution<br>DisplayRefresh |

| | |
|---|---|
| Default | [ComputerSettings]<br><br>DisplayResolution = "800x600x16" |
| Executes | Always |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Partitioning disks and formatting drives |
| Winbom.ini | [DiskConfig]<br><br>DiskN<br><br>[description.Config]<br><br>WipeDisk<br><br>ForceFormat<br><br>FileSystemN<br><br>PartitionTypeN<br><br>QuickFormatN<br><br>SetActiveN<br><br>SizeN<br><br>N is the (1-based) index of the physical disk. |

| | |
|---|---|
| Default | On 32-bit versions of Windows:<br>• [description.Config]<br>• WipeDisk = No<br>• ForceFormat = No<br>• FileSystemN = NTFS<br>• PartitionTypeN = Primary<br>• QuickFormatN = Yes<br>• SetActiveN = No<br><br>On 64-bit versions of Windows:<br>• [description.Config]<br>• WipeDisk = Yes<br>• ForceFormat = No<br>• FileSystemN = NTFS<br>• PartitionTypeN = Primary<br>• QuickFormatN = Yes<br>• SetActiveN = No |
| Executes | Always |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Creating Page File |
| Winbom.ini | [WinPE]<br>PageFileSize |
| Default | If the computer has less than 64 MB of physical memory:<br>• [WinPE]<br>• PageFileSize = 64 |
| Executes | Always |
| Variables | No |
| Comments | If the machine has more than 64 MB of physical memory, the page file size is 0 by default. |

| | |
|---|---|
| State | Starting Networking |
| Winbom.ini | [WinPE.Net]<br>Startnet<br>IPConfig<br>SubnetMask<br>Gateway |
| Default | [WinPE.Net]<br>Startnet = Yes<br>IPConfig = DHCP |
| Executes | Always |
| Variables | No |
| Comments | If StartNet = No, then subsequent values are ignored.<br>If IPConfig = DHCP, then SubnetMask and Gateway are ignored. |

| | |
|---|---|
| State | Installing applications |
| Winbom.ini | [OEMRunOnce] |
| Default | Nothing |
| Executes | Always |
| Variables | No |
| Comments | Credentials come from the UserName and Password entries in the [Factory] section. |

| | |
|---|---|
| State | Launching [OEMRun] programs |
| Winbom.ini | [OEMRun] |
| Default | None |
| Executes | Always |
| Variables | No |
| Comments | Credentials come from the UserName and Password entries in the [Factory] section. |

| | |
|---|---|
| State | Installing the Configuration Set |
| Winbom.ini | [WinPE]<br>ConfigSet<br>Lang<br>Quiet<br>SKU<br>SourceRoot |

| | |
|---|---|
| Default | [WinPE]<br><br>Quiet = No |
| Executes | Always |
| Variables | No |
| Comments | Credentials come from [WinPE] section or from the UserName and Password entries in the [Factory] section. |

| | |
|---|---|
| State | Processing INF settings |
| Winbom.ini | [UpdateSystem] |
| Default | None |
| Executes | Always |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Finishing Windows PE |
| Winbom.ini | [WinPE]<br><br>Restart |
| Default | [WinPE]<br><br>Restart = Prompt |
| Executes | Always |
| Variables | No |
| Comments | None |

**Winbom.ini Processing During Sysprep in Factory Mode**

The states in this section are the Winbom.ini entries processed when you run the command `Sysprep -factory`. The WinbomType entry, located in the [Factory] section of the Winbom.ini file, must include the value Factory.

The following tables describe the states in the order in which they are processed.

**Note**

- The `Sysprep -factory` command starts very early in the operating system boot sequence to enable operations that must occur before other system processes start. For example, during Plug and Play device enumeration, other system services and boot processes run, the `Sysprep -factory` command performs other tasks with the full Windows operating system running in the background.

| | |
|---|---|
| State | Extending system drive |
| Winbom.ini | [ComputerSettings]<br><br>ExtendPartition |
| Default | [ComputerSettings]<br><br>ExtendPartition = 0 |
| Executes | Once |

| | |
|---|---|
| Variables | No |
| Comments | You can extend only NTFS file system partitions. The partition to extend must have unpartitioned space available on its disk following the partition. |

| | |
|---|---|
| State | Setting source path |
| Winbom.ini | [ComputerSettings]<br><br>SourcePath |
| Default | Nothing |
| Executes | Once |
| Variables | Yes |
| Comments | This should point to the folder that contains the I386 folder. If the files exist in the root, and this entry is present, and the source path that it points to does not exist, Factory.exe moves the files from the root to where the source path points. |

| | |
|---|---|
| State | Installing test certificate |
| Winbom.ini | [ComputerSettings]<br><br>TestCert |
| Default | Nothing |
| Executes | Once |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Setting factory computer name |
| Winbom.ini | [Factory]<br><br>FactoryComputerName<br><br>RebootAfterComputerName |
| Default | [Factory]<br><br>RebootAfterComputerName = No |
| Executes | Once |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Copying updated drivers |
| Winbom.ini | [PNPDrivers]<br><br>[PNPDriverUpdate]<br><br>DevicePath<br><br>TargetRoot |

| | |
|---|---|
| Default | [PNPDrivers]<br>[PNPDriverUpdate]<br>TargetRoot = %SYSTEMROOT%\drivers |
| Executes | Once |
| Variables | Yes |
| Comments | None |

| | |
|---|---|
| State | Starting Plug and Play |
| Winbom.ini | Nothing |
| Default | Nothing |
| Executes | Always |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Setting display resolution |
| Winbom.ini | [ComputerSettings]<br>DisplayResolution<br>DisplayRefresh |
| Default | [ComputerSettings]<br>DisplayResolution = "800x600x16" |
| Executes | Always |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Customizing shell settings |
| Winbom.ini | [Shell]<br>MSNExplorer<br>DefaultStartPanelOff<br>DefaultThemesOff<br>CustomDefaultThemeFile<br>DoDesktopCleanup |
| Default | Nothing |
| Executes | Once |
| Variables | CustomDefaultThemeFile |
| Comments | DefaultStartPanelOff, DefaultThemesOff, and CustomDefaultThemeFile change the relevant setting only when new users are created. These settings are not changed on the administrator/owner account. |

| | |
|---|---|
| State | Preparing for automatic logon |
| Winbom.ini | [ComputerSettings]<br><br>AuditAdminAutoLogon |
| Default | [ComputerSettings]<br><br>AuditAdminAutoLogon = No |
| Executes | Once |
| Variables | No |
| Comments | If AuditAdminAutoLogon = Yes, then Factory.exe logs on to the desktop by using the administrator account. On Windows XP Home Edition, the owner account is used instead of the administrator account. |

| | |
|---|---|
| State | Waiting for Plug and Play to finish |
| Winbom.ini | [PNPDriverUpdate]<br><br>WaitForPnP |
| Default | [PNPDriverUpdate]<br><br>WaitForPnP = Yes |
| Executes | Always |
| Variables | No |
| Comments | Runs only if WaitForPnP = Yes. |

| | |
|---|---|
| State | Updating installed drivers |
| Winbom.ini | [PnPDriverUpdate]<br><br>UpdateInstalledDrivers |
| Default | If the first-run experience is Windows Welcome:<br>• [PNPDriverUpdate]<br>• UpdateInstalledDrivers = Yes<br><br>If the first-run experience is Mini-Setup:<br>• [PNPDriverUpdate]<br>• UpdateInstalledDrivers = No |
| Executes | Once |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Setting display resolution |

| | |
|---|---|
| Winbom.ini | [ComputerSettings]<br>DisplayResolution<br>DisplayRefresh |
| Default | [ComputerSettings]<br>DisplayResolution = "800x600x16" |
| Executes | Always |
| Variables | No |
| Comments | This state is run a second time, in case Plug and Play installed a new display driver. |

| | |
|---|---|
| State | Optimizing Shell |
| Winbom.ini | [Factory]<br>OptimizeShell |
| Default | [Factory]<br>OptimizeShell = Yes |
| Executes | Always |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Customizing shell font settings |
| Winbom.ini | [ComputerSettings]<br>FontSmoothing |
| Default | Nothing |
| Executes | Once |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Customizing shell settings |
| Winbom.ini | [Shell]<br>DefaultStartPanelOff<br>DefaultThemesOff<br>CustomDefaultThemeFile |
| Default | Nothing |
| Executes | Once |
| Variables | CustomDefaultThemeFile |
| Comments | DefaultStartPanelOff, DefaultThemesOff, and CustomDefaultThemeFile change the relevant setting only when new users are created. These settings are not changed on the administrator/owner account. |

| | |
|---|---|
| State | Customizing power settings |
| Winbom.ini | [ComputerSettings]<br>Hibernation<br>PowerScheme |
| Default | Nothing |
| Executes | Once |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Customizing home network settings |
| Winbom.ini | [SetupHomeNet]<br>EnableFirewall |
| Default | Nothing |
| Executes | Once |
| Variables | No |
| Comments | If this section exists, Factory.exe uses the Home Networking feature to configure settings. |

| | |
|---|---|
| State | Adding user identities |
| Winbom.ini | [UserAccounts] |
| Default | Nothing |
| Executes | Once |
| Variables | No |
| Comments | User accounts are not configured on the Windows Server 2003 family. |

| | |
|---|---|
| State | Processing INF settings |
| Winbom.ini | [UpdateSystem] |
| Default | Nothing |
| Executes | Always |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Configuring Optional Components |
| Winbom.ini | [Components] |
| Default | Nothing |
| Executes | Once |

| | |
|---|---|
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Installing applications |
| Winbom.ini | [OEMRunOnce] |
| Default | Nothing |
| Executes | Always |
| Variables | Yes |
| Comments | Credentials come from the UserName and Password entries in the [Factory] section. |

| | |
|---|---|
| State | Adding Start Menu frequently used links |
| Winbom.ini | [StartMenuMFUlist] |
| Default | Nothing |
| Executes | Once |
| Variables | Yes |
| Comments | None |

| | |
|---|---|
| State | Recording OEM application preferences |
| Winbom.ini | [Shell]<br>DefaultClientStartMenuInternet<br>DefaultClientMail<br>DefaultClientMedia<br>DefaultClientIM<br>DefaultClientJavaVM |
| Default | Nothing |
| Executes | Once |
| Variables | Yes |
| Comments | None |

| | |
|---|---|
| State | Applying OEM Start Menu branding |
| Winbom.ini | [OEMLink]<br>[DesktopShortcutsFolder] |
| Default | Nothing |
| Executes | Once |
| Variables | Yes |

| | |
|---|---|
| Comments | None |

| | |
|---|---|
| State | Launching [OEMRun] programs |
| Winbom.ini | [OEMRun] |
| Default | Nothing |
| Executes | Always |
| Variables | Yes |
| Comments | Credentials come from the UserName and Password entries in the [Factory] section |

| | |
|---|---|
| State | Waiting for Plug and Play to Finish |
| Winbom.ini | [PnPDriverUpdate]<br>WaitForPnP |
| Default | [PNPDriverUpdate]<br>WaitForPnP = Yes |
| Executes | Always |
| Variables | No |
| Comments | Runs only if WaitForPnP = Yes. |

| | |
|---|---|
| State | Launching Sysprep |
| Winbom.ini | [Factory]<br>Reseal<br>ResealFlags<br>ResealMode |
| Default | On Windows XP Home Edition or Windows XP Professional:<br>• [Factory]<br>• Reseal = No<br>• ResealoMode = OOBE<br><br>On Windows XP 64-Bit Edition or the Windows Server 2003 family:<br>• [Factory]<br>• ResealMode = Mini |
| Executes | Always |
| Variables | No |
| Comments | On Windows XP 64-Bit Edition or the Windows Server 2003 family, the default behavior is for Sysprep to run and present its user interface. |

**Winbom.ini Processing During Windows Welcome**

The states in this section are the Winbom.ini entries processed at the beginning of Windows Welcome on Windows XP. These states are not processed if the first-run experience is Mini-Setup. The WinbomType entry, located in the [Factory] section of the Winbom.ini file, must include the value OOBE.

The following tables describe the states in the order in which they are processed.

| | |
|---|---|
| State | Extending system drive |
| Winbom.ini | [ComputerSettings]<br><br>ExtendPartition |
| Default | Nothing |
| Executes | Once |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Setting source path |
| Winbom.ini | [ComputerSettings]<br><br>SourcePath |
| Default | Nothing |
| Executes | Once |
| Variables | Yes |
| Comments | The value of SourcePath the folder that contains the I386 folder. If the files exist in the root, this entry is present, and the source path that it points to does not exist, then Factory.exe moves the files from the root to the location specified by SourcePath. |

| | |
|---|---|
| State | Installing test certificate |
| Winbom.ini | [ComputerSettings]<br><br>TestCert |
| Default | Nothing |
| Executes | Once |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Updating installed drivers |
| Winbom.ini | [PnPDriverUpdate]<br><br>UpdateInstalledDrivers |
| Default | [PNPDriverUpdate]<br><br>UpdateInstalledDrivers = Yes |
| Executes | Once |

| | |
|---|---|
| Variables | No |
| Comments | Only functions if UpdateInstalledDrivers = Yes. |

| | |
|---|---|
| State | Setting display resolution |
| Winbom.ini | [ComputerSettings]<br>DisplayResolution<br>DisplayRefresh |
| Default | [ComputerSettings]<br>DisplayResolution = "800x600x16" |
| Executes | Once |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Optimizing Shell |
| Winbom.ini | [Factory]<br>OptimizeShell |
| Default | [Factory]<br>OptimizeShell = Yes |
| Executes | Always |
| Variables | No |
| Comments | Does not function if OptimizeShell = No. If OptimizeShell = Yes, the Windows shell settings are configured every time Windows Welcome runs, even if that causes the computer to restart. |

| | |
|---|---|
| State | Customizing shell settings |
| Winbom.ini | [Shell]<br>MSNExplorer<br>DefaultStartPanelOff<br>DefaultThemesOff<br>CustomDefaultThemeFile<br>DoDesktopCleanup |
| Default | Nothing |
| Executes | Once |
| Variables | CustomDefaultThemeFile |
| Comments | DefaultStartPanelOff, DefaultThemesOff, and CustomDefaultThemeFile change the relevant setting only when new users are created. These settings are not changed on the administrator/owner account. |

| | |
|---|---|
| State | Customizing power settings |
| Winbom.ini | [ComputerSettings]<br>Hibernation<br>PowerScheme |
| Default | Nothing |
| Executes | Once |
| Variables | No |
| Comments | None |

| | |
|---|---|
| State | Configuring Optional Components |
| Winbom.ini | [Components] |
| Default | Nothing |
| Executes | Once |
| Variables | No |
| Comments | None |

**Mini-Setup Processes and Interactions**

Mini-Setup is a shortened version of an interactive setup. Syssetup.dll controls Mini-Setup, which is the same DLL that controls the final stage (GUI mode stage) of an interactive setup. However, not all of the interactive setup steps are performed during Mini-Setup because the operating system was already installed when the master installation was created.

The primary processes and interactions that occur during the Mini-Setup stage are described below in the approximate order in which they occur.

- Search for a Sysprep.inf file. If a Sysprep.inf is found, read it and save the settings.
- Begin Plug and Play enumeration and installation of devices.
- Determine whether any network components need to be reconfigured because the SIDs changed, and perform the necessary configuration tasks.
- Extend the primary partition, if specified in the answer file.
- Start the Mini-Setup wizard, which displays the following dialog boxes (if Sysprep.inf contains the configuration information required for a dialog box, the box is not displayed or it is displayed briefly and then closed).
    - Welcome to the Windows Setup Wizard (click Next)
    - End-User License Agreement (accept or not accept)
    - Regional and Language Options
    - Personalize Your Software (user name and organization name)
    - Your Product Key
    - Licensing Modes (per server or per device or per user)
    - Computer Name and Administrator Password

    - Date and Time Settings
    - Networking Settings (typical or custom)
    - Workgroup or Computer Domain
    - Completing the Windows Setup Wizard (click Finish)
- Execute the commands in Cmdlines.txt.
- Write any commands listed in the [GUIRunOnce] section to the registry so they can run the first time the computer starts and a user logs on.
- Update the HAL, if specified in the answer file.
- Delete the Sysprep folder, which is in the systemroot root.

When the Mini-Setup stage finishes, the computer restarts and the entries specified in the [GUIRunOnce] section are run.

**Post Installation Processes and Interactions**
Several Sysprep installation processes occur after an operating system is installed on a destination computer. These processes occur when you automate post-installation configuration tasks. Examples of post-installation configuration tasks include running command-line programs to configure system services, running scripts to configure Group Policy settings, and installing software programs. The most commonly used mechanisms for automating post-installation tasks is the Cmdlines.txt file and the [GUIRunOnce] in the Sysprep.inf answer file.

**Cmdlines.txt Processes and Interactions**
A Cmdlines.txt file contains a list of commands, programs, scripts, or batch files that run just after the Mini-Setup stage finishes but before the destination computer restarts. By default, Cmdlines.txt does not exist, so you must manually create the file with a text editor, such as Notepad.

The syntax for Cmdlines.txt is as follows:

```
              [Commands]
"command_1"
"command_2"
     .
     .
"command_x"
```

Where *command_1*, *command_2*, and *command_x* refer to the commands, programs, scripts, or batch files that you want to run when the Mini-Setup stage is complete. Note that all commands must be enclosed in quotation marks. Also, if you are using the command window (Cmd.exe) to run commands, programs, scripts, or batch files, then you need to use the `/c` parameter with the `cmd` command.

For example, to create a new folder named Test on drive C, you type:

```
              "cmd /c mkdir c:\Test"
```

In addition, to use a Cmdlines.txt file, you need to:

- Add the following section, entry, and value to your Sysprep.inf answer file:

  ```
  [Unattended]
  InstallFilesPath = C:\Sysprep\i386
  ```

- In the distribution share that you used to create the master installation, create the following folder:

*systemdrive*\Sysprep\i386\$OEM$.

- Copy Cmdlines.txt to the *systemdrive*\Sysprep\i386\$OEM$ folder.

You can only have one Cmdlines.txt file, but you can use it to run multiple commands, programs, scripts, or batch files. When these commands, programs, scripts, or batch files run, the following processes and interactions occur:

- The commands, programs, scripts, and batch files run synchronously, which means each command, program, script, or batch file runs to completion before the next one starts running.
- All commands, programs, scripts, and batch files specified in a Cmdlines.txt run under the Local System security account.
- Network connectivity is not available when the commands, programs, scripts, and batch files listed in a Cmdlines.txt file run.
- Windows Installer packages (.msi files) cannot be run from a Cmdlines.txt file.

**[GuiRunOnce] Processes and Interactions**

The [GuiRunOnce] section of an answer file contains a list of commands, programs, scripts, or batch files that run the first time an administrator or technician logs on to the destination computer after the operating system is installed.

The syntax for [GuiRunOnce] is:

```
              [GuiRunOnce]
"command_1"
"command_2"
     .
     .
"command_x"
```

Where *command_1*, *command_2*, and *command_x* refer to the commands, programs, scripts, or batch files that you want to run after the operating system is installed and the administrator or technician logs on. Note that all commands must be enclosed in quotation marks.

The commands that are listed in the [GuiRunOnce] section are stored in the following registry location:

HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Runonce

When an administrator or technician logs onto the destination computer for the first time after the Mini-Setup stage is complete, Windows Server 2003 reads and then runs the commands that are listed in this registry location. When these commands, programs, scripts, or batch files run, the following processes and interactions occur:

- The commands, programs, scripts, and batch files run synchronously, which means each command, program, script, or batch file runs to completion before the next one starts running.
- The commands, programs, scripts, and batch files listed in the [GuiRunOnce] section run under the security account of the user who logged onto the destination computer (usually an administrator or a technician).
- Network connectivity is available when the commands, programs, scripts, and batch files run.
- You can use Windows Installer packages (.msi files) to install applications (unlike Cmdlines.txt).
- You can run commands, programs, scripts, and batch files from hard disk drives, CD drives, shared folders on the network, or other storage devices (unlike Cmdlines.txt, which runs everything from the $OEM$ folder in your distribution share).

In addition, there are some interactions and processes that you might need to control if you run certain commands, programs, scripts, and batch files with the [GuiRunOnce] section.

**Prevent restarts**

You can run commands, programs, scripts, and batch files only if you can prevent the command, program, script, or batch file from restarting the computer. When a computer restarts, all remaining entries in the [GuiRunOnce] section are lost because the Runonce registry entry is deleted. If the system restarts before completing entries listed in the [GuiRunOnce] section, the remaining items will not run. Therefore, you need to suppress restarts. If you cannot suppress a restart within a command, program, script, or batch file, you can try to repackage the command, program, script, or batch file into a Windows Installer package.

**Do not rely on the Windows Explorer shell**

The Windows Explorer shell is not loaded when the operating system starts running commands, programs, scripts, or batch files that are listed in the [GuiRunOnce] section of an answer file. In some cases, you can get an updated installer program from the application vendor that does not rely on the Windows Explorer shell. If you cannot, you might be able to repackage the command, program, script, or batch file as a Windows Installer package (.msi file).

**Control the processes by using the /wait parameter**

Commands, programs, scripts, and batch files often start and stop several different processes. In some cases, when you are running multiple programs — especially installation programs — this can inadvertently cause the next program listed in the [GuiRunOnce] section to start before the previous program is finished running. When this occurs, the second program usually fails. To prevent this, you can run the programs from batch files by using the `start` command with the `/wait` parameter. This forces each program to complete before the next command listed in [GuiRunOnce] runs.

# Sysprep Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sysprep Tools and Settings**

**In this section**

- Sysprep Tools
- Sysprep.inf Answer File Settings
- Winbom.ini Answer File Settings
- Sysprep Command-Line Parameters

The following tools, answer files, and command-line parameters are associated with image-based installations with the System Preparation tool (Sysprep). You use the tools and answer files to perform image-based installations with Sysprep.

**Sysprep Tools**

The following tools are associated with image-based installations with Sysprep.

**Winnt.exe: Windows Setup program for 16-bit operating systems**

**Category**

Windows setup and installation tool available on the Microsoft Windows Server 2003 product CD.

**Version compatibility**

Runs on Microsoft MS-DOS and Windows for Workgroups.

You can use this tool to initiate an unattended installation from the 16-bit operating systems MS-DOS and Windows for Workgroups. Typically, you use Winnt.exe to perform an unattended installation on a master computer prior to running the Sysprep tool. You cannot perform an upgrade with Winnt.exe; you can only perform clean installations with Winnt.exe.

For more information about Winnt.exe, see “Command Line References” in the Tools and Settings Collection.

**Winnt32exe: Windows Setup program for 32-bit and 64-bit operating systems**

**Category**

Windows setup and installation tool available on the Windows Server 2003 product CD.

**Version compatibility**

Runs on Microsoft Windows Server 2003, Windows XP, Windows 2000, Windows NT, Windows Millennium Edition, Windows 98, and Windows 95.

You can use this tool to perform an interactive setup or an unattended installation on a computer that has an existing operating system. To perform an interactive setup or an unattended installation from a 32-bit Windows operating system you must use the 32-bit version of Winnt32.exe. To perform an interactive setup or an unattended installation from a 64-bit Windows operating system you must use the 64-bit version of Winnt32.exe. Typically, you use Winnt32.exe to create a master installation on a master computer prior to running the Sysprep tool.

For more information about Winnt32.exe, see “Command Line References” in the Tools and Settings Collection.

**DiskPart.exe: DiskPart**

**Category**

Windows Server 2003 operating system tool.

**Version compatibility**

DiskPart is identical for all versions of Windows Server 2003. DiskPart includes a few 64-bit parameters that are only available on Itanium-based computers.

DiskPart is a text-mode command interpreter that enables you to manage objects (disks, partitions, or volumes) by using scripts or direct input from a command prompt.

For more information about DiskPart, see “Command Line References” in the Tools and Settings Collection.

**Setupmgr.exe: Setup Manager**
**Category**
Windows deployment tool available on the Windows Server 2003 product CD.

**Version compatibility**
Runs on the 32-bit versions of Windows Server 2003 and Windows XP.

Setup Manager is a wizard-like program that helps you configure distribution shares and answer files that can be used to perform automated installations, including unattended installation, image-based installation with Sysprep, and Remote Installation Services (RIS) installations. Setup Manager prompts you for information in a series of dialog boxes. Setup Manager configures answer file settings and distribution shares based on the information you provide in these dialog boxes.

Usually, you run Setup Manager on the administrator or technician computer. Setup Manager does not affect the system files of the technician computer on which the tool runs and does not actually run Setup. Also, you do not need to specify all of your customizations with Setup Manager. Instead, you can create an answer file in Setup Manager and then manually edit the file with Notepad. If you later open the answer file in Setup Manager, the tool displays your changed settings.

Setup Manager is not installed when you install Windows XP or Windows Server 2003. You must manually install Setup Manager on the administrator or technician computer.

**To install Setup Manager**

1. Insert a Windows XP or Windows Server 2003 product CD into your CD drive and open the \Support\Tools folder.
2. Double-click **Deploy.cab**.
3. Right-click the file named **Setupmgr.exe** and click **Extract**.
4. In the **Select a Destination** dialog box, select a location on your hard drive where you want to save Setup Manager, and then click **Extract**.

You can run Setup Manager from the graphical user interface by double-clicking the Setupmgr.exe file that you saved to your hard disk, or from the command line by typing `setupmgr`.

### Note

- If you use Setup Manager to create or modify a distribution share that is not on the local computer, be sure you run Setup Manager under a user account that has the minimum user rights to connect to the remote computer. This is because Setup Manager sends the user name and the password across the network in plaintext when it connects to a remote distribution share.

The following sections provide information about each Setup Manager dialog box. The section names correspond to the dialog box name that you see in Setup Manager.

**New or Existing Answer File**
Enables you to create a new answer file or edit an existing one.

Answer file sections and entries configured:

- None

**Type of Setup**
Provides three Setup options: Unattended, Sysprep, or Remote Installation Services (RIS).

Answer file sections and entries configured:

- None

**Product**
Prompts you to select the Windows product that you want to install.

Answer file sections and entries configured:

- None

**User Interaction**
Prompts you to select the level of user interaction you want. This dialog box is not used if you are configuring a Sysprep or RIS installation.

Answer file sections and entries configured:

- [Unattended]
- UnattendMode

**Distribution Share**
Enables you to create a new distribution share, modify an existing one, or set up Windows from a product CD.

Answer file sections and entries configured:

- None

**Location of Setup Files**
Prompts you for the location of the Setup files you want to copy.

Answer file sections and entries configured:

- None

**Distribution Share**
Prompts you for the location of the distribution share you want to create or modify. This section is used only by Setup Manager when an existing distribution share is edited. It is not used by Setup during an unattended installation.

Answer file sections and entries configured:

- [SetupMgr]
- DistFolder
- DistShare

**Name and Organization**
Enables you to provide a default user name and organization name.

Answer file sections and entries configured:

- [UserData]
- FullName
- OrgName

**Display Settings**
Enables you to change the change settings for colors, screen area, and refresh frequency.

Answer file sections and entries configured:

- [Display]
- BitsPerPel
- XResolution

- YResolution
- VRefresh

**Time Zone**
Prompts you to select a default time zone.

Answer file sections and entries configured:

- [GuiUnattended]
- TimeZone

**Product Key**
Prompts you to provide a Product Key to identify your copy of Windows.

Answer file sections and entries configured:

- [UserData]
- ProductKey

**Computer Names**
Prompts you to provide names for the destination computers.

Answer file sections and entries configured:

- [UserData]
- ComputerName

**Administrator Password**
Enables you to specify a password for the Administrator account on all destination computers.

Answer file sections and entries configured:

- [GuiUnattended]
- AdminPassword
- EncryptedAdminPassword

**Networking Computers**
Enables you to choose typical or custom network settings.

Answer file sections and entries configured:

- [Networking]
- [NetAdapters] (if custom settings are configured)
- [NetClients] (if custom settings are configured)
- [NetProtocols] (if custom settings are configured)

**Workgroup or Domain**
Prompts you to specify how the destination computers will participate in a network.

Answer file sections and entries configured:

- [Identification]

**Windows Components**
Enables you to install commonly used Windows components.

Answer file sections and entries configured:

- [Components]

**Telephony**
Enables you to provide telephony information for the user.

Answer file sections and entries configured:

- [TapiLocation]

**Regional Settings**
Enables you to customize Windows for different regions and languages.

Answer file sections and entries configured:

- [RegionalSettings]

**Languages**
Prompts you to select the language groups you want to use.

Answer file sections and entries configured:

- [RegionalSettings]

- Language

**Browser and Shell Settings**
Enables you to customize the browser and shell settings for Windows.

Answer file sections and entries configured:

- [FavoritesEx]

**Installation Folder**
Enables you to specify the name of the Windows folder.

Answer file sections and entries configured:

- [Unattended]

- TargetPath

**Install Printers**
Enables you to install network printers on the destination computers.

Answer file sections and entries configured:

- [GuiRunOnce]

**Run Once**
Enables you to automatically run a command the first time the user logs on.

Answer file sections and entries configured:

- [GuiRunOnce]

**Additional Commands**
Enables you to add commands to run at the end of the Mini-Setup stage.

Answer file sections and entries configured:

- [Commands] (in the Cmdlines.txt file)

**Sysprep.inf Answer File Settings**
This section describes the settings that you can configure in the Sysprep.inf answer file, which controls the Mini-Setup stage of an image-based installation with Sysprep. For more information about how to structure the Sysprep.inf answer file, see "Sysprep Physical Structures" in How Sysprep Works.

The following table lists all of the valid sections that can appear in a Sysprep.inf file.

**Answer File Sections for Sysprep.inf**

| Section | Description |
|---|---|
| [adapter_specific_protocol_section] | Contains an entry for specifying a network component. Used in conjunction with the [Networking] section. |
| [Display] | Contains entries for specifying display settings for graphics devices. |
| [GuiRunOnce] | Contains commands to run the first time a user logs on to the computer after the Mini-Setup stage completes and the destination computer restarts. |
| [GuiUnattended] | Contains entries for configuring the way the Mini-Setup stage runs as well as time and date settings. . |
| [Identification] | Contains entries for specifying the network identification of a computer. If these entries are not present, Setup adds the computer to the default workgroup. If there is not enough information for this entry, Setup prompts the user to provide this information. |
| [IEHardening] | Contains entries for configuring Web content zones. |
| [LicenseFilePrintData] | Contains entries for installing licensing information for Windows Server 2003. |
| [MS_AppleTalk parameters] | Contains entries for configuring AppleTalk. |
| [MS_ATMArps parameters] | Contains no entries. |
| [MS_ATMLANE parameters] | Contains no entries. |
| [MS_ATMUni parameters] | Contains no entries. |
| [MS_L2TP parameters] | Contains entries for the Layer 2 Tunneling Protocol (L2TP). |
| [MS_MSClient parameters] | Contains entries for Client for Microsoft Networks. |
| [MS_NetMon parameters] | Contains no entries. |
| [MS_NWClient parameters] | Contains entries for Client Service for NetWare. |
| [MS_NWIPX parameters] | Contains entries for the Internetwork Packet Exchange (IPX) protocol. Its parameters are network adapter–independent. |
| [MS_NwSapAgent parameters] | Contains no entries. |
| [MS_PPTP parameters] | Contains entries for the Point-to-Point Tunneling Protocol (PPTP). |

| | |
|---|---|
| [MS_Psched parameters] | Contains no entries. |
| [MS_RAS parameters] | Contains entries for the Routing and Remote Access service. |
| [MS_RasSrv parameters] | Contains entries for the Routing and Remote Access service for remote access servers. |
| [MS_Server parameters] | Contains entries for the File and Print Service. |
| [MS_TCPIP parameters] | Contains entries for configuring the TCP/IP protocol. |
| [MS_WLBS parameters] | Contains parameters for configuring Network Load Balancing (formerly, Windows Load Balancing Service, or WLBS) and binding Network Load Balancing to multiple network adapters. |
| [NetAdapters] | Contains entries that specify network adapters. |
| [NetBindings] | Contains entries for disabling, enabling, and demoting binding rules for network components such as services, protocols, and adapters. |
| [NetClients] | Contains an entry for specifying the network clients to install. |
| [NetOptionalComponents] | Contains entries for installing optional network components. |
| [NetProtocols] | Contains an entry for installing the network protocols. |
| [NetServices] | Contains entries for installing network services. |
| [Networking] | Contains no entries. However, to configure network protocols, you must include the [Networking] section name in your answer file. |
| [params.adapter_instance] | Contains entries for specifying an adapter's instance on a computer. |
| [protocol_parameters_section] | Contains an entry for specifying network protocol parameters that are also specified in the [NetProtocols] section. |
| [RegionalSettings] | Contains entries for installing regional options during the setup process. |
| [Sysprep] | Contains an entry for automatically generating the entries in the pre-existing [SysprepMassStorage] section and then installing those mass-storage controllers. |
| [SysprepMassStorage] | Contains entries for identifying the different mass-storage controllers that you want to install on each destination computer. |
| [TapiLocation] | Contains entries for specifying the telephony API (TAPI). It is valid only if a modem is present on the computer. |
| [Unattended] | Contains entries that control the Mini-Setup stage. |
| [UserData] | Contains entries for specifying user settings during the setup process. |

**Winbom.ini Answer File Settings**

This section describes the settings that you can configure in the Winbom.ini answer file, which controls the Factory mode stage of an image-based installation with Sysprep. For more information about how to structure the Winbom.ini answer file, see "Sysprep Physical Structures" in How Sysprep Works.

The following table lists all of the valid sections that can appear in a Winbom.ini file.

**Answer File Sections for Winbom.ini**

| Section | Description |
|---|---|
| [Components] | Contains entries for installing the components of Windows XP Professional and Windows Server 2003. |

| | |
|---|---|
| [ComputerSettings] | Contains entries for configuring user settings on the destination computer. |
| [DesktopShortcutsFolder] | Contains an entry for specifying a shortcuts folder on the desktop. |
| [DiskConfig] | Contains entries for configuring and partitioning one or more physical hard disks when Factory.exe runs in the Windows Preinstallation Environment (Windows PE) |
| [description.config] | Contains entries for configuring partitions located on a physical disk. |
| [Factory] | Contains entries for managing the actions of Factory.exe. |
| [NetCards] | Contains an entry for configuring the network adapter on the destination computer, if Setup requires a network connection. |
| [OEMLink] | Contains entries for adding graphics and text to the Start menu so that users have easy access to an OEM's customized folder, .htm file, or .exe file for a tour. |
| [OEMRun] | Enables you to run external applications and command-line scripts when auditing the computer in Factory mode, by using the `Sysprep -factory` command. |
| [OEMRunOnce] | Enables you to control how and when external applications and command shell scripts run when auditing the computer in Factory mode, by using the `Sysprep -factory` command. |
| [section_name] | Contains entries for configuring the preinstallation of applications during the Factory-mode stage of Sysprep. This section can be used only with the [OEMRunOnce] section. |
| [PnPDrivers] | Lists all the updated drivers to copy onto the destination computer. |
| [PnPDriverUpdate] | Contains entries for specifying optional user credentials and a source location of drivers to place on an installed image. |
| [SetupHomenet] | Contains an entry for setting up a firewall on a computer with a preconfigured Internet connection. |
| [Shell] | Contains entries for specifying the visual style of the user interface. |
| [StartMenuMFUList] | Contains entries for installing shortcut links in the Start menu. |
| [UpdateSystem] | Contains entries, called directives, for performing registry or file system updates. |
| [UserAccounts] | Contains entries for controlling the creation of user accounts on the destination computer. |
| [UserDefined] | Contains branding information or any other data that other processes might need to access. |
| [WinPE] | Contains entries for identifying the configuration set and Windows operating system that you install. |
| [WinPE.Net] | Contains entries for controlling the settings that Windows Preinstallation Environment (Windows PE) uses to connect to a network. |

**Sysprep Command-Line Parameters**

Sysprep.exe can be run from the command line or it can be run in the Windows graphical user interface (GUI). Use the following syntax when running Sysprep.exe from the command line.

```
sysprep [-bmsd] | {{[-factory] | [-reseal]} {[-clean] | [-activated] [-
audit] [-forceshutdown] [-mini] [-noreboot] [-nosidgen] [-pnp] [-quiet] [-reboot]}}
```

**Parameters**

Sysprep.exe uses the following parameters.

**-bmsd**

If the [SysprepMassStorage] section header exists in Sysprep.inf, and you run the `Sysprep -bmsd` command, then Sysprep populates the [SysprepMassStorage] section with the `Plug_and_Play_ID = path_to_device_inf_file` entries corresponding to the Plug and Play IDs of mass-storage devices specified in the Machine.inf, Scsi.inf, Pnpscsi.inf, and Mshdc.inf files. Sysprep builds the list of mass-storage devices; it does not install these devices in the critical device database or do any other processing.

After using the `Sysprep -bmsd` command to generate entries in the [SysprepMassStorage] section, you can delete items from this section before running `Sysprep -reseal` or `Sysprep -factory`. Installing a smaller number of items in the critical device database reduces the time required for this image to reboot into the operating system.

Do not use the `-bmsd` parameter with any other command-line parameters.

**-factory**
Restarts the destination computer in a network-enabled state without running Mini-Setup. This parameter is useful for updating drivers, running Plug and Play enumeration, installing applications, testing, configuring the computer with customer data, or making other configuration changes. For companies that use disk imaging (or cloning) software, Factory mode can reduce the number of images you need to create.

When you have finished your Factory mode tasks, run the `Sysprep -reseal` command to prepare the computer for delivery.

**-reseal**
Prepares the computer for final delivery and configures the computer so that Mini-Setup runs the next time the computer is started. If you run the `Sysprep -factory` command, you must seal the installation as the last step in your preinstallation process, either by running the `Sysprep -reseal` command or by clicking the Reseal button in the Sysprep dialog box.

**-clean**
Clears unused mass-storage drivers added by the [SysprepMassStorage] section of Sysprep.inf, and removes previously installed but nonexistent devices created by Plug and Play.

**-activated**
Does not reset the grace period for Windows Product Activation.

Use this parameter only if you have activated the Windows operating system on the destination computer prior to running Mini-Setup. The Product Key that you use to activate the Windows installation must match the Product Key located on the COA sticker attached to that computer.

**-audit**
Restarts the computer into Factory mode without generating new security IDs (SIDs) or processing any items in the [OEMRunOnce] section of Winbom.ini.

Use this parameter only if the computer is in Factory mode.

**-forceshutdown**
Shuts down the computer after Sysprep finishes.

Use this option if your computers have an ACPI BIOS that does not shut down properly with the Sysprep default settings.

**-mini**
Configures Windows XP Professional to use Mini-Setup instead of Windows Welcome. This parameter has no effect on Windows XP Home Edition, where the first-run experience is always Windows Welcome. Likewise, this parameter is not needed on Windows Server 2003 because Mini-Setup is the default first-run experience.

**-noreboot**
Modifies registry keys without the system restarting or preparing for duplication. This option is used mainly for testing, specifically to see if the registry is modified properly. This option is not recommended because making changes to a computer after Sysprep has run may invalidate the preparation done by Sysprep. Do not use this option in a production environment.

**-nosidgen**
Runs Sysprep without generating new SIDs. You must use this option if you do not duplicate the computer, or if the computer is a domain controller.

**-pnp**
Runs the full Plug and Play device enumeration and installation during the Mini-Setup stage. This command-line option has no effect if the first-run experience is Windows Welcome.

Use the `-pnp` parameter only to detect and install legacy, non-Plug and Play devices. Do not use the `-pnp` parameter on computers that use only Plug and Play devices. Otherwise, you will increase the time required for the first-run experience without providing any additional benefit to the user.

**-quiet**
Runs Sysprep without displaying onscreen confirmation messages. This is useful if you automate Sysprep. For example, if you plan to run Sysprep immediately after an unattended installation, add the `Sysprep -quiet` command to the [GuiRunOnce] section of the Unattend.txt file.

**-reboot**

Forces the computer to restart automatically and then start the Mini-Setup stage or the Factory-mode stage, as specified. This is useful when you want to audit the system and verify that the first-run experience operates correctly.

# Remote Installation Services Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote Installation Services Technical Reference**
Remote Installation Services (RIS) is an automated installation technology that you can use to create installation images of operating systems or of complete computer configurations, including desktop settings and applications. These installation images can then be made available to users at client computers. RIS is typically used during large-scale deployments when it would be too slow and costly to have administrators or end users interactively install the operating system on individual computers.

When you use RIS, a CD-ROM is not required for installing an operating system on a client computer. The client computers must support remote startup with the Pre-Boot eXecution Environment (PXE) ROM, or they must be started with a remote-startup floppy disk and have a network adapter that is supported by that disk.

The Setup program in Microsoft Windows Server 2003 provides the method for carrying out an automated installation using RIS.

**In this subject**

- What Is Remote Installation Services?
- How Remote Installation Services Work
- Remote Installation Services Tools and Settings

# What Is Remote Installation Services?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Remote Installation Services?**

**In this section**

- Remote Installation Services Dependencies and Requirements
- Remote Installation Services Limitations
- Technologies Related to Remote Installation Services

Remote Installation Services (RIS) is an automated installation technology that you can use to create installation images of operating systems or of complete computer configurations, including desktop settings and applications. These installation images can then be made available to users at client computers. RIS is typically used during large-scale deployments when it would be too slow and costly to have administrators or end users interactively install the operating system on individual computers.

Compared to a standard interactive installation, RIS decreases installation time, eliminates the need to use CDs during installation, and minimizes end user and administrator interaction during installations. To accomplish this, RIS relies on Pre-Boot eXecution Environment (PXE) technology. PXE technology enables computers without an operating system to start up and connect remotely over a TCP/IP network connection to a RIS server, which then installs an operating system. The client computers must support remote booting with the PXE ROM, or they must be started with a remote-startup floppy disk and have a network adapter that is supported by that disk.

To perform a RIS installation, an administrator or end user typically boots a client computer from a PXE-capable network adapter by pressing F12 early in the startup process. This instructs the computer to acquire an IP address and connect to a RIS server. The client computer then downloads a small version of the Windows Setup program from the RIS server. You can configure a RIS installation so that the Windows Setup program interactively steps the administrator or end user through a shortened setup process, or you can configure it so that the entire setup process is automated after the end user or administrator presses F12. Also, you can configure a RIS installation so the installation is image-based or setup-based. By using image-based installations, you can deploy applications with an operating system. By using setup-based installations, you have more flexibility in terms of handling hardware differences among the computers in your organization.

The following figure shows how a RIS installation differs from an interactive installation.

**Comparison of RIS and Interactive Installations**

Like all automated installation technologies, RIS has many benefits that a standard interactive installation does not. These benefits include:

**Fewer errors during installation**
Because RIS installation uses either preconfigured disk images or answer files to install and configure the operating system, there is minimal user interaction during the setup process. This reduces the number of errors that are introduced during setup.

**Greater consistency**
By using the same disk image or answer file to install and configure the operating system, you can ensure that all of the computers in your organization are set up exactly the same way.

**Shorter installation times**
RIS installation is faster than interactive installation because the operating system and applications are preinstalled and preconfigured on the disk image and require only minimal configuration after the disk image is copied to a destination computer. In addition, you can speed up the installation process by using the fully automated installation features of RIS. Instead of prompting end users or administrators for configuration information, the Setup program reads configuration settings from an answer file.

**Lower support costs**
By minimizing errors during the setup process, increasing the consistency of the computers in your organization, and reducing the amount of time an administrator needs to spend setting up a computer, you can reduce the overall support costs in your organization.

RIS is more complex and requires more upfront configuration and planning than other automated installation technologies. This is because RIS relies on several operating system services and protocols, as well as specialized hardware that supports the PXE specification. However, RIS installation is an efficient deployment technology if you have a high-speed network and you need to install clean operating systems and preconfigured applications onto a large number of computers with minimal end user or administrator interaction.

**RIS Dependencies and Requirements**
RIS relies on specialized hardware as well as several Windows Server 2003 features and technologies. This includes the following:

**High speed network connectivity**
The computers on which you are installing an operating system must all be connected to a reliable, high speed network. Wide area networks (WANs) that are connected with analog modems or Integrated Services Digital Network (ISDN) do not have

sufficient bandwidth to support RIS installation.

**PXE-enabled hardware**
To take full advantage of RIS, each of the computers on which you are installing an operating system must have a Peripheral Component Interconnect (PCI), Mini-PCI, or CardBus type of network adapter that supports the PXE specification. PXE-enabled network adapters allow client computers to be remotely booted. In addition, the basic input/output system (BIOS) for each computer must be capable of using the network adapter as a boot device (also known as remote-boot capability). A ROM BIOS that is at least version .99n satisfies this requirement. Also, most computers that conform to the Net PC or PC98 specifications have a PXE remote boot–enabled network adapter and remote boot–enabled BIOS.

The published PXE specification defines the remote boot process and also establishes the PXE compliance standards for hardware manufacturers and other vendors. RIS uses PXE environment extensions to Dynamic Host Configuration Protocol (DHCP), an industry-supported technology, to allow workstations to do the following:

- Boot remotely using their network adapters to access boot code from a network location.
- Install an operating system from a remote source to a client's local hard disk.

The PXE environment is built upon Internet protocols and services that are widely used in the computer industry. This includes TCP/IP, DHCP, and TFTP. The PXE extensions to the DHCP protocol enable information to be sent to network-bootable systems and also allow these systems to locate remote installation services.

**TCP/IP network**
Your network must support TCP/IP to perform RIS installations.

**Dedicated RIS server**
You need to install Remote Installation Services on a dedicated server running Windows Server 2003. The RIS server must have at least two NTFS disk partitions — one for booting the server operating system and another to contain the directory structure for the client operating system images or distribution shares. The partition containing the images or distribution shares must be large enough to store one or more operating system images, depending on your requirements. In addition, the RIS server must run the following services: Remote Installation Services, Single Instance Store service (SIS), and the Trivial File Transfer Protocol Daemon (TFTPD).

**DNS**
RIS servers rely on the Domain Name System (DNS) to locate the required Active Directory domain controllers to facilitate domain operations. If you use Windows Server 2003 DNS, you have the benefit of dynamic updates for your DNS server. However, it is not a requirement to use Windows Server 2003 DNS for RIS to function. Whichever DNS server software you use, it must support the SRV RR record type and the dynamic update protocol specified in RFCs 2052 and 2136, respectively.

**DHCP**
RIS servers require a DHCP server on the network which is authorized and has an activated scope. Remote boot–enabled computers must receive an IP address from a DHCP server before they can contact a RIS server to request an operating system installation. You can install Windows Server 2003 DHCP or you can use the DHCP services provided with Windows 2000 Server. In addition, you can use a non-Microsoft DHCP server software.

**Active Directory**
You must install RIS on a computer running Windows Server 2003 in an Active Directory domain. For best results, configure this computer as a member server. Although you can install RIS on a domain controller, the heavy traffic load generated by RIS can impact the performance of the domain controller.

RIS uses Active Directory to locate RIS clients and other RIS servers. You can administer the RIS server from the Active Directory Users and Computers snap-in (Dsa.msc) located on the RIS server. For more information about Active Directory, see the *Directory Services Guide* of the *Windows Server 2003 Resource Kit*.

**RIS Limitations**
Although RIS is a fast, efficient automated installation technology, it has the following limitations:

**Clean installation only**
You can only use RIS to install a clean version of an operating system, with or without software applications. You cannot use RIS to upgrade an operating system or software configuration.

**Limited configuration of server components**
You might not be able to include all the server components that you want to provide with RIS installation. For example, some server components require that you install and configure them only after the RIS-based installation is complete. This can include components such as Certificate Services, the Cluster service, or software that is dependent on Active Directory.

**No support for installing domain controllers**
You cannot install a preconfigured domain controller using a RIS image. However, you can use RIS to install a stand-alone server and then configure the server as a domain controller by running the Active Directory Installation Wizard.

**No support for configuring encryption and security settings**
You cannot use RIS to deploy files that are encrypted with a system such as the Encrypting File System (EFS). Also, you cannot use RIS to deploy systems with preconfigured user-level security settings such as file and folder permissions. To configure these settings, you can run a script after completing your RIS-based installation.

**No support for wireless networks**
You cannot use RIS to deploy images over a wireless network. Wireless networks do not support remote-booting computers that use PXE technology.

**Limited support for multihomed computers**
Multihomed RIS servers are supported if the network adapters use multiple separate subnets or if all network adapters use the same subnet. In both cases, the RIS server must also be the DHCP server. The DHCP server must have active scopes for each subnet serviced and must be authorized for each IP address on the network adapters being serviced.

**Technologies Related to RIS**
RIS installation is similar to other automated installation technologies: unattended installation, image-based installation with Sysprep and Windows Server 2003, and Automated Deployment Services (ADS). Like RIS installation, these technologies are designed specifically as mass deployment solutions. Although you can use all of these technologies to automate the installation of Windows Server 2003, each of these technologies is based on a different set of installation processes, and rely on a different set of programs and tools. If you want to automate installations with minimal user interaction, use an unattended installation. To copy preconfigured operating systems and software applications, you should use an image-based installation with the Sysprep tool. RIS is typically used during large-scale deployments with minimal administrator or end user interaction.

**Unattended installation**
Unattended installation is a method of automating clean installations and upgrades with minimal user interaction. Unattended installations are particularly useful if you are:

- Upgrading a Windows server to Windows Server 2003, Standard Edition or Windows Server 2003, Enterprise Edition operating systems.
- Performing automated installations on computers that have various hardware configurations.
- Performing automated installations on specific types of servers, such as domain controllers, remote access servers, and servers that run Certificate Services or the Cluster service.
- Configuring a wide range of operating system settings during an automated installation without using batch files and scripts.

In addition to these deployment solutions, unattended installation is a useful method of creating master installations for image-based and RIS installations.

To perform an unattended installation, you first create an answer file, which is a text file that contains answers to the questions that Windows Setup normally prompts you for during an installation. After you configure your answer file, you typically create a distribution share (a folder that contains the Windows Server 2003 installation files) as well as any device drivers or other files that are required to customize the installation.

### Note

- You do not need to use a distribution share to perform an unattended installation. You can use an operating system CD instead of a distribution share.

After you have created an answer file and a distribution share, you are ready to start the unattended installation on a destination computer. To do this, you run the Windows Setup program (either Winnt.exe or Winnt32.exe), and specify the name of the answer file that you want Setup to use and the location of the distribution share that contains the installation files. Setup then runs and carries out all of the instructions that are specified in the answer file.

Unattended installation requires some upfront planning and design, but it is the most flexible and robust automated installation technology.

**Image-based installation with Sysprep**
Image-based installation with the System Preparation (Sysprep) tool is a method of copying, also known as *cloning*, preconfigured operating systems and software applications onto servers.

Image-based installation with Sysprep is a suitable automated installation technology if you need to:

- Install identical operating systems and software configurations on multiple computers.
- Install an operating system and software configuration as quickly as possible.
- Perform clean installations of an operating system, rather than upgrade an existing installation.
- Minimize end user interaction and post-installation tasks.
- Install operating systems on computers that have similar hardware and hardware abstraction layers (HALs).

To perform an image-based installation with Sysprep, you first set up a master installation — a computer with the operating system, software applications, and configuration settings that you want to install onto the destination computers in your organization. Then you run Sysprep, which prepares the master installation so that you can create a disk image (that is, a functionally identical replica of its disk) that can be copied onto multiple computers. Next, you use a non-Microsoft disk-imaging program to create the disk image of the master installation. Finally, you copy the disk image onto your destination computers.

You need two tools to perform an image-based installation with Sysprep: Sysprep, which can be found on any Windows Server 2003 operating system CD, and a non-Microsoft disk-imaging program, which you must purchase from a non-Microsoft vendor. You run Sysprep on the master computer before you create an image of the master computer's hard disk. Sysprep configures various operating system settings on the master computer to ensure that every copy of the master computer's disk image is unique when you distribute it to a destination computer. Specifically, Sysprep configures a master installation so that unique security identifiers (SIDs) are generated on each destination computer. Sysprep also configures the master computer's disk image so that every destination computer starts in a special setup mode known as *Mini-Setup*. After you copy a disk image onto a destination computer, Mini-Setup runs the first time you start the destination computer.

You use the non-Microsoft disk-imaging program to create an image of the master computer's hard disk. You also use the disk-imaging program to copy the disk image from the master computer onto a shared folder or a CD, and from the shared folder or CD onto a destination computer.

Image-based installation with Sysprep requires substantial planning and design, but it is the fastest method of installing operating systems and applications. You cannot use it to perform operating system upgrades.

**Automated Deployment Services**
You can use Automated Deployment Services (ADS) to remotely and automatically deploy Windows 2000 Server and Windows Server 2003 family operating system images onto servers without an operating system. You can also use ADS to configure, maintain, and manage servers. By using ADS, you can reduce administration costs of your data center. ADS is designed for organizations that are running data centers like service providers and corporations.

ADS reduces the number and complexity of the steps required to deploy and configure a server by using task sequences. The processes required to deploy and configure a server have been captured by a set of scripts or tasks that are easily extensible by the data center to follow their business and technical processes. Placing the configuration steps within scripts makes it easy to automatically perform the deployment or configuration of a server or group of servers based on external events (such as the arrival of a customer order, or the need to add additional servers because the existing servers are overloaded).

With ADS, you use a single server, called a "Controller," to perform large-scale server administration in your data center. The Controller, together with the other ADS services, enables you to deploy operating system images onto servers or to repurpose existing devices with new operating system images. In the data-center environment, you can use ADS to:

- Mount an image as a file and edit the image.
- Remotely purpose a device that has no operating system to a useful state or repurpose a device from one state to another state.
- Run extensible and configurable operations, such as scripts, on one or more systems from a single administration point.

- Leverage the ADS WMI Object Model to build custom applications.

# How Remote Installation Services Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Remote Installation Services Works**

**In this section**

- Remote Installation Services Architecture
- Remote Installation Services Physical Structures
- Remote Installation Services Dependencies
- Remote Boot and Installation Setup Processes
- Network Ports Used by Remote Installation Services
- Related Information

Remote Installation Services (RIS) is a Windows component that you can install with Windows Server 2003 or add at any time after the operating system is installed. RIS is an automated installation technology that you can use to create installation images of operating systems or of complete computer configurations, including desktop settings and applications. These installation images can then be made available to users at client computers. RIS is typically used during large-scale deployments when it would be too slow and costly to have administrators or end users interactively install the operating system on individual computers.

These sections provide a detailed view of how RIS works in an optimal environment. You can create an optimal environment for RIS by doing the following:

- RIS requires a significant amount of disk space. You should dedicate an entire partition or preferably an entire physical disk to store the RIS installation images.
- Use the appropriate number of Remote Installation Services (RIS) servers on your network.
- Use RIS with computers that use the Pre-Boot eXecution Environment (PXE) architecture. PXE is a remote-boot technology that allows the client computer to begin a boot sequence from the network adapter. When a PXE-enabled client computer starts for the first time, it uses the Dynamic Host Configuration Protocol (DHCP) to request an Internet Protocol (IP) address and the IP address of an active RIS server. As part of the initial request, the client computer sends out its globally unique identifier (GUID), which identifies the client computer within Active Directory.
- Dedicate an entire partition to the RIS folder tree. RIS requires a significant amount of disk space.

**Remote Installation Services Architecture**

RIS consists of several components that facilitate the remote installation of client operating systems. The Remote Installation service (Binlsvc) is the boot service that interacts with directory services to remotely boot a client computer. Trivial File Transfer Protocol Daemon (TFTPD) is a service protocol used to transfer the files needed to remotely boot, maintain, and troubleshoot a client computer. These and other RIS components are described in detail in this section.

The Setup program in Windows Server 2003 provides the basis for creating installation images using RIS. For background information about how Setup works, see Setup Technical Reference.

The following figure shows how a client that requests an installation image interacts with the RIS server to verify the client account and server settings, and then finally receives the downloaded Client Installation Wizard.

**Remote Installation Services Architecture**

**Remote Installation Service (Binlsvc)**
This service is part of the Remote Installation Services component. It detects PXE-initiated DHCP requests from RIS clients and facilitates a response to those requests. The Remote Installation service also directs clients to files on the RIS server that initiate the installation process and then responds to Client Installation Wizard requests. In addition, the Remote Installation service checks Active Directory to verify client credentials, determines if a client can be serviced, and confirms whether to create a new computer account object or reset an existing account on behalf of the client. Also, if a client that is prestaged in Active Directory has settings specifying that a particular RIS server must answer the client, then the Remote Installation service facilitates the response to that client from the specified RIS server.

The Remote Installation service was formerly known as the Boot Information Negotiation Layer (BINL) service in Windows 2000 and Windows XP Professional.

**Trivial File Transfer Protocol Daemon (TFTPD)**
This service is used by a RIS server to download the Client Installation Wizard and the initial files that are required to start the remote installation process on the client computer.

On a RIS server, TFTP is called a *daemon* or service (TFTPD), while on the client, it is referred to as a *protocol* (TFTP).

The first file that downloads is Startrom.com, which is a small startup program that displays the **Press F12 for Network Boot** prompt to the client. If the user presses F12 within 3 seconds, the Client Installation Wizard downloads to the client so the installation process can begin. The file Startrom.com is located on your RIS server in the directory path *ServerName*\RemoteInstall\OSChooser\i386\.

### Note

- For installations of Windows XP 64-Bit Edition Version 2003, the first file downloaded is Oschoice.efi. It is not necessary to press F12 for these installations.

**Single Instance Store Service**
This service consists of an NTFS file-system filter driver and a groveler agent that interacts with RIS images. The Single Instance Store (SIS) service reduces the hard-disk storage requirements for RIS images. The SIS service does this by monitoring the RIS server partition for duplicate files. To reduce the amount of disk space used by the installation folders, SIS "grovels" through the partition containing the RIS installation directory using the groveler agent. Whenever the groveler agent finds a duplicate file, the SIS service copies the original file into a directory and copies an NTFS reparse point that contains the current location, size, and attributes of the original file. (Reparse points are NTFS file system objects that have a definable attribute containing user-controlled data and that are used to extend functionality in the input/output (I/O) subsystem.) By doing this, the SIS service retains only a single instance of the file, while replacing duplicate files with links to the single instance. The SIS service then can store the duplicate files it finds in RIS images and reduce the amount of disk space that is used on your RIS server.

**RIS Components**
With the following RIS components, you can install, configure, and implement RIS in your organization.

**Remote Installation Services**
RIS is a Windows component that you can install with Windows Server 2003 or add at any time after the operating system is installed. Services that install with RIS include the Remote Installation service, TFTPD, and the SIS service.

**Remote Installation Services Setup (Risetup.exe)**
You can use Risetup.exe to initially set up the RIS server and create at least one CD-based operating system image. You can initiate the setup process from the **Start** menu of your RIS server. If you click **Remote Installation Services Setup** from the **Administrative Tools** menu, the Remote Installation Services Setup Wizard starts. The wizard performs the following actions:

- Requests preliminary information, including the installation folder name and the path to the operating system installation files.

- Copies Windows installation files.
- Updates the Client Installation Wizard screens.
- Creates a default answer file (Ristndrd.sif).
- Starts the RIS services, which include the Remote Installation service, TFTPD, and the SIS service.
- Authorizes the DHCP server.
- Risetup is also used to create any additional CD-based operating system images after the initial installation is created.

**Remote Installation Preparation Wizard (Riprep.exe)**
You can use Riprep.exe to create a customized image of an operating system such as Windows XP Professional. To create an image means that you create a replica of a hard disk that you can install on other computers in your organization. You use Riprep to create an image of an existing operating system installation on a master computer and then replicate that image onto an available RIS server on your network. The image can include the operating system with default parameters applied by the administrator, or the operating system with a preconfigured desktop, locally-installed applications, and drivers.

A 64-bit version of the Remote Installation Preparation (RIPrep) Wizard is included with the 64-bit versions of Windows Server 2003. For more information about using the RIPrep Wizard to create an installation image of a 64-bit operating system, see article 891128, "Updated Remote Installation Service (RIS) functionality in Windows Server 2003 Service Pack 1," in the Microsoft Knowledge Base.

**Remote Boot Floppy Generator (Rbfg.exe)**
You can use Rbfg.exe to create remote-boot floppy disks for RIS client computers that are not PXE-enabled, so that these clients can emulate the remote boot process and install an operating system over the network using RIS. However, for RIS clients that are not PXE-enabled to use the remote-boot floppy disk, they must each have a supported Peripheral Component Interconnect (PCI)–based network adapter supported by the Rbfg.exe utility. PC Card adapters, CardBus adapters, and adapters that are not PCI-based are not supported. You can view the list of supported network adapters by starting the Rbfg.exe utility and clicking **Adapter List**. The client computer's basic input/output system (BIOS) must be configured to use the network adapter as its primary boot device.

**Client Installation Wizard (OSChooser)**
OSChooser is a service of the Client Installation Wizard that is run by the client computer. It is a text-based program downloaded by the RIS server to the client that allows the client to communicate with the RIS server during the installation process. Remote Installation service is the server component that sends a default set of Client Installation Wizard screens to guide the client through the remote installation process. Clients that can remote boot use this wizard to log on and select from operating system installation options. You can customize these setup screens to meet the needs of your organization.

**Active Directory Users and Computers Extension for RIS (Dsa.msc)**
When you create the RIS server, the Active Directory Users and Computers extension installs on the RIS server. The extension provides a **Remote Install** tab within the computer account **Properties** dialog box of each RIS server that you can use to manage the RIS server. You can start this extension by specifying the Microsoft Management Console (MMC) snap-in Dsa.msc in the **Run** dialog box or you can start it from the command line.

You can use the Active Directory Users and Computers extension to manage RIS locally or through a Terminal Services session on another network computer. You can also administer RIS from a computer running Windows XP Professional if you install the Adminpak.msi on that computer.

**Remote Installation Services Physical Structures**
The physical structure of RIS depends on whether you are using a CD-based or an image-based installation and whether you are also using an answer file.

**CD-based RIS installations**
Using Risetup.exe, you can create a CD-type image, also called a flat image, to be used with RIS installations on client computers. Using a flat image is similar to setting up a client directly from the installation CD, except that the operating system image source files reside on an available RIS server.

Use an installation image created by Risetup if you want to distribute the network equivalent of CD-based installation functionality. A Risetup image is a replica of an operating system CD file structure, located across the network on a remote

server using RIS.

You create Risetup images by running the Risetup Wizard on a RIS server, while using an operating system CD to create the image. When using Risetup images, you cannot provide a fully-configured clone of an operating system with applications and desktop customizations, as you can with Riprep images. However, you can add applications and drivers to the distribution folder where the Risetup images are located and use answer files to install the applications and specify the location of drivers.

Installing a Risetup image is similar to setting up a workstation directly from a CD. However, the source files are located across the network on a RIS server. The following figure shows the directory structure of your RIS server under the RemoteInstall folder where Risetup images are stored. You can define the name of the folder <imagename> where the images are located.

**Directory Structure of a RIS Server**

When you install remote installation services on your RIS server, it automatically creates one Risetup image of the server operating system and stores it under the Images folder within the RIS directory structure, as shown in the figure. This image is available to remote boot–enabled clients. Clients that request installation of an operating system can access Risetup images on a remote RIS server, if you configure them to do so.

You can make additional Risetup images using operating system CDs for Windows 2000 Professional, Windows 2000 Server, and Windows 2000 Advanced Server, in addition to Windows XP Professional and Windows Server 2003. To create a Risetup image, place the CD in the CD drive of your RIS server and run the Risetup Wizard from the **Images** tab of RIS server **Properties**. You can also specify the following command string at the command-line interface to start the Risetup Wizard:

```
risetup -add
```

You can create and associate multiple answer files with Risetup images, which allows you to customize the applications and drivers that you want to install with each image. However, you cannot include preconfigured application or desktop configurations with a Risetup image. Also, Risetup images take longer to install than an equivalent size Riprep image.

**Image-based RIS installations**

Use an image created by Riprep if you want to distribute an image of a fully-configured workstation complete with applications. A Riprep image is essentially a file system image that is located on a remote RIS server. It is similar to the hard disk-images you create using a non-Microsoft disk-imaging tool and the Windows System Preparation tool (Sysprep).

You create Riprep images by running the Riprep Wizard (Riprep.exe) on a master computer which has the operating system configuration, applications and settings, and desktop customizations that you want to deploy to client computers in your organization.

Riprep images are most useful for cloning a standard operating system configuration to clients. Riprep images generally require more disk space on your RIS server than Risetup images because they usually include preconfigured applications and tools. However, they install faster than equivalent size Risetup images.

To create a Riprep-based installation, you must first set up a *master installation*. This is the reference computer that contains the operating system, software applications, and configuration settings you plan to install on destination computers in your organization. After you configure the master installation, you run Riprep.exe, which is on the server at the following location: *servername*\reminst\admin\i386\riprep. This converts the master installation into a remote installation image, which is a functionally identical replica of the master computer disk that you can install on multiple destination computers. Riprep also replicates the image to a RIS server where it is available for installation on remote boot–enabled client computers. Clients who request installation of an operating system can access Riprep-based images on a remote RIS server if you configure them to do so.

The best way to install the operating system on your master computer is to use RIS with an unattended installation. However, you can also install the operating system locally using the appropriate operating system CD. If you do this, use the disk-partitioning utility on the Windows Server 2003 installation CD and use the text-mode Setup to clear the disk partition and ensure a clean installation.

Riprep configures various operating system settings on the master computer to ensure that every copy of the master computer's disk image is unique when you install it on destination computers. This includes resetting the security identifiers (SIDs) and access control lists (ACLs). Riprep also configures the master installation image so that, after the initial installation of the image, every destination computer starts in a special setup mode known as Mini-Setup.

**RIS Client HAL Types**

If you want to create an image-based RIS installation using the tool Riprep.exe, you first need to determine if your RIS clients have a Hardware Abstraction Layer (HAL) that is compatible with the master computer from which you create your image. For example, if the master computer where you run Riprep.exe has an Advanced Configuration and Power Interface (ACPI) HAL, then the client computers you designate to receive operating system images that are generated from that master computer must also have an ACPI HAL. The HAL type is indicated by the original file name of the file Hal.dll.

You need to verify how many different HAL types exist in your organization. This determines how many different master installations you will need with HALs that are compatible with the client HALs in your organization. To verify the type of HAL on your client computers, you can do one of the following:

- Use a management tool such as Systems Management Server (SMS) to obtain your client inventory, from which you can determine the HAL types.
- View the properties of Hal.dll to determine the HAL types.

You can install RIS-based operating system images if any of the following conditions are true regarding HALs:

- The master and destination computer HALs are identical.
- The master and destination computers both have either uniprocessor or multiprocessor Advanced Programmable Interrupt Controller (APIC) HALs.
- The master and destination computers both have either uniprocessor or multiprocessor Advanced Configuration and Power Interface (ACPI) HALs.

**Using answer files with a RIS installation**

Using answer files with a RIS installation is similar to using an unattended answer file with RIS-specific sections and values. For a CD-based installation, the default answer file is Ristndrd.sif, and for an image-based installation, the default answer file is Riprep.sif. Multiple answer files can be associated with an installation. You can create the answer files by using Setup Manager (Setupmgr.exe) or you can create it manually by using a text editor, such as Notepad.

As with most answer files, Ristndrd.sif and Riprep.sif contain multiple predefined sections that you can modify. Section names are always enclosed in square brackets (for example, [Unattended]).

### RIS-Specific Sections in an Answer File

| Section | Description |
|---|---|
| [RemoteInstall] | Contains entries Repartition and UseWholeDisk. |
| [Oschooser] | Contains entries for values which are displayed after the operating system is selected. For example, the image type and start file. |

For additional information about unattended installation, see Unattended Installation Technical Reference.

**Remote Installation Services Dependencies**

Remote Installation Services (RIS) uses or depends upon a variety of technologies and components.

**Network infrastructure**

RIS depends on a network infrastructure that can identify computers on the network. RIS therefore requires that DHCP, DNS, and Active Directory be available on the network.

**Remote-boot technology**
RIS uses remote-boot technology to enable a computer with no operating system to begin a boot sequence from the network adapter, after which an operating system can be installed across the network. This remote-boot technology is called the Pre-Boot eXecution Environment (PXE). For client computers that are not PXE-enabled—that is, pre–Net PC/PC98 computers—you can use a special remote-boot disk, Rbfg.exe, if the client computer has a supported network adapter. Most computers that conform to the Net PC or PC98 specifications have a PXE remote boot–enabled network adapter and remote boot–enabled BIOS. A computer on which you use the remote boot disk must have a Peripheral Component Interconnect (PCI)–based network adapter supported by the Rbfg.exe utility. PC Card adapters, CardBus adapters, and adapters that are not PCI–based are not supported. You can view the list of supported network adapters by starting the Rbfg.exe utility and clicking Adapter List.

**Technology to create an installation image**
RIS includes a technology that you can use to create an image of an operating system that will be installed on client computers. You can create the image in one of two formats: a flat image or a Remote Installation Preparation Wizard (RIPrep) image format. Use the flat image option to create an image directly from a set of operating system files, for example, the files on a CD. Use the RIPrep image format to create an image that includes an operating system with specific settings and applications, such as an image that complies with a corporate desktop standard.

**Technologies for communication between RIS client and server**
RIS includes technologies that establish communication between a client computer that has begun a PXE boot sequence and the RIS server that contains installation images that are available to that client. For this process, RIS uses DHCP to provide the client with an Internet Protocol (IP) address. RIS then downloads the Client Installation Wizard, which prompts the user to log on and provides a menu of installation options that are customized for that user. You can control these images through Group Policy.

**PXE architecture**
Remote Installation Services (RIS) uses the Dynamic Host Configuration Protocol (DHCP) that follows the Pre-Boot eXecution Environment (PXE) architecture to start a client computer.

When a new PXE remote boot–enabled client computer starts for the first time, it uses DHCP to request an Internet Protocol (IP) address and the IP address of an active RIS server. As part of the initial request, the client computer sends out its globally unique identifier (GUID), which identifies the client computer within Active Directory.

After the client computer receives an IP address from the DHCP server, it then requests service from a RIS server. The request to the RIS server is a broadcast, which means all of the RIS servers on the network will receive the request. If the RIS server can answer, it queries its preferred domain controller for the client computer's GUID. If the server fails to find the GUID, it queries the global catalog for the forest. If the GUID is found in either location, the client computer is considered "known". If the GUID is not found, it is considered "unknown". In this case —that is, the query by the RIS server found no computer account object in Active Directory with this computer's GUID —only RIS servers that are configured to answer unknown clients will do so.

If the client is known, all the available RIS servers query the domain to determine whether the client computer account has been prestaged with settings that specify that the client computer is to be answered by a particular server. If so, only the designated server answers the service request. The other servers respond by telling the client which server will answer it. This is called a referral. If the client computer account settings do not require the client computer to be answered by a particular server, all RIS servers answer it if they are aware of this client and configured to answer it. Each RIS server then offers its own files to download.

After the client computer receives a reply to its service request, it initiates a Trivial File Transfer Protocol (TFTP) download of the boot program. The Remote Installation Services implementation of this program is called Startrom.com (located at \\RIS_server_name\REMINST\oschooser\i386\startrom.com).

After Startrom.com has been downloaded, the client computer runs it. The default version of Startrom.com then prompts the user to press F12 to initiate a network installation. If the user fails to press F12 within three seconds, the network boot is stopped, and the client computer attempts to start up from the next available boot device. When the user presses F12, the client computer uses TFTP to download the Client Installation Wizard. The wizard then requests the user to log on to the network.

**Remote Installation Services directory service planning**
The Remote Installation Services (RIS) environment relies on a well-designed and well-planned Active Directory architecture. Normally, determining the physical location of a server can be a challenge. This can become even more difficult when you must find and configure several servers that are located in different buildings, different offices, or on different floors. Using Active Directory, however, can simplify this process.

In a given domain, Active Directory provides organizational units or containers that you can use to organize users and resources into logical administrative groups. This makes it easier to locate and configure servers at multiple locations.

**Remote Boot and Installation Setup Processes**

RIS uses PXE technology to enable RIS client computers without an operating system to initiate the boot sequence from their network adapters, thus facilitating operating system installations from remote network locations. To initiate the remote boot process and set up a RIS-based operating system installation, PXE interacts with the Dynamic Host Configuration Protocol (DHCP), the Remote Installation services, and TFTPD, as shown in the following figure:

**How RIS Works**

When you start a new PXE-enabled RIS client computer, the following sequence of events occurs:

1. The client computer initiates the communication by sending a DHCP Discover broadcast on its subnet. A DHCP server with an active scope for that subnet will issue an IP address to the client.

2. All Remote Installation servers that receive the client's DHCP Discover broadcast extract (from the PXE data portion of the packet) the universally unique identifier (UUID) of the client that is requesting service. The RIS server then queries its preferred domain controller to search for this UUID in all prestaged computer accounts in Active Directory.

   If the domain controller does not find the UUID in the local domain, the RIS server queries the global catalog to locate the client computer account. If the UUID is found in either location, the client computer is recognized as a known client; otherwise, it is considered an unknown client. If the client is unknown, it will only receive an answer from a RIS server that is configured to answer unknown clients, provided that one exists on the network.

3. If the client is known, all available RIS servers query the domain to determine whether the prestaged client computer account has a setting that specifies that only a particular RIS server can answer the client.

   If this is the case, then only the designated RIS server answers the service request, and other RIS servers simply notify the client of the particular RIS server that is configured to answer it. If the client computer account does not have a setting that requires it to be answered by a particular server, any RIS server can answer the request. However, the client only receives service from the first RIS server it contacts.

4. The user receives a prompt to press the F12 key to initiate a network service boot request from the RIS server.

5. Using TFTPD, the contacted RIS server downloads the Client Installation Wizard to the RIS client, along with all client dialog boxes contained within the wizard.

6. The Client Installation Wizard prompts the user to log on with a valid user name, password, and domain name.

7. The user receives a selection of operating system images that are hosted on the RIS server for installation on the client computer.

   The list of operating system images that are offered to the user is based on the user's credentials or security group membership.

**PXE Specification**

The published PXE specification defines the remote-boot process and also establishes the PXE compliance standards for hardware manufacturers and other vendors. RIS uses PXE environment extensions to DHCP, an industry-supported technology, to allow workstations to do the following:

- Boot remotely using their network adapters to access boot code from a network location.
- Install an operating system from a remote source to a client's local hard disk.

The PXE environment is built upon Internet protocols and services that are widely used in the computer industry. This includes TCP/IP, DHCP, and TFTP. The PXE extensions to the DHCP protocol enable information to be sent to systems that support remote network booting and also allow these systems to locate remote installation services.

**Note**

- Network adapters that meet the PXE .99n specification will work correctly with RIS.

**RIS Technology Limitations**

You can use RIS technology to install operating systems, with or without software applications, to portable and desktop computers in your organization, which include member servers, stand-alone servers, and domain controllers. However, limitations to the scope of RIS-based operating system installations include the following:

**Clean Installs**

You can only use RIS to provide a clean version of an operating system, with or without software applications. You cannot use RIS to upgrade an operating system or software configuration.

**Server Components**

If you use RIS to install a server operating system, you might not be able to include all the server components that you want to provide with the RIS image. For example, some server components require that you install and configure them only after the RIS-based installation is complete. This can include components such as Certificate Services, Cluster service, or software that is dependent on Active Directory.

**Domain controllers**

You cannot install a preconfigured domain controller using a RIS image. However, you can use RIS to install a stand-alone server and then configure the server as a domain controller by running the Active Directory Installation Wizard.

**Encryption and security settings**

You cannot use RIS to deploy files that are encrypted with a system such as the Encrypting File System (EFS). Also, you cannot use RIS to deploy systems with preconfigured user-level security settings such as file and folder permissions. To configure these settings, you can run a script after completing your RIS-based installation.

**Wireless networks**

Wireless networks do not support remotely booting computers using PXE technology.

**Multihomed computers**

Multihomed RIS servers are supported if the network adapters use multiple separate subnets or if all network adapters service the same subnet. In both cases the RIS server must also be the DHCP server. The DHCP server must have active scopes for each subnet serviced and must be authorized for each IP address on the network adapters being serviced.

**Supported operating systems**

RIS has certain limitations depending on the operating system that you are installing. For more information about operating systems supported by RIS, see "Operating Systems Supported by Remote Installation Services" in Help and Support Center for Windows Server 2003.

**Network Ports Used by Remote Installation Services**

The following table lists the ports that are used by RIS.

### Port Assignments for Remote Installation Services

| Service Name | UDP | TCP |
|---|---|---|
| Dynamic Host Configuration Protocol (DHCP) | 67 | N/A |
| Boot Information Negotiation Layer (BINL) | 4011 | N/A |

| | | |
|---|---|---|
| Trivial File Transfer Protocol Daemon (TFTPD) | 69 | N/A |

# Remote Installation Services Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote Installation Services Tools and Settings**

### In this section

- Remote Installation Services Tools
- Remote Installation Services Group Policy Settings
- Remote Installation Services Answer-File Settings
- Network Ports Used by Remote Installation Services
- Related Information

**Remote Installation Services Tools**

The following tools are associated with Remote Installation Services.

**Risetup.exe: Remote Installation Services Setup program**

**Category**

Tool included in the Windows Server 2003 family.

**Version compatibility**

Available on computers running the Windows Server 2003 family of products or the Windows 2000 Server family.

This component is used to initially set up the RIS server and create at least one CD-based operating system image. You can initiate the setup process from the Start menu of your RIS server. By clicking **Remote Installation Services Setup** from the Administrative Tools group, a wizard starts and does the following:

- Requests preliminary information, including the installation folder name and the path to the operating system installation files.
- Copies Windows installation files.
- Updates the Client Installation Wizard screens.
- Creates a default answer file (Ristndrd.sif).
- Starts RIS services.
- Authorizes the DHCP server.

For more information about Risetup.exe, see “Command-Line References” in the Tools and Settings Collection.

### Note

- Risetup is also used to create any additional CD-based operating system images after the initial installation is created.

**Riprep.exe: Remote Installation Preparation Wizard**

**Category**

Tool included in the Windows Server 2003 family.

**Version compatibility**

Available on computers running the Windows Server 2003 family of products or the Windows 2000 Server family.

Riprep.exe is used to create a customized image of an operating system such as Windows XP Professional. To create an image means that you create a replica of a hard disk that you can install on other computers in your organization. You use Riprep to image an existing Windows XP Professional operating system installation on a master computer and replicate that image to an available RIS server on your network. The image can include the operating system with default parameters applied, or the operating system with a preconfigured desktop, locally installed applications, and drivers.

For more information about Riprep.exe, see Windows Server 2003 Help.

**Rbfg.exe: Remote Boot Floppy Generator**
**Category**
Tool included in the Windows Server 2003 family.

**Version compatibility**
Available on computers running the Windows Server 2003 family of products or the Windows 2000 Server family.

Rbfg.exe is used to create remote-boot floppy disks for RIS client computers that are not PXE-enabled, so that these clients can emulate the remote boot process and install an operating system over the network using RIS. However, for RIS clients that are not PXE-enabled to use the remote-boot floppy disk, they must each have a supported Peripheral Component Interconnect (PCI) network adapter–based network adapter supported by the Rbfg.exe utility. PC Card adapters, CardBus adapters, and adapters that are not PCI–based are not supported. You can view the list of supported network adapters by starting the Rbfg.exe utility and clicking Adapter List. The client computer's basic input/output system (BIOS) must be configured to use the network adapter as its primary boot device.

For more information about Riprep.exe, see Windows Server 2003 Help.

**OSChooser.exe: Client Installation Wizard**
**Category**
Tool included in the Windows Server 2003 family.

**Version compatibility**
Available on computers running the Windows Server 2003 family of products or the Windows 2000 Server family.

OSChooser.exe is a service of the Client Installation Wizard that is run by the client computer. It is a text-based program downloaded by the RIS server to the client that allows the client to communicate with the RIS server during the installation process. Remote Installation service is the server component that sends a default set of Client Installation Wizard screens to guide the client through the remote installation process. Clients that can remote boot use this wizard to log on and select from operating system installation options. You can customize these setup screens to meet the needs of your organization.

For more information about Riprep.exe, see Windows Server 2003 Help.

**DSA.msc: Active Directory Users and Computers Extension for RIS**
**Category**
Tool included in the Windows Server 2003 family.

**Version compatibility**
Available on computers running the Windows Server 2003 family of products or the Windows 2000 Server family.

When you create the RIS server, the Active Directory Users and Computers extension installs on the RIS server. The extension provides a **Remote Install** tab within the computer account **Properties** dialog box of each RIS server that you can use to manage the RIS server. You can start this extension by specifying the Microsoft Management Console (MMC) snap-in Dsa.msc in the **Run** dialog box or you can start it from the command line.

You can use the Active Directory Users and Computers extension to manage RIS locally or through a Terminal Services session on another network computer. You can also administer RIS from a computer running Windows XP Professional if you install the Adminpak.msi on that computer.

For more information about Riprep.exe, see Windows Server 2003 Help.

**Remote Installation Services Group Policy Settings**
You can use Group Policy to configure certain installation options presented by the Client Installation Wizard. With Group Policy, you can create different Group Policy objects to apply to specific users. The following table lists and describes the Group Policy settings that are associated with RIS. Each of these settings has three different settings associated with it: Enabled, Disabled, and Not Configured.

### Group Policy Settings Associated with RIS

| Group Policy Setting | Description |
|---|---|
| Automatic Setup | Predefines the computer name and a location within Active Directory for the client computer accounts. (Another alternative is prestaging client computer accounts.) |
| Custom Setup | Allows users to define a unique name for this computer and specify where the computer account will be created within Active Directory. |
| Restart Setup | Restarts an operating system installation attempt if it fails during the text-mode portion of the setup process. |
| Tools | Gives users the ability to access tools, including the Recovery Console, from the Client Installation Wizard. |

For more information about Group Policy settings, see "Group Policy Settings Reference" in the Tools and Settings Collection.

**Remote Installation Services Answer-File Settings**

To simplify the process of setting up an operating system on multiple computers, you can run Setup unattended. To run Setup unattended, you create and use an answer file, a customized script that answers the Setup questions automatically. The unattended installation Setup answer files (.sif) are text files that describe the installation process for an installation image. An unattended installation template, which you can customize, is provided by RIS. The .sif file must be associated with one of the available installation images.

[OsChooser] and [RemoteInstall] are specific answer file entries for RIS. These are used in addition to the other answer file entries in an unattended installation. For information about unattended installation, see "Unattended Installation Technical Reference."

The section below describes the settings that you can configure in an unattended installation answer file. For more information about how to structure an answer file, see "Unattended Installation Physical Structures" in How Unattended Installation Works.

The following table lists all of the valid sections that can appear in an answer file for a RIS installation.

**Answer File Sections for RIS Installation**

| Section | Description |
|---|---|
| [adapter_specific_protocol_section] | Contains an entry for specifying a network component. Must be used in conjunction with the [Networking] section. |
| [Branding] | Contains entries for branding Microsoft Internet Explorer during an unattended installation. If you do not specify this section, Setup uses the default for Windows Server 2003. |
| [CertSrv_Client] | Contains entries for the Web client component of Certificate Services. You do not need to include this section in the answer file to install the Web client component of Certificate Services on the computer. Enabling Certificate Services in the [Components] section of the answer file installs the necessary files. |
| [CertSrv_Server] | Contains entries for specifying the server components of Certificate Services. The entries in this section are supported only for the Windows Server 2003. |
| [Components] | Contains entries for installing the optional components of Windows XP Professional and Windows Server 2003. |
| [Data] | Contains entries for starting directly from the Windows Server 2003 product CD when performing an unattended installation. |
| [DCInstall] | Contains entries for installing a domain controller after the initial setup of the operating system finishes. |
| [Display] | Contains entries for specifying display settings for graphics devices. |
| [FavoritesEx] | Contains the default Favorites settings for the Windows browser. If not present, Setup uses the default Uniform Resource Locator (URL) for Windows XP or Windows Server 2003. |

| | |
|---|---|
| [Fax] | Contains entries for specifying custom installation information for the Fax service. |
| [GuiRunOnce] | Contains commands that run the first time a user logs on to the computer after final (GUI-mode) stage of Setup completes. |
| [GuiUnattended] | Contains entries for preparing the graphical user interface (GUI) for unattended installation. |
| [Homenet] | Contains entries for installing Home Networking settings for network adapters, Internet Connection Sharing (ICS), and Internet Connection Firewall (ICF). |
| [Identification] | Contains entries for specifying the network identification of a computer. If these entries are not present, Setup adds the computer to the default workgroup. If there is not enough information for this entry, Setup prompts the user to provide this information. |
| [IEHardening] | Contains entries for configuring Web content zones. |
| [InternetServer] | Contains entries for configuring the installation folder for Internet Information Services (IIS) components. |
| [LicenseFilePrintData] | Contains entries for installing licensing information for Windows Server 2003. |
| [MassStorageDrivers] | Contains an entry for loading retail or original equipment manufacturer (OEM) small computer system interface (SCSI) drivers in the Setup Loader during the intermediate (text-mode) stage of Setup |
| [MS_AppleTalk parameters] | Contains entries for configuring AppleTalk. |
| [MS_ATMArps parameters] | Contains no entries. |
| [MS_ATMLANE parameters] | Contains no entries. |
| [MS_ATMUni parameters] | Contains no entries. |
| [MS_L2TP parameters] | Contains entries for the Layer 2 Tunneling Protocol (L2TP). |
| [MS_MSClient parameters] | Contains entries for Client for Microsoft Networks. |
| [MS_NetMon parameters] | Contains no entries. |
| [MS_NWClient parameters] | Contains entries for Client Service for NetWare. |
| [MS_NWIPX parameters] | Contains entries for the Internetwork Packet Exchange (IPX) protocol. Its parameters are network adapter–independent. |
| [MS_NwSapAgent parameters] | Contains no entries. |
| [MS_PPTP parameters] | Contains entries for the Point-to-Point Tunneling Protocol (PPTP). |
| [MS_Psched parameters] | Contains no entries. |
| [MS_RAS parameters] | Contains entries for the Routing and Remote Access service. |
| [MS_RasSrv parameters] | Contains entries for the Routing and Remote Access service for remote access servers. |
| [MS_Server parameters] | Contains entries for the File and Print Service. |
| [MS_TCPIP parameters] | Contains entries for configuring the TCP/IP protocol. |
| [MS_WLBS parameters] | Contains entries for configuring Network Load Balancing (formerly, Windows Load Balancing Service, or WLBS) and binding Network Load Balancing to multiple network adapters. |
| [NetAdapters] | Contains entries for network adapters that you want to install. |

| | |
|---|---|
| [NetBindings] | Contains entries for disabling, enabling, and demoting binding rules for network components such as services, protocols, and adapters. |
| [NetClients] | Contains an entry for specifying the network clients to install. |
| [NetOptionalComponents] | Contains entries for installing optional network components. |
| [NetProtocols] | Contains an entry for installing the network protocols. |
| [NetServices] | Contains entries for installing network services. |
| [Networking] | Contains no entries. However, to configure network protocols in unattended installation, you must include the [Networking] section name in your answer file. |
| [OEMBootFiles] | Contains entries for specifying OEM-supplied boot files. |
| [OsChooser] | Contains entries for selecting the operating system. Only clients installed with access to Remote Installation Services (RIS) can use these entries. |
| [params.adapter_instance] | Contains entries for specifying an adapter's instance on a computer by using either PCI location information or a Plug and Play device ID. |
| [PCHealth] | Contains entries for configuring error reporting, Remote Assistance, and Help and Support Center. |
| [protocol_parameters_section] | Contains an entry for specifying network protocol parameters that are also specified in the [NetProtocols] section. |
| [Proxy] | Contains entries for specifying proxy server settings for the Windows XP or Windows Server 2003 browser. |
| [RegionalSettings] | Contains entries for installing regional options during the setup process. |
| [RemoteInstall] | Contains entries for Remote Installation Services (RIS). You can only use this section for client operating systems that are installed by RIS. |
| [SetupData] | Contains the OSLoadOptionsVar entry, which is used to modify the /NoExecute option in Boot.ini used by Data Execution Prevention (DEP). |
| [SetupMgr] | Contains entries for specifying the server and folder in which the distribution share resides and the name of the distribution share. This section is used only by Setup Manager when an existing distribution share is edited. It is not used by Setup during an unattended installation. |
| [SetupParams] | Contains an entry for running an additional post-Setup command. |
| [Shell] | Contains entries for specifying the visual style of the user interface. |
| [SNMP] | Contains entries for specifying the Simple Network Management Protocol (SNMP) service. |
| [SystemFileProtection] | Contains entries for specifying Windows File Protection (WFP) settings. |
| [SystemRestore] | Contains entries for specifying the System Restore feature. |
| [TapiLocation] | Contains entries for specifying the telephony API (TAPI). It is valid only if a modem is present on the computer. |
| [TerminalServices] | Contains entries for configuring Terminal Services features (Terminal Server and Remote Desktop). |
| [UDDIDatabase] | Contains entries for configuring the optional Universal Description, Discovery and Integration (UDDI) Database feature. |

| | |
|---|---|
| [UDDIWeb] | Contains entries for configuring the optional Universal Description, Discovery and Integration (UDDI) Web services feature. |
| [Unattended] | Contains entries for running Setup. |
| [Uninstall] | Contains entries for allowing users who upgrade to Microsoft Windows XP to remove the operating system if they encounter problems. |
| [URL] | Contains entries for specifying default Uniform Resource Locator (URL) settings for the browser available in Windows XP or Windows Server 2003. |
| [UserData] | Contains entries for specifying user settings during the setup process. |
| [WindowsFirewall | This section must be included in your answer file to configure firewall sections and entries in unattended installations. To configure Windows Firewall settings, you must include the [WindowsFirewall] section along with one or more of the other Windows Firewall settings sections. |
| [WindowsFirewall.profile_name] | Contains entries for specifying a domain type of profile, a standard type, or a profile that applies to both domain and standard. |
| [WindowsFirewall.program_name] | Contains entries for adding programs to the Windows Firewall Exceptions list. |
| [WindowsFirewall.service_name] | Contains entries for adding services to the Windows Firewall Exceptions list. |
| [WindowsFirewall.portopening_name] | Contains entries for adding static ports to the Windows Firewall Exceptions list. |
| [WindowsFirewall.icmpsetting_name] | The default configuration for Windows Firewall blocks all Internet Control Message Protocol (ICMP) message types, the entries in this section allows you to modify this behavior. |
| [Win9xUpg] | Contains entries for specifying an unattended upgrade from Windows 98, Windows 98 Second Edition, or Windows Millennium Edition to either Windows XP Home Edition or Windows XP Professional. |

**Network Ports Used by Remote Installation Services**

The following table lists the ports are used by RIS.

### Port Assignments for Remote Installation Services

| Service Name | UDP | TCP |
|---|---|---|
| Dynamic Host Configuration Protocol (DHCP) | 67 | N/A |
| Boot Information Negotiation Layer (BINL) | 4011 | N/A |
| Trivial File Transfer Protocol Daemon (TFTPD) | 69 | N/A |

# Group Policy Collection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group Policy Collection**
Group Policy is an infrastructure that allows you to implement specific configurations for users and computers. Group Policy settings are contained in Group Policy objects (GPOs), which are linked to the following Active Directory directory service containers: sites, domains, or organizational units (OUs). The settings within GPOs are then evaluated by the affected targets, using the hierarchical nature of Active Directory. Consequently, Group Policy is one of the top reasons to deploy Active Directory because it allows you to manage user and computer objects.

Group Policy is one of a group of management technologies, collectively known as IntelliMirror management technologies, which provide users with consistent access to their applications, application settings, roaming user profiles, and user data, from any managed computer—even when they are disconnected from the network. IntelliMirror is implemented through a set of Microsoft Windows features, including Active Directory, Group Policy, Software Installation, Windows Installer, Folder Redirection, Offline Folders, and Roaming User Profiles.

This collection includes detailed information about each of the following areas of Group Policy:

- Core Group Policy
- Group Policy Components
- Group Policy Administrative Tools

This page introduces Group Policy management concepts and architecture, summarizes the areas included in the Group Policy collection, and describes Group Policy scenarios.

**Group Policy Management**
Administrators face increasingly complex challenges in managing the IT infrastructure. You must deliver and maintain customized desktop configurations for more types of workers such as mobile users, information workers, or others assigned to strictly defined tasks, such as data entry. Security settings and updates must be delivered efficiently to all the computers and devices in the organization. New users need to be productive quickly without costly training. In the event of a computer breakdown or disaster, service must be restored with a minimum of data loss and interruption. All of these tasks, known collectively as Change and Configuration Management, must be achieved at the lowest possible cost. You need to be able to implement change quickly and affect large numbers of users and computers. Group Policy is the infrastructure that allows you to implement change on the object level in Active Directory.

You need to be able to define configurations once and rely on the operating system to enforce that state. With Active Directory, GPOs can be linked to sites, domains, and OUs, allowing Group Policy settings to be applied to users and computers. In addition, GPOs can be used to help manage server computers, through many server-specific operational and security settings. This infrastructure provides a high degree of flexibility, allowing you to customize configurations, such as delivering a specific piece of software to specialized users based on their membership in an OU. In addition, the Group Policy Management Console (GPMC) simplifies implementation and management of Group Policy.

**Group Policy Architecture**
Group Policy uses a document-centric approach to creating, storing, and associating Group Policy settings. Similar to the way in which Microsoft Word stores information in .doc files, Group Policy settings are contained in GPOs. A GPO is a virtual object; policy-setting information is stored in two locations: the Active Directory container to which the GPO is linked, and the Sysvol on the domain controller.

Group Policy is configured primarily through the use of two tools: Group Policy Object Editor, (previously known as the Group Policy snap-in, Group Policy Editor, or Gpedit) and Group Policy Management Console (GPMC), available for download from the Microsoft Web site. Whereas Group Policy Object Editor is used to configure and modify settings within GPOs, GPMC is used to create, view, and manage GPOs. Group Policy architecture is shown in the following diagram, which shows how the primary components interact through read or write access. Components are described in the figure below.

**Group Policy Architecture**

**Group Policy Components**

| Component | Description |
|---|---|
| Server (Domain Controller) | In an Active Directory forest, the domain controller is a server that contains a writable copy of the Active Directory database, participates in Active Directory replication, and controls access to network resources. |
| Active Directory | Active Directory, the Windows-based directory service, stores information about objects in a network and makes this information available to users and network administrators. Administrators link GPOs to Active Directory containers such as sites, domains, and OUs that include user and computer objects. In this way, Group Policy settings can be targeted to users and computers throughout the organization. |
| Group Policy object (GPO) | A GPO is a collection of Group Policy settings, stored at the domain level as a virtual object consisting of a Group Policy container (GPC) and a Group Policy template (GPT). The GPC, which contains information on the properties of a GPO, is stored in Active Directory on each domain controller in the domain. The GPT contains the data in a GPO and is stored in the Sysvol in the **/Policies** sub-directory. GPOs affect users and computers that are contained in sites, domains, and OUs. |
| Sysvol | Sysvol is a shared directory that stores the server copy of the domain's public files, which are replicated among all domain controllers in the domain. The Sysvol contains the data in a GPO: the GPT, which includes Administrative Template-based Group Policy settings, security settings, script files, and information regarding applications that are available for software installation. It is replicated using the File Replication Service (FRS). |
| Local Group Policy object | The local Group Policy object (local GPO) is stored on each individual computer, in the hidden **%systemroot%\System32\GroupPolicy** directory. Each computer running Windows 2000, Windows XP Professional, Windows XP 64-Bit Edition, Windows XP Media Center Edition, or Windows Server 2003 has exactly one local GPO, regardless of whether the computers are part of an Active Directory environment.<br><br>Local GPOs do not support certain extensions, such as Folder Redirection or Group Policy Software Installation. Local GPOs do support many security settings, but the Security Settings extension of Group Policy Object Editor does not support remote management of local GPOs. Local GPOs are always processed, but are the least influential GPOs in an Active Directory environment, because Active Directory-based GPOs have precedence.<br><br>Although you can configure local GPOs on individual computers, the full power of Group Policy can only be realized in a Windows Server network with Active Directory installed. In addition, some features and Group Policy settings require client computers running Windows XP. |
| Group Policy Object Editor | Group Policy Object Editor is a Microsoft Management Console (MMC) snap-in that is used to edit GPOs. It was previously known as the Group Policy snap-in, Group Policy Editor, or Gpedit. |

| | |
|---|---|
| Server-Side Snap-Ins | The MMC snap-in is loaded, by default, in Group Policy Object Editor. Server-side snap-in extensions provide the user interface to allow you to configure various policy settings while client-side extensions implement the actual policy settings on target client computers.<br><br>Snap-in extensions include Administrative Templates, Scripts, Security Settings, Software Installation, Folder Redirection, Remote Installation Services, Internet Explorer Maintenance, Disk Quotas, Wireless Network Policy, and QoS Packet Scheduler. Snap-ins may in turn be extended. For example, the Security Settings snap-in includes several extension snap-ins. Developers can also create their own MMC extension snap-ins to Group Policy Object Editor to provide additional Group Policy settings. |
| Client-Side Extensions | Client-side extensions (CSEs) run within dynamic-link libraries (DLLs) and are responsible for implementing Group Policy at the client computer. The following CSEs are loaded, by default, in Windows Server 2003:<br><br>Administrative Templates, Wireless Network Policies, Folder Redirection, Disk Quotas, QoS Packet Scheduler, Scripts, Security, Internet Explorer Maintenance, EFS Recovery, Software Installation, and IP Security. |
| Group Policy Management Console (GPMC) | GPMC is a new tool designed to simplify implementation and management of Group Policy. It consists of a new MMC snap-in and a set of scriptable interfaces for managing Group Policy. The Group Policy Management Console provides:<br>• A user interface based on how customers use and manage Group Policy, rather than on how the technology is built.<br>• Import/Export, Copy/Paste, and searching of GPOs.<br>• Simplified management of Group Policy-related security.<br>• Reporting (printing, saving, read-only access to GPOs) for GPO and Resultant Set of Policy (RSoP) data.<br>• Backup/Restore of GPOs.<br>• Scripting of GPO operations that are exposed within this tool (but NOT scripting of settings within a GPO). |
| Resultant Set of Policy (RSoP) snap-in | The Resultant Set of Policy (RSoP) snap-in is an MMC snap-in that that simplifies Group Policy implementation and troubleshooting. RSoP uses Windows Management Instrumentation (WMI) to determine how Group Policy settings are applied to users and computers. For RSoP functionality, it is recommended to use the reporting features in GPMC. |
| Winlogon | A component of the Windows operating system that provides interactive logon support, Winlogon is the service in which the Group Policy engine runs. |
| Group Policy engine | The Group Policy engine is the framework that handles common functionalities across client-side extensions including scheduling of Group Policy application, obtaining GPOs from relevant configuration locations, and filtering and ordering of GPOs. |
| File System | The NTFS file system on client computers. |

| | |
|---|---|
| Registry | A database repository for information about a computer's configuration, the registry contains information that Windows continually references during operation, such as:<br>1. Profiles for each user.<br>2. The programs installed on the computer and the types of documents that each can create.<br>3. Property settings for folders and program icons.<br>4. The hardware on the system.<br>5. Which ports are being used.<br><br>The registry is organized hierarchically as a tree, and it is made up of keys and their subkeys, hives, and entries. The Group Policy engine has read and write access to the Registry.<br><br>Registry settings can be controlled via the Group Policy Administrative Templates extension. |
| Event Log | The Event log is a service, located in Event Viewer, which records events in the system, security, and application logs. The Group Policy engine has write access to the Event Log on client computers and domain controllers. The Help and Support Center on each computer has read access to the Event Log. |
| Help and Support Center | The Help and Support Center is a component on each computer that provides HTML reports on the Group Policy settings currently in effect on the computer. |
| Resultant Set of Policy (RSoP) infrastructure | All Group Policy processing information is collected and stored in a Common Information Model Object Management (CIMOM) database on the local computer. This information, such as the list, content and logging of processing details for each GPO, can then be accessed by tools using WMI.<br><br>In logging mode (Group Policy Results), RSoP queries the CIMOM database on the target computer, receives information about the policies and displays it in GPMC. In planning mode (Group Policy Modeling), RSoP simulates the application of policy using the Group Policy Directory Access Service (GPDAS) on a domain controller. GPDAS simulates the application of GPOs and passes them to virtual client-side extensions on the domain controller. The results of this simulation are stored to a local CIMOM database on the domain controller before the information is passed back and displayed in GPMC. |
| WMI | WMI is a management infrastructure that supports monitoring and controlling of system resources through a common set of interfaces and provides a logically organized, consistent model of Windows operation, configuration, and status.<br><br>WMI makes data about a target computer available for administrative use. Such data can include hardware and software inventory, settings, and configuration information. For example, WMI exposes hardware configuration data such as CPU, memory, disk space, and manufacturer, as well as software configuration data from the registry, drivers, file system, Active Directory, the Windows Installer service, networking configuration, and application data. WMI Filtering in Windows Server 2003 allows you to create queries based on this data. These queries (also called WMI filters) determine which users and computers receive all of the policy configured in the GPO where you create the filter. |

**Core Group Policy**
This subject explains Group Policy infrastructure including how the Group Policy engine controls policy processing, including retrieval of GPOs, invocation of individual extensions, and other infrastructure functionality.

**Group Policy Components**
The Group Policy Components subcollection describes the role of extensions including server-side snap-in extensions and client-side extensions. These extensions include: Administrative Templates, Software Installation, Security Settings, Scripts, Remote Installation Services, Internet Explorer Maintenance, Folder Redirection, QoS Packet Scheduler, Disk Quotas, and Wireless Network Policies.

**Group Policy Administrative Tools**
This subcollection explains administrative tools including the Group Policy Object Editor, Group Policy Management Console,

and the Resultant Set of Policy (RSoP) snap-in.

**Group Policy Scenarios**
Group Policy is used to define configurations for groups of users and computers. With Group Policy, you can specify specific configurations for a wide range of areas including Administrative Templates (registry-based policies), security, software installation, scripts, folder redirection, remote installation services, and Internet Explorer maintenance. Group Policy settings are contained in a GPO. By associating a GPO with selected Active Directory system containers—sites, domains, and organizational units—the GPO's Group Policy settings are applied to the users and computers in those Active Directory containers. This section provides an overview of what you can do with Group Policy.

**Managing Desktops, Applications, and Components with Registry-Based Policies**
Administrative Templates (or .adm files) enable you to control registry settings using Group Policy, providing the means to configure the behavior and appearance of the desktop, including the operating system, components, and applications. Windows comes with a predefined set of Administrative template files, which are implemented as text files (with an .adm extension), that define the registry settings that can be configured in a GPO. These .adm files are stored in two locations by default: inside GPOs in the **Sysvol** folder and in the **%windir%\inf** directory on the local computer.

**Managing Security**
Group Policy is used to manage the following types of securityoptions for users, clients, servers, and domain controllers:

- **Security settings**. These Group Policy settings are used to define values for various security-relevant operating system parameters, such as password policy, user rights assignment, audit policy, registry values, file and registry ACLs, and service startup modes.

- **IPSec policies**. These Group Policy settings are used to configure IPSec services for authenticating or encrypting network traffic. An IPSec policy consists of a set of security rules, and each security rule consists of an IP filter with an action.

- **Software restriction policies**. These Group Policy settings are used to help protect computers from code that is not trusted by identifying and specifying which applications are permitted to run.

- **Wireless network policies**. These Group Policy settings are used to configure settings for the Wireless Configuration Service, a user-mode service that operates on each of the IEEE 802.11 wireless network adapters that are installed on a computer.

- **Public Key Policies**. These Group Policy settings are used to:

    - Specify that computers automatically submit a certificate request to an enterprise certification authority and install the issued certificate.

    - Create and distribute a certificate trust list.

    - Establish common trusted root certification authorities.

    - Add encrypted data recovery agents and change the encrypted data recovery policy settings.

**Implementing Group Policy–based Software Installation**
The Software Installation snap-in is used to centrally manage software. Software can be assigned or published to users and assigned to computers. Group Policy-based software installation can be used to install software applications when a computer is started, when the user logs on, or on demand. Software installation Group Policy settings can be applied to users or computers in an Active Directory structure.

Group Policy-based software installation can also be used to upgrade deployed applications or remove earlier applications that are no longer required. Users can be restricted from installing any software from local media, such as a CD-ROM, or disk, or other unapproved applications.

Medium and large organizations may wish to consider using Systems Management Server (SMS). SMS provides advanced capabilities such as inventory-based targeting, status reporting, server- and client-side scheduling, multisite facilities, complex targeting, centralized hardware and software inventory, remote diagnostic tools, software metering, software distribution-point population and maintenance, support for Windows 95, Windows 98, Windows NT 4.0, Windows 2000, and Windows XP clients, and enhanced software deployment features. SMS does not require Active Directory.

**Managing Remote Operating System Installations**
Remote Installation Services (RIS) is used to control the behavior of the Remote Operating System Installation feature as displayed to client computers. Remote Installation enables administrators to perform a new installation of Windows on Preboot eXecution Environment (PXE) remote boot-enabled client computers throughout an organization. Using a customized, fully automated installation process from a remote source, an administrator does not have to visit the new computer to install a new operating system and core applications.

**Managing with Scripts**
Scripts are used to automate tasks at computer startup and shutdown, and at user logon and logoff. Scripts can be written in any language supported by Windows Script Host including the Microsoft Visual Basic development system, Scripting Edition (VBScript), JavaScript, PERL, and MS DOS-style batch files (.bat and .cmd).

**Managing Internet Explorer**
Internet Explorer Maintenance is used to manage and customize Internet Explorer on computers running Windows 2000 or later. You can set options for the Browser UI, connections, URLs, proxy settings, security zones, Favorites, and Internet Explorer Enhanced Security Configuration component (also known as Microsoft Internet Explorer hardening). .

**Managing Folder Redirection**
You can use folder redirection to redirect special directories on Windows 2000 or Windows Server 2003 from their default user profile location to an alternate location on the network. These special folders include **My Documents**, **Application Data**, **Desktop**, and the **Start** menu.

# Core Group Policy Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Core Group Policy Technical Reference**
Group Policy is an infrastructure that allows you to specify managed configurations for users and computers in an Active Directory directory service environment. Group Policy settings are contained in Group Policy objects (GPOs). GPOs exist in a domain, and can be linked to the following Active Directory containers: sites, domains, or organizational units (OUs). A GPO consists of two parts — one part is located in Active Directory, the other is located in the Sysvol folder — both of which are replicated to all domain controllers in the domain. The settings within GPOs are then evaluated by the affected targets, using the hierarchical nature of Active Directory. Core Group Policy or the Group Policy engine is the framework that handles common functionalities across all client side extensions.

**In this section**

- Change and Configuration Management
- Core Group Policy Infrastructure
- Core Group Policy Scenarios
- Core Group Policy Dependencies
- Related Information

Group Policy is an infrastructure used to deliver and apply one or more desired configurations or policy settings to a set of targeted users and computers within an Active Directory environment. This infrastructure consists of a Group Policy engine and multiple client-side extensions (CSEs) responsible for writing specific policy settings on target client computers.

Group Policy settings are contained in Group Policy objects (GPOs), which live in the domain and can be linked to the following Active Directory containers: sites, domains, or organizational units (OUs). The settings within GPOs are then evaluated by the affected targets, using the hierarchical nature of Active Directory. Consequently, Group Policy is one of the top reasons to deploy Active Directory.

Group Policy is one of a group of management technologies, collectively known as IntelliMirror, that provides users with consistent access to their applications, application settings, roaming user profiles, and user data, from any managed computer — even when they are disconnected from the network. IntelliMirror is implemented through a set of Windows features, including Active Directory, Group Policy, Group Policy-based Software Installation, Windows Installer, Folder Redirection, Offline Folders, and Roaming User Profiles.

Core Group Policy or the Group Policy engine is the framework that handles common functionalities across Administrative Template settings and other client-side extensions. The following figure shows how the Group Policy engine interacts with other components as part of processing policy settings. You use Group Policy Management Console (GPMC) to create, view, and manage GPOs and use Group Policy Object Editor to set and configure the policy settings in GPOs.

**Group Policy Components**

**Change and Configuration Management**

Administrators face increasingly complex challenges in managing their IT infrastructures. You must deliver and maintain customized desktop configurations for many types of workers, including mobile users, information workers, or others assigned

to strictly defined tasks, such as data entry. Changes to standard operating system images might be required on an ongoing basis. Security settings and updates must be delivered efficiently to all the computers and devices in the organization. New users need to be productive quickly without costly training. In the event of a computer failure or disaster, service must be restored with a minimum of data loss and interruption.

Specifically, an IT department must respond to various factors that require change in an IT environment including:

- New operating systems and applications.
- Updates to operating systems and applications.
- New hardware.
- New business requirements that require configuration changes.
- Security influences that require configuration changes.
- New users.

Managing this change can be viewed as a continuous cycle, in which new business requirements demand changes that must first be tested before they can be deployed as a standard configuration. This cycle is shown in the following figure.

**Change and Configuration Management Process**

These roles, known collectively as Change and Configuration Management, enable administrators to implement change quickly and affect large numbers of users and computers at the lowest possible cost. You can use Group Policy to maintain standard operating environments for specific groups of users, such as developers or information workers. As software changes and policies change over time, Group Policy can be used to update the already-deployed standard operating environment until the image can be updated. Group Policy can also enforce rules, if necessary, by restricting the programs that can be run on company computers. For example, it can prevent access to games or other programs unrelated to the workplace.

Group Policy is a key enabling technology that allows you to implement Change and Configuration Management along with other technologies in IntelliMirror. For example, you can deploy new operating systems with Remote Installation Services or other imaging technology. You can deliver updates to computers throughout the network using Software Update Services (SUS). Although you can deploy software using Group Policy, larger organizations might want to use Microsoft Systems Management Server (SMS) to take advantage of the scalability that SMS provides.

In summary, Group Policy is the delivery mechanism that allows you to implement change and configuration for users and computers on the object level in Active Directory. Because you can target Group Policy settings to individual objects throughout the Active Directory hierarchy, Group Policy is the central enabling technology that allows organizations to effectively use Active Directory as a management tool. In addition, the Group Policy Management Console simplifies implementation and management of Group Policy.

**Core Group Policy Infrastructure**

Group policy is an infrastructure with pluggable extensions. Extensions that exist on client computers include Administrative Templates (also known as registry-based policy), Security Settings, Software Installation, Folder Redirection, Scripts, and Wireless Network Policies.

The policy settings exist in a GPO. A GPO is a virtual object that lives in the domain; part of the GPO is located in Active Directory and is called the Group Policy container. The other part of a GPO is located in the Sysvol and is called the Group Policy template. When policy settings need to be applied, the framework calls each extension and the extension then applies the necessary settings.

Each Group Policy extension has two extensions — a client extension that is called by the Group Policy engine to apply policy, and a server-side extension that plugs into Group Policy Object Editor to define and set the policy settings that need to be applied to client computers.

Although you can configure Local Group Policy objects (Local GPOs) on individual computers, the full power of Group Policy can only be realized in a Windows 2000 or Windows Server 2003-based network with Active Directory installed. In addition, some features and policy settings require client computers running Windows XP.

**Group Policy and Active Directory**
Active Directory organizes objects by sites, domains, and OUs. Domains and OUs are organized hierarchically, making the containers and the objects within them easy to manage. The settings defined in a GPO can only be applied when the GPO is linked to one or more of these containers.

By linking GPOs to sites, domains, and OUs, you can implement Group Policy settings for as broad or as narrow a portion of the organization as you want. GPO links affect users and computers in the following ways:

- A GPO linked to a site applies to all users and computers in the site.
- A GPO linked to a domain applies directly to all users and computers in the domain and by inheritance to all users and computers in child OUs. Note that policy is not inherited across domains.
- A GPO linked to an OU applies directly to all users and computers in the OU and by inheritance to all users and computers in child OUs.

When a GPO is created, it is stored in the domain. When the GPO is linked to an Active Directory container, such as an OU, the link is a component of that container, not a component of the GPO.

An example of how GPOs can be linked to sites, domains, and OUs is shown in the following figure.

**Sample Active Directory Organizational Structure**

In this configuration, the Servers OUs have the following GPOs applied: A1, A2, A3, A4, A6. The Marketing OUs have the following GPOs applied: A1, A2, A3, A5.

**Loopback processing with merge or replace**
Loopback is an advanced Group Policy setting that is useful on computers in certain closely managed environments, such as servers, kiosks, laboratories, classrooms, and reception areas. Setting loopback causes the User Configuration settings in GPOs that apply to the computer to be applied to every user logging on to that computer, instead of, or in addition to, the User Configuration settings of the user. This allows you to ensure that a consistent set of policies is applied to any user logging on to a particular computer, regardless of their location in Active Directory. Loopback is controlled by the setting, User Group Policy loopback processing mode, which is located in **Computer Configuration\Administrative Templates\System\Group Policy**. Loopback only works when both the user account and the computer account are in a Windows 2000 or later domain. Loopback does not work for computers joined to a workgroup. Loopback is not enabled if the computer or user is not in an Active Directory domain.

**Filtering the Scope of the Group Policy Object**
Group Policy is a powerful tool for managing the Windows Server 2003 environment. The value of Group Policy can only be realized through properly applying the GPOs to the Active Directory containers you want to manage. Determining which users and computers will receive the settings in a GPO is referred to as "scoping the GPO." Scoping a GPO is based on three factors:

- The site(s), domain(s), or organization unit(s) where the GPO is linked.
- The security filtering on the GPO.
- The WMI filter on the GPO.

You can use the site, domain, and OU links from a GPO as the primary targeting principle for defining which computers and users should receive a GPO. You can then use security filtering and WMI filtering to further reduce the set of computers and users to which the GPO will apply.

Scoping or targeting of a GPO allows you to apply or deny an entire GPO; you cannot choose to filter settings within a GPO.

**Group Policy Inheritance**
In addition to the ability to filter the scope of GPOs, you can change the way GPOs are applied by managing Group Policy inheritance. In most environments, the actual settings for a given user and computer are the result of the combination of GPOs that are applied at a site, domain, or OU. When multiple GPOs apply to these users and computers, the settings in the GPOs are aggregated. The settings deployed by GPOs linked to higher containers (parent containers) in Active Directory are inherited by default to child containers and combine with any settings deployed in GPOs linked to child containers. If multiple GPOs attempt to set a setting to conflicting values, the GPO with the highest precedence sets the setting. GPO processing is based on a "last writer wins" model, and GPOs that are processed later have precedence over GPOs that are processed earlier.

**Viewing and Reporting of Policy Settings**
In order to properly implement, troubleshoot, and plan Group Policy, administrators need to be able to quickly view the settings in a GPO. When multiple GPOs apply to a given user or computer, they can contain conflicting policy settings. For most policy settings, the final value of the policy setting is set only by the highest precedent GPO that contains that setting. Resultant Set of Policy (RSoP) helps you understand and identify the final set of policy that is applied as well as settings that did not apply as a result of policy inheritance.

Specifically, Resultant Set of Policy helps you determine:

- The final value of the setting that is applied as a result of all the GPOs.
- The final GPO that set the value of this setting (also known as the winning GPO).
- Precedence details that show any other GPOs that attempted to set this setting and the value that each GPO attempted to set for that policy setting.

Group Policy Management Console, available as a separate download from the Microsoft Web site, addresses some common reporting requirements including the ability to document all the settings in a GPO to a file for printing or viewing. Users can either print the reports, or save them to a file as either HTML or XML.

**Delegating Administration of Group Policy**
Organizations need to be able to delegate administration of Group Policy to other administrators who can take responsibility for a given OU, domain, or other container. Active Directory is designed to allow you to delegate control of portions of the directory service in managing aspects of Group Policy. The following areas can be delegated:

- **GPO delegation.** This includes permission to create GPOs in a domain or permission to edit an existing GPO. Note that having permission to edit a GPO does not include any delegated rights on the GPO links.
- **Link delegation.** This includes permission to add, delete, or change links to GPOs. Note that having link delegation does not include any delegated rights on the GPO itself.
- **RSOP delegation.** This includes permission to run RSoP (in either planning or logging mode) on objects under a container.
- **WMI filter delegation.** This includes permission to create WMI filters or permission to edit an existing filter.

In GPMC, delegation is simplified because it manages the various Access Control Entries (ACEs) required for a task as a single bundle of permissions for the task. You can also use the Access Control List (ACL) editor to view or manage these permissions manually.

The underlying mechanism for achieving delegation is the application of the appropriate DACLs to GPOs and other objects in Active Directory. This mechanism is identical to using security groups to filter the application of GPOs to various users. You can also specify Group Policy to control who can use MMC snap-ins. For example, you can use Group Policy to manage the rights to create, configure, and use MMC consoles, and to control access to individual snap-ins.

**Core Group Policy Scenarios**

The Group Policy engine is designed to apply policy configurations to individual computers and users through Group Policy objects. Settings within a GPO are configured by individual client-side extensions and are applied to individual computers and users by the client-side extension. This section summarizes the core scenarios for the Group Policy engine.

- **Scheduling of Group Policy application.** Group Policy starts each time the computer starts or a user logs in, a process called foreground policy application. Group Policy is also applied in the background at regular refresh intervals. In addition, it can be forced to apply through command line tools such as Gpupdate.

- **Obtaining GPOs from the relevant configuration locations.** The Group Policy engine obtains GPOs from the appropriate site, domain, and OU containers, known collectively as Scope of Management (SOM).

- **Handling special cases affecting all CSEs.** The Group Policy engine implements additional changes specified by the administrator such as changing the link order in which GPOs should be applied. In addition, the Group Policy engine handles any loopback processing that has been set by an administrator. Loopback processing, typically used for public workstations or kiosks, specifies that the user settings defined in the computer's GPOs replace or are merged with the user settings normally applied to the user.

- **Filtering and ordering of GPOs.** The Group Policy engine checks for any conditions set by the administrator to filter GPOs or specify the order in which GPOs should be applied.

- **Configuring CSEs.** CSEs can be configured to run only in some conditions, as specified in the registry.

- **Maintaining version numbers and histories for all CSEs.** A history list is maintained for each CSE in the Registry, showing when the CSE last applied policy. A status is also maintained to figure out whether the client-side extension applied policy successfully last time the policy was applied by the CSE.

- **Calling into the CSE.** When the Group Policy engine has determined that a particular CSE needs to be executed, it loads the dynamic link library (DLL) associated with the CSE and loads up the entry point.

- **Notifying various components of any changes made by Group Policy.** After all the extensions have been called, the Group Policy engine updates the registry information to specify what the next policy foreground application should be, as well as schedule the next background refresh time.

- **Processing RSoP data.** The Group Policy engine periodically refreshes the RSoP data, ensuring that actual policy application is updated and stored in the WMI namespace on each computer.

**Group Policy Dependencies**

Group Policy has several key dependencies. Domain-based Group Policy requires an Active Directory environment with DNS properly configured.

**Active Directory**

Active Directory is the Windows 2000 Server and Windows Server 2003 directory service that stores information about all objects on the computer network and makes this information easy for administrators and users to find and apply. With Active Directory, users can gain access to resources anywhere on the network with a single logon. Similarly, administrators have a single point of administration for all objects on the network, which can be viewed in a hierarchical structure. In a network environment, Group Policy depends on Active Directory as the targeting framework that allows you to link GPOs to specific Active Directory containers such as sites, domains, or OUs.

In a stand-alone environment without Active Directory, you can use Local Group Policy objects to configure settings on individual computers.

**Domain Name System (DNS)**

DNS is a hierarchical, distributed database that contains mappings of DNS domain names to various types of data, such as IP addresses. DNS enables the location of computers and services by user-friendly names, and it also enables the discovery of other information stored in the database.

Group Policy application requires clients to access specified servers, including domain controllers and other servers such as share points and install points. Group Policy management also requires access to domain controllers. DNS is used to locate and identify these servers. In Windows 2000 Server and later Active Directory requires DNS support. If the network is

functioning, but clients or consoles such as the Group Policy Object Editor or GPMC are unable to locate the servers, there might be a problem with your network's DNS system.

**Replication**

Group Policy depends on other technologies in order to properly replicate between domain controllers in a network environment. A GPO is a virtual object stored in both Active Directory and the Sysvol of a domain controller. Property settings, stored in the Group Policy container, are replicated through Active Directory replication. Replication automatically copies the changes that originate on a writable directory partition replica to all other domain controllers that hold the same directory partition replica. More specifically, a destination domain controller pulls these changes from the source domain controller. Data settings, stored in the Sysvol as the Group Policy template, are replicated through the File Replication Service (FRS), which provides multi-master file replication for designated directory trees between designated servers running Windows Server 2003. The Group Policy container stores GPO properties, including information about version, GPO status, and a list of components that have settings in the GPO. The Group Policy template is a directory structure within the file system that stores Administrative Template-based policy settings, security settings, script files, and information regarding applications that are available for software installation. The Group Policy template is located in Sysvol in the \Policies sub-directory for its domain. GPOs are identified by their globally unique identifiers (GUIDs) and stored at the domain level. The settings from a GPO are only applied when the Group Policy container and Group Policy template are synchronized.

**DFS publishing**

The Sysvol folder is shared on each domain controller and is accessible through the UNC path \\dcname.domainname\sysvol.

The Sysvol is also published as a domain-based Distributed File System (DFS) share. This allows clients to access the Sysvol by using the generic path *domainname*\sysvol. A request for a DFS referral for *domainname*\sysvol will always return a replica in the same Active Directory site as the client if one is available. This is the mechanism that the Group Policy client-side extensions use to retrieve a local copy of the Group Policy template information.

**Related Information**

The following contains additional information that is relevant to this section.

Group Policy Settings Reference for Windows Server 2003

# How Core Group Policy Works

Updated: September 2, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Core Group Policy Works**

**In this section**

- Core Group Policy Architecture
- Core Group Policy Physical Structure
- Core Group Policy Processes and Interactions
- Network Ports Used by Group Policy
- Related Information

Core Group Policy or the Group Policy engine is the infrastructure that processes Group Policy components including server-side snap-in extensions and client-side extensions. You use administrative tools such as Group Policy Object Editor and Group Policy Management Console to configure and manage policy settings.

At a minimum, Group Policy requires Windows 2000 Server with Active Directory installed and Windows 2000 clients. Fully implementing Group Policy to take advantage of all available functionality and the latest policy settings depends on a number of factors including:

- Windows Server 2003 with Active Directory installed and with DNS properly configured.
- Windows XP client computers.
- Group Policy Management Console (GPMC) for administration.

**Core Group Policy Architecture**

The Group Policy engine is a framework that handles client-side extension (CSE) processing and interacts with other elements of Group Policy, as shown in the following figure:

**Core Group Policy Architecture**

The following table describes the components that interact with the Group Policy engine.

**Core Group Policy Components**

| Component | Description |
| --- | --- |
| Server (domain controller) | In an Active Directory forest, the domain controller is a server that contains a writable copy of the Active Directory database, participates in Active Directory replication, and controls access to network resources. |
| Active Directory | Active Directory, the Windows-based directory service, stores information about objects on a network and makes this information available to users and network administrators. Administrators link Group Policy objects (GPOs) to Active Directory containers such as sites, domain, and organizational units (OUs) that include user and computer objects. In this way, policy settings can be targeted to users and computers throughout the organization. |
| Sysvol | The Sysvol is a set of folders containing important domain information that is stored in the file system rather than in the directory. The Sysvol folder is, by default, stored in a subfolder of systemroot folder (%\systemroot\sysvol\sysvol) and is automatically created when a server is promoted to a domain controller. The Sysvol contains the largest part of a GPO: the Group Policy template, which includes Administrative Template-based policy settings, security settings, script files, and information regarding applications that are available for software installation. It is replicated through the File Replication Service (FRS) between all domain controllers in a domain. |
| Group Policy object (GPO) | A GPO is a collection of Group Policy settings, stored at the domain level as a virtual object consisting of a Group Policy container and a Group Policy template. The Group Policy container, which contains information about the properties of a GPO, is stored in Active Directory on each domain controller in the domain. The Group Policy template contains the data in a GPO and is stored in the Sysvol in the /Policies subdirectory. GPOs affect users and computers that are contained in sites, domains, and OUs. |
| Local Group Policy object | The Local Group Policy object (Local GPO) is stored on each individual computer, in the hidden **Windows\System32\GroupPolicy** directory. Each computer running Windows 2000, Windows XP Professional, Windows XP 64-Bit Edition, Windows XP Media Center Edition, or Windows Server 2003 has exactly one Local GPO, regardless of whether the computers are part of an Active Directory environment.<br><br>Local GPOs are always processed, but are the least influential GPOs in an Active Directory environment, because Active Directory-based GPOs have precedence. |
| Winlogon | A component of the Windows operating system that provides interactive logon support, Winlogon is the service in which the Group Policy engine runs. |
| Group Policy engine | The Group Policy engine is the framework that handles common functionalities across registry-based settings and client-side extensions (CSEs). |
| Client-side extensions | CSEs run within dynamic-link libraries (DLLs) and are responsible for implementing Group Policy at the client computer.<br><br>The CSEs are loaded on an as-needed basis when a client computer is processing policy |
| File system | The NTFS file system on client computers. |

| | |
|---|---|
| Registry | A database repository for information about a computer's configuration, the registry contains information that Windows continually references during operation, such as:<br>• Profiles for each user.<br>• The programs installed on the computer and the types of documents that each can create.<br>• Property settings for folders and program icons.<br>• The hardware on the system.<br>• Which ports are being used.<br><br>The registry is organized hierarchically as a tree, and it is made up of keys and their subkeys, hives, and entries.<br><br>Registry settings can be controlled through Group Policy, specifically, Administrative Templates (.adm files). Windows Server 2003 comes with a predefined set of Administrative Template files, which are implemented as text files (with an .adm extension), that define the registry settings that can be configured in a GPO. These .adm files are stored in two locations by default: inside GPOs in the Sysvol folder and in the **Windows\inf** directory on the local computer. |
| Event log | The Event log is a service, located in Event Viewer, which records events in the system, security, and application logs. |
| Help and Support Center | The Help and Support Center is a component on each computer that provides HTML reports on the policy settings currently in effect on the computer. |
| Resultant Set of Policy (RSoP) infrastructure | All Group Policy processing information is collected and stored in a Common Information Model Object Management (CIMOM) database on the local computer. This information, such as the list, content, and logging of processing details for each GPO, can then be accessed by tools using Windows Management Instrumentation (WMI). |
| WMI | WMI is a management infrastructure that supports monitoring and controlling of system resources through a common set of interfaces and provides a logically organized, consistent model of Windows operation, configuration, and status.<br><br>WMI makes data about a target computer available for administrative use. Such data can include hardware and software inventory, settings, and configuration information. For example, WMI exposes hardware configuration data such as CPU, memory, disk space, and manufacturer, as well as software configuration data from the registry, drivers, file system, Active Directory, the Windows Installer service, networking configuration, and application data. WMI filtering in Windows Server 2003 allows you to create queries based on this data. These queries (WMI filters) determine which users and computers receive all of the policy configured in the GPO where you create the filter. |

**Group Policy Engine Architecture**

The primary purpose of Group Policy is to apply policy settings to computers and users in an Active Directory domain. GPOs can be targeted through Active Directory containers, such as sites, domains, and OUs, containing user or computer objects. The Group Policy engine is in userenv.dll, which runs inside the Winlogon service. This is shown in the following figure.

**Group Policy Engine Architecture and CSE Components**

**Group Policy Engine Architecture and CSE Components**

| Component | Description |
|---|---|
| Group Policy Engine | The framework that handles functionalities across CSEs, the Group Policy engine runs inside userenv.dll. |
| Winlogon.exe | A component of the Windows operating system that provides interactive logon support, Winlogon is the service in which the Group Policy engine runs. Winlogon is the only system component that actively interacts with the Group Policy engine. |
| Userenv.dll | Userenv.dll runs inside Winlogon and contains the Group Policy engine and the Administrative Templates extension. |
| gptext.dll | Used to configure Scripts, IP Security, QoS Packet Scheduler, and Wireless settings. |
| fdeploy.dll | Used to configure folder redirection |
| scecli.dll | Used to configure security settings. |
| iedkcs32.dll | Used to manage various Internet Explorer settings. |
| appmgmts.dll | Used to configure software installation settings. |
| dskquota.dll | Used for setting disk quotas. |

**RSoP Architecture**

Resultant Set of Policy (RSoP) uses WMI to determine how policy settings are applied to users and computers. RSoP has two modes: logging mode and planning mode. Logging mode determines the resultant effect of policy settings that have been applied to an existing user and computer based on a site, domain, and OU. Logging mode is available on Windows XP and later operating systems. Planning mode simulates the resultant effect of policy settings that are applied to a user and computer. Planning mode requires a Windows Server 2003 computer as a domain controller. For RSoP functionality, using GPMC is recommended, which includes RSoP features integrated with the rest of GPMC. In GPMC, RSoP logging mode is referred to as Group Policy Results; planning mode is referred to as Group Policy Modeling.

The following figure shows the high-level architecture of RSoP for Group Policy Results and Group Policy Modeling:

**RSoP Architecture**

Windows Server 2003 collects Group Policy processing information and stores it in a WMI database on the local computer. (The WMI database is also known as the CIMOM database.)This information, such as the list, content and logging of processing details for each GPO, can then be accessed by tools using WMI.

In Group Policy Results, RSoP queries the WMI database on the target computer, receives information about the policies and displays it in GPMC. In Group Policy Modeling, RSoP simulates the application of policy using the Resultant Set of Policy Provider on a domain controller. Resultant Set of Policy Provider simulates the application of GPOs and passes them to virtual CSEs on the domain controller. The results of this simulation are stored to a local WMI database on the domain controller before the information is passed back and displayed in GPMC (or the RSoP snap-in). This is explained in greater detail in the following section.

**Windows Management instrumentation (WMI) and Common Information Model Object Management (CIMOM)**
WMI provides a common scriptable interface to retrieve, and in some cases set, a wide variety of system and application information. WMI is implemented through the winmgmt.exe service. The WMI information hierarchy is modeled as a hierarchy of objects following the Common Information Model (CIM) standards.

This information hierarchy is extensible, which allows different applications and services to expose configuration information by supplying a WMI provider. WMI providers are the interface between the WMI service and the application's data in its native format.

WMI data can be dynamic (generated on demand when required by a management application) or static. Static data is stored in the CIMOM database. This data can be accessed at any time (security controls permitting) by management applications. RSoP uses WMI and the CIMOM to write, store and query RSoP settings information.

**Resultant Set of Policy Provider**
RSoP in planning mode has the special requirement that no settings information is actually applied to the client system during the RSoP data generation. In fact, in many planning scenarios, there might not be a computer or user object to apply the settings to. To meet this requirement, the RSoP provider runs on domain controllers and performs some of the functions of a client system for GPO application.

The RSoP provider is actually a WMI provider that performs the role of Winlogon in invoking CSEs to log RSoP information to the CIM repository. It takes parameters supplied by the RSoP wizard to select GPOs from the directory. It uses the following parameters:

- **Scope of management (SOM).** This is the combination of user object OU and computer object OU and Site (although the latter is optional). Either the User or Computer SOM can be omitted but one must be specified. This can be specified as either an existing computer, user, or both, or as existing OUs for the computer, user, or both.

- **Security group memberships for the computer and user objects.** By default, these are the existing security group memberships if actual user or computer objects are chosen as the SOM. Security filtering can be ignored entirely or a new or a modified set of groups can be chosen.

- **WMI filter.** New or modified WMI filters can be applied to the GPOs during the RSoP generation.

RSoP provider is a service on a domain controller and runs in system context. There are two ramifications to this design. The service manually evaluates the security descriptor of each GPO in the SOM against the user object and computer object security identifiers (SIDs) and their security group membership. If Active Directory is locked down, some security group membership analyses might fail until the user is provided the correct access.

In addition, because the RSoP provider has Domain Admin-equivalent access rights, some control needs to be placed on who can generate RSoP information in the directory. This control is achieved by an extended access right — GenerateRSoPData. To execute an RSoP session for a particular container, the user must have the Generate RSoP (planning) access right for that container.

**Planning Mode (Group Policy Modeling)**
In planning mode, RSoP provider performs the RSoP data generation in the following steps:

1. RSoP tool gets the user, computer and domain controller name from the wizard.

2. RSoP connects to the WMI database on the specified domain controller.

3. WMI service in turn calls the WMI Provider (an out-of-process service provider) on the same computer to create the RSoP data.

4. RSoP provider gets the list GPOs for the user and computer from Active Directory.

5. RSoP provider populates the WMI database with instances of the GPOs for user and computer.

6. The list of registered CSEs is retrieved. Each of the policy extensions is dynamically loaded in succession by the RSoP provider and the list of computer and user GPOs is passed to each extension. Each policy extension takes the list of GPOs and instead of applying the policy, it populates the WMI database with instances of policy objects that describe the effective policy.

7. After the WMI database population is over, RSoP provider returns the namespace under which the RSoP data was created to the WMI service. This returns the namespace to the RSoP tool.

8. The RSoP tool connects to the namespace on the WMI database on the domain controller. RSoP navigates or iterates through the populated data in the WMI database using WMI enumeration APIs to retrieve the policy data.

9. The RSoP data is displayed to the user. When the user is done looking at the RSoP data, the RSoP tool calls RsopDeleteSession on the WMI service to delete the data in WMI's database that was previously created.

**Logging Mode (Group Policy Results)**
In logging mode, the RSoP data generation is controlled by Winlogon and is part of the normal GPO processing operation.

The Winlogon process retrieves the list of GPOs from the Active Directory using the security context of the user or computer.

- Winlogon process populates the WMI database with instances of the GPOs.

- The list of registered policy extensions is retrieved. Each of the policy extensions is dynamically loaded in succession by the Winlogon process and the list of GPOs is passed to each policy extension. Each extension takes the list of GPOs and, in addition to applying the policy, it populates the WMI database with the policies set and which GPOs applied them.

**Core Group Policy Physical Structure**
Understanding where GPOs are stored and how they are structured can help you troubleshoot problems you might encounter when you implement Group Policy. Although GPOs can be linked to sites, domains, and OUs, they are stored only in the domain. As explained earlier, a GPO is a virtual object that stores its data in two locations: a Group Policy container and a Group Policy template.

**Group Policy Container**
A Group Policy container is a location in Active Directory that stores GPOs and their properties. The properties of a GPO include both computer and user Group Policy information. The Policies container is the default location of GPOs. The path to the Policies container, in Lightweight Directory Access Protocol (LDAP) syntax, is **CN=Policies,CN=System,DC=Domain_Name**, where the Domain_Name values specify a fully qualified domain name (FQDN).

The Active Directory store contains the Group Policy container of each GPO in the domain. The Group Policy container contains attributes that are used to deploy GPOs to the domain, to OUs, and to sites within the domain. The Group Policy container also

contains a link to the file system component of a GPO — the Group Policy template. Some of the information in a Group Policy container includes:

- **Version information.** Ensures that the information is synchronized with the Group Policy template information.
- **Status information.** Indicates whether the user or computer portion of the GPO is enabled or disabled.
- **List of components.** Lists (extensions) that have settings in the GPO. These attributes are **gPCMachineExtensionNames** and **gPCUserExtensionNames**.
- **File system path.** Specifies the Universal Naming Convention (UNC) path to the Sysvol folder. This attribute is **gPCFileSysPath**.
- **Functionality version.** Gives the version of the tool that created the GPO. Currently, this is version 2. This attribute is **gPCFunctionalityVersion**.
- **WMI filter.** Contains the distinguished name of the WMI filter. This attribute is **gPCWQLFilter**.

**System Container**

Each Windows Server 2003 domain contains a System container. The System container stores per-domain configuration settings, including GPO property settings, Group Policy container settings, IP Security settings, and WMI policy settings. IP Security and WMI policy are deployed to client computers through the GPO infrastructure.

The following subcontainers of the System container hold GPO-related settings:

- **Policies.** This object contains groupPolicyContainer objects listed by their unique name. Each groupPolicyContainer object holds subcontainers for selected computer and user policy settings.
- **Domain, OUs and Sites.** These objects contain two GPO property settings, **gPLink** and **gPOptions**.
- **Default Domain Policy.** This object contains the **AppCategories** container, which is part of the Group Policy Software installation extension.
- **IP Security.** This object contains IP Security policy settings that are linked to a GPO. The linked IP Security policy is applied to the recipients (user or computer) of the GPO.
- **WMIPolicy.** This object contains WMI filters that can be applied to GPOs. WMI filters contain one or more Windows Query Language (WQL) statements.

**System\Policies Container**

The System container is a top level container found in each domain naming context. It is normally hidden from view in the Active Directory Users and Computers snap-in but can be made visible by selecting “Advanced Features” from the snap-in View menu inside MMC. (Objects appear hidden in the Active Directory Users and Computers snap-in when they have the property showInAdvancedViewOnly = TRUE.) Group Policy information is stored in the Policies subcontainer of this container. Each GPO is identified by a GroupPolicyContainer object stored within the Policies container.

The Group Policy container is located in the **Domain_Name/System/Policies** container. Each Group Policy container is given a common name (CN) and this name is also assigned as the container name. For example, the name attribute of a Group Policy container, might be: {923B9E2F-9757-4DCF-B88A-1136720B5AF2}, which is also assigned to the Group Policy container's CN attribute.

The default GPOs are assigned the same Group Policy container CN on all domains. All other GPOs are assigned a unique CN. The default GPOs and their Group Policy container common names are:

- Default Domain Policy: {31B2F340-016D-11D2-945F-00C04FB984F9}.
- Default Domain Controllers Policy: {6AC1786C-016F-11D2-945F-00C04fB984F9}.

Knowing the common names of the default GPOs will help you distinguish them from non-default GPOs.

**How a Group Policy Container is Named**

Group Policy containers are named automatically when they are created. The CN of each Group Policy container is a GUID (Globally Unique Identifier). This is distinct from and unrelated to the Object GUID given to each Active Directory object. The CN is the name of the Group Policy container used to ensure uniqueness of Group Policy container names within the Policies container. There is no requirement for these GUIDs to be unique between domains (the Default Domain Policy and the Default Domain Controllers Policy GPOs each have identical GUIDs in all Active Directory installations). However, an Object GUID is always unique across all installations of the Active Directory store.

The following table shows permissions on Group Policy container:

**Default Group Policy Container Permissions**

| Trustee | Access |
|---|---|
| Authenticated Users | Read, Apply Group Policy |
| Domain Admins | Read, Write |
| System | Read, Write |

**GPO Attributes in the Policies CN**

GPOs are created by instantiating the groupPolicyContainer class in the Active Directory schema and storing the resulting GPO in the System/Policies container of the Active Directory store. After creating a GPO, you can review its CN from the Active Directory Users and Computers snap-in by enabling the Advanced view and then expanding the Policies CN. You can review all GPO attributes and their values from the Active Directory Services Interface Editor snap-in, ADSI Edit.

Object attributes are either mandatory or optional, as defined in the Active Directory schema. The CN attribute is mandatory for the class **Container**, Group Policy container's parent class. Three attributes — instanceType, objectCategory, and objectClass — are mandatory for the class **Top**, CN's parent class. Thus the Group Policy container class inherits all four mandatory attributes. The following table describes the mandatory attributes:

**Mandatory Attributes of the groupPolicyContainer Class**

| Name | Description |
|---|---|
| CN | The common name of the GPO. This is in the form of a GUID to avoid GPO naming conflicts within the Policies container. |
| instanceType | An attribute that dictates how an object is instantiated from its class on a particular server. In this case, it describes how the groupPolicyContainer class is created into a GPO in the Active Directory. A GPO is assigned the instanceType value of 4. |
| objectCategory | An object class name, including the object's path, used to group object's of the instantiated class. For example, the objectCategory of a GPO in the contoso.com domain is: CN=Group-Policy-Container,CN=Schema,CN=Configuration,DC=contoso,DC=com. |
| objectClass | The list of classes from which this class is derived. For a GPO, the objectClass is Container, groupPolicyContainer, and top. |

There are also a number of optional attributes inherited from the top class, and others that are assigned directly to the Group Policy container. Many optional attributes are required in order for the Group Policy container to function properly. For example, the GPCFileSysPath optional attribute must be present or the Group Policy container will not be linked to its corresponding Group Policy template.

**GroupPolicyContainer Subcontainers**

Within the GroupPolicyContainer there are a series of subcontainers. The first level of subcontainers — User and Machine — belong to the class Container. These two containers are used to separate some User-specific and Computer-specific Group Policy components.

**Group Policy Container-Related Attributes of Domain, Site, and OU Containers**

Windows Server 2003 uses domain, DNS, site, and organizational unit classes to create domain, site, and OU container objects respectively. These objects contain two optional Group Policy container-related attributes, **gPLink** and **gPOptions**. The **gPLink**

property contains the prioritized list of GPOs and the **gPOptions** property contains the Block Policy Inheritance setting.

The **gPLink** attribute holds a list of all Group Policy containers linked to the container and a number for each listed Group Policy container, that represents the **Enforced** (previously known as No Override) and **Disabled** option settings. The list appears in priority order from lowest to highest priority GPO.

The **gPOptions** attribute holds an integer value that indicates whether the Block Policy Inheritance option of a domain or OU is enabled (1) or disabled (0).

**Managing Group Policy Links for a Site, Domain, or OU**
To manage GPO links to a site, domain, or OU, you must have read and write access to the **gPLink** and **gPOptions** properties. By default, Domain Admins have this permission for domains and organizational unit, and only Enterprise Admins and Domain Admins of the forest root domain can manage links to sites. Active Directory supports security settings on a per-property basis. This means that a non-administrator can be delegated read and write access to specific properties. In this case, if non-administrators have read and write access to the gPLink and gPOptions properties, they can manage the list of GPOs linked to that site, domain, or OU.

**How WMIPolicy Objects are Stored and Associated with Group Policy Container Objects**
A single WMI filter can be assigned to a Group Policy container. The Group Policy container stores the distinguished name of the filter in **gPCWQLFilter** attribute. The Group Policy container locates the assigned filter in the System/WMIPolicy/SOM container. Each Windows Server 2003 domain stores its WMI filters in this Active Directory container. Each WMI filter stored in the SOM container lists the rules that define the WMI filter. Each rule is listed separately. For example, consider a WMI filter containing the following three WQL queries:

```
SELECT * FROM Win32_Product WHERE IdentifyingNumber = "{5E076CF2-EFED-43A2-A623-
13E0D62EC7E0}"
SELECT * FROM Win32_Product WHERE IdentifyingNumber = "{242365CD-80F2-11D2-989A-
00C04F7978A9}"
SELECT * FROM Win32_Product WHERE IdentifyingNumber = "{00000409-78E1-11D2-B60F-
006097C998E7}"
```

Three WMI rules are defined in the details of the filter. Each rule contains a number of attributes, including the query language (WQL) and the WMI namespace queried by the rule.

**Group Policy Template**
The majority of Group Policy settings are stored in the file system of the domain controllers. This part of each GPO is known as the Group Policy template. The GroupPolicyContainer object for each GPO has a property, GPCFileSysPath, which contains the UNC path to its related Group Policy template.

All Group Policy templates in a domain are stored in the ***domain_name*\Sysvol*domain_name*\Policies** folder, where domain_name is the FQDN of the domain. The Group Policy template for the most part stores the actual data for the policy extensions, for example Security Settings inf file, Administrative Template-based policy settings .adm and .pol files, applications available for the Group Policy Software installation extension, and potentially scripts.

**The Gpt.ini File**
The Gpt.ini file is located at the root of each Group Policy template. Each Gpt.ini file contains GPO version information. Except for the Gpt.ini files created for the default GPOs, a display name value is also written to the file.

Each Gpt.ini file contains the GPO version number of the Group Policy template.

```
[General]
Version=65539
```

Normally, this is identical to the version-number property of the corresponding GroupPolicyContainer object. It is encoded in the same way — as a decimal representation of a 4 byte hexadecimal number, the upper two bytes of which contain the GPO user settings version and the lower two bytes contain the computer settings version. In this example the version is equal to 10003 hexadecimal giving a user settings version of 1 and a computer settings version of 3.

Storing this version number in the Gpt.ini allows the CSEs to check if the client is out of date to the last processing of policy settings or if the currently applied policy settings (cached policies) are up-to-date. If the cached version is different from the version in the Group Policy template or Group Policy container, then policy settings will be reprocessed.

**Group Policy Template Subfolders**
The Group Policy template folder contains the following subfolders:

- **Machine.** Includes a Registry.pol file that contains the registry settings to be applied to computers. When a computer initializes, this Registry.pol file is downloaded and applied to the **HKEY_LOCAL_MACHINE** portion of the registry. The **Machine** folder can contain the following subfolders (depending on the contents of the GPO):
    - **Scripts\Startup.** Contains the scripts that are to run when the computer starts up.
    - **Scripts\Shutdown.** Contains the scripts that are to run when the computer shuts down.
    - **Applications.** Contains the advertisement files (.aas files) used by the Windows installer. These are applied to computers.
    - **Microsoft\Windows NT\Secedit.** Contains the Gpttmpl.inf file, which includes the default security configuration settings for a Windows Server 2003 domain controller.
    - **Adm.** Contains all of the .adm files for the GPO.
- User. Includes a Registry.pol file that contains the registry settings to be applied to users. When a user logs on to a computer, this Registry.pol file is downloaded and applied to the HKEY_CURRENT_USER portion of the registry. The User folder can contain the following subfolders (depending on the contents of the GPO):
    - **Applications.** Contains the advertisement files (.aas files) used by the Windows installer. These are applied to users.
    - **Documents and Settings.** Contains the Fdeploy.ini file, which includes status information about the Folder Redirection options for the current user's special folders.
    - **Microsoft\RemoteInstall.** Contains the OSCfilter.ini file, which holds user options for operating system installation through Remote Installation Services.
    - **Microsoft\IEAK.** Contains settings for the Internet Explorer Maintenance snap-in.
    - **Scripts\Logon.** Contains all the user logon scripts and related files for this GPO.
    - **Scripts\Logoff.** Contains all the user logoff scripts and related files for this GPO.

The User and Machine folders are created at install time, and the other folders are created as needed when policy is set.

The permissions of each Group Policy template reflect the read and write permissions applied to the GroupPolicyContainer through the Group Policy Object Editor. These permissions are automatically maintained and are shown in the following table.

**Default Group Policy Template Permissions**

| Trustee | Access |
|---|---|
| Authenticated Users | Read and Execute |
| Administrators | Full Control |
| Group Policy Creator Owners | Read and Execute |
| Creator Owner | Full Control (Subfolders and Files only) |
| System | Full Control |

**Group Policy Object Editor use of Sysvol**

Each policy setting changed in a GPO causes at least two files to be rewritten — the GPT.ini and the file holding the changed setting. Making many changes to a GPO can cause a lot of network traffic as Sysvol replicates these changes. This congestion should only occur on a local area network where Sysvol replication occurs frequently. Across wide area network links, the

inter-site replication schedule will cause these changes to be amalgamated into a smaller amount of traffic (for example, four changes to the Registry.pol file will result in only a single file replication).

#### The Local Group Policy Object

The Local GPO has no Active Directory component. Information stored in the Group Policy container of an Active Directory GPO is instead stored in the Group Policy template of a Local GPO. The Group Policy template of a Local GPO is located in the **Windows\system32\GroupPolicy** folder. The Gpt.ini file in this GroupPolicy folder must hold more management information than its counterpart in a domain-based GPO because there is no Active Directory component to hold this information. The following table shows the attributes for the Group Policy template.ini file.

**Local GPO GPT.INI Attributes**

| Attribute | Description |
|---|---|
| gPCUserExtensionNames | Includes a list of GUIDs that tells the client-side engine which CSEs have User data in the GPO.<br><br>The format is: [{GUID of CSE}{GUID of MMC extension}{GUID of second MMC extension if appropriate}][repeat first section as appropriate]. |
| GPCMachineExtensionNames | Includes a list of GUIDs that tells the client-side engine which CSEs have computer data in the GPO. |
| Options | Refers to GPO options such as User portion disabled or Computer portion disabled. |

The following extensions are disabled in a Local GPO:

- Group Policy Software installation extension
- Folder Redirection

The following extensions have reduced functionality in a Local GPO:

- Public Key policies; EFS only; there are not any options for trust lists or auto enrollment.
- Security Settings; there are not any options for Restricted Groups or File System, Registry or Service Access Control Lists (ACLs).

#### Core Group Policy Processes and Interactions

Application of GPOs to targeted users and computers relies on many interactive processes. This section explains how GPOs are applied and filtered to Active Directory containers such as sites, domains, and OUs. It includes information about how the Group Policy engine processes GPOs in conjunction with CSEs. In addition, it explains how Group Policy is replicated among domain controllers.

#### Group Policy Processing Rules

GPOs that apply to a user or computer do not all have the same precedence. Settings that are applied later can override settings that are applied earlier. Group Policy settings are processed in the following order:

- **Local Group Policy object.** Each computer has exactly one Group Policy object that is stored locally. This processes for both computer and user Group Policy processing.
- **Site.** Any GPOs that have been linked to the site that the computer belongs to are processed next. Processing is in the order that is specified by the administrator, on the Linked Group Policy Objects tab for the site in GPMC. The GPO with the lowest link order is processed last, and therefore has the highest precedence.
- **Domain.** Processing of multiple domain-linked GPOs is in the order specified by the administrator, on the Linked Group Policy Objects tab for the domain in GPMC. The GPO with the lowest link order is processed last, and therefore has the highest precedence.
- **Organizational units.** GPOs that are linked to the organizational unit that is highest in the Active Directory hierarchy are processed first, then GPOs that are linked to its child organizational unit are processed, and so on. Finally, the GPOs that are linked to the organizational unit that contains the user or computer are processed.

To summarize, the Local GPO is processed first, and the organizational unit to which the computer or user belongs (the one that it is a direct member of) is processed last. All of this processing is subject to the following conditions:

- WMI or security filtering that has been applied to GPOs.

- Any domain-based GPO (not Local GPO) can be enforced by using the **Enforce** option so that its policies cannot be overwritten. Because an Enforced GPO is processed last, no other settings can write over the settings in that GPO. If you have more than one Enforced GPO, it's possible to set the same setting in each GPO to a different value, in which case, the link order of the GPOs determines which one contains the final settings.

- At any domain or organizational unit, Group Policy inheritance can be selectively designated as **Block Inheritance.** However, because enforced GPOs are always applied, and cannot be blocked, blocking inheritance does not prevent policy from **Enforced** GPOs from applying.

Every computer has a single Local GPO that is always processed regardless of whether the computer is part of a domain or is a stand-alone computer. The Local GPO can't be blocked by domain-based GPOs. However, settings in domain GPOs always take precedence since they are processed after the Local GPO.

**Targeting GPOs**

The site, domain, and OU links from a GPO are used as the primary targeting principle for defining which computers and users should receive a GPO. Security filtering and WMI filtering can be used to further reduce the set of computers and users to which the GPO will apply. The Group Policy engine uses the following logic in processing GPOs: If a GPO is linked to a domain, site, or OU that applies to the user or computer, the Group Policy engine must then determine whether the GPO should be added to its GPO list for processing. A GPO is blocked from processing in the following circumstances:

- **The GPO is disabled.** You disable either or both the computer or user components of a GPO from its Policy Properties dialog box.

- **The computer or user does not have permission to read and apply the GPO.** You control permission to a GPO through security filtering, as explained in the following section.

- **A WMI filter applied to a GPO evaluates to false on the client computer.** A WMI filter must evaluate to true before the Group Policy engine will allow it to be processed, as explained in the following section.

**Security Filtering**

Security filtering is a way of refining which users and computers will receive and apply the settings in a GPO. By using security filtering to specify that only certain security principals within a container where the GPO is linked apply the GPO, you can narrow the scope of a GPO so that it applies only to a single group, user, or computer. Security filtering determines whether the GPO as a whole applies to groups, users, or computers; it cannot be used selectively on different settings within a GPO.

In order for the GPO to apply to a given user or computer, that user or computer must have both **Read** and **Apply Group Policy (AGP)** permissions on the GPO, either explicitly, or effectively though group membership.

By default, all GPOs have **Read** and **AGP** both **Allowed** for the Authenticated Users group. The Authenticated Users group includes both users and computers. This is how all authenticated users receive the settings of a new GPO when it is applied to an organizational unit, domain or site. Therefore, the default behavior is for every GPO to apply to every Authenticated User. By default, Domain Admins, Enterprise Admins, and the local system have full control permissions, without the Apply Group Policy access-control entry (ACE). However, administrators are members of Authenticated Users, which means that they will receive the settings in the GPO by default.

These permissions can be changed to limit the scope to a specific set of users, groups, or computers within the organizational unit, domain, or site. The Group Policy Management Console manages these permissions as a single unit, and displays the security filtering for the GPO on the GPO Scope tab. In GPMC, groups, users, and computers can be added or removed as security filters for each GPO.

**How Security Filtering is Processed**

Before processing a GPO, the Group Policy engine checks the Access Control List ACL associated with the GPO. If an ACE on a GPO denies a security principal to which the computer or user belongs, either the Apply Group Policy or Read permission, the Group Policy engine does not add the GPO to its list of GPOs to process. Additionally, an ACE on a GPO must allow the

appropriate security principal both Apply Group Policy and Read permissions in order for the Group Policy engine to add the GPO to the GPO processing list.

If appropriate permissions are granted to the GPO, it is added to the list of GPOs to download.

In general, **Deny** ACEs should be avoided because you can achieve the same results by granting or not granting **Allow** permissions.

**Windows Management Instrumentation (WMI) Filtering**
WMI makes data about a target computer available for administrative use. Such data can include hardware and software inventory, settings, and configuration information. For example, WMI exposes hardware configuration data such as CPU, memory, disk space, and manufacturer, as well as software configuration data from the registry, drivers, file system, Active Directory, the Windows Installer service, networking configuration, and application data.

WMI filtering allows you to filter the application of a GPO by attaching a Windows Query Language query to a GPO. The queries can be written to query WMI for multiple items. If the query returns true for all queried items, then the GPO will be applied to the target user or computer.

When a GPO that is linked to a WMI filter is applied on the target computer, the filter is evaluated on the target computer. If the WMI filter evaluates to false, the GPO is not applied (except if the client computer is running Windows 2000, in which case the filter is ignored and the GPO is always applied). If the WMI filter evaluates to true, the GPO is applied.

The WMI filter is a separate object from the GPO in the directory. A WMI filter must be linked to a GPO in order to apply. Each GPO can have only one WMI filter; however the same WMI filter can be linked to multiple GPOs. WMI filters, like GPOs, are stored only in domains. A WMI filter and the GPO it is linked to must be in the same domain.

**How Windows Management Instrumentation (WMI) Filtering is Processed**
If, after security filtering, appropriate permissions are granted to the GPO, it is added to the list of GPOs to download. Upon download, the Group Policy engine reads the **gPCWQLFilter** attribute in the Group Policy container to determine if a WMI filter is applied to the GPO. If so, the WMI filter, which contains one or more WQL statements, is evaluated. If the statement evaluates to true, then the GPO is processed. There are tradeoffs in using WMI filters because they can increase the amount of time it takes to process policy especially if the filter to be evaluated takes a long time to process.

**Windows Management Instrumentation (WMI)Filtering Scenarios**
Sample uses of WMI filters include:

- Services. Computers where DHCP is turned on.
- Registry. Computers that have this registry key populated.
- Hardware inventory. Computers with a Pentium III processor.
- Software inventory. Computers with Visual Studio .NET installed.
- Hardware configuration. Computers with network interface cards (NICs) on interrupt level 3.
- Software configuration. Computers with multi-casting turned on.
- Associations. Computers that have any services dependent on Systems Network Architecture (SNA) service.

Client support for WMI filters exists only on Windows XP, Windows Server 2003, and later operating systems. Windows 2000 clients will ignore any WMI filter and the GPO is always applied, regardless of the WMI filter. WMI filters are only available in domains that have at least one Windows Server 2003 domain controller.

**Application of Group Policy**
Application of Group Policy involves a series of processes, beginning with user and computer logon.

**Initial Processing of Group Policy**
Group Policy for computers is applied at computer startup. For users, Group Policy is applied when they log on. In Windows 2000, the processing of Group Policy is synchronous, which means that computer Group Policy is completed before the logon dialog box is presented, and user Group Policy is completed before the shell is active and available for the user to interact with it. As explained in the following section, Windows XP with Fast Logon-enabled (which is the default setting) allows users to log

on while Group Policy is processed in the background.)

**Synchronous and Asynchronous Processing**
Synchronous processes can be described as a series of processes where one process must finish running before the next one begins. Asynchronous processes, on the other hand, can run on different threads simultaneously because their outcome is independent of other processes.

You can change the default processing behavior by using a policy setting for each GPO so that processing is asynchronous instead of synchronous. For example, if the policy has been set to remove the **Run** command from the **Start** menu, it is possible under asynchronous processing that a user could logon prior to this policy taking effect, so the user would initially have access to this functionality.

**Fast Logon in Windows XP Professional**
By default in Windows XP Professional, the Fast Logon Optimization feature is enabled for both domain and workgroup members. This means that policy settings apply asynchronously when the computer starts and when the user logs on. This process of applying policies is similar to a background refresh process. As a result, users can logon and begin using the Windows shell faster than they would with synchronous processing. Fast Logon Optimization is always off during logon under the following conditions:

- When a user first logs on to a computer.
- When a user has a roaming user profile or a home directory for logon purposes.
- When a user has synchronous logon scripts.

Note that under the preceding conditions, computer startup can still be asynchronous. However, because logon is synchronous under these conditions, logon does not exhibit optimization. The following table compares policy processing of Windows 2000 and Windows XP client computers.

**Default Policy Processing for Client Computers**

| Client | Application at startup/log on | Application at refresh |
|---|---|---|
| Windows 2000 | Synchronous | Asynchronous |
| Windows XP Professional | Asynchronous | Asynchronous |

Windows XP clients support Fast Logon Optimization in any domain environment. Fast Logon Optimization can be disabled with the following policy setting:

**Computer Configuration\Administrative Templates\System\Logon\ Always wait for the network at computer startup and logon.**

Note that Fast Logon Optimization is not a feature of Windows Server 2003.

**Folder Redirection and Software Installation Policies**
Note that when Fast Logon Optimization is on, a user might need to log on to a computer twice before folder redirection policies and software installation policies are applied. This occurs because the application of these types of policies requires the synchronous policy application. During a policy refresh (which is asynchronous), the system sets a flag indicating that the application of folder redirection or a software installation policy is required. The flag forces synchronous application of the policy at the user's next logon.

**Time Limit for Processing of Group Policy**
Under synchronous processing, there is a time limit of 60 minutes for all of Group Policy to finish processing on the client computer. Any CSEs that are not finished after 60 minutes are signaled to stop, in which case the associated policy settings might not be fully applied.

**Background Refresh of Group Policy**
In addition to the initial processing of Group Policy at startup and logon, Group Policy is applied subsequently in the background on a periodic basis. During a background refresh, a CSE will only reapply the settings if it detects that a change was made on the server in any of its GPOs or its list of GPOs.

In addition, software installation and folder redirection processing occurs only during computer startup or user logon. This is because background processing could cause undesirable results. For example, in software installation, if an application is no

longer assigned, it is removed. If a user is using the application while Group Policy tries to uninstall it or if an assigned application upgrade takes place while someone is using it, errors would occur. Although the Scripts CSE is processed during background refresh, the scripts themselves only run at startup, shutdown, logon, and logoff, as appropriate.

**Periodic Refresh Processing**
By default, Group Policy is processed every 90 minutes with a randomized delay of up to 30 minutes — for a total maximum refresh interval of up to 120 minutes.

Group Policy can be configured on a per-extension basis so that a particular extension is always processed during processing of policy even if the GPOs haven't changed. Policy settings for each extension are located in **Computer Configuration\Administrative Templates\System\Group Policy**.

**On-Demand Processing**
You can also trigger a background refresh of Group Policy on demand from the client. However, the application of Group Policy cannot be pushed to clients on demand from the server.

**Messages and Events**
When Group Policy is applied, a **WM_SETTINGCHANGE** message is sent, and an event is signaled. Applications that can receive window messages can use them to respond to a Group Policy change. Those applications that do not have a window to receive the message (as with most services) can wait for the event.

**Refreshing Policy from the Command Line**
You can update or refresh Group Policy settings manually through a command line tool. On Windows 2000, you can use Secedit with the /refreshpolicy option; on Windows XP and Windows Server 2003, you can use Gpupdate.

**Group Policy and Slow Links**
When Group Policy detects a slow link, it sets a flag to indicate to CSEs that a policy setting is being applied across a slow link. Individual CSEs can determine whether or not to apply a policy setting over the slow link. The default settings are as follows:

### Default Slow Link Settings

| Extension | Default Setting |
|---|---|
| Security Settings | On (and cannot be turned off) |
| Administrative Templates | On (and cannot be turned off) |
| Software Installation | Off |
| Scripts | Off |
| Folder Redirection | Off |

**Group Policy Loopback Support**
Group Policy is applied to the user or computer, based on where the user or computer object is located in Active Directory. However, in some cases, users might need policy applied to them, based on the location of the computer object, not the location of the user object. The Group Policy loopback feature gives you the ability to apply User Group Policy, based on the computer that the user is logging onto. The following figure shows a sample site, domain, and OU structure and is followed by a description of the changes that can occur with loopback processing.

### Sample Active Directory Structure

Normal user Group Policy processing specifies that computers located in the Servers organizational unit have the GPOs A3, A1, A2, A4, and A6 applied (in that order) during computer startup. Users of the Marketing organizational unit have GPOs A3, A1, A2, and A5 applied (in that order), regardless of which computer they log on to.

In some cases this processing order might not be what you want. An example is when you do not want applications that have been assigned or published to the users of the Marketing organizational unit to be installed while they are logged on to the computers in the Servers organizational unit. With the Group Policy loopback feature, you can specify two other ways to retrieve the list of GPOs for any user of the computers in the Servers organizational unit:

- Merge mode. In this mode, the computer's GPOs have higher precedence than the user's GPOs. In this example, the list of GPOs for the computer is A3, A1, A2, A4, and A6, which is added to the user's list of A3, A1, A2, A5, resulting in A3, A1, A2, A5, A3, A1, A2, A4, and 9A6 (listed in lowest to highest priority).

- Replace mode. In this mode, the user's list of GPOs is not gathered. Only the list of GPOs based upon the computer object is used. In this example, the list is A3, A1, A2, A4, and A6.

The loopback feature can be enabled by using the **User Group Policy loopback processing mode** policy under **Computer Settings\Administrative settings\System\Group Policy.**

The processing of the loopback feature is implemented in the Group Policy engine. When the Group Policy engine is about to apply user policy, it looks in the registry for a computer policy, which specifies which mode user policy should be applied in.

**How the Group Policy Engine Processes Client-Side Extensions**
Client-side extensions are the components running on the client system that process and apply the Group Policy settings to that system. There are a number of extensions that are pre-installed in Windows Server 2003. Other Microsoft applications and third party application vendors can also write and install additional extensions to implement Group Policy management of these applications.

The default Windows Server 2003 CSEs are listed in the following table:

Default Windows Server 2003 CSEs

| Client-Side Extension | Active Directory Component | Sysvol Component |
|---|---|---|
| Software Installation | PackageRegistration objects | .aas files |
| Security Settings | | Gptmpl.inf |
| Folder Redirection | | fdeploy.ini |
| Scripts | | Scripts.ini |
| IP Security | IPSec Policy objects | |
| Internet Explorer Maintenance | | .ins + branding .inf files. |
| Administrative Templates | | Registry.pol and .adm files |
| Disk Quota | | Registry.pol |
| EFS Recovery | | Registry.pol |
| Remote Installation | | Oscfilter.ini |
| Wireless Network Policies | | Registry.pol and .adm files |
| QoS Packet Scheduler | | Registry.pol and .adm files |

**Client-Side Extension Operation**
CSEs are called by the Winlogon process at computer startup, user logon and at the Group Policy refresh interval. CSEs are registered with Winlogon in the registry. This registration information includes a DLL and a DLL entry point (function call) by which the CSE processing can be initiated. The Winlogon process uses these to trigger Group Policy processing.

Each extension can opt not to perform processing at any of these points (for example, avoid processing during background

refresh).

**Client-Side Extensions Registered with WinLogon**
Each of the CSEs is registered under the following key:

**HKEY_LOCAL_MACHINE\Software\Microsoft\WindowsNT\CurrentVersion\Winlogon\GPExtensions**

Each extension is identified by a key named after the GUID of the extension. These extensions are shown in the following table.

**CSE Extensions**

| Extension GUID | Extension Name |
|---|---|
| 25537BA6-77A8-11D2-9B6C-0000F8080861 | Folder Redirection |
| 35378EAC-683F-11D2-A89A-00C04FBBCFA2 | Administrative Templates Extension |
| 3610EDA5-77EF-11D2-8DC5-00C04FA31A66 | Disk Quotas |
| 426031c0-0b47-4852-b0ca-ac3d37bfcb39 | QoS Packet Scheduler |
| 42B5FAAE-6536-11D2-AE5A-0000F87571E3 | Scripts |
| 827D319E-6EAC-11D2-A4EA-00C04F79F83A | Security |
| A2E30F80-D7DE-11d2-BBDE-00C04F86AE3B | Internet Explorer Maintenance |
| B1BE8D72-6EAC-11D2-A4EA-00C04F79F83A | EFS Recovery |
| C6DC5466-785A-11D2-84D0-00C04FB169F7 | Software Installation |
| E437BC1C-AA7D-11D2-A382-00C04F991E27 | IP Security |

**How Group Policy Processing History Is Maintained on the Client Computer**
Each time GPOs are processed, a record of all of the GPOs applied to the user or computer is written to the registry. GPOs applied to the local computer are stored in the following registry path:

**HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion\Group Policy\History**

GPOs applied to the currently logged on user are stored in the following registry path:

**HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Group Policy\History**

**Preferences and Policy Configuration**
Manipulating these registry values directly is not recommended. Most of the items in which you might need to change the behavior of an extension (such as forcing a CSE to run over a slow link), are available as Group Policy settings. These can be found in the Group Policy Object Editor in the following location:

**Computer Settings\Administrative Templates\System\Group Policy**

The behavior can be changed for the following CSEs:

- Administrative Templates (Registry-based policy)
- Internet Explorer Maintenance
- Software Installation
- Folder Redirection
- Scripts
- Security

- IP Security
- EFS recovery
- Disk Quotas

**Order of Extension Processing**
Administrative Templates policy settings are always processed first. Other extensions are processed in an indeterminate order.

**Policy Application Processes**
There are two primary milestones that the Group Policy engine uses for GPO processing:

- Creating the list of GPOs targeted at the user or computer.
- Invoking the relevant CSEs to process the policy settings relevant to them within the GPO list.

The following figure shows the steps required to reach the first milestone in GPO processing, GPO list creation.

**GPO List Creation**

Creating the GPO list involves the following steps:

1. Query the Active Directory for the **gPLink** and **gPOptions** properties in the Site and Domain hierarchies to which the user or computer object belongs.
2. Query the Active Directory for the GroupPolicyContainer objects referenced in the **gPLink** properties.
3. Evaluate security filtering to determine if the user or computer have the Apply Group Policy access permission to the GPO.
4. Evaluate the WMI query against the WMI repository on the client computer to determine if the computer meets the query requirements.

Once the GPO list is created, the Group Policy engine and the CSEs work together to process Group Policy template components. The following figure shows the steps required to determine which CSEs to call.

**Determining CSEs to Call**

Determining which CSEs to call involves the following steps:

1. Retrieve the list of CSEs registered with Winlogon.

2. Check to see whether it is appropriate to run a particular CSE (for example, whether background processing or slow link processing is enabled for the extension).

3. Check the CSE history against list of Applied GPOs. GPOs with new version numbers and GPOs that have settings relevant to the CSE (that is, they have the CSE extension GUID in the Group Policy container gpcUserExtension or gpcMachineExtension properties) are added to the Changed GPO List. GPOs no longer in the Applied GPO List are added to the Deleted GPO List.

4. Check to see whether the appropriate CSE should be processing policy settings for the user or the computer.

5. Check the version number listed in the GPO against its recorded version history in the registry to determine whether the GPO needs reprocessing.

If all of the version numbers are unchanged the MaxNoGPOListChanges interval might have expired; if so, the CSE processes policy settings without regard to an unchanged version number.

Steps 3 through 5 are repeated by each CSE for all GPOs in the GPO list. After one CSE is done, the next CSE that needs to run repeats the entire process.

Group Policy updates are dynamic and occur at specific intervals. If there have been no changes to Group Policy, the client computer still refreshes the security policy settings at regular intervals for the GPO.

If no changes are discovered, GPOs are not processed. Security policies have a periodic force apply every 16 hours. For security policies, there is a value that sets a maximum limit of how long a client can function without reapplying non-changed GPOs. By default, this setting is every 16 hours plus a randomized delay of up to 30 minutes. Even when GPOs that contain security policy settings do not change, the policy is reapplied every 16 hours

**Group Policy Replication**
In a domain that contains more than one domain controller, Group Policy information takes time to propagate, or replicate, from one domain controller to another. Low bandwidth network connections between domain controllers slow replication. The Group Policy infrastructure has mechanisms to manage these issues.

Each GPO is stored partly in the Sysvol on the domain controller and partly in Active Directory. GPMC and Group Policy Object Editor present and manage the GPO as a single unit. For example, when you set permissions on a GPO in GPMC, GPMC is actually setting permissions on objects in both Active Directory and the Sysvol. It is not recommended that you manipulate these separate objects independently outside of GPMC and the Group Policy Object Editor. As shown in the following figure, it is important to understand that these two separate components of a GPO rely on different replication mechanisms. The file system portion is replicated through FRS, independently of the replication handled by Active Directory. Only the Sysvol subfolder (%systemroot%\SYSVOL\sysvol) is shared and replicated. Sysvol was designed to allow multiple domain's Sysvols to be replicated in the same tree — each domain's Sysvol is contained under a subfolder of the Sysvol share. For the current domain, a copy of the domain's Sysvol subtree is also stored directly under the **%systemroot%\SYSVOL\domain** folder.

**Group Policy Replication**

FRS is a multi-master replication service that synchronizes folders between two or more Windows Server 2003 or Windows 2000 systems. Modified files are queued for replication at the point the file is closed. In the case of conflicting modifications between two copies of an FRS replica, the file with the latest modification time will overwrite any other copies. This is referred to as a "last-writer-wins" model.

FRS replication topology configuration is stored as a combination of child objects of each FRS replica partner (in the FRS Subscriptions subcontainer) and objects within another hidden subcontainer of the domain System container. Replication links between systems are maintained as FRS subscription objects. These objects specify the replica partner and the replication schedule. It is possible to view the schedule by browsing to an FRS subscription object and viewing the properties. The replica partner is stored as the object GUID of the computer account of that partner.

The Sysvol folder is a special case of FRS replication. Active Directory automatically maintains the subscription objects and their schedules as the directory replication is built and maintained. It is possible, but not recommended, to modify the properties (for example, the schedule) of the Sysvol subscription objects manually.

The FRS replication schedule only approximates to the directory replication schedule so it is possible for the directory-based Group Policy information and the file-based information to get temporarily out of synch. Since GPO version information is stored in both the Group Policy container object and in the Group Policy template, any discrepancy can be viewed with tools such as Gpotool.exe and Repadmin.exe.

For those Group Policy extensions that store data in only one data store (either Active Directory or Sysvol), this is not an issue, and Group Policy is applied as it can be read. Such extensions include Administrative Templates, Scripts, Folder Redirection, and most of the Security Settings.

For any Group Policy extension that stores data in both storage places (Active Directory and Sysvol), the extension must properly handle the possibility that the data is unsynchronized. This is also true for extensions that need multiple objects in a single store to be atomic in nature, since neither storage location handles transactions.

An example of an extension that stores data in Active Directory and Sysvol is Group Policy Software installation extension. The .aas files are stored on Sysvol and the Windows Installer package definition is in Active Directory. If the .aas file exists, but the corresponding Active Directory components are not present, the software is not installed. If the .aas file is missing, but the package is known in Active Directory, application installation fails gracefully and will be retried on the next processing of Group Policy.

The tools used to manage Active Directory and Group Policy, such as GPMC, the Group Policy Object Editor, and Active Directory Users and Computers all communicate with domain controllers. If there are several domain controllers available, changes made to objects like users, computers, organizational units, and GPOs might take time to appear on other domain controllers. The administrator might see different data depending on the last domain controller on which changes were made and which domain controller they are currently viewing the data from.

If multiple administrators manage a common GPO, it is recommended that all administrators use the same domain controller when editing a particular GPO, to avoid collisions in FRS. Domain Admins can use a policy to specify how Group Policy chooses a domain controller — that is, they can specify which domain controller option should be used. The Group Policy domain controller selection policy setting is available in the Administrative Templates node for User Configuration, in the System\Group Policy subcontainer.

**Network Ports Used by Group Policy**

### Port Assignments for Group Policy

| Service Name | UDP | TCP |
|---|---|---|
| Lightweight Directory Access Protocol | n/a | 389 |
| SMB | n/a | 445 |
| DCOM | Dynamicallly assigned | Dynamically assigned |
| RPC | Dynamically assigned | Dynamically assigned |

# Core Group Policy Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Group Policy Tools
- Group Policy Settings
- Group Policy WMI Classes
- Related Information

This section summarizes the tools and settings associated with Group Policy.

**Group Policy Tools**
The following is a list of administrative tools associated with Group Policy. For more information about Group Policy administrative tools, see the following topics in this collection:

- Group Policy Administrative Tools
- Group Policy Object Editor Tools and Settings
- Group Policy Management Console Technical Reference
- What Is Resultant Set of Policy?

For information about tools specific to Group Policy extensions, see the appropriate Group Policy Components topics in this collection. For more information about other Resource Kit tools, see the Windows Server 2003 Deployment Kit Tools page.

**GPUpdate.exe**
This tool is used for refreshing local and Active Directory policy settings on the computer from which you run the **GPUpdate** command.

**Category**
This command-line tool is included in Windows XP and Windows Server 2003.

**Version compatibility**
You can use GPUpdate locally on Windows XP and higher computers to refresh policy immediately. On computers running Windows 2000, this behavior is provided by the using the secedit.exe command line tool, with a specific parameter.

GPUpdate refreshes local Group Policy settings and Group Policy settings that are stored in Active Directory, including security settings, on the computer from which it is run. This command supersedes the now obsolete **/refreshpolicy** option for the secedit command line tool. For more information about GPUpdate, type **GPUpdate /?** at the command line.

**GPResult.exe**
GPResult.exe is a Group Policy tool for examining the settings applied during Group Policy refresh.

**Category**
There are two versions of GPResult: One shipped with the Windows 2000 Resource Kit; the other is included with Windows XP and Windows Server 2003. The Windows 2000 version runs only locally on Windows 2000. The windows Server 2003 version runs locally or remotely on Windows XP or Windows Server 2003.

The different versions are not compatible.

**Version compatibility**
GPResult utilizes Resultant Set of Policy (RSoP) data. You can use GPResult that shipped with Windows Server 2003 family on Windows XP and higher computers. You can use GPResult that shipped with Windows 2000 Resource Kit for Windows 2000.

GPResult for Windows Server 2003 displays Group Policy settings and Resultant Set of Policy (RSoP) for a user or a computer. Because you can apply overlapping levels of policies to any computer or user, the Group Policy feature generates a resulting set of policies at logon. GPResult displays the resulting set of policies that were enforced on the computer for the specified user at logon.

GPResult for Windows 2000 estimates the Group Policy settings that would be applied at a specific computer. Full documentation for this version of GPResult is available in the readme file distributed with the tool.

**Dcgpofix.exe: Dcgpofix**
**Category**
Dcgpofix ships with Windows Server 2003.

**Version compatibility**
You can run Dcgpofix only on servers running Windows Server 2003 family. This tool can restore default domain policy and default domain controllers policy to their original state after installation, except for some security-related settings that are impossible to return to their exact original state. When you run Dcgpofix, you will lose any changes made to these Group Policy objects. For more information about Dcgpofix, type **Dcgpofix /?** at the command line.

This tool should be used as a last-resort disaster-recovery tool. A better solution is to use GPMC to back up and restore these GPOs.

**GPMonitor.exe: Group Policy Monitor Tool**
**Category**
Group Policy Monitor tool is included in the Windows Server 2003 Deployment Kit.

**Version compatibility**
The Group Policy Monitor tool works on Windows XP and higher computers. Group Policy Monitor tool collects Group Policy information at every Group Policy refresh and sends that information to a centralized location that you specify. You can then use the Group Policy Monitor user interface (UI) to view the data. The Group Policy Monitor UI can provide a historical view of policy changes. The UI is also designed to make it easy to navigate through historical snapshots of data and trace changes. For more information about the Group Policy Monitor tool, type **GPMonitor /?** at the command line. You can find full documentation for the Group Policy Monitor tool in the Windows Server 2003 Deployment Kit Tools.

**GPOTool.exe: Group Policy Verification Tool**
**Category**
Group Policy Verification tool is included in the Windows Server 2003 Deployment Kit.

**Version compatibility**
The Group Policy Verification tool works on Windows 2000 and higher computers. You use Group Policy Verification tool to check the health of the Group Policy objects on domain controllers. The tool checks GPOs for consistency on each domain controller in your domain. The tool also determines whether the policies are valid and displays detailed information about replicated Group Policy objects (GPOs).

GPOTool.exe ships with the Microsoft Windows 2003 Server Resource Kit and is also available as a free download at the Gpotool.exe: Group Policy Verification Tool page.

For more information about the Group Policy Verification tool, type **GPOTool /?** at the command line. You can find full documentation for Group Policy Verification tool in the Windows Server 2003 Deployment Kit Tools.

**AdmX.exe: ADM File Parser**
**Category**
The ADM File Parser (AdmX) is a command-line tool that enables an administrator to export Group Policy settings to a tab-delimited text file. The administrator can then use the text produced by ADM File Parser (AdmX) to find changes for the policy settings between different versions of the operating systems. AdmX is for use only with policies based on administrative templates.

**Version compatibility**
The AdmX.exe tool runs on Windows 2000, Windows Server 2003, and Windows XP Professional. AdmX.exe also requires the Microsoft .NET Framework 1.0.

Administrators use AdmX.exe to extract policy setting information from .adm files and to list differences between two .adm files.

For more information about the ADM File Parser, type **AdmX.exe /?** at the command line.

**Other Tools**
For information about tools specific to Group Policy extensions, see the appropriate Group Policy Components Tools topics in

this collection.

**Group Policy Settings**
Many Group Policy settings are configurable within the Administrative Template (.adm) files supplied with Windows 2000 and Windows Server 2003. Administrators can access these files from the Group Policy Object Editor for a specific GPO, and can configure Group Policy settings contained in the template files.

A registry setting exists for a Group Policy template setting only when the setting state has been changed from **Not Configured** to either **Enabled** or **Disabled**. You can change the setting state from the appropriate Administrative Template node in the Group Policy Object Editor.

To download a complete reference to the Group Policy settings in the .adm files supplied with Windows Server 2003, see the Group Policy Settings Reference for Windows Server 2003. This reference is in Microsoft Excel spreadsheet format.

For a reference to settings specific to Group Policy behavior, and for a list of registry locations that are associated with Group Policy on the domain controller, target, or both, see the Group Policy Object Editor Tools and Settings topic in this collection.

For a reference to settings specific to Group Policy extensions, see the appropriate Group Policy Components topics in this collection.

**Group Policy WMI Classes**
For complete information about WMI classes associated with Group Policy, see the WMI SDK documentation on MSDN.

# Group Policy Components

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group Policy Components**

Depending on the size and complexity of the organization, administrators must set, maintain, and manage various standard configurations for groups of users and computers. Users may require specialized software or have unique needs, such as the ability to always work remotely. Client computers must be set up for specific purposes with configurations for kiosks, labs, general office use, and other roles.

Group Policy is the infrastructure that enables you to deliver and apply these and other configurations to targeted users and computers within an Active Directory directory service environment.

The Group Policy infrastructure consists of a Group Policy engine and various individual components known as client-side extensions that "plug" into the infrastructure. These client-side extensions are used to configure Group Policy settings either by modifying the registry (through the Administrative Templates extension) or setting Group Policy settings for security settings, software installation, folder redirection, wireless network settings, and other areas. Group Policy settings are contained in Group Policy objects (GPOs) that are applied to users and computers.

Group Policy components provide you with the means of enforcing and maintaining a wide variety of configurations, thereby reducing the risk of disruption in your computing environment. In addition, the Group Policy infrastructure is designed to be flexible and extensible, allowing you to develop your own extensions, if desired.

You administer Group Policy components using two primary tools. The first tool is Group Policy Management Console (GPMC), which lets you create, view, and manage GPOs. The second tool is Group Policy Object Editor, which which lets you configure and modify settings within GPOs.

**Group Policy Component Architecture**

Group Policy settings are implemented by a variety of components. There are two basic types of components:

- Extensions that allow you to administer and configure Group Policy settings using Group Policy Object Editor. These are server-side snap-ins that are extensions to the Microsoft Management Console (MMC) snap-in.
- Extensions that interpret Group Policy settings and apply them on the client computer. These are extensions to the logon process – Winlogon – and are known as client-side extensions.

**Group Policy Component Architecture**

**Group Policy Components**

**Server Side MMC Snap-in Extensions**

You configure Group Policy settings using Microsoft Management Console (MMC) snap-ins. The snap-in provides the basic organization of the Group Policy Object Editor and the top-level namespace (Software Settings, Windows Settings, and Administrative Templates). There are server-side snap-in extensions for most of the client-side extensions shown in the figure earlier. However, some client-side extensions, such as Disk Quotas, do not require separate server side snap-ins. In many cases client-side extensions only require registry settings to be transferred to the client system and these can be configured using the Administrative Templates snap-in.

Server-side snap-in extensions include:

- Administrative Templates.
- Security Settings.
- IP Security.
- Scripts.
- Software Installation.
- Internet Explorer Maintenance.

All MMC snap-ins and extensions are registered under the following registry key:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MMC\SnapIns
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MMC\Nodetypes
```

Each extension may have further child extensions. In this way, Group Policy Object Editor consists of an extensible tree of administrative components. This allows components to be updated or new components to be added without affecting other components.

**Client-Side Extensions**

Client-side extensions are the components running on the client system that process and apply the Group Settings to that system. There are a number of extensions that are preinstalled in Windows Server 2003. Other Microsoft applications and third-party application vendors can also write and install additional extensions to implement Group Policy management of these applications. The default CSEs are listed in the following table.

**Default Client-Side Extensions**

| Client-Side Extension | Active Directory Component | Sysvol Component |
|---|---|---|
| Administrative Templates | | Registry.pol (+ .adm) |
| Software Installation | PackageRegistration objects | .aas files |
| Security Settings | | Gptmpl.inf |
| Folder Redirection | | fdeploy.ini |
| Scripts | | Scripts |
| IP Security | IPSec Policy objects | |
| Internet Explorer Maintenance | | .ins and branding .inf files. |
| Disk Quotas | | Registry.pol |
| EFS Recovery | | Registry.pol |
| Remote Installation | | Oscfilter.ini |
| QoS Packet Scheduler | | Registry.pol and .adm files. |

Client-side extensions are implemented within DLLs that are installed and registered on the client computer during operating

system installation. To trigger Group Policy processing, the Group Policy engine running within Winlogon calls each CSE DLL using the CSE registration settings contained below the Winlogon key in the registry.

Each of the CSEs is registered under the following registry key: `HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Winlogon\GPExtensions`

**Group Policy Component Scenarios**
Group Policy is used to define configurations for groups of users and computers. With Group Policy, administrators can specify Group Policy settings for registry-based policies, security, software installation, scripts, folder redirection, remote installation services, and Internet Explorer maintenance. Group Policy settings are contained in a GPO. By linking a GPO with selected Active Directory system containers—sites, domains, and organizational units—the GPO's Group Policy settings are applied to the users and computers in those Active Directory containers.

**Administrative Templates**
Administrative Templates enable administrators to control registry settings using Group Policy, providing the means to configure the behavior and appearance of the desktop, including the operating system, components, and applications. Windows comes with a predefined set of Administrative Template files, which are implemented as text files (with an .adm extension), that define the registry settings that can be configured in a GPO. These .adm files are stored in two locations by default: inside GPOs in the **Sysvol** folder and in the **%windir%\inf** directory on the local computer. Administrative Templates Group Policy settings are also referred to as .adm settings or registry-based settings.

As new versions of Windows are released, new Administrative Templates policy settings are added. In addition to supporting these new settings, each successive version of Windows supports all registry policy settings that were available in earlier versions of Windows. For example, the Windows Server 2003 family of operating systems supports all Administrative Templates policy settings available in Windows 2000 and Windows XP.

**Security Settings**
You can define security settings that are enforced on any number of computers, by using the Security Settings extension of Group Policy. By specifying the security configuration of a Group Policy object (GPO), you can affect the computers in a site, domain, or organizational unit to which the GPO is linked.

You can configure the following types of security settings:

- Account Policies. This includes settings for Password Policy, Account Lockout Policy, and Kerberos Policy.
- Local Policies. This includes settings for Audit Policy, User Rights Assignment, and Security Options.
- Event Log. This includes settings for application, system, and security Event Log settings.
- Restricted Groups. This specifies policies for membership of security-sensitive groups.
- System Services. This specifies policies for startup and permissions for system services.
- Registry. This includes policies that specify permissions for registry keys.
- File System. This includes policies that specify permissions for folders and files.

**IP Security Policy**
Internet Protocol security (IPSec) is a framework of open standards designed to ensure private, secure communications over Internet Protocol (IP) networks, through the use of cryptographic security services. IPSec supports network-level data integrity, data confidentiality, data origin authentication, and replay protection.

In an Active Directory environment, you can use Group Policy to centralize IPSec policy distribution and management. You can use the **IP Security Policies** snap-in to configure IPSec policies to meet the security requirements of a user, group, application, domain, site, or global organization. You can also specify IPSec policies on a local computer that is not a member of a domain.

**Software Restriction Policies**
The Windows Server 2003 family of operating systems and Windows XP include software restriction policies, a new policy-based feature that identifies software programs running on computers in a domain, and controls the ability of those programs to run. Software restriction policies are a part of Microsoft's security and management strategy to assist enterprises in increasing the reliability, integrity, and manageability of their computer networks. You can specify software restriction policies in an Active Directory environment or on a local computer.

You can use **Software Restriction Policies** to:

- Fight viruses.
- Regulate which ActiveX controls can be downloaded.
- Run only digitally signed scripts.
- Enforce that only approved software is installed on system computers.
- Highly restrict (lock down) a computer.

**Wireless Network Policies**
A new Wireless Network (IEEE 802.11) Policies Group Policy extension allows you to configure wireless network settings that are part of Group Policy for Computer Configuration. Wireless network settings include the list of preferred networks, Wired Equivalent Privacy (WEP) settings, and IEEE 802.1X settings. These settings are downloaded to targeted domain members, making it much easier to deploy a specific configuration for secure wireless connections to wireless client computers.

**Public Key Policies**
These Group Policy settings are used to:

- Specify that computers automatically submit a certificate request to an enterprise certification authority and install the issued certificate.
- Create and distribute a certificate trust list.
- Establish common trusted root certification authorities.
- Add encrypted data recovery agents and change the encrypted data recovery policy settings.

**Software Installation**
The Software Installation snap-in is used to centrally manage software. Software can be assigned or published to users and assigned to computers. Group Policy-based Software Installation can be used to install software applications when a computer is started, when the user logs on, or on demand. Software installation Group Policy settings can be applied to users or computers in an Active Directory structure.

Group Policy-based Software Installation can also be used to upgrade deployed applications or remove earlier applications that are no longer required. Users can be restricted from installing any software from local media, such as a CD-ROM, or disk, or other unapproved applications.

Medium and large organizations may wish to consider using Microsoft Systems Management Server (SMS). SMS provides advanced capabilities such as inventory-based targeting, status reporting, server- and client-side scheduling, multisite facilities, complex targeting, centralized hardware and software inventory, remote diagnostic tools, software metering, software distribution-point population and maintenance, support for Windows 95, Windows 98, Windows NT 4.0, Windows 2000, and Windows XP clients, and enhanced software deployment features. SMS does not require Active Directory.

**Remote Installation Services**
Remote Installation Services (RIS) is an optional component that is included in the Windows Server operating system and works with other Windows Server 2003 technologies to implement the Remote Operating System Installation feature. Administrators use Remote Operating System Installation to remotely install a copy of the Windows XP Professional operating system on supported computers. Administrators use the RIS extension of Group Policy to specify which options are presented to users by the Client Installation Wizard, for example, Automatic Setup, Custom Setup, and Restart Setup.

**Scripts**
Scripts are used to automate tasks at computer startup and shutdown, and at user logon and logoff. Scripts can be written in any language supported by Windows Script Host including the Microsoft Visual Basic development system, Scripting Edition (VBScript), JavaScript, PERL, and MS DOS-style batch files (.bat and .cmd).

**Internet Explorer Maintenance**
Internet Explorer Maintenance is used to manage and customize Internet Explorer on computers running Windows 2000 or later. Administrators can set options for the Browser UI, connections, URLs, proxy settings, security zones, Favorites, and

Internet Explorer Enhanced Security Configuration component (also known as Microsoft Internet Explorer hardening).

**Folder Redirection**
Folder redirection is used to redirect special directories on Windows 2000 or Windows Server 2003 from their default user profile location to an alternate location on the network. These special folders include **My Documents**, **Application Data**, **Desktop**, and the **Start** menu.

**Disk Quotas**
Disk quotas provide a way to limit each users utilization of disk space on a volume. Disk quotas are implemented as part of the NTFS File System. Disk quota settings are read from the registry at startup and during GPO processing. Disk Quotas are configured through the Administrative Templates snap-in and are stored in the registry.pol GPO registry settings file – there is no GPO snap-in for disk quotas. The Disk Quota CSE retrieves the resultant setting from the client system's registry and configures the disk quota parameters accordingly. Prioritization of multiple GPO settings is handled by the Administrative Templates CSE.

**QoS Packet Scheduler**
Quality of service (QoS) allows you to use your existing resources efficiently and guarantee that critical applications receive high-quality service, without having to expand as quickly or even over-provision your networks. Quality of Service parameters are configured as registry settings using the Administrative Templates snap-in. The QoS Packet Scheduler CSE reads these settings from the registry and configures the Packet Scheduler service on the client system with these parameters.

# Administrative Templates Extension Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Administrative Templates extension consists of a Microsoft Management Console (MMC) server-side snap-in used to configure policy settings and a client-side extension that sets registry keys on target computers. Administrative Templates policy is also known as registry-based policy or registry policy. Although other Group Policy extensions manipulate the registry to implement policy settings, the Administrative Templates Extension exists specifically for registry-based policy.

# What Is Administrative Templates Extension?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Core Scenarios for Administrative Templates Extension
- Related Information

The Administrative Templates Extension is the largest of all available Group Policy extensions and includes more than 700 policy settings for applications and operating system components. These policy settings are applied by modifying the registry on target clients. Administrative Templates policy settings is also referred to as registry-based policy or simply registry policy.

Administrators need a simple way to configure policy settings and apply those changes to many users and computers throughout the network. You need to be able to modify policy settings quickly and be able to delete policy settings and remove them from all target computers without the risk of old policy settings remaining in the registry. In addition, developers need a way to integrate policy management into new applications. Administrative Templates provides dynamic management capabilities to administrators and an infrastructure for developers to policy-enable their applications.

The Administrative Templates Extension consists of a server-side snap-in that is loaded by default in Group Policy Object Editor and a client-side extension that writes policy settings that manipulate registry keys on target client computers. The server-side snap-in loads a predefined set of Administrative Template files, which are implemented as text files (with an .adm extension), that define the registry settings that can be configured in a Group Policy object (GPO).

.Adm files are Unicode files which consist of a hierarchy of categories and subcategories that define how the options are displayed through the Group Policy Object Editor and GPMC. They also indicate the registry locations where changes should be made if a particular selection is made, specify any options or restrictions (in values) that are associated with the selection, and in some cases, indicate a default value to use if a selection is activated. It's important to note that the functionality of .adm files is limited. The only purpose of .adm files is to enable a user interface to configure policy settings. .Adm files do not contain actual policy settings; these are contained in registry.pol files located in the Sysvol on domain controllers.

**Core Scenarios for Administrative Templates Extension**
You use Administrative Templates Extension to modify and remove registry-based policy settings. Developers can create .adm files to integrate policy settings management into their applications.

**Manipulating Administrative Template Extension Policy Settings**
The Administrative Templates server-side snap-in provides an Administrative Templates node that appears twice in Group Policy Object Editor; once under the Computer Configuration node, and again under the User Configuration node. The settings under the computer node manipulate registry settings for the computer, while settings under the user node manipulate registry settings for users. Although some policy settings require simple UI elements, such as text boxes to enter values, most settings contain only the following options:

- Enabled
- Disabled
- Not configured

The default setting is not configured, so you only need to decide whether to turn the setting on or to turn it off.

Administrative Templates provide administrators with a Group Policy interface for the DSQ and QoS CSEs, among others.

**Removing Policy Settings Implemented by Administrative Template Extension**
In addition to being easy to set, administrators can also easily remove default registry-based policy settings implemented with Administrative Templates Extension. This is accomplished by having all default registry-based policy settings from Windows 2000 or later stored in one of four specific registry keys:

- HKEY_LOCAL_MACHINE\SOFTWARE\policies (preferred location)

- HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\policies
- HKEY_CURRENT_USER\SOFTWARE\policies (preferred location)
- HKEY_ CURRENT_USER\SOFTWARE\Microsoft\Windows\CurrentVersion\policies

Policy settings that are stored in these locations are known as true policies. Registry keys used for true policy are secured so they cannot be modified by a non-administrator. More importantly, when Group Policy changes, for any reason, all settings from these registry keys are removed, and new registry keys are written based on the policy settings in the GPO. This prevents the behavior that was often present in Windows NT 4.0, whereby System Policies resulted in persistent settings in the user and computer registry. The policy remained in effect until the value was reversed, either by a counteracting policy or by editing the registry. Persistent policy settings persist because they are stored outside the approved registry locations. These types of settings are known as preferences.

All the policy settings in the default administrative template files manipulate settings under the approved registry keys—resulting in true policy settings. This means that they will not cause persistent settings in the registry when the GPO that applies them is no longer in effect. By default, Group Policy Object Editor only displays true policy settings.

**Default Administrative Template Files**
Windows Server 2003 includes the following administrative template files: System.adm, Inetres.adm, Conf.adm, Wmplayer.adm, and Wuau.adm, which contain all the settings initially displayed in the Administrative Templates node. These administrative template files are stored in two locations by default: inside GPOs in the Sysvol folder and in the Windows\inf directory on the local computer.

As new versions of Windows are released, new policy settings are added. In addition to supporting these new settings, each successive version of Windows supports all registry policy settings that were available in earlier versions of Windows. For example, the Windows Server 2003 family supports all registry policy settings available in Windows 2000 and Windows XP.

On Windows XP and Windows Server 2003, each registry setting contains a "Supported on" tag that indicates which operating system versions support that policy setting. If a setting is specified and deployed to a client operating system that does not support that setting, the settings are ignored.

Because all successive iterations of administrative template files include settings from earlier versions, and because there is no harm if a new setting is applied inadvertently to a computer running an earlier operating system that does not support that setting, it is recommended to always create and edit GPOs from a computer that has the latest administrative template files available.

**Extending Registry-Based Policy with Administrative Template Files**
If a developer needs to provide policy settings specific to an application, they can extend registry-based policy by using administrative template files. The Administrative Templates Extension to Group Policy provides this capability.

Developers can specify that that Administrative Templates Extension writes settings under the secure registry keys to create true policy settings; these policy settings are designed to be manipulated by an administrator using Group Policy Object Editor. Developers can also specify that the application write policy settings outside the secure registry keys to create preferences; these settings are designed to be manipulated by end-users working from within the developer's application. The Group Policy settings set by administrators take precedence over user preferences. Because Group Policy stores the policy settings set by administrators under the approved Group Policy keys, users cannot change or disable these policy settings.

**Related Information**

# How Administrative Templates Extension Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Administrative Templates are the primary means of configuring the client computer's registry settings through Group Policy. Organizations benefit the most by using Administrative Templates policy settings in a Windows Server 2003 environment with Active Directory installed and Windows XP client computers.

**In this section**

- Administrative Templates Extension Architecture
- Administrative Templates Extension Physical Structure
- Administrative Templates Extension Processes and Interactions
- Network Ports Used by Administrative Templates Extension
- Related Information

**Administrative Templates Extension Architecture**

The following diagram shows how components interact in implementing Administrative Templates policy settings.

**Administrative Templates Extension Architecture**

Components and protocols significant to Administrative Templates Extension are included in the following table.

**Administrative Templates Components**

| Component | Description |
|---|---|
| Administrator | The computer that you use to configure Administrative Templates policy settings in Local Group Policy Editor or Group Policy Management Console (GPMC). |

| | |
|---|---|
| Domain controller | The server that contains a writable copy of the Active Directory database, participates in Active Directory replication, and controls access to network resources. Each domain controller contains:<br>• The Group Policy container (GPC), which stores information about GPO properties in Active Directory.<br>• The Group Policy template (GPT), which stores GPO data in the Sysvol. Data includes the Registry.pol file that stores Administrative Templates policy settings. |
| Target client | The computer(s) to which you intend to apply Administrative Templates policy settings. |
| Registry | A database repository for information about a computer's configuration, the registry is organized hierarchically as a tree, and is made up of keys and their subkeys, hives, and entries. Administrative Templates Extension directly modifies registry keys in order to configure Machine and User policy settings. |
| Administrative Templates Snap-in Extension | The MMC server-side snap-in extension used to configure and modify Administrative Templates-based policy settings. The snap-in is contained within userenv.dll located in Windows\System32\. It appears in Local Group Policy Editor or GPMC as a node under Computer Configuration and User Configuration. |
| Administrative Templates client-side extension | Administrative Templates client-side extension runs inside userenv.dll and is responsible for modifying the registry according to the Administrative Template policy settings that you configure in Local Group Policy Editor or GPMC.<br>Userenv.dll is registered at the following location:<br>HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\GPExtensions.<br>This is the location of all Group Policy CSE registration. |
| Active Directory | A requirement for implementing domain-based Group Policy, Active Directory provides the containers in which you link Group Policy objects (GPOs). |
| Group Policy engine | The framework that handles functionalities across client-side extensions (CSEs). The Group Policy engine invokes the Administrative Templates client-side extension with a list of GPOs to be applied. |
| Event log | The Event log is a service, located in Event Viewer, which records events in the system, security, and application logs. |
| File system | The NTFS file system on client computers. |
| Group Policy object | Administrative Templates policy settings are contained in GPOs, which can then be linked to Active Directory containers such as sites, domains, and OUs. |
| Local Group Policy object | The GPO stored on each individual computer in the hidden *%systemroot%*\System32\GroupPolicy directory. Although you can configure Administrative Templates policy settings in local GPOs, they are the least influential GPOs in an Active Directory environment, because Active Directory-based GPOs have precedence. |
| Kerberos | Any time the registry extensions (client or server) access any information about the Sysvol, or any other domain resource, authentication traffic is generated to the Active Directory. Kerberos is an authentication mechanism used to verify user or host identity. The Kerberos V5 authentication protocol is the default authentication service. Administrative Templates client-side extension communicates with Active Directory using Kerberos. |
| NTLM | A security package that provides authentication between clients and servers. NTLM is also used by Administrative Templates client-side extension to communicate with Active Directory. |

| | |
|---|---|
| WMI | Windows Management Infrastructure (WMI) is a management infrastructure that supports monitoring and controlling of system resources through a common set of interfaces and provides a logically organized, consistent model of Windows operation, configuration, and status.<br><br>Each computer contains a WMI database that stores information about policy settings. WMI makes data about a target computer available for administrative use.<br><br>The actual Administrative Templates policy settings that are in effect on a client computer (known as Resultant Set of Policy or RSoP) is periodically updated. During processing, the Administrative Templates CSE writes the processing data to the RSoP namespace in WMI.<br><br>The namespaces in WMI to which the extension writes are:<br><br>● Root/RSoP/Computer.<br><br>● Root/RSoP/User/<user SID>. |
| LDAP | The Lightweight Directory Access Protocol used to communicate with Active Directory. |
| SMB | Server Message Block (SMB) protocol is the primary method of file and print sharing. Both the Administrative Templates client-side extension and the Administrative Templates snap-in use SMB to access the Sysvol as well as back up and retrieve files to a remote file system. The client computer also uses SMB to read the Sysvol on the domain controller.<br><br>When you edit policy settings, the Administrative Templates snap-in writes changes to the Registry.pol file in the GPO located on the Sysvol. (Or the local GPO on the local computer). The ADM files in the ADM directory can also be updated at administration time.<br><br>During processing the Administrative Templates CSE only reads the Registry.pol files from the GPO. No other files are read. No files are written to the Sysvol during processing. Communication to the Sysvol takes place through standard Win32 file system API calls. |
| Distributed Component Object Model (DCOM) | DCOM is used by the Administrative Templates CSE to communicate with the WMI database. |
| dskquoui.dll | The dskquoui.dll file provides the Quota tab user interface on NTFS volumes. |
| dskquota.dll | The dskquota.dll file provides the Disk Quotas client-side extension and server-side extension. |
| gptext.dll | The gptext.dll file provides the QoS Packet Scheduler client-side extension and server-side extension |

**Administrative Templates Extension Physical Structure**

The following figure shows the files used by the Administrative Templates Extension.

Descriptions of these files are included in the following table.

**Physical Structure Components**

| Component | Description |
|---|---|
| Sysvol | The Sysvol is a set of folders containing important domain information that is stored in the file system rather than in Active Directory. The Sysvol folder is stored in a subfolder of systemroot folder (*%\systemroot*\sysvol\sysvol) and is automatically created when a server is promoted to a domain controller. |
| . adm files | .Adm files are Unicode text files that enable a user interface to allow you to modify Registry-based policy settings using Local Group Policy Editor or GPMC. .Adm files do not contain any policy setting information. Actual policy setting information is contained in Registry.pol files.<br><br>.Adm files are stored in two places:<br><br>• Local .adm files stored on the computer where you run Local Group Policy Editor or GPMC.<br><br>• Domain-based .adm files stored on the Sysvol. These files are copies of the local .adm files and are updated whenever you modify Administrative Templates policy settings. |
| System.adm | Provides policy settings to configure the operating system. System.adm is loaded by default in Windows Server 2000, Windows XP, and Windows Server 2003. |
| Inetres.adm | Provides policy settings to configure Internet Explorer. Ineteres.adm is loaded by default in Windows 2000 Server, Windows XP, and Windows Server 2003. |
| Conf.adm | Provides policy settings to configure NetMeeting. Conf.adm is loaded by default in Windows 2000 Server, Windows XP, and Windows Server 2003.<br><br>**Note:** Conf.adm is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. |
| Wmplayer.adm | Provides policy settings to configure Windows Media Player. Wmplayer.adm is loaded by default in Windows XP and Windows Server 2003. Wmplayer.adm is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. |

| | |
|---|---|
| Wuau.adm | Provides policy settings to configure Windows Update. Wuau.adm is loaded by default in Windows 2000 Service Pack 3 (SP3), Windows XP Service Pack 1 (SP1), and Windows Server 2003. |
| Registry.pol | Unicode files that contain the Administrative Templates policy settings that are to be applied to the computer or user portion of the registry.<br><br>In contrast to .adm files, the Registry.pol files contain the actual Group Policy settings used by the Group Policy engine during processing. Registry.pol files contain instructions to add or delete registry keys, corresponding to the policy settings you specify in Local Group Policy Editor or GPMC. |
| Ntuser.pol | An archive file on client computers that is updated each time the Administrative Templates CSE sets a policy setting. As processing completes, an Ntuser.pol containing the history of applied registry based policies in the Group Policy managed policies tree is written to the root of the user's profile containing user policy settings and to the "all users" profile containing computer policy settings.(%Allusersprofile%\ntuser.pol for computer policy and %userprofile%\ntuser.pol for user policy.) |
| Userenv.dll | The dynamic link library in which the Administrative Templates CSE runs. Userenv.dll is part of the code of the Group Policy engine and is always called whenever policy settings are processed. |
| Userenv.log | A log file that records warnings and events as a result of Administrative Templates processing. The Userenv.log contains more verbose logging than the event log and is not enabled by default. It is located on client target computers in Windows\debug\usermode. UserEnv.log also contains entries for profiles. |
| Gptext.log | A log file located on client computers in Windows\debug\usermode. You can use gptext.log to view errors in the processing of Administrative Templates policy settings. |

**Administrative Templates Extension Processes and Interactions**
The Administrative Templates CSE is invoked by the Group Policy engine with a list of GPOs to be applied. Each GPO contains a Registry.pol file. In order to modify settings in the registry, the Administrative Templates CSE parses the ntuser.pol files to remove previously set registry settings, returning the registry settings to a "default" state. The Administrative Templates Extension then retrieves the Registry.pol files from each GPO in the list and applies the Registry.pol changes to the local registry in order of precedence for the GPOs. Data is also written to WMI by the Administrative Templates Extension for RSoP to retrieve later. As the Registry.pol files are processed, the ntuser.pol file is created to centrally manage the registry keys that have been set. Events are written to the event log during this process. If debugging is enabled, data is written to the userenv.log as well.

Unlike other CSEs, the Administrative Templates CSE is coded within the Group Policy engine as a piece of userenv.dll. As a result, the extension is always called whenever Group Policy is processed. In addition, the Administrative Templates CSE is always called first by the Group Policy engine, in advance of any other CSEs that might be processed. Administrative Templates CSE will run only if there are any changes in any the GPOs that the Administrative Templates CSE has enabled.

**True Policies and Preferences**
The Administrative Templates CSE has control over a part of the registry for both user and computer registry hives and treats these specially. These parts are for the computer and user hives respectively:

- HKEY_LOCAL_MACHINE\SOFTWARE\policies (preferred location)
- HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\policies
- HKEY_CURRENT_USER\SOFTWARE\policies (preferred location)
- HKEY_ CURRENT_USER\SOFTWARE\Microsoft\Windows\CurrentVersion\policies

These trees cannot be modified by a non-administrator. Because all keys and values beneath these paths are erased before applying the resultant registry policy settings, the registry policies applied in these subtrees will only persist as long as a valid Group Policy setting exists. Policy settings that are stored in these specific locations of the registry are known as true policies.

All the policy settings in the standard Administrative Template files that shipped with Windows 2000 Server and Windows Server 2003 use true policies. This prevents the behavior that was often present in Windows NT 4.0, whereby System Policies resulted in persistent settings in the user and computer registry. The policy remained in effect until the value was reversed, either by a counteracting policy or by editing the registry. These settings are stored outside the approved registry locations listed and are known as preferences.

Although Group Policy settings take priority over preferences, they do not overwrite or touch the registry key used by the preference. If both a policy and preference are present, the preference will be successfully restored if the policy is removed or disabled. Preference settings persist in the registry until they are reversed by a counteracting policy setting or by editing the registry.

The configuration of the wallpaper on the Windows desktop illustrates an example of simultaneous policy and preference settings. In the Windows shell, it is possible for a user to configure their desktop wallpaper using the Display icon in Control Panel. An administrator can also configure desktop wallpaper using a default policy setting called **Active Desktop Wallpaper**, which can be found under **User Configuration\Administrative Templates\Desktop\Active Desktop** node in Local Group Policy Editor or GPMC.

The following table lists the resultant behavior for Group Policy settings and preferences.

**Results of Group Policy Settings and Preferences**

| Scenario | Policy present | Preference present | Resultant behavior |
|---|---|---|---|
| 1 | No | No | Default |
| 2 | No | Yes | Preference configures behavior |
| 3 | Yes | No | Policy configures behavior |
| 4 | Yes | Yes | Policy configures behavior; preference ignored |

It is common practice to offer both a preference and a policy setting for most applications. The application reads the registry keys and uses them accordingly. Registry-based data is appropriate for many types of policy settings and is also the least complex way to create custom policy settings. In addition, Registry-based policy managed through administrative template files automatically supports Resultant Set of Policy (RSoP) capabilities.

**Registry.pol Files**

Registry.pol files are formed by the following process:

- When you start Local Group Policy Editor or GPMC, a temporary registry tree is created that consists of two nodes: **USER** and **MACHINE**.
- As you navigate the Administrative Templates node of the Local Group Policy Editor or GPMC, .adm file nodes are displayed. The .adm files within Local Group Policy Editor or GPMC nodes are loaded dynamically when a particular node is selected, and the .adm file is then cached.
- When a policy is selected in the details pane (the right side of the Local Group Policy Editor or GPMC), the temporary registry is queried to determine whether the selected policy already has registry values assigned to it; if it does, those values are displayed in the **Policy** dialog box. If the selected policy does not have a registry value assigned to it, the default value from the .adm file or from the associated MMC snap-in extension is used.
- After you modify a policy, the registry values that you specify are written to the appropriate portion of the temporary registry (either **MACHINE** or **USER**).
- When you close Local Group Policy Editor or GPMC, the temporary registry hives are exported to the Registry.pol files in the appropriate folders of the Group Policy template: GPT\Machine and GPT\User.
- The next time you start Local Group Policy Editor or GPMC for the same Group Policy object for which you have previously set Group Policy settings, the registry information from the corresponding Registry.pol files is imported into the temporary registry tree. Therefore, when you view the policy settings, they reflect the current state.

**Registry.pol in the Local GPO**

During processing, the local Registry.pol files in the Machine and User directories of the Local GPO are read. There is a Registry.pol file in both the Machine and User directories of the Local GPO directory structure for machine- and user-based policies respectively. The Local GPO is distinct from domain policy in that it updates the Registry.pol file as each policy setting is set and refreshes policy settings on the computer at the time each policy setting is configured.

**.Adm Files**

Administrative Template files describe where Registry-based policy settings are stored in the registry, by associating a description and explain text with a registry key and value. Local Group Policy Editor or GPMC displays only the descriptive text and provides various dialog boxes that you can use to modify the setting. A section of the user's hive is mapped to the registry policy setting. .Adm files, unlike Registry.pol files, do not affect the actual policy processing by the Administrative Templates CSE. .Adm files only affect the display of the policy settings in the Local Group Policy Editor or GPMC snap-in. If an .adm file is removed, the settings corresponding to the .adm file will not appear in Local Group Policy Editor or GPMC. However, the policy settings that are configured from the .adm file will remain in the Registry.pol file and continue to apply to the appropriate target client or user.

Each administrative workstation that is used to run Local Group Policy Editor or GPMC stores .adm files in the Windows\Inf folder. When GPOs are created and first edited, the .adm files from this folder are copied to the \adm subfolder in the Group Policy template (GPT).

By default, when GPOs are edited, Local Group Policy Editor or GPMC compares the time stamps of the .adm files in the workstation's Windows\Inf folder with those that are stored in the GPT \adm folder. If the workstation's files are newer, Local Group Policy Editor or GPMC copies these files to the GPT \adm folder, overwriting any existing files of the same name. This comparison occurs when the Administrative Templates node (computer or user configuration) is selected in Local Group Policy Editor or GPMC, regardless of whether you actually edit the GPO. The .adm files stored in the Group Policy template can be updated by viewing a GPO in Local Group Policy Editor or GPMC. The process is simplified for local GPOs where all adm files are stored locally in a single adm folder.

Because of the importance of time stamps on .adm file management, the editing of system-supplied .adm files is not recommended. If a new policy setting is required, Microsoft recommends that you create a custom .adm file. This prevents the replacement of system-supplied .adm files when service packs are released.

**Using the latest .adm files**
As a general rule, each operating system or service pack release includes a superset of the .adm files provided by earlier releases, including policy settings that are specific to operating systems that are different to those of the new release. For example, the .adm files that are provided with Windows Server 2003 include all policy settings for all operating systems, including those that are only relevant to Windows 2000 or Windows XP Professional. This means that only viewing a GPO from a computer with the new release of an operating system or service pack effectively upgrades the .adm files.

**How .adm files are handled by Local Group Policy Editor or GPMC**
By default Local Group Policy Editor or GPMC attempts to read .adm files from the GPO (from the Sysvol on the domain controller). Alternatively, the .adm file can be read from the local workstation computer. This behavior can be controlled by a policy setting.

By default, if the version of the .adm file found on the local computer is newer (based on the time stamp of the file) than the version on the Sysvol, the local version is copied to the Sysvol and is then used to display the settings. This behavior can be controlled by a policy setting.

If the GPO contains registry settings for which there is no corresponding .adm file, these settings cannot be seen in Local Group Policy Editor or GPMC. However, the policy settings are still active and will be applied to users or computers targeted by the GPO.

**How .adm files are handled by Group Policy Management Console**
GPMC uses .adm files to display the friendly names of policy settings when generating HTML reports for GPOs, Group Policy Modeling, and Group Policy Results.

By default, GPMC uses the local .adm file, regardless of time stamp. If the file is not found, GPMC will look in the GPO's directory on Sysvol.

You can specify an alternate path for where to find .adm files. If specified, this takes precedence over the previous locations. GPMC never copies the .adm file to the Sysvol.

**Extensions that use Administrative Templates**
There are additional extensions that are located within the Administrative Templates for Computer Configuration in the Local Group Policy Editor or GPMC. These are:

- Disk Quotas
- QoS Packet Scheduler.

**Disk Quotas**
Disk Quotas are used to manage NTFS file system disk space. Administrators use the Disk Quotas Extension to configure

Group Policy for Disk Quotas on target computers. The Disk Quotas Extension includes a server-side extension and a client-side extension.

Administrators manage Disk Quotas policy settings under the following node in the Local Group Policy Editor or GPMC: Computer Configuration\Administrative Templates\System\Disk Quotas. The Disk Quotas node is the user interface for the server-side component of the Disk Quotas extension. There is no user interface for the client-side component, although you can view changes made by the CSE on the Quota Property tab for NTFS volumes. The Group Policy engine, using the Disk Quotas client-side extension component, applies settings to the target computer.

The Disk Quotas CSE is registered with Winlogon in the registry at the following path: {HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WindowsNT\CurrentVersion\Winlogon\GPExtensions\{3610eda5-77ef-11d2-8dc5-00c04fa31a66}

**QoS Packet Scheduler**
QoS Packet Scheduler Extension is an extension to Local Group Policy Editor or GPMC. Administrators use QoS Packet Scheduler Extension to set QoS Packet Scheduler Group Policy.

QoS Packet Scheduler Extension is included in the same binary (gptext.dll) as the Scripts, IP Security, and Wireless Group Policy extensions. Administrators manage QoS Packet Scheduler policy settings under the following node in the Local Group Policy Editor or GPMC: Computer Configuration\Administrative Templates\Network\QoS Packet Scheduler.

The QoS Packet Scheduler CSE is registered with Winlogon in the registry at the following path:

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\ GPExtensions\{426031c0-0b47-4852-b0ca-ac3d37bfcb39}

**Network Ports Used by Administrative Templates Extension**
Administrative Templates CSE communicates with Active Directory using LDAP to complete the following tasks:

- GPO list retrieval.
- Group Policy container retrieval.

It uses SMB to complete the following tasks:

- Request DFS referral for \\domainname\sysvol.
- SysvolDFS replica location \\dcname.domainname\sysvol.
- Open and read GPT.INI.
- Return GPT.INI.
- Open and read GPT settings files.
- Return GPT file.

### Port Assignments for Group Policy Administrative Templates

| Service Name | UDP | TCP |
|---|---|---|
| Lightweight Directory Access Protocol | n/a | 389 |
| SMB | n/a | 445 |

- Related Information

This section describes the tools and templates available for the Group Policy Administrative Templates extension.

**Administrative Templates Extension Tools**
The following tools are associated with the Group Policy Administrative Templates extension. For more information about Group Policy administrative tools, see the following topics in this collection:

- Group Policy Administrative Tools
- Group Policy Object Editor Tools and Settings
- Group Policy Management Console Technical Reference
- What Is Resultant Set of Policy?

For information about tools specific to other Group Policy extensions, see the appropriate Group Policy Components Tools topics in this collection. For more information about other Resource Kit tools, see the Windows Server 2003 Resource Kit Tools page.

**AdmX.exe: ADM File Parser**
**Category**
The ADM File Parser (AdmX) is a command-line tool that enables an administrator to export Group Policy settings to a tab-delimited text file. The administrator can then use the text produced by ADM File Parser (AdmX) to find changes for the policy settings between different versions of the operating systems. AdmX is for use only with policies based on administrative templates.

**Version compatibility**
The AdmX.exe tool runs on Windows 2000, Windows Server 2003, and Windows XP Professional. AdmX.exe also requires the Microsoft .NET Framework 1.0.

Administrators use AdmX.exe to perform the following two tasks:

- Extract policy setting information from .adm files.
- Compare two .adm files. This can be used to determine what has changed between two like files, such as the system.adm file from two different operating systems.

For more information about the ADM File Parser, type **AdmX.exe /?** at the command line.

**GPUpdate.exe**

This tool is used for refreshing local and Active Directory policy settings on the computer from which you run the **GPUpdate** command.

**Category**
This command-line tool is included in Windows XP and Windows Server 2003.

**Version compatibility**
You can use GPUpdate locally on computers running Windows XP and higher to refresh policy immediately. On computers running Windows 2000, this behavior is provided by the using the secedit.exe command line tool, with a specific parameter.

GPUpdate refreshes changed local Group Policy settings and Group Policy settings that are stored in Active Directory, including security settings, on the computer from which it is run. This command supersedes the now obsolete **/refreshpolicy** option for the secedit command line tool. Group Policy can be forced to reprocess all policy settings whether there has been a change or not by using the **/force** switch.

For more information about GPUpdate, see "Core Group Policy Tools and Settings" in this collection.

**GPResult.exe: Group Policy Results**
This command line tool displays Resultant Set of Policy (RSoP) for a user or computer. You can use GPResult.exe to see what policy is in effect and to troubleshoot problems on computers running Windows XP or later.

**Category**
There are two versions of GPResult: One shipped with the Windows 2000 Resource Kit; the other is included with Windows XP and Windows Server 2003. The Windows 2000 version of GPResult runs only locally on Windows 2000. The Windows Server 2003 version runs locally or remotely on Windows XP or Windows Server 2003.

The different versions are not compatible.

**Version compatibility**
The GPResult.exe that ships with Windows XP and Windows Server 2003 family is completely different than the original version of GPResult.exe that shipped in the Windows 2000 Resource Kit. The newer version cannot be used to view policy information for computers running Windows 2000.

For more information about GPResult, see "Core Group Policy Tools and Settings" in this collection.

**Dcgpofix.exe: Dcgpofix**
**Category**
Dcgpofix ships with Windows Server 2003.

**Version compatibility**
You can run Dcgpofix only on servers in a Windows Server 2003 domain. This tool can restore default domain policy and default domain controllers policy to their original state after installation. When you run Dcgpofix, you will lose any changes made to these Group Policy objects. This tool should be used as a last-resort disaster-recovery tool. A better solution is to use Group Policy Management Console (GPMC) to back up and restore these GPOs.

For more information about Dcgpofix, type **Dcgpofix /?** at the command line.

**GPMonitor.exe: Group Policy Monitor Tool**
**Category**
Group Policy Monitor tool is included in the Windows Server 2003 Deployment Kit.

**Version compatibility**
The Group Policy Monitor tool works on Windows XP and higher computers. Group Policy Monitor tool collects Group Policy information at every Group Policy refresh and sends the information to a centralized location that you specify. You can then use the Group Policy Monitor user interface (UI) to view the data. The Group Policy Monitor UI can provide a historical view of policy changes. The UI is also designed to make it easy to navigate through historical snapshots of data and trace changes. For more information about the Group Policy Monitor tool, type **GPMonitor /?** at the command line. You can find full documentation for the Group Policy Monitor tool in the Windows Server 2003 Resource Kit Tools.

**GPOTool.exe: Group Policy Verification Tool**
**Category**
Group Policy Verification Tool is included in the Windows Server 2003 Deployment Kit.

**Version compatibility**
The Group Policy Verification tool works on Windows 2000 and higher computers. You can use Group Policy Verification Tool to check the health of the Group Policy objects on domain controllers. The tool checks GPOs for consistency on each domain controller in your environment. The tool also determines whether the policies are valid and displays detailed information about replicated Group Policy objects (GPOs).

GPOTool.exe ships with the Microsoft Windows 2003 Server Resource Kit and is also available as a free download at the Gpotool.exe: Group Policy Verification Tool page.

For more information about the Group Policy Verification tool, type **GPOTool /?** at the command line. You can find full documentation for Group Policy Verification Tool in the Windows Server 2003 Resource Kit Tools.

**Regview.exe: Registry.pol Viewer Tool**
**Category**
Regview.exe is a Group Policy tool for viewing the contents of any registry.pol file, which is created by the Group Policy Object Editor for containing the administrative settings. It is included in the Windows Server 2003 Deployment Kit.

**Version compatibility**
The Group Policy Viewer tool works on Windows 2000 and higher computers. Because the registry.pol file is not an ASCII file, you cannot easily view the contents. If an administrator needs to troubleshoot or just wants to document the contents of the file, this tool supplies the contents in a delimited format.

**Other Tools**
For information about tools specific to Group Policy extensions, see the appropriate Group Policy Components Tools topics in this collection.

**Administrative Templates Extension Registry Locations**
The following registry locations are associated with the Administrative Templates extension. All default registry-based policy settings from Windows 2000 or later are stored in one of four specific registry keys:

- HKEY_LOCAL_MACHINE\SOFTWARE\Policies (preferred location)
- HKEY_CURRENT_USER\SOFTWARE\Policies (preferred location)
- HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\policies
- HKEY_ CURRENT_USER\SOFTWARE\Microsoft\Windows\CurrentVersion\policies

Policy settings that are stored in these locations are known as true policies.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. You should not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**Administrative Templates Extension Group Policy Settings**
Administrative templates (.adm files) enable administrators to configure registry settings by using Group Policy. These settings appear under the Administrative Templates item for both User Configuration and Computer Configuration in the console tree of the Group Policy Object Editor (GPEdit.dll), and in HTML reports produced by the Group Policy Management Console (GPMC).

For a full list of Administrative Templates policy settings, see Group Policy Settings Reference for Windows Server 2003.

**Group Policy Settings**
For more information about Group Policy settings, see the Group Policy Settings Reference for Windows Server 2003.

**Administrative Templates Extension WMI Classes**
Like other Administrative Templates policy settings, RSoP data is updated whenever policies applied to a computer changes. The extension writes this data into WMI during processing so that the data maintained in WMI is consistent with what is applied to the computer. The administrative template files themselves used in editing the GPO are stored in the Windows/inf folder of the administrative computer. The extension writes to the following WMI namespaces:

- Root/RSoP/Computer
- Root/RSoP/User/<user SID>

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by Administrative Templates Extension**
The Group Policy Administrative Templates extension communicates with Active Directory using Lightweight Directory Access Protocol (LDAP) to complete the following tasks:

- GPO list retrieval
- Group Policy container retrieval

The Administrative Templates extension uses Server Message Block (SMB) to complete the following tasks:

- Request Distributed File System (DFS) referral for \\domainname\sysvol
- SysvolDFS replica location \\dcname.domainname\sysvol
- Open and read GPT.INI
- Return GPT.INI
- Open and read Group Policy template (GPT) settings files
- Return GPT file

The following table lists the network ports used by the Administrative Templates extension.

**Port Assignments for Group Policy Administrative Templates**

| Service Name | UDP | TCP |
|---|---|---|
| Lightweight Directory Access Protocol | n/a | 389 |
| SMB | n/a | 445 |

# Group Policy Software Installation Extension Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By using the Group Policy Software installation extension of Microsoft Windows Server 2003, an administrator can centrally deploy, install, and manage applications throughout an organization. From a central location, the administrator can also perform routine maintenance tasks such as upgrading, patching, and removing applications without going to individual workstations, which gives users reliable access to the applications that they need to perform their jobs, no matter which computer they are using.

The Group Policy Software installation extension relies on both the Active Directory directory service included with Windows Server 2003 and Group Policy.

# What Is Group Policy Software Installation Extension?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Group Policy Software Installation Extension?**

**In this section**

- Group Policy Software Installation Extension Scenarios
- Group Policy Software Installation Extension Dependencies
- Comparing Microsoft Software Management Solutions

This section provides a high-level overview of the Group Policy Software installation extension and compares it with other Microsoft software-management technologies.

Microsoft offers several key technologies to aid organizations with deploying new software and software upgrades or updates. One of the key reasons for implementing the Group Policy Software installation extension, a Group Policy-based technology, is to lower the company's total cost of ownership of its computers. Because installing, upgrading, and updating applications are critical business processes, companies can leverage the built-in Group Policy software distribution technology to increase users' productivity as changes occur.

The following table describes the capabilities of the Group Policy Software installation extension.

**Group Policy-Based Software Installation Capabilities**

| Capability | Description |
|---|---|
| Central location to create distribution instructions | Windows Server 2003 administrators create the packages and configure the details of the packages that are published to Active Directory. |
| Central location to initiate delivery of software | By using Group Policy configurations, software is made available to computers and users that are part of the Active Directory hierarchy. |
| Scheduling | Software is made available to users immediately in **Add or Remove Programs** in Control Panel, or is automatically installed at computer startup or user logon. |
| Distribution targeting | Software deployment uses the Active Directory and Group Policy infrastructure services that are built into Windows Server 2003 to perform its targeting. |
| Installation and configuration status | Group Policy Results (formerly known as RSoP) provides detailed information on the client about what has been installed and why. |
| Distribution reporting | Group Policy provides interfaces for collecting data on individual software installations, but provides no such network-wide data collection mechanisms. |
| Disaster recovery for applications | With Group Policy, assigned applications automatically reinstall after system loss, and published applications are available for users to reinstall on-demand or by choosing the software in **Add or Remove Programs**. |

**Group Policy Software Installation Extension Scenarios**

The Group Policy Software installation extension enables the administrator to create a controlled environment, providing on-demand software installation and automatic repair of applications. Users benefit from reliable access to the applications that they need to perform their jobs on any computer they use on their network.

Scenarios where organizations might use Group Policy-based software distribution include the following:

- Publish applications that are nonessential for the users. When software is published for a user, it does not initially appear

to be installed on the computer. There is no Windows Installer advertisement information about the software on the computer in the registry, on the desktop, or on **Start** menu as a shortcut. On an as-needed basis, the user installs the published software by using **Add or Remove Programs** in **Control Panel**. Users can also install the published application by selecting a file that has a file name extension for an application.

- Assign software to users or computers for either of the following reasons:
  - To make a particular application available to all users of a computer, assign the application to the computer.
  - To make mission-critical software available to users or computers at all times, assign the application to the users.

**Group Policy Software Installation Extension Dependencies**
The Microsoft Windows 2000, Windows XP Professional, and Windows Server 2003 operating systems provide software distribution by using Group Policy, which is built on the management infrastructure services in the operating system. Group Policy requires Active Directory directory service. Windows Server 2003 provides a robust and feature-laden software distribution mechanism for organizations by using Active Directory. The Group Policy Software installation extension also depends on Windows Installer.

For detailed information about Group Policy dependencies, see "Core Group Policy Technical Reference."

**Comparing Microsoft Software Management Solutions**
Microsoft offers several software solutions for networked users. An organization might already have objectives and requirements for a software installation and management product. This section compares Microsoft technologies for software deployment.

Group Policy, which is built-in to the Windows 2000, Windows XP Professional, and Windows Server 2003 operating systems, offers a convenient method for distributing software in an Active Directory environment, especially if it already uses Group Policy for other purposes, such as securing client and server computers. However, a Group Policy-based software installation has some basic limitations, including difficulties with scheduling installation, consistently managing network bandwidth, and providing feedback on the status of the installation.

To carefully schedule installations, manage network use, perform hardware and software inventory, or monitor installation status, consider using Microsoft Systems Management Server (SMS). For more information about SMS, see the Microsoft Systems Management Server Product Information page.

Using the right solutions can benefit an organization by providing a centralized, efficient means to perform routine tasks such as updating software. The following table compares the various software management technologies.

**Comparing Software Management Technologies**

| Management Function | Group Policy | Microsoft Systems Management Server (SMS) | Terminal Services | Microsoft Software Update Services (SUS) |
|---|---|---|---|---|
| Patch and upgrade Windows XP, Windows Server 2003, and Windows 2000 | N/A | Yes<br><br>When using SMS for software management, also use it to patch Windows-based computers instead of SUS. | Although Terminal Services does not automate patching, it can be used it to remotely log on and apply patches. | Windows patches only (no upgrade) |
| Create consistent user environment (persistence of data, software, and settings) | Yes | Software only | Yes | N/A |
| Perform disaster recovery for applications in Windows 2000, Windows XP, and Windows Server 2003 | Yes | Yes | N/A | N/A |

| | | | | |
|---|---|---|---|---|
| Perform inventory, advanced deployment, troubleshooting, and diagnostic tools | Limited | Yes | Limited | None |
| Manage environments that are not Active Directory-based | No | Yes | Yes | Yes (Windows patches only) |

Although all these Microsoft management technologies provide important software distribution capabilities, SMS is the preferred Microsoft software distribution solution for medium-sized, and especially for enterprise-sized, organizations. SMS provides advanced features for deploying and managing software, Windows patches, and critical updates. For organizations that use SMS as a software management solution, the Microsoft Software Update Services (SUS) SMS Feature Pack for SMS 2.0 provides the features of SUS for users of SMS 2.0 for distributing patches and critical updates to clients. However, SUS used with the Automatic Updates client is the recommended solution for distributing Windows patches in conjunction with Group Policy–based software distribution.

Although there are specific instances where an administrator might choose one software deployment method over another, many of these Microsoft technologies can be used together, depending on an organization's needs.

The following sections describe each of these solutions.

**Group Policy Software Installation Extension**

The Group Policy Software installation extension is well-suited to deploy and manage software if the organization is small or medium in size, and the following conditions exist:

- The administrator has deployed Active Directory.
- The administrator has determined that Group Policy provides the management features the organization requires.
- The administrator has a base of client computers running Windows 2000 Professional or Windows XP Professional and member servers running Windows 2000 Server and Windows Server 2003. Note that the servers do not have to run Windows Server 2003 to use Group Policy–based software deployment.

Group Policy can also serve the needs of large enterprises that use other software installation solutions, such as SMS, across the organization. In conjunction with SMS or other solutions, Group Policy can be useful for distributing software within various groups, such as individual divisions, where the advanced capabilities of SMS might not be needed.

The following figure shows the Group Policy Object Editor interface after a new package has been added to a GPO by using the Group Policy Software installation extension.

**Group Policy Software Installation Extension**

This topic details the Group Policy Software installation extension for providing application management.

**Systems Management Server**

SMS is appropriate for organizations if any of the following conditions exist:

- The organization is medium or large in size.

- Its users are running operating systems earlier than Windows 2000 Professional.
- The organization requires more advanced capabilities for planning, scheduling, distributing, and tracking software.

The advanced capabilities of SMS include such features as inventory-based targeting, status reporting, server-side and client-side scheduling, support for multisite facilities, centralized hardware and software inventorying, remote diagnostic tools, software metering, software distribution-point population and maintenance, and other enhanced software deployment features. SMS also provides support for Microsoft Windows 95, Windows 98, Windows NT 4.0, Windows 2000, and Windows XP clients. Additionally, SMS does not require Active Directory. For more information about SMS, see the Microsoft Systems Management Server Product Information page.

**Terminal Services**

Terminal Services can be very useful if an organization has Windows-based desktop applications that require frequent updates, and the users who require those applications are in remote locations and have low bandwidth. When used as a terminal server, a server becomes a Windows application server. This allows the user to run Windows-based applications remotely on the server while only the mouse, keyboard, and display data are transmitted to the local computer. Terminal Services allows an administrator to offer users software as a remote service instead of as a local installation package, as with Group Policy-based software distribution. For more information about Microsoft Terminal Services, see the Terminal Services topic.

**Microsoft Software Update Services**

Microsoft Software Update Services (SUS) can be used to quickly acquire and distribute critical Windows patches to computers in an organization. By using SUS, an administrator can choose which of the latest critical or security patches to download, test them in a company-standard operating environment, and then efficiently deploy the patches to the appropriate computers running the Automatic Updates client.

# How Group Policy Software Installation Extension Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Group Policy Software Installation Extension Works**

**In this section**

- Terms and Definitions
- Group Policy Software Installation Extension Architecture
- Group Policy Software Installation Extension Components
- Group Policy Software Installation Extension Processes and Interactions

The Group Policy Software installation extension allows administrators to use the Group Policy Object Editor to centrally manage the installation of software on all client computers in an organization. This is accomplished either by assigning applications to users or computers, or by publishing applications for users.

Software can be assigned on a per-user or per-computer basis when an organization does not want to give users the choice to install or remove the software. For example, if a user removes a user-assigned application by using Add or Remove Programs in Control Panel, the Group Policy Software installation extension automatically reapplies the advertisement information after the user logs on or the computer restarts, and the software is reinstalled the next time a user selects it or tries to open a file with an associated file name extension. It is not possible for a user to delete a computer-assigned application. In most cases, packages that are assigned to users or computers include applications that are essential but do not create congestion between the clients and the software distribution points.

Group Policy-based software deployment allows administrators to publish software for users only; in other words, published software is not available for computers. Publishing software for users allows them to decide if and when they want to install it. They can install the software from a list of published applications in Add or Remove Programs. For example, not everyone in the organization requires software for project management. Therefore, a software administrator is likely to publish a project management package for only those users who require it. Managers who require the software can then choose to install it.

Users can always see both assigned and published applications in Add or Remove Programs. Add or Remove Programs includes an active Web link for each application, which provides users with the support information they need to install certain applications. However, administrators can overwrite the default link by using the Group Policy Software installation extension. The support link then corresponds to the internal product support resources.

This Web link can also point to a support page that includes information such as an FAQ about a specified application, a help desk article about using the application, or instructions for requesting support.

**Group Policy–based Software Installation in the Ideal Environment**

The following components are necessary to deploy software using the Group Policy Software installation extension:

- Group Policy.
- Windows 2000 Server or Windows Server 2003 domain controllers.
- A network that uses Active Directory directory service–based domains.
- Target computers that run Windows 2000 Server, Windows 2000 Professional, Windows XP Professional, or Windows Server 2003.

The Group Policy Management Console (GPMC) is not required but necessary for simple, powerful, and efficient administration. See the Group Policy topic for more information about GPMC.

**Terms and Definitions**

The following are terms used in this document to describe aspects of Group Policy–based software deployment.

**Advertisement**
The process of making an application that supports Windows Installer appear installed on the desktop, by installing the shortcuts for the application on the Start menu or desktop, and by populating the registry with the application information.

**Advertisement script**
The output of the Group Policy Software installation extension Microsoft Management Console (MMC) snap-in, which advertises an application that supports Windows Installer. The advertisement script is stored in Active Directory.

**Assigned**
One of the modes of targeting supported by Group Policy-based software deployment. Administrators can assign the software that users require to perform their jobs. Administrators can assign software to users and to computers. User-assigned applications are advertised on the desktop; they appear to be installed on the user's desktop, but they get installed the first time that the user starts the application, typically from the Start menu. If a user deletes an assigned application, it will be re-advertised. Computer-assigned applications are installed the next time that the computer restarts.

**Package**
A Windows Installer .msi file. At its core is a database that contains the instructions to manage the software on a computer.

**Published**
One of the modes of targeting supported by Group Policy-based software deployment. Administrators can publish software to users. Published applications are not advertised on the desktop; there is no physical appearance of published applications on the user's desktop. Users install published applications from the Add or Remove Programs in Control Panel or by opening a file type associated with an application.

**Repackaging**
The process of preparing software for distribution by making an image of a correctly configured computer, then installing the software and making a post-installation image of the computer. The repackaging software takes the difference of the two images and creates the necessary installation instructions to reproduce the installation.

**Group Policy Software installation extension snap-in**
The MMC component of Group Policy Object Editor that an administrator uses to manage software.

**Transform**
(Verb) The process of modifying or customizing a Windows Installer-based .msi package.

**Transform**
(Noun) A Windows Installer customized package that, if associated with another Windows Installer-based .msi package at deployment time, results in a customized installation.

**Windows Installer**
Windows Installer is a Windows operating system–based service that can install, modify, repair, and remove software. Windows Installer includes the operating system–based service, a package format, and an application-programming interface (API) that allows both the operating system and applications to interact with the service to install, modify, or repair the software.

**Group Policy Software Installation Extension Architecture**
This section details the architecture behind Group Policy–based software distribution. The Group Policy Software installation extension performs two processes: application publishing and application assignment. The following figure shows the server-side perspective of Group Policy–based software deployment.

### Server Architecture and Components of the Group Policy Software Installation Extension

**Application Publishing**

*Publishing* is simply advertising that a package is available to be installed – it does not mandate that an application be installed. A published package is created by using the Group Policy Software installation extension. The Group Policy Software installation extension extracts advertising information about the package and stores this, in modified form, in both the directory and the Sysvol folder. Advertising information includes the name and installation path of the application; it also includes information about the file associations, Program IDs (ProgID), and Component Object Model (COM) Class IDs (CLSID) that the application supports or implements.

Published applications can be either Windows Installer .msi files or text-based .zap files. Each is treated differently: The Group Policy Software installation extension uses the Windows Installer subsystem to extract advertising information from the .msi package. This information is programmed into the .msi package by the author of the package, normally the application vendor. A .zap package is a simple text wrapper around a setup command. The author of the .zap file can include information such as file name extension and COM support in the .zap file. This information is extracted directly by the Group Policy Software installation extension.

A subset of the advertising information – file name extensions, CLSIDs, and ProgIDs – is used to create an Active Directory package publication object (PackageRegistration) in the ClassStore container. This is located in the *GPO GUID*\User\Class Store\Packages subcontainer of the Group Policy object (GPO) in which the package is published and given a newly generated globally unique identifier (GUID) for a common name (CN). This published package then becomes available to all recipients of the advertised application.

The Group Policy Software installation client-side extension (CSE) also creates an Application Advertising script in the Sysvol folder that is derived from the same advertising information. This has the same name as the related PackageRegistration object with a file name extension of .aas. In this case, more of the advertising information – such as Start menu shortcuts created by the application, which are omitted from the PackageRegistration object – is used in the creation of the .aas file. This file is stored in *GPO GUID*\User\Applications.

Published applications do not cause any change on the client computer during normal GPO processing, so no information is downloaded from Active Directory or Sysvol. However, the applications published to the user can be viewed in Add or Remove Programs. The user must perform some action to cause the published application to be installed. The simplest case is that the user chooses to install the application from Add or Remove Programs.

The Group Policy Software installation extension also supports a more sophisticated method for installing applications. If a user attempts to open a document with a file name extension for which there is no application currently installed, or tries to call a COM object for which there is no local definition in the registry, the Group Policy Software installation extension service searches Active Directory for PackageRegistration objects that support the file name extension or COM CLSID and that have been published to the user by using a GPO. If one is found, the .aas script is downloaded to the client computer and runs to create advertisements on the computer. When the user again attempts to open a document or a COM operation is retried, the advertisement triggers the installation of the application (or at least that part of it required to support the document or COM operation attempted). If more than one suitable PackageRegistration object is found, the one in the highest-priority GPO is selected. Where there is more than one in the same GPO, the one with the latest creation date is selected.

The following figure shows the Group Policy–based software publishing architecture.

**Group Policy–based Software Deployment Processing Architecture and Components (Published Software)**

**Application Assignment**

Assigning is a superset of publishing. The same description for published-application processing applies to assignment except that the application is either fully or partly installed on the client computer during GPO processing.

Assignment differs from publishing in that the Group Policy Software installation extension either advertises the application on the client computer (in the case of a user assignment) or fully installs the application (in the case of a computer assignment). Assigning to a user creates an advertisement of the application on the client computer – this can include application shortcuts on the Start menu and registry entries defining COM and program registrations supported by the application. Unlike publishing, applications can also be assigned to computers. The Group Policy Software installation CSE only processes during startup and logon, never during periodic refresh. By default, it also does not process over a slow link (this behavior can be changed).

The creation of an assigned package is similar to that of a published package. This produces an almost identical PackageRegistration object and .aas file. The only difference is that the PackageFlags property of the PackageRegistration object identifies this as an Assigned rather than a Published application.

Advertising is a function of Windows Installer and works by placing entry points to the application on the client system. Examples of these entry points are Start menu shortcuts, COM Class IDs, Program IDs, and Multipurpose Internet Mail Extensions (MIME) types. These entry points are configured so that, if any of them are called, Windows Installer installs the application. Windows Installer checks to see whether the application or application component that implements the call has been installed. If not, it installs the application. To the user, the advertisements appear to be already installed.

During GPO processing, the Group Policy Software installation CSE queries the directory for available assigned PackageRegistration objects for applied GPOs that have changed or are new. Any packages found are compared to those already downloaded onto the client computer – the client computer records received packages in the registry and caches .aas files. Any new or changed packages are processed. The corresponding .aas file is read from the Sysvol folder and then cached in %systemroot%\appmgmt. This folder also contains AppMgmt.ini, which stores configuration settings.

The following figure shows Group Policy–based software assignment architecture.

**Group Policy–based Software Deployment Processing Architecture and Components (Assigned Software)**

**Software Distribution Point Servers**

*Deploying applications* is the process of setting up and managing distribution points or server shares where users have access to the packaged software and can install it on their computers. These servers act as file shares for the .msi packages identified in software installation GPOs.

Two methods can be used for deploying and managing software distribution point servers:

- Universal naming convention (UNC) path to a server share.
- Distributed File System (DFS).

**UNC Paths to Server Shares**

By using UNC paths, a user or application can specify the physical server and share names to gain access to file information. For example: *Server**Share**Path**File_name*. A UNC path can be used to allow direct access to a shared file by mapping to a network drive, where the drive letter denotes *Server**Share*. Administrators can also perform a **net use** command to navigate beyond the redirected drive.

However, as networks grow and as organizations begin using existing storage for new purposes, mapping a single drive letter to individual shares becomes inefficient. Also, despite the fact that users and applications can refer to UNC names directly, the increasing number of places users must go to retrieve data can be overwhelming.

**DFS and Software Distribution Point Servers**

DFS provides fault tolerance for software distribution points by mapping a specific logical name to shared folders on multiple file servers. This way, software remains available for installation, regardless of whether one of the physical servers where the software deployment files reside becomes unavailable. DFS also improves storage scalability because administrators can deploy additional or higher-performance file servers and present the storage on the new computers as new directories in an existing namespace.

When using DFS in combination with Group Policy–based software deployment, organizations benefit from its load-sharing abilities and location-independence. These features simplify management and optimize the installation for users. Instead of allowing all users to install software from a single server, and taxing the server, a DFS namespace can distribute network traffic across multiple servers.

**Group Policy Software Installation Extension Components**

Group Policy–based software deployment uses the Windows Server 2003 features and technologies described in the following table.

**Essential Tools and Components for Group Policy–based Software Deployment**

| Component or Tool | General Description | Combined with Group Policy Software Installation Extension |
|---|---|---|

| | | |
|---|---|---|
| Active Directory | A hierarchical collection of objects including domains, sites, organization units (OUs), users, computers, and printers that allow an organization to manage these resources. | Provides the scope of management mechanism to locate users and computers.<br><br>Stores software deployment information through Group Policy. |
| Group Policy | An administrative tool for defining and controlling the way programs, network resources, and the operating system work for users and computers in an organization. In an Active Directory environment, Group Policy is applied to users or computers on the basis of their membership within sites, domains, or OUs. | Enables administrators to deploy applications in a GPO associated with one or more Active Directory containers, such as sites, domains, or OUs. Use the Group Policy Software Installation extension snap-in to deploy applications. |
| Windows Installer | A service based on an operating system, which provides software installation services using a standard package format. Administrators can use Windows Installer to manage the installation, modification, upgrade, and removal of software applications. | Installs, modifies, upgrades, and removes software applications. |
| Group Policy Software installation extension | An extension of the Group Policy Object Editor snap-in that includes a user interface that allows administrators to deploy and manage software. | Communicates with Active Directory, GPOs, and Windows Installer to assign or publish applications as follows:<br><br>● Assigns software to users. Installs user-assigned applications entirely the first time the user logs on after deployment, or allows users to install certain components or features of an application as needed.<br><br>● Assigns software to computers. Installs an application the next time the computer starts. The application is available for all the users on that computer.<br><br>● Publishes applications for users only: Users can choose to install the software from a list of published applications located in Add or Remove Programs in Control Panel. |
| Appmgmts.dll | The client-side extension for the software installation component of Group Policy. | This is the extension file on the client that configures software installation settings. |
| Group Policy Management Console (GPMC) | A new tool that consists of an MMC snap-in and command-line tools. This tool unifies management of all aspects of Group Policy across an enterprise. GPMC allows administrators to manage all GPOs, Windows Management Instrumentation (WMI) filters, and permissions on a network. | Group Policy Modeling (formerly known as RSoP planning) allows administrators to run hypothetical scenarios to verify software configurations under various sites, domains, and OUs. Provides printable HTML-based reports.<br><br>Group Policy Results(formerly known as RSoP logging)verifies which software applications are properly installed for a specific group of users or computers. It also pinpoints the causes of unintended removal or damage to software. Provides printable HTML-based reports. |
| Add or Remove Programs | A user interface in Control Panel of Windows XP Professional and Windows 2000 Professional. Add or Remove Programs lets users manage software on their own computers. | Lists both published and assigned applications so that users can install, modify, and remove software from their desktop computers. |

| | | |
|---|---|---|
| Command-line and Graphical User Interface (GUI) tools or scripts | These include GPResult.exe, GPOTool.exe, GPUpdate.exe, ReplMon.exe, NetDiag.exe, InstallShield, and the new Group Policy Management Console (GPMC) MMC snap-in. Some are installed by default; others must be installed manually. | Helps manage, optimize, or troubleshoot Group Policy–based software deployment. |

**How Windows Installer Works**

Many software authors develop applications to include native Windows Installer packages. A native Windows Installer package contains a single product, such as Microsoft Office 2000, which can be made up of several features, such as Microsoft Word, Microsoft Excel, and Microsoft PowerPoint. However, software can be configured to install features individually. When the user selects an uninstalled feature, the feature is installed. Each feature (Word, Excel, PowerPoint, and so on) contains components, such as a thesaurus, spelling checker, or an additional user-interface language. When the user selects a feature or component that is not installed, the feature or component is automatically installed. Automatic (or "on-demand") installation of selected features saves network bandwidth during the initial installation. It also gives users only the features and components that they need to do their jobs. Automatic installation can also save space on users' local disk drives. However, this type of installation delays the availability of a feature when the user first selects it.

Windows Installer packages ensure that an accidentally deleted file, such as Winword.exe, is reinstalled the next time the user tries to start Word because Windows Installer detects and reinstalls missing files.

Windows Installer technology uses the following two components to help an organization install and manage software:

- A Windows Installer package (an .msi file), which is a database containing information that describes the installed state of an application. The Windows Installer package performs the installation, modification, and removal of the software.
- An application programming interface (API) that allows applications and management tools to interact with Windows Installer to install or remove additional features of the application after the initial installation is completed.

The managed state of an application includes installation, modification, upgrade, or removal. Windows Installer provides administrators with consistent and reliable methods to customize installations, update and upgrade applications, and resolve configuration problems. The following are some of its advantages:

- Helps manage the state of software during and after installation.
- Defines a standard format for application setup and tracks components such as groups of files, registry entries, shortcuts, and other aspects of the application that must be managed together.
- Detects whether software is installed correctly or whether a program file is missing. It can immediately reinstall the damaged or missing files.
- Repairs applications and ensures that they are installed or removed without overwriting or deleting files that are required by another application.
- Enables administrators to modify an installation by adding or removing features after the installation.
- Enables deployment of 32-bit and 64-bit Windows applications using Windows Installer version 2.0.

**Note**

- Versions of Windows Installer earlier than version 2.0 can install and manage 32-bit Windows Installer packages only on 32-bit operating systems. Windows Installer version 2.0 supports all of the setup functionality that is available in earlier Windows Installer versions.

Software installed by using the Windows Installer uses the following parameters:

```
\>msiexec /I \\servername\share\<software.msi> TRANSFORMS = \\servername\share\
<software.mst> /qb
```

In this example, *Software.msi* is the Windows Installer package, and *Software.mst* is the transform applied at deployment time.

**Transforms for Customizing Windows Installer Packages**
A transform (.mst file) is a collection of specified changes that are applied to a base Windows Installer package file at the time of deployment. Windows Installer packages are modular to simplify deployment. When transforms are applied to an .msi file, Windows Installer can dynamically add or modify data in the installation database to customize the installation of the application.

For example, Office 2000 provides the Office 2000 Custom Installation wizard, which can be used to build transforms. Administrators can create a transform for managing the configuration of Office 2000 that is deployed to users in an organization. Other tools in the Windows Installer software development kit (SDK), or other non-Microsoft tools, can also help to create transforms for Windows Installer packages that do not include their own custom installation tools.

Transforms tailor the installation of an application. Although they are optional, transforms can be used for a variety of purposes including customizing and encapsulating.

**Customizing**
Customizing can involve configuring installations so that a particular set of features from a specified software application, or suite of software applications, is installed locally on the computer.

Transforms can also add new features to an existing application's package. For example, they can add custom Excel templates for an organization's Finance group.

**Encapsulating**
Administrators can encapsulate numerous customizations of a base package that are required by different groups. For example, in organizations where the Finance and Marketing departments require different installations of an application, the base package of the application can be made available to everyone at one software distribution point. Then the appropriate customizations can be distributed separately as transforms to each group of users.

**Reauthoring Applications for Windows Installer**
When administrators reauthor an application, they create applications that adhere to the Windows Installer format. Reauthoring is essentially redeveloping the setup portion of the application to take full advantage of the advanced capabilities of Windows Installer.

There are some authoring tools available to help developers create new Windows Installer packages, but the procedures can be resource-intensive and costly. If an organization determines that the application will play a key role in its future, it is important to weigh the benefits of reauthoring with the costs.

**.Zap Files**
Applications that do not use the .msi file format for the Windows Installer Service can be set up for distribution by creating a text file that has a .zap file name extension. When organizations have many applications that do not contain native Windows Installer packages and plan to discontinue these applications, they often create software installation settings (.zap) files for the installation executable files, such as Setup.exe or Install.exe. Additionally, if an organization uses custom applications that do not have Windows Installer support, but plan to use them in the long term, .zap files might be the only choice. Users of .zap files do not benefit from the capabilities of Windows Installer. The Group Policy Software installation extension recognizes .zap files that wrap 32-bit or 64-bit Setup.exe files into a .zap file format. Applications published in this format are available for users to install by using Add or Remove Programs.

Because these applications do not use Windows Installer setup programs, they do not do the following:

- Use elevated permissions for installation. While applications that are installed by using .zap files run their original setup programs, they do not run with the elevated permissions that Windows Installer packages have. If installing the application requires administrative permissions, only users who have those permissions can install it.
- Install a feature on the first use of the feature.
- Roll back an unsuccessful operation, such as install, modify, repair, or removal.
- Detect a broken state and automatically repair it.
- Implement customized installations (also known as transforms).

**64-Bit Application Packaging**
In Windows Server 2003, the Group Policy Software installation extension and Windows Installer version 2.0 continue to

support and protect the investment that organizations have made in 32-bit applications. Additionally, Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, introduce support for 64-bit application installation.

Windows Installer version 2.0 can install three types of Windows Installer packages on a computer running a 64-bit operating system:

- 32-bit packages that contain only 32-bit components
- 64-bit packages containing some 64-bit components and some 32-bit components
- 64-bit packages containing only 64-bit components

**Note**

- 64-bit applications cannot be published or installed on 32-bit operating systems. Group Policy will attempt to install an incorrectly configured 64-bit package for 32-bit clients, but then removes the package during logon. It then installs the package again the next time a user logs on, and so on.

The Group Policy Software installation extension can be configured to allow or disallow installation of 32-bit applications to 64-bit clients. More .zap applications fail on 64-bit clients than on 32-bit clients. Unless the default behavior is changed, 32-bit .zap applications are deployed so that they are not listed in Add or Remove Programs on 64-bit clients.

**Repackaging Applications for Windows Installer**
Administrators repackage an .msi package for Windows Installer when they cannot reauthor it. Repackaging an application for Windows Installer involves making an image of a fresh computer (including the registry settings, files, and system settings), installing the software, and then taking a post-installation image of the computer. The repackaging software detects the difference between the two images, and then creates the necessary instructions to reproduce the installation. If any registry changes, files changes, or system setting changes occur during the capture process, they are included in the installation. Repackaging is useful when administrators do not have control over dynamic-link library (DLL) files, source code, and registry entries, or for applications about which they do not have in-depth knowledge.

Repackaging requires a thorough knowledge of the application's installation program and of the Windows Installer configuration on the Windows platform. Success with repackaging is affected by the state of the computer on which an administrator performs the repackaging. The computer should have only the operating system and operating system service packs installed before running the repackaging software. Because of this limitation, and other issues, repackaging is not recommended.

Repackaging is not a function or a feature of Windows Installer. As with reauthoring applications, several vendors provide tools to enable administrators to repackage applications for a variety of needs. The same vendors who provide tools to reauthor applications can also help repackage them.

During repackaging, an application, the existing components, such as DLLs, .ini files, registry settings, and shortcuts, are replaced, and then the administrator creates a path for Windows Installer to find these items at installation time.

For more information about repackaging applications in the .msi format, see the Windows Installer SDK for detailed documentation about the Windows Installer package format.

**Group Policy Software Installation Extension Processes and Interactions**
Because software can be published for users, assigned to users, or assigned to computers, administrators can establish a workable combination of those three options to meet an organization's software management goals.

**Publishing Software for Users**
The benefit of publishing software, instead of assigning it, is that it requires less management when change occurs in the Active Directory structure. Typically, applications that are nonessential for the users are published. When software is published for a user, it does not initially appear to be installed on the computer. There is no Windows Installer advertisement information about the software on the computer in the registry, on the desktop, or on Start menu as a shortcut. On an as-needed basis, the user installs the published software by using Add or Remove Programs in Control Panel. An exception is when an application is published in a new GPO, when the GPO must be simultaneously linked to the users in a site, domain, or OU. If a GPO is linked and the software is deployed at the same time, the GPO must be refreshed by an administrator or by a user logging on before the application appears in Add or Remove Programs.

Users can also install a published application by opening an associated document if the application is deployed to do that (if Auto-Installis selected).

The user can remove published software, and then later choose to reinstall it, by using Add or Remove Programs.

The following figure shows how Group Policy–based software publishing works.

**Group Policy–based Software Publishing for Users**

**Assigning Software**

There are three methods for assigning software: assign to users on-demand, assign to users, or assign to computers.

**Note**

- By default, Group Policy allows administrators to configure a user-assigned application that has a staggered, on-demand installation. Windows Server 2003 allows administrators to turn off the default installation and install the entire application at once. This is the same behavior as computer-assigned application installation.

**Assigning Software to be Available on Demand**

After a software package is assigned to users in a site, domain, or OU, the software is advertised on user desktops. The application becomes available to the user the next time the user logs on (if the application's GPO applies to that user). The application is fully installed by the user from the Start menu, from Add or Remove Programs, from a desktop shortcut, or by opening a document (on demand) that has a file name extension that is associated with the application.

The user can remove the software, and then later choose to reinstall it as they did previously. Group Policy ensures that assigned applications that are available on-demand are available, regardless of whether users remove them, and that the applications are available again the next time the user logs on or starts the computer.

**Assigning Software to Users**

After a software package is assigned to users in a site, domain, or OU, administrators can use the **Install this application at logon** option to install the whole application the next time the computer starts, or after the user logs off and then logs on again. Alternatively, for users of Windows XP Professional, Logon Optimization can delay the installation of software to the second logon to prevent installation during the first logon. The application is also immediately available in Add or Remove Programs.

The user can remove the software, and then later choose to reinstall it.

**Note**

- Some published applications might not appear in Add or Remove Programsin a domain that has multiple domain controllers until the changes have replicated to all domain controllers in the domain.

The following figure shows the client-side perspective of assigning Group Policy–based software deployment.

**Group Policy–based Software Assignment to Users**

**Assigning Software to Computers**

After assigning a software package to computers in a site, domain, or OU, the software is installed the next time the computer restarts or the user logs on. For users of Windows XP Professional, Logon Optimization can delay the installation of software to the second logon to prevent installation during the first logon.

Only the local or network administrator can remove the software, though a user can repair the software.

The following figure shows the client-side perspective of publishing Group Policy–based software deployment.

**Group Policy–based Software Assignment to Computers**

**Patches for Installed Applications**

Installing a patch updates a previously installed application or applications. A patch package (.msp file) is obtained from the software manufacturer or from the internal developers of the original program. Installing patches allows existing applications to be updated without removing the product. This preserves the customizations of the installation and can lower the cost of making the change. The patch might change only a few bytes of a single application file. It is more efficient to distribute those few bytes than to remove and redeploy the whole product.

**Note**

- A patch might change all of the files and registry keys in a product.

After a patch is applied, it is cached on the user's computer, this allows the user to:

- Perform any installation on demand.
- Reinstall the application.
- Repair the application.
- Remove the application.

A patch package (.msp file) does not include a database as a regular installation package does. Instead, it contains, at a minimum, one database transform that adds patching information to the database of its target Windows Installer .msi package. For an application to perform maintenance operations, such as adding, removing, or repairing the installation, the package codes for both the installed application and the source must match.

**Software Upgrades**

During an upgrade where the ProductVersion or ProductCode property of the package has changed, Windows Installer searches for upgradeable products by querying the Upgrade table of the upgrade package. The newer version of the product is installed. If Windows Installer finds an older version of the product, it removes the old version. The author of the application's setup can choose to remove the old version, and then install the new version. The maintenance mode and removal do not trigger these actions because "remove existing versions of an application" is now automatic.

The Windows Installer package for a repackaged application does not have declared upgrade relationships. Administrators must manually create upgrade relationships. The Group Policy Software installation extension can be used to create upgrade relationships between the new package and the packages that the application replaces. This includes making a formal upgrade relationship between two similar products from completely different vendor's. A vendors application can replace another's, or an administrator can upgrade a repackaged application.

# Group Policy Software Installation Extension Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group Policy Software Installation Extension Tools and Settings**

**In this section**

- Group Policy Software Installation Extension Tools
- Group Policy Software Installation Extension Group Policy Settings and Registry Entries
- Related Information

This section summarizes the tools and settings associated with the Group Policy Software installation extension.

**Group Policy Software Installation Extension Tools**

The following tools are associated with the Group Policy Software installation extension:

- InstallShield
- Application Experience Lookup Service
- Windows Installer

**InstallShield**

**Category**

InstallShield products do not ship with Windows.

**Version compatibility**

InstallShield Corporation creates several tools for building Windows Installer packages that work on all versions of Windows managed by Group Policy. Make sure you use the correct version for the systems that you manage.

InstallShield creates popular tools for developing Windows Installer .msi packages.

**Application Experience Lookup Service**

**Category**

The Application Experience Lookup Service is a new service included in Windows Server 2003 with Service Pack 1 (SP1).

**Version compatibility**

This service is part of an infrastructure that provides a way to apply fixes to applications in order to ensure that they run on newly released Windows operating systems or service packs.

This service needs to be running for the application fixes to work. There are no entry points to this service for customizations and it is for operating system internal use only. There is no out-of-the box communication in the service. This service does not use any Active Directory, network, or internet resources.

The functionality of the service can be disabled though Group Policy settings for application compatibility. When this setting is disabled, the service will continue to run, but there will be no calls made to the service. The service itself cannot be stopped or disabled.

**Windows Installer**

**Category**

Windows Installer ships with Microsoft Windows Server 2003 family, Windows XP, Windows 2000, and Windows Millennium Edition (Windows Me). The installer is also provided as a service pack for Microsoft Windows NT version 4.0, Windows 98, and Windows 95.

**Version compatibility**

Windows Installer version 2.0 adds advanced features and requires Windows NT 4.0 with Service Pack 6 or later,

Windows 2000, Windows Me, or Windows XP. Earlier Windows Installer versions require Windows NT 4.0 with Service Pack 3 or later, Windows 2000, or Windows Me.

Windows Installer supports advertisement of applications and features according to operating system. The following table outlines Windows Installer advertisement support on different operating systems.

**Group Policy Software Installation Advertisement Support on Different Operating Systems**

| Operating System | Advertisement Support |
|---|---|
| Windows 2000<br><br>Windows XP | • Shortcuts and their icons.<br><br>**NOTE**: AppId and Typelib information is only written when an advertised component is installed.<br><br>• Extensions and their icons specified in the ProgId table.<br><br>• Shell and command Verbs registered underneath the ProgId key.<br><br>• CLSID contexts and InProcHandler.<br><br>• Install-On-Demand through OLE is only available programmatically through CoCreateInstance (C or C++) and CreateObject or GetObject (Visual Basic). |
| Windows 98<br><br>Windows Me | All of the above except CLSID, which is only written when installing an advertised component.<br><br>Shell and MIME support. |
| Microsoft Windows 95<br><br>with IE4.01 Service Pack 1 installed<br><br>with Windows Desktop Update installed<br><br>(shell32.dll of 4.72.3110.0 or newer)<br><br>Windows NT 4.0<br><br>with IE4.01 Service Pack 1 installed<br><br>with Windows Desktop Update installed<br><br>(shell32.dll of 4.72.3110.0 or newer) | All of the above except CLSID, which is only written when installing an advertised component.<br><br>Shell and MIME support. |
| Windows 95<br><br>Windows NT 4.0<br><br>(shell32.dll older than 4.72.3110.0) | Advertisement is not supported by these platforms. |

On Windows 98 or Windows 95 with the updated shell32.dll, advertised shortcuts do not work until the computer is restarted. This only affects the first product that installs the package for Windows Installer. The installation of the product might not require a restart, but any advertised shortcuts do not work until the computer has been restarted. Advertised shortcuts of subsequent installations work without a restart. Conditional statements can check the **ShellAdvtSupport** property and **Version9X** property.

Windows Installer is a Windows operating system-based service that reduces the total cost of ownership by allowing

administrators to manage the installation, modification, upgrade, and removal of software applications using a standard package format.

Windows Installer includes the operating system-based service, a package format, and an application-programming interface (API) that allows both the operating system and applications to interact with the service to install, modify, or repair the software.

**Group Policy Software Installation Extension Group Policy Settings and Registry Entries**
In addition to setting configuration options for the application in **Properties**, you can use several Group Policy settings to control the behavior of Windows Installer and the Add or Remove Programs feature of Windows.

The following tables list the Group Policy settings and associated registry keys that control Windows Installer and Add or Remove Programs. The settings are all part of the System.adm file.

The following table lists the Group Policy Machine settings and associated registry keys that control Windows Installer. These settings are found in these locations:

- Group Policy Location: MACHINE\Administrative Templates\Windows Components\Windows Installer
- Registry Location: HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows

**Group Policy Settings for Windows Installer (Machine)**

| Setting | Description |
|---|---|
| Disable Windows Installer | Disables or restricts the use of Windows Installer. This setting can prevent users from installing software on their systems or permit users to install only those programs offered by a system administrator. |
| Always install with elevated privileges | Directs Windows Installer to use system permissions when it installs any program on the system. This setting extends elevated privileges to all programs. |
| Prohibit rollback | Prohibits Windows Installer from generating and saving the files it needs to reverse an interrupted or unsuccessful installation. This setting prevents Windows Installer from recording the original state of the system and sequence of changes it makes during installation. It also prevents Windows Installer from retaining files it intends to delete later. As a result, Windows Installer cannot restore the computer to its original state if the installation does not complete. |
| Remove browse dialog box for new source | Prevents users from searching for installation files when they add features or components to an installed program. This setting disables the **Browse** button beside the Use feature from list in the Windows Installer dialog box. |
| Prohibit patching | Prevents users from using Windows Installer to install patches. |
| Disable IE security prompt for Windows Installer scripts | Allows Web-based programs to install software on the computer without notifying the user. |
| Enable user control over installs | Permits users to change installation options that typically are available only to system administrators. This setting bypasses some of the security features of Windows Installer. It permits installations to complete that otherwise would be halted due to a security violation. |

| | |
|---|---|
| Enable user to browse for source while elevated | Allows users to search for installation files during privileged installations. This setting enables the **Browse** button in the Use feature from dialog box. As a result, users can search for installation files, even when the installation program is running with elevated system privileges. |
| Enable user to use media source while elevated | Allows users to install programs from removable media, such as floppy disks and CD-ROMs, during privileged installations. This setting permits all users to install programs from removable media, even when the installation program is running with elevated system privileges. |
| Enable user to patch elevated products | Allows users to upgrade programs during privileged installations. This setting permits all users to install patches, even when the installation program is running with elevated system privileges. |
| Allow admin to install from Terminal Services session | Allows Terminal Services administrators to install and configure programs remotely. |
| Cache transforms in secure location on workstation | Saves copies of transform files in a secure location on the local computer. |
| Logging | Specifies the types of events that Windows Installer records in its transaction log for each installation. The log, **Msi.log**, appears in the **Temp** directory of the system volume. |
| Prohibit User Installs | Allows you to configure user installs. This setting is useful in environments where the administrator only wants per-computer applications installed, such as on a kiosk or a Windows Terminal Server. |
| Turn off creation of System Restore Checkpoints | If you disable this setting or do not configure it, the Windows Installer automatically creates a System Restore checkpoint each time an application is installed. |

The following table lists the Group Policy User settings and associated registry keys that control Windows Installer. These settings are found in these locations:

- Group Policy Location: USER\Administrative Templates\Windows Components\Windows Installer
- Registry Location: HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows

**Group Policy Settings for Windows Installer (User)**

| Setting | Description |
|---|---|
| Always install with elevated privileges | Directs Windows Installer to use system permissions when it installs any program on the system. This setting extends elevated privileges to all programs. |
| Search order | Specifies the order in which Windows Installer searches for installation files. |

| | |
|---|---|
| Prohibit rollback | Prohibits Windows Installer from generating and saving the files it needs to reverse an interrupted or unsuccessful installation. This setting prevents Windows Installer from recording the original state of the system and sequence of changes it makes during installation. It also prevents Windows Installer from retaining files it intends to delete later. As a result, Windows Installer cannot restore the computer to its original state if the installation does not complete. |
| Prevent removable media source for any install | Prevents users from installing programs from removable media. |

The following table lists the Group Policy User settings and associated registry keys that control Add or Remove Programs. These settings are found in these locations:

- Group Policy Location: USER\Administrative Templates\Control Panel\Add or Remove Programs
- Registry Location: HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion\Policies\

**Group Policy Settings for Add or Remove Programs (User)**

| Setting | Description |
|---|---|
| Remove **Add or Remove Programs** | Prevents users from using **Add or Remove Programs**. This setting removes **Add or Remove Programs** from Control Panel and removes the **Add or Remove Programs** item from menus. |
| Hide Change or Remove Programs page | Removes the **Change or Remove Programs** button from the **Add or Remove Programs** bar. |
| Hide Add New Programs page | Removes the **Add New Programs** button from the **Add or Remove Programs** bar. |
| Hide Add/Remove Windows Components page | Removes the **Add/Remove Windows Components** button from the **Add or Remove Programs** bar. |
| Hide the Set Program Access and Defaults page | Removes the **Set Program Access and Defaults** button from the **Add or Remove Programs** bar. |
| Hide the Add a program from CD-ROM or floppy disk option | Removes the **Add a program from CD-ROM or floppy disk section** from the **Add New Programs** page. |
| Hide the Add programs from Microsoft option | Removes the **Add programs from Microsoft** section from the **Add New Programs** page. |
| Hide the Add programs from your network option | Prevents users from viewing or installing published programs. This setting removes the **Add programs from your network** section from **the Add New Programs** page. |
| Go directly to Components Wizard | Prevents users from using **Add or Remove Programs** to configure installed services. This setting removes the **Set up services** section of the **Add/Remove Windows Components** page. |
| Remove Support Information | Removes links to the **Support Info** dialog box from programs on the **Change or Remove Programs** page. |
| Specify default category for **Add New Programs** | Specifies the category of programs that appears when users open the **Add New Programs** page. If you enable this setting, only the programs in the category you specify are displayed when the **Add New Programs** page opens. |

The following table lists the Group Policy Machine settings and associated registry keys for application compatibility. These settings are found in these locations:

- Group Policy Location: MACHINE\Administrative Templates\Windows Components\Application Compatibility

- Registry Location: HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows

**Group Policy Settings for Application Compatibility (Machine)**

| Setting | Description |
|---|---|
| Turn Off Application Compatibility Engine | Controls the state of the application compatibility engine in the system. |
| Turn Off Program Compatibility Wizard | Controls the state of the Program Compatibility Wizard. When enabled, this setting disables the start page of the wizard in Help and Support, and in the Start menu. |
| Remove Program Compatibility Property Page | Controls the visibility of the Program Compatibility property page shell extension. |
| Turn On Application Help Log Events | Blocks known incompatible applications and displays a dialog to the end-user regarding the problem. |
| Prevent access to 16-bit applications | Specifies whether to prevent the MS-DOS subsystem (ntvdm.exe) from running on this computer. This setting affects the launching of 16-bit applications in the operating system. |

The following table lists the Group Policy User settings and associated registry keys for application compatibility. These settings are found in these locations:

- Group Policy Location: USER\Administrative Templates\Windows Components\Application Compatibility

- Registry Location: HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows

**Group Policy Setting for Application Compatibility (User)**

| Setting | Description |
|---|---|
| Prevent access to 16-bit applications | Specifies whether to prevent the MS-DOS subsystem (ntvdm.exe) from running for all users. This setting affects the launching of 16-bit applications in the operating system. |

# Security Settings Extension Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In an Active Directory directory service environment, you can use the Security Settings snap-in to modify the security policy assigned to a Group Policy object that is linked to an organizational unit, domain, or site. The Security Settings snap-in is an extension of the Group Policy Object Editor Microsoft Management Console (MMC) snap-in. You can use the Security Settings snap-in from any computer that is joined to a domain. On a local computer, you can use the Local Security Policy snap-in to modify account and local policies, public key policies, and IP security policies.

# What Is Security Settings Extension?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Security Settings Extension Overview
- Securing Distributed Systems
- Related Information

Security settings policies are rules that administrators configure on a computer or multiple computers for the purpose of protecting resources on a computer or network. The Security Settings extension of the Group Policy Object Editor snap-in allows you to define security configurations as part of a Group Policy object (GPO). The GPOs are linked to Active Directory containers such as sites, domains, or organizational units, and enable administrators to manage security settings for multiple computers from any computer joined to the domain. Security settings policies are used as part of your overall security implementation to help secure domain controllers, servers, clients and other resources in your organization.

Security settings can control:

- User authentication to a network or computer.
- The resources that users are permitted to access.
- Whether to record a user's or group's actions in the Event log.
- Membership in a group.

**Security Settings Extension Overview**

Administrators can use the Security Settings extension to specify the security configuration of a Group Policy object. This in turn affects all the computers in the Active Directory container to which the Group Policy object is linked. All security policies are computer-based policies.

To manage security configurations for multiple computers, you can use one of the following options:

- Edit specific security settings in a GPO.
- Use the Security Templates snap-in to create a security template that contains the security policies you want to apply, and then import the security template to a Group Policy object. A security template is a file that represents a security configuration, and can be imported to a GPO, or applied to a local computer, or can be used to analyze security.

The Security Settings extension of Group Policy Object Editor includes the following types of security policies:

- **Accounts Policies.** These polices are defined on computers; they affect how user accounts can interact with the computer or domain. Accounts policies include the following types of policies:
    - **Password Policy.** These policies determine settings for passwords, such as enforcement and lifetimes. Password policies are used for domain accounts.
    - **Account Lockout Policy.** These policies determine the conditions and length of time that an account will be locked out of the system. Account lockout policies are used for domain or local user accounts.
    - **Kerberos Policy.** These policies are used for domain user accounts; they determine Kerberos-related settings, such as ticket lifetimes and enforcement.

- **Local Policies.** These policies apply to a computer and include the following types of policy settings:
    - **Audit Policy.** Specifies whether to log security events into the Security log on the computer, and specifies what types of security events to log (success, failure, or both).
    - **User Rights Assignment.** Specify the users or groups that have logon rights or privileges on a computer.
    - **Security Options.** Specify security settings for the computer such as Administrator and Guest Account names, access to floppy disk drive and CD-ROM drive, installation of drivers, logon prompts and so on.
- **Event Log.** Specifies settings for the application, security, and system logs.
- **Restricted Groups.** Controls membership in a security-sensitive (restricted) group, and specifies the groups to which a restricted group should belong. Restricted Groups policy states that only the members that you have added can belong to that group.
- **System Services.** Specifies startup options for system services, and define access permissions.
- **Registry.** Specifies access permissions (on discretionary access control lists (DACLs) and audit settings (on system access control lists (SACLs)) for registry keys.
- **File System.** Specifies access permissions and audit settings for file system objects.

**Securing Distributed Systems**

Organizations are faced with the complex, costly, and time-consuming task of securing and managing network systems, and keeping their desktops and servers protected with up-to-date security updates.

Administrators' tasks include:

- Keeping desktops and servers up-to-date with the latest security patches.
- Ensuring that the corporate security policies are enforced across desktops and servers.
- Monitoring systems for potential security compromises.

Organizations need efficient ways to maintain network security and manage updates, while reducing total costs for security management.

**Policy-Based Security Settings Management**

Windows Server 2003, Windows 2000, and Windows XP provide an integrated policy-based management infrastructure to help administrators manage and enforce their security policies.

Windows Server 2003 and Windows 2000, through Group Policy and Active Directory, enable IT administrators to define and apply security settings policies to users, groups, and network servers and clients. A group of servers with the same functionality can be created (for example, a Microsoft Internet Information Services (IIS) server), and then Group Policy objects can be used to apply common security settings to the group. If more servers are added to this group later, many of the common security settings are automatically applied, reducing deployment and administrative labor.

Using security settings policies simplifies and centralizes security configuration and management for computers running Windows Server 2003. Security policies can help reduce administrative tasks by automating some processes for applying security to servers. Computers running Windows Server 2003 that are members of a domain periodically access Active Directory; if they detect that a new policy exists or that an existing one has been changed, they automatically download the policy and apply it locally.

**Common Scenarios for Using Security Settings Policies**

Security Settings policies are used to manage the following aspects of security: accounts policy, local policy, user rights assignment, registry values, file and registry Access Control Lists (ACLs), and service startup modes.

As part of your security strategy, you can create GPOs with security settings policies configured specifically for the various computer roles in your organization, such as domain controllers, file servers, member servers, clients, and so on.

You can create an organizational unit (OU) structure that groups computers according to their roles. Using OUs is the best method for separating specific security requirements for the different computer roles in your network. This approach also allows you to apply customized security templates to each class of server or computer. After creating the security templates, you create a new Group Policy object (GPO) for each of the OUs, and then import the security template (.inf file) into the new GPO.

Importing a security template to a Group Policy object ensures that any accounts to which the GPO is applied automatically receive the template's security settings when the Group Policy settings are refreshed. On a workstation or server, the security settings are refreshed every 90 minutes, and on a domain controller, this process occurs every 5 minutes if changes have occurred in any of the GPO settings that apply. The settings are also refreshed every 16 hours, whether or not any changes have occurred.

By using Group Policy-based security configurations in conjunction with the delegation of administration, you can ensure that specific security settings, rights, and behavior are applied to all servers and computers within an OU. This approach makes it simple to update a number of servers with any additional changes required in the future.

**Dependencies on Other Operating System Components**
For computers that are members of a Windows Server 2003 or Windows 2000 Server domain, Security Settings policies depend on the following components:

**Active Directory.**
The Windows-based directory service, Active Directory, stores information about objects on a network and makes this information available to administrators and users. By using Active Directory, you can view and manage network objects on the network from a single location, and users can access permitted network resources by using a single logon.

**Group Policy.**
The infrastructure within Active Directory that enables directory-based configuration management of user and computer settings on computers running Windows Server 2003, Windows 2000, and Windows XP Professional operating systems. By using Group Policy, you can define configurations for groups of users and computers, including policy settings for Windows Server 2003 registry-based policies, software installation, scripts, folder redirection, Remote Installation Services, Internet Explorer maintenance, and security.

**Domain Name System (DNS).**
A hierarchical naming system used for locating domain names on the Internet and on private TCP/IP networks. DNS provides a service for mapping DNS domain names to IP addresses, and IP addresses to domain names. This allows users, computers, and applications to query the DNS to specify remote systems by fully qualified domain names rather than by IP addresses.

**Winlogon.**
A component of the Windows operating system that provides interactive logon support. Winlogon is designed around an interactive logon model that consists of three components: the Winlogon executable, a Graphical Identification and Authentication dynamic-link library (DLL), and any number of network providers.

**Setup.**
Security configuration interacts with the operating system setup process during a clean installation or upgrade of Windows Server 2003 or Windows 2000 Server.

**Security Accounts Manager (SAM).**
A Windows service used during the logon process. SAM maintains user account information, including groups to which a user belongs.

**Local Security Authority (LSA).**
A protected subsystem that authenticates and logs users onto the local system. LSA also maintains information about all aspects of local security on a system, collectively known as the Local Security Policy of the system.

**Windows Management Instrumentation (WMI).**
A component of the Microsoft Windows operating system, WMI is the Microsoft implementation of Web-Based Enterprise Management (WBEM), which is an industry initiative to develop a standard technology for accessing management information in an enterprise environment. WMI provides access to information about objects in a managed environment. Through WMI and the WMI application programming interface (API), applications can query for and make changes to static information in the Common Information Model (CIM) repository and dynamic information maintained by the various types of providers.

**Resultant Set of Policy (RSoP).**
An enhanced Group Policy infrastructure that uses WMI in order to make it easier to plan and debug policy settings. RSoP provides public methods that expose what an extension to Group Policy would do in a what-if situation, and what the extension has done in an actual situation. This allows administrators to determine easily the combination of policy settings that apply to, or will apply to, a user or computer.

**Service Control Manager (SCM).**
Used for configuration of service startup modes and security.

**Registry.**
Used for configuration of registry values and security.

**File system.**
Used for configuration of security.

**File system conversions.**
Security is set when an administrator converts a file system from FAT to NTFS.

**Microsoft Management Console (MMC).**
The user interface for the Security Settings tool is an extension of the Group Policy Object Editor MMC snap-in.

**Security Settings Policies and Group Policy**
The Security Settings extension of Group Policy Object Editor is part of the Windows Server 2003 Security Configuration Manager tool set. The following components are associated with Security Settings: a configuration engine; an analysis engine; a template and database interface layer; setup integration logic; and the secedit.exe command line tool. The security configuration engine runs on computers running Windows Server 2003, Windows 2000 and Windows XP and is responsible for handling security configuration editor-related security requests for the system on which it runs. The analysis engine analyzes system security for a given configuration and saves the result. The template and database interface layer handles reading and writing requests from and to the template or database (for internal storage). The Security Settings extension of Group Policy Object Editor handles Group Policy from a domain-based or local computer. The security configuration logic integrates with Windows Server 2003 and Windows 2000 setup and manages system security for a clean installation or upgrade of Windows Server 2003 and Windows 2000 systems. Security information is stored in templates (.inf files) or in the Secedit.sdb database.

The following figure shows Security Settings and related components, including:

- Scesrv.dll. Provides the core security engine functionality.
- Scecli.dll. Provides the client-side interfaces to the security configuration engine and provides data to Resultant Set of Policies (RsoP).
- Wsecedit.dll. The Security Settings extension of Group Policy Object Editor. Scecli.dll is loaded into Wsecedit.dll to support the Security Settings user interface.
- Gpedit.dll. The Group Policy Object Editor MMC snap-in.

# How Security Settings Extension Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Security Settings Extension Architecture
- Security Settings Policy Processes and Interactions
- Related Information

The Security Settings extension of the Group Policy Object Editor MMC snap-in allows you to specify security configurations as part of Group Policy objects, which can be linked to Active Directory sites, domains, or organizational units.

An Active Directory-based deployment of security settings policy requires deployment of at least Windows 2000 Server, and Windows 2000 Professional or Windows XP clients. However, to gain full advantage of the latest security settings policies, you need:

- Windows Server 2003 with Active Directory installed and DNS dynamic update protocol properly configured.
- Windows XP client computers.
- Group Policy Object Editor, which you can access by using Group Policy Management Console (GPMC).
- The Security Settings extension of Group Policy Object Editor.

For computers that are not participating in a domain, you can use the Local Security Policy snap-in.

This section discusses how the Security Settings extension of Group Policy Object Editor works. It presents information about how security settings are stored and how security settings policy is processed.

**Security Settings Extension Architecture**

The Security Settings extension of Group Policy Object Editor is part of the Security Configuration Manager tools, as shown in the following diagram:

**Security Settings Architecture**

The security settings configuration and analysis tools include a security configuration engine, which provides local computer (non-domain member) and Group Policy-based configuration and analysis of security settings policies. The security configuration engine also supports the creation of security policy files. The primary components of the security configuration engine are:

**Scecli.dll**
Provides client side interfaces to the security configuration engine and does Resultant Set of Policies (RsoP) logging during policy propagation.

**Scesrv.dll**
Provides core security engine functionality including support for import, configure, analyze, and policy propagation operations.

Communications between components of the Security Settings extension occurs by using the following methods:

- Component Object Model (COM) calls
- Local remote procedure call (LRPC)
- Lightweight Directory Access Protocol (LDAP)
- Active Directory Service Interfaces (ADSI)
- Server Message Block (SMB)
- Win32 APIs
- Windows Management Instrumentation (WMI) calls

The following table describes the Security Settings-related components:

**Components and Description**

| Component | Description |
|---|---|

| | |
|---|---|
| Scesrv.dll | This .dll is hosted in Services.exe and runs under local system context. Scesrv.dll provides core Security Configuration Manager functionality, such as import, configure, analyze, and policy propagation.<br><br>Scesrv.dll performs configuration and analysis of various security-related system parameters by calling corresponding system APIs, including LSA, SAM, and the registry.<br><br>Scesrv.dll exposes APIs such as import, export, configure, and analyze. It checks that the request is made over LRPC (Windows XP) and fails the call if it is not.<br><br>On domain controllers, Scesrv.dll receives notifications of changes made to SAM and the LSA that need to be synchronized across domain controllers. Scesrv.dll incorporates those changes into the Default Domain Controller Policy GPO by using in-process Scecli.dll template modification APIs.<br><br>Scesrv.dll also performs configuration and analysis operations. |
| Scecli.dll | This is the client-side interface or wrapper to scesrv.dll. Scecli.dll is loaded into Wsecedit.dll to support MMC snap-in UIs. It is used by setup to configure default system security and security of files, registry keys, and services installed by the Setup API .inf files.<br><br>The command line version of the security configuration and analysis user interfaces, Secedit.exe, uses Scecli.dll.<br><br>Scecli.dll implements the client side extension for Group Policy.<br><br>Scesrv.dll uses Scecli.dll to download applicable Group Policy files from Sysvol in order to apply Group Policy security settings to the local computer.<br><br>Scecli.dll logs application of security policy into WMI (RSoP).<br><br>Scesrv.dll policy filter uses Scecli.dll to update Default Domain Controller Policy GPO when changes are made to SAM and LSA. |
| Wsecedit.dll | The Security Settings extension of the Group Policy Object Editor snap-in. You use this tool to configure security settings in a Group Policy object for a site, domain, or organizational unit. You can also use SecuritySettings to import security templates to a GPO. |
| Secedit.sdb | This is a permanent system database used for policy propagation including a table of persistent settings (sometimes referred to as a *tattoo* table) for rollback purposes. |
| User databases | A user database is any database other than the system database created by administrators for the purposes of configuration or analysis of security. |
| .Inf Templates | These are text files that contain declarative security settings. They are loaded into a database before configuration or analysis. Group Policy security policies are stored in .Inf files on the Sysvol folder of domain controllers, where they are downloaded (by using file copy) and merged into the system database during policy propagation. |

**Security Settings Policy Processes and Interactions**
Before learning about how Security Settings policy is processed, it is useful to review some basic concepts related to Group Policy processing.

**Group Policy Processing**
When a computer starts and a user logs on, computer policy and user policy are applied according to the following sequence:

- The network starts. Remote Procedure Call System Service (RPCSS) and Multiple Universal Naming Convention Provider (MUP) start.
- An ordered list of Group Policy objects is obtained for the computer. The list might depend on these factors:
    - Whether the computer is part of a domain and, therefore, subject to Group Policy through Active Directory.
    - The location of the computer in Active Directory.
    - Whether the list of Group Policy objects has changed. If the list of Group Policy objects has not changed, no

processing is done.

- Computer policy is applied. These are the settings under Computer Configuration from the gathered list. This is a synchronous process by default and occurs in the following order: local, site, domain, organizational unit, child organizational unit, and so on. No user interface appears while computer policies are processed.

- Startup scripts run. This is hidden and synchronous by default; each script must complete or time out before the next one starts. The default time-out is 600 seconds. You can use several policy settings to modify this behavior.

- The user presses CTRL+ALT+DEL to log on.

- After the user is validated, the user profile loads; it is governed by the policy settings that are in effect.

- An ordered list of Group Policy objects is obtained for the user. The list might depend on these factors:

    - Whether the user is part of a domain and, therefore, subject to Group Policy through Active Directory.

    - Whether loopback policy processing is enabled, and if so, the state (Merge or Replace) of the loopback policy setting.

    - The location of the user in Active Directory.

    - Whether the list of Group Policy objects has changed. If the list of Group Policy objects has not changed, no processing is done.

- User policy is applied. These are the settings under User Configuration from the gathered list. This is synchronous by default and in the following order: local, site, domain, organizational unit, child organizational unit, and so on. No user interface appears while user policies are processed.

- Logon scripts run. Unlike Windows NT 4.0 scripts, Group Policy-based logon scripts are hidden and asynchronous by default. The user object script (which, as in Windows NT 4.0, is run in a normal window) runs last.

- The operating system user interface that is prescribed by Group Policy appears.

**Note**

- In mixed environments, there are three special cases you need to consider:

- If the computer account object is in a Windows NT 4.0 domain and the user account object is in Active Directory, only computer (not user) System Policy is processed when the user logs on. Then, user (not computer) Group Policy is processed.

- If the computer account object is in Active Directory and the user account object is in a Windows NT 4.0 domain, computer (not user) Group Policy is processed during computer startup. When the user logs on, user (not computer) System Policy is processed.

- If the Windows XP computer and user accounts are members of a Windows NT 4.0 domain, only System Policy (not Group Policy) for the computer and user is applied when the user logs on.

**Group Policy Objects (GPOs) Storage**

A Group Policy object is a virtual object that is identified by a Globally Unique Identifier (GUID) and stored at the domain level. The policy setting information of a GPO is stored in the following two locations:

- Group Policy containers in Active Directory. The Group Policy container is an Active Directory container that contains GPO properties, such as version information, GPO status, plus a list of other component settings.

- Group Policy templates in a domain's system volume folder(Sysvol). The Group Policy template is a file system folder that includes policy data specified by .adm files, security settings, script files, and information about applications that are available for installation. The Group Policy template is located in the Sysvol folder in the domain \Policies subfolder.

The **GROUP_POLICY_OBJECT** structure provides information about a GPO in a GPO list, including the version number of the GPO, a pointer to a string that indicates the Active Directory portion of the GPO, and a pointer to a string that specifies the path to the file system portion of the GPO.

**Group Policy Processing Order**

Group Policy settings are processed in the following order:

1. **Local Group Policy object:** Each Windows XP computer has exactly one Group Policy object that is stored locally.

2. **Site:** Any Group Policy objects that have been linked to the site are processed next. Processing is synchronous and in an order that is specified by the administrator.

3. **Domain:** Processing of multiple domain-linked Group Policy objects is synchronous and in an order specified by the administrator.

4. **Organizational units:** Group Policy objects that are linked to the organizational unit that is highest in the Active Directory hierarchy are processed first, then Group Policy objects that are linked to its child organizational unit, and so on. Finally, the Group Policy objects that are linked to the organizational unit that contains the user or computer are processed.

At the level of each organizational unit in the Active Directory hierarchy, one, many, or no Group Policy objects can be linked. If several Group Policy objects are linked to an organizational unit, their processing is synchronous and in an order that is specified by the administrator.

This order means that the local Group Policy object is processed first, and Group Policy objects that are linked to the organizational unit of which the computer or user is a direct member are processed last, which overwrites the earlier Group Policy objects.

This is the default processing order and administrators can specify exceptions to this order. A Group Policy object that is linked to a site, domain, or organizational unit (not a local Group Policy object) can be set to **Enforced** with respect to that site, domain, or organizational unit, so that none of its policy settings can be overridden. At any site, domain, or organizational unit, you can mark Group Policy inheritance selectively as **Block Inheritance**. Group Policy object links that are set to **Enforced** are always applied, however, and they cannot be blocked.

**Security Settings Policy Processing**

Security Settings policy is processed in the context of Group Policy processing.

1. During Group Policy processing, the Group Policy engine determines which security settings policies to apply.

2. If security settings policies exist in a GPO, Group Policy invokes the Security Settings client-side extension.

3. The Security Settings extension downloads the policy from the appropriate location such as a specific domain controller.

4. The Security Settings extension merges all security settings policies according to precedence rules. The processing is according to the Group Policy processing order of local, site, domain, and organizational unit (OU), as described earlier in the Group Policy Processing Order section.If multiple GPOs are in effect for a given computer and there are no conflicting policies, then the policies are cumulative and are merged.

   This example uses the Active Directory structure shown in the following figure (Multiple GPOs and Merging of Security Policy). A given computer is a member of OU2, to which the **GroupMembershipPolGPO** GPO is linked. This computer is also subject to the **UserRightsPolGPO** GPO, which is linked to OU1, higher in the hierarchy. In this case, no conflicting policies exist so the computer receives all of the policies contained in both the **UserRightsPolGPO** and the **GroupMembershipPolGPO** GPOs.

   **Multiple GPOs and Merging of Security Policy**

5. The resultant security policies are stored in secedit.sdb, the security settings database. The security engine gets the security template files and imports them to secedit.sdb.

6. The security settings policies are applied to computers.

The following figure illustrates the security settings policy processing.

**Security Settings Policy Processing**

**Merging of Security Policies on Domain Controllers**

Password policies, Kerberos, and some security options are only merged from GPOs that are linked at the root level on the domain. This is done to keep those settings synchronized across all domain controllers in the domain. The following security options are merged:

- **Network Security: Force logoff when logon hours expire**
- **Accounts: Administrator account status**
- **Accounts: Guest account status**
- **Accounts: Rename administrator account**
- **Accounts: Rename guest account**

Another mechanism exists that allows security policy changes made by administrators using net accounts to be merged into the **Default Domain Policy** GPO. User rights changes that are made by using Local Security Authority (LSA) APIs are filtered into the **Default Domain Controllers Policy** GPO.

**Special Considerations for Domain Controllers**

If an application is installed on a primary domain controller (PDC) with operations master role (also known as flexible single master operations or FSMO) and the application makes changes to user rights or password policy, these changes must be communicated to ensure that synchronization across domain controllers occurs. Scesrv.dll receives a notification of any changes made to the security account manager (SAM) and LSA that need to be synchronized across domain controllers and incorporates the changes into the **Default Domain Controller Policy** GPO by using Scecli.dll template modification APIs.

**When Security Settings are Applied**
There are several instances after you have edited the security settings policies, when the settings are refreshed on the computers in the organizational unit linked to your Group Policy object:

- When a computer is restarted.
- Every 90 minutes on a workstation or server and every 5 minutes on a domain controller.
- By default, Security Policy settings delivered by Group Policy are also applied every 16 hours (960 minutes) even if a GPO has not changed.

  It is possible to change this default period by using the registry entry **MaxNoGPOListChangesInterval** in the following subkey:

  **HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Winlogon \GPExtentions\ {827D319E-6AC-11D2-A4EA-00C04F79F83A},**

  The data type of this entry is **REG_DWORD** and the value is number of minutes.

### Note

- Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Registry Reference on the *Microsoft Windows Server 2003 Deployment Kit* companion CD.

**Persistence of Security Settings Policy**
Security settings can persist even if a setting is no longer defined in the policy that originally applied it.

In Windows Server 2003 and Windows XP, security settings might persist in the following cases:

- The setting has not been previously defined for the computer.
- The setting is for a registry security object.
- The settings are for a file system security object.

In Windows 2000, security settings might persist even if the setting is no longer defined in the GPO that originally applied it. All settings applied through local policy or through a Group Policy object are stored in a local database on your computer. Whenever a security setting is modified, the computer saves the security setting value to the local database, which retains a history of all the settings that have been applied to the computer. If a policy first defines a security setting and then no longer defines that setting, then the setting takes on the previous value in the database. If a previous value does not exist in the database then the setting does not revert to anything and remains defined as is. This behavior is sometimes referred to as "tattooing."

Registry and file security settings will maintain the values applied through Group Policy until that setting is set to other values.

On domain controllers running Windows Server 2003 or Windows 2000, all security settings persist.

**Permissions Required for Policy to Apply**
Both Apply Group Policy and Read permissions are required to have the settings from a Group Policy object apply to users or groups, and computers.

**Filtering Security Policy**
By default, all GPOs have Read and Apply Group Policy both Allowed for the AuthenticatedUsers group. The Authenticated Users group includes both users and computers. Security settings policies are computer-based. To specify which client computers will or will not have a Group Policy object applied to them, you can deny them either the Apply Group Policy or Read permission on that Group Policy object. Changing these permissions allows you to limit the scope of the GPO to a specific set of computers within a site, domain, or OU.

### Note

- Do not use security policy filtering on a domain controller as this would prevent security policy from applying to it.

**Migration of GPOs Containing Security Settings**
In some situations, a policy administrator might want to migrate GPOs from one domain environment to another environment. The two most common scenarios are test-to-production migration, and production-to-production migration. The GPO copying process has implications for some types of security settings.

Data for a single GPO is stored in multiple locations and in various formats; some data is contained in Active Directory and other data is stored on the Sysvol share on the domain controllers. Certain policy data might be valid in one domain but might be invalid in the domain to which the GPO is being copied. For example, Security Identifiers (SIDs) stored in security policy settings are often domain-specific. So copying GPOs is not as simple as taking a folder and copying it from one computer to another.

The following security policies can contain security principals and might require some additional work to successfully move them from one domain to another.

- User rights assignment
- Restricted groups
- Services
- File system
- Registry
- The GPO DACL, if you choose to preserve it during a copy operation

To ensure that data is copied correctly, administrators can use Group Policy Management Console (GPMC). When migrating a GPO from one domain to another, GPMC ensures that all relevant data is properly copied. GPMC also introduces migration tables, which can be used to update domain-specific data to new values as part of the migration process. GPMC hides much of the complexity involved in the migrating GPO operations, and provides simple and reliable mechanisms for performing operations such as copy and backup of GPOs.

For more information about GPMC, see "How Group Policy Management Console Works" in this collection.

**Security Settings Policies**
Security Settings includes the following types of policies:

**Account Policies**
Defined for computers, account policies affect how user accounts can interact with the computer or domain. Account policies are implemented at the domain level. For domain controllers, Windows Server 2003 and Windows 2000 allow only one domain account policy: the account policy applied to the root domain of the domain tree. The domain account policy becomes the default account policy of any Windows-based computer that is a member of the domain; this account policy affects all domain users. If an account policy is defined for an organizational unit (OU), it will affect only local accounts on member servers. The account policy settings for the OU affect the local policy on any computers contained in the OU.

For domain accounts, only one account policy is permitted per domain. This account policy must be specified in the **Default Domain Policy** GPO, or in a new GPO that is linked to the root of the domain and has precedence over the **Default Domain Policy** GPO. The **Default Domain Policy** GPO is created when a computer running Windows Server 2003 or Windows 2000 Server is first promoted to domain controller. A domain controller always gets the account policy from a GPO linked to the domain, by default from the **Default Domain Policy** GPO.

Account policies include the following types of policies:

**Password Policy**
Used for domain or local user accounts. Determines settings for passwords, such as enforcement and lifetimes.

**Account Lockout Policy**
Used for domain or local user accounts. Determines the circumstances and length of time that an account will be locked out of the system.

**Kerberos Policy**

Used for domain user accounts. Determines Kerberos-related settings, such as ticket lifetimes and enforcement. Kerberos policies do not exist in local computer policy.

**Local Policies**
These policies apply to the local computer and include the following settings:

**Audit Policy**
Determine whether security events are logged into the Security log on the computer. Also determines whether to log successful attempts, failed attempts or both. (The Security log is part of Event Viewer.)

**User Rights Assignment**
Determine which users or groups have logon rights or privileges on the computer.

**Security Options**
Enable or disable security settings for the computer, such as digital signing of data, Administrator and Guest account names, floppy drive and CD-ROM access, driver installation, and logon prompts.

**Event Log**
Event Log security policies specify attributes for events logs such as log size maximum, access rights, and retention methods. There are settings for application, security, and system logs.

**Restricted Groups**
You can define two properties for restricted groups, Members, and Members Of. The Members list defines who belongs and who does not belong to the restricted group. The Member Of list specifies which other groups the restricted group belongs to.

**System Services**
You can specify security policy for starting system services in automatic or manual mode, or to disable them. You can also set security properties on the objects to specify access permissions, inheritance or auditing settings, and ownership.

**Registry**
You can configure security descriptors for registry keys.

**File System**
You can use Security Settings to configure security descriptors for files, folders for file system objects.

**Predefined Security Templates**
Windows 2000 and Windows Server 2003 provide predefined security templates that you can use as a starting point for creating security policies that are customized to meet different organizational requirements. The templates can be customized using the Security Templates snap-in. After you customize the predefined security templates, they can be used to configure an individual computer or multiple computers. To configure individual computers, you can use the Security Configuration and Analysis snap-in, the secedit.exe command line tool, or you can import the template into Local Security Settings. You can configure multiple computers by importing a template into a Group Policy object.

You can also use a security template as a baseline for analyzing a system for potential security gaps or policy violations using the Security Configuration and Analysis snap-in. By default, the predefined security templates are stored in: *Systemroot*\Security\Templates.

**Compatible (compatws.inf)**
Default permissions for workstations and servers are primarily granted to three local groups: Administrators, Power Users, and Users. Administrators have the highest privilege, while Users have the lowest. One way to significantly improve the security, reliability, and total cost of system ownership is to do the following:

- Make sure that end-users are members of the Users group

- Deploy applications that can run successfully under a User context.

  Applications that comply with the *Certified for Windows Program* meet this criterion. However, applications that are not certified for Windows 2000 or Windows Server 2003 might not run under a User context. *The Certified for Windows Program* is designed to ensure that applications that run on Windows Server 2003 or Windows 2000 Server can meet the highest standards for reliability, availability, security, and supportability.

  If you must support non-certified applications, you have two options:

  - Allow end-users to be members of the Power Users group.

- Relax the default permissions granted to the Users group.

Since Power Users have inherent capabilities, such as creating users, groups, printers and shares, some customers would rather relax the default User permissions than allow end-users to be members of the Power Users group. This is precisely what the Compatible template is for. The Compatible template loosens the default file and registry permissions granted to Users in a manner that is consistent with the requirements of most non-certified applications. Additionally, since it is assumed that the administrator applying the compatible template does not want end users to be Power Users, the compatible template also removes all members of the Power Users group.

**Note**

- The Compatible template should *not* be applied to domain controller computers. For example, do not import the compatible template to the **Default Domain Policy** GPO or the **Default Domain Controller Policy** GPO.

Information about the Microsoft Certified for Windows Program is available on the Windows Server 2003 Web site.

**Secure (secure*.inf)**
The Secure templates (secure*.inf) define enhanced security settings that are least likely to impact application compatibility. For example, the Secure templates define stronger password, lockout, and audit settings.

The Secure templates also limit the use of the LAN Manager and NTLM authentication protocols by configuring clients to send only NTLMv2 responses and Servers to refuse LAN Manager responses:

- In order to apply securews.inf to a member computer, all of the domain controllers that contain the accounts of all users that will logon to the client must be running Windows NT 4.0 Service Pack 4 or higher.

- In order to apply securews.inf to a member computer that is joined to a domain containing Windows NT 4.0 domain controllers, the clocks between the NT 4.0 domain controllers and the member computers must be within 30 minutes of each other.

- If a client is configured with securews.inf, it will not be able to connect to servers that only use the LAN Manager authentication protocol or Windows NT 4.0 servers prior to SP 4 using a local account defined on the target server.

- If a client is configured with securews.inf, it will not be able to connect to Windows 2000 or Windows NT 4.0 servers using a local account defined on the target server unless the clock on the target server is within 30 minutes of the clock on the client.

- If a client is configured with securews.inf, it will not be able to connect to a computer running Windows XP by using a local account that is defined on the target computer unless the clock on the target computer is within 20 hours of the clock on the client.

- If a client is configured with securews.inf, then it will not be able to connect to servers running LAN Manager that are operating in share-level security mode.

- If a server is configured with securews.inf, then a user with a local account on that server will not be able to connect to the server by using that local account from a client computer that is running only LAN Manager.

- If a Windows 2000 server is configured with securews.inf, then a client using a local account on that server that is also configured to use NTLMv2 authentication will not be able to connect unless the clocks on the two computers are within 30 minutes of each other.

- If a computer running Windows 2000 or Windows Server 2003 is configured with securews.inf, then a client with a local account on that server that is also configured to use NTLMv2 authentication will not be able to connect unless the clocks on the two computers are within 20 hours of each other.

- If a domain controller is configured with securedc.inf, then a user with an account in that domain will not be able to connect to any member server from a client computer that is running only LAN Manager using their domain account.

LAN Manager clients include Windows for Workgroups, Windows 95, and Windows 98 platforms that do not have the Active Directory Client Extensions Pack installed. If the Active Directory Client Extensions Pack is installed on Windows 95 or Windows 98 platforms, those clients can use NTLMv2. Microsoft Windows Millennium Edition supports NTLMv2.

Windows NT-based computers (SP 4 and higher) can be configured to send only NTLMv2 responses by setting **HKEY_LOCAL_MACHINE\System CurrentControlSet\Control\Lsa\LMCompatibilityLevel** =3 or higher. The **LMCompatibilityLevel** registry value is exposed in the **Local Policies\Security Options** node of the **Security Configuration Manager** tools (**Local Security Policy** and **Security Settings** extension of **Group Policy Object Editor**) as **Network Security: Lan Manager authentication level** policy setting. Clients that have the secure or high secure template applied to them will have **LMCompatibility** set to 3 or higher.

The Secure templates also provide further restrictions for anonymous users by preventing anonymous users (for example, users from untrusted domains) from doing the following:

- Enumerating account names and shares
- Performing SID to Name or Name to SID translations

Finally, the Secure templates enable server-side SMB packet signing, which is disabled by default for workstations and servers. Since client-side SMB packet signing is enabled by default, SMB packet signing is always negotiated when workstations and servers are operating at the secure level.

**High Secure (hisec*.inf)**
The High Secure templates are supersets of the Secure templates that impose further restrictions on the levels of encryption and signing required for authentication and for the data that flows over Secure Channels and between SMB clients and servers. For example, while the Secure templates cause servers to refuse LAN Manager responses, the High Secure templates cause servers to refuse both LAN Manager and NTLM responses. The secure template enables server-side SMB packet signing, but the High Secure template requires it. The High Secure Template also requires strong (128 bit) encryption and signing for the Secure Channel data that constitutes domain-member and domain-domain trust relationships.

- To apply hisecws.inf to a member computer, the following requirements must be met:
    - All the domain controllers that contain the accounts of all users that will logon to the client must be running Windows NT 4.0 Service Pack 4 or higher, Windows 2000, or Windows Server 2003.
    - All the domain controllers for the domain to which the client is joined must be running at least Windows 2000.
- To apply hisecdc.inf to a domain controller, all of the domain controllers in all trusted or trusting domains must be running Windows 2000 or later.
- If a client is configured with hisecws.inf, it will not be able to connect to servers running only LAN Manager or Windows NT 4.0 servers prior to SP 4 using a local account defined on the target server.
- If a client is configured with hisecws.inf, it will not be able to connect to Windows 2000 or Windows NT 4.0 servers using a local account defined on the target server unless the clock on the target server is within 30 minutes of the clock on the client.
- If a client is configured with hisecws.inf, it will not be able to connect to a computer running Windows 2000 server or Windows Server 2003 using a local account defined on the target server unless the clock on the target server is within 20 hours of the clock on the client.
- If a client is configured with hisecws.inf, then it will not be able to connect to servers running LAN Manager operating in share level security mode.
- If a server is configured with hisecws.inf, then a client with a local account on that server will not be able to connect to it from a client that does not support NTLMv2.
- If a server is configured with hisecws.inf, then a Windows NT client with a local account on that server will not be able to connect to the server unless the Windows NT client is configured to send NTLMv2 responses.

- If a server is configured with hisecws.inf, then all clients that want to use SMB to connect to that server must have client-side SMB packet signing-enabled. Client-side SMB packet-signing is enabled by default for all Windows 2000 computers.

- If a domain controller is configured with hisecdc.inf, then a user with an account in that domain will not be able to connect to member servers by using the domain account if the connection is being made from a computer using only LAN Manager authentication protocol.

- If a domain controller is configured with hisecdc.inf, then a user with an account in that domain will not be able to connect to member servers using that domain account unless the following conditions apply:

    - Both client and target server are Windows 2000 or Windows Server 2003 and, thus, can use Kerberos rather than LAN Manager-based authentication.

    - The client is configured to send NTLMv2 responses.

- If a domain controller is configured with hisecdc.inf, then LDAP clients will not be able to bind with the Active Directory LDAP server unless data signing is negotiated. Thus, bind requests using **ldap_simple_bind** or **ldap_simple_bind_s** are rejected. By default, all Microsoft LDAP clients that ship with Windows XP or Windows Server 2003 request data signing if Transport Layer Security\Secure Sockets Layer (TLS\SSL) protocol is not already being used. If TLS\SSL is being used, then data signing is considered to be negotiated.

Clients that do not support NTLMv2 include Windows for Workgroups, Windows NT clients prior to SP 4, and Windows 95 and Windows 98 platforms that do not have the DS Client Pack installed. Windows NT-based computers (SP 4 and higher) can be configured to send only NTLMv2 responses by setting **HKEY_LOCAL_MACHINE\System CurrentControlSet\Control\Lsa\LMCompatibilityLevel** = 3 or higher. The **LMCompatibilityLevel** registry value is exposed in the **Local Policies\Security Options** node of the security configuration manager tools (Local Security Settings and Security Settings extension of Group Policy Object Editor) as the **Network Security: Lan Manager authentication level** policy setting. Clients that have the secure or high secure template applied to them will have **LMCompatibility** set to 3 or higher.

In addition to further restrictions on the use of computers running LAN Manager protocols and the requirements for encryption and signing of secure channel and SMB traffic, the High Secure templates also restrict clients from caching domain credentials for subsequent logons when the domain controllers aren't available. For example, this would prohibit traveling users who don't have a network connection available for domain authentication from being able to login to their laptop.

Finally, Hisecws.inf uses restricted group settings to:

- Remove all members of the Power Users group.

- Ensure that only Domain Admins and the local Administrator account are members of the local Administrators group.

Hisecws defines these group restrictions under the assumption that only applications that are certified for Windows 2000 or Windows Server 2003 are deployed. With certified applications in place, neither the unsecured Compatible template nor the unsecured Power Users group is needed. Instead, end users can successfully run certified applications under the secure context of a normal User, which is defined by the default file system and registry ACLs.

**Root Directory Permissions (rootsec.inf)**
Specifies the new root permissions introduced with Windows XP. By default, rootsec.inf defines these permissions for the root of the system drive. This template can be used to reapply the root directory permissions if they are inadvertently changed or the template can be modified to apply the same root permissions to other volumes. As specified, the template does not overwrite explicit ACEs defined on child objects, it propagates only the permissions that are inherited by child objects.

**No Terminal Server SID (notssid.inf)**
The default file system and registry ACLs on servers grant permissions to a Terminal Server SID. The Terminal Server SID is used only when Terminal Server is running in application compatibility mode. If Terminal Server is not being used, this template can be applied to remove the unnecessary Terminal Server SID from these file system and registry locations. Removing the ACE for the Terminal Server SID from these default file system and registry locations does not increase the security of the system. Instead of removing the Terminal Server SID, it is recommended to simply run Terminal Server in Full Security mode rather than Application Compatibility mode. When running in Full Security mode, the Terminal Server SID is not

used.

**Setup security.inf**
Setup security is a computer-specific template that represents the default security settings applied during installation of the operating system including the file permissions for the root of the system drive. This template, or portions thereof, can be used for disaster recovery purposes. Setup security.inf should *not* be applied by using Group Policy.

### Note

- Do not apply the predefined security templates to production systems without performing comprehensive testing first to ensure that the security and functionality requirements for your specific organization are met.

You can view Security template settings by using the Security Templates snap-in. You can also examine the changes that a template would make if it were applied by using the Security Configuration and Analysis snap-in. To examine the proposed changes, import the template into a database then perform an analysis against that database. Performing an analysis does not change any system settings, but will highlight the differences between the settings specified in the template and the settings as they currently exist on the system.

# Security Settings Extension Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this subject**

- Resultant Set of Policies
- Command Line Tools
- Security Settings Policies
- Related Information

This section presents an overview of Resultant Set of Policies (RSoP), which you use to determine which policy settings are currently in effect for a computer or user, and to assess how policy settings would affect computers or users if a specific Group Policy object were applied to them. It also describes the Windows Server 2003 command-line tools for configuring and analyzing security settings.

**Resultant Set of Policies**

Windows XP and the Windows Server 2003 family of operating systems support an enhanced Group Policy infrastructure that utilizes Windows Management Instrumentation (WMI) to collect Group Policy-related data for planning and troubleshooting Group Policy. This structure is the Resultant Set of Policy (RSoP), a query engine that polls existing policy settings and planned policy settings, and then reports the results of those queries. RSoP polls existing policies based on site, domain, domain controller, and organizational unit. RSoP gathers this information from the Common Information Management Object Model (CIMOM) database (also known as the CIM-compliant object repository) by using WMI. Administrators can use RSoP in one of two modes. To determine which policy settings are in effect for a particular computer or user, administrators use Resultant Set of Policy – Logging Mode, and to evaluate how policy settings would affect a computer or user if a specific Group Policy object were applied to users or computers, they use Resultant Set of Policy – Planning Mode.

In Windows Server 2003, you can use the Group Policy Results node Group Policy Management Console (GPMC) to access the Resultant Set of Policy – Logging Mode capabilities. Group Policy Results represents the actual resultant set of policy that was applied to a given user and computer. This information is obtained by directly querying the target user/computer. Each sub-node represents a different RSoP query for a given user/computer combination. The Group Policy Modeling node in GPMC allows administrators to access the Resultant Set of Policy – Planning Mode capabilities of Windows Server 2003.

**Note**

- As with other Group Policy settings, you must fully test your implementation in a test domain before you deploy your security settings to your production environment.

Some of the security settings extensions of Group Policy provide RSoP classes to represent data pertaining to security policy settings. The *Security Policy RSoP Classes* section, later in this document, lists the RSoP classes for security policy settings.

On Windows 2000 computers, you can use the Gpresults.exe tool to display information about how Group Policy affects both the currently logged-on user and the computer. For information about the Gpresults syntax, see "IPSec Policy Extension Tools and Settings" in this collection.

The Gpresults command-line tool is available in the Windows 2000 Resource Kit. To download this tool, see the download site for Windows 2000 Server Resource Kit tools.

For more detailed information about RSoP and WMI and to download SDKs, see the Microsoft Platform SDK link on the Web Resources page.

For more information about GPMC, see the Group Policy Management Console link on the Web Resources page.

**Security Policy RSoP Classes**

The RSoP Windows Management Instrumentation (WMI) Method Provider supports the following security policy classes, as listed in the following table.

**Security Policy RSoP Classes**

| Class | Description |
|---|---|
| RSOP_AuditPolicy | This class represents the security setting for a local Group Policy that relates to the auditing of an event type. Events can include, among others, system events and account management events. |
| RSOP_File | This class represents a security policy setting that defines the access permissions and audit settings for a securable file system object. |
| RSOP_RegistryKey | This class represents a security policy setting that defines the access permissions and audit settings for a particular registry key. |
| RSOP_RegistryValue | This class represents specific security-related registry values. |
| RSOP_RestrictedGroup | This class represents a security policy setting that defines the members of a restricted (security-sensitive) group. |
| RSOP_SecurityEventLogSettingBoolean | This class represents a security policy setting that determines whether or not guests can access the system, application and security event logs. |
| RSOP_SecurityEventLogSettingNumeric | This class represents a security policy setting that determines numeric properties related to the system, application and security event logs. Properties include the number of days to retain entries and maximum log size. |
| RSOP_SecuritySettingBoolean | This class represents the Boolean security setting for an account policy. Account policies include password policies and account lockout policies. |
| RSOP_SecuritySettingNumeric | This class represents the numeric security setting for an account policy. Account policies include password policies, account lockout policies, and Kerberos-related policies. |
| RSOP_SecuritySettings | This is the abstract class from which other RSoP security classes derive. Instances of this class are not logged. RSOP_SecuritySettings derives from the RSOP_PolicySetting class. |
| RSOP_SecuritySettingString | This class represents the string security setting for an account policy. |
| RSOP_SystemService | This class represents the security policy setting that defines the start-up mode and access permissions for a particular system service. |
| RSOP_UserPrivilegeRight | This class represents the security setting for a local Group Policy that relates to the assignment of a particular user privilege. |

**RSOP_PolicySetting**

The **RSOP_PolicySetting** WMI class is the class from which policy objects for client-side extensions are inherited. An instance of this class corresponds to a specific policy setting. This class was added for Windows XP.

Requirements for this class are as follows:

- **Client:** Included in Windows XP Professional.
- **Server:** Included in Windows Server 2003.

**Command Line Tools**

This section describes the Windows Server 2003 command line tools for configuring, analyzing, and updating security settings:

- Secedit.exe
- Gpupdate.exe

**Secedit.exe**

You can use the secedit.exe command to configure and analyze system security by comparing your current configuration to at least one template.

**Note**

- **Secedit /refreshpolicy** has been replaced with **gpupdate**. To refresh local Group Policy settings and Group Policy settings that are stored in Active Directory, including security settings, use **gpudate**. See "Gpupdate," later in this section.

Secedit supports the following commands:

- analyze
- configure
- export
- import
- validate
- generateRollback

**Secedit /analyze**
This command allows you to analyze the security settings on a computer by comparing them against the baseline settings in a database. You can view the results of the analysis in the Security Configuration and Analysissnap-in.

**Syntax**

```
              secedit /analyze /dbFileName.sdb [/cfgFileName] [/overwrite]
[/logFileName] [/quiet]
```

**Parameters**
**/db** *FileName* **.sdb**

This parameter specifies the database used to perform the analysis.

**/cfg** *FileName*

This parameter specifies a security template to import into the database prior to performing the analysis. Security templates are created using the Security Templates snap-in.

**/log** *FileName*

This parameter specifies a file in which to log the status of the configuration process. If not specified, configuration data is logged in the scesrv.log file which is located in the %windir%\security\logs directory.

**/quiet**

This parameter specifies that the analysis process should take place without further comments.

**Examples**
The following is an example of how you can use this command:

**secedit /analyze /db** hisecws.sdb

**Secedit /configure**
You can use secedit /configure to configure local computer security by applying the settings stored in a database.

**Syntax**

```
              secedit
              /configure
              /db
              FileName [/cfg FileName ] [/overwrite][/areasArea1 Area2 ...]
```

```
[/logFileName] [/quiet]
```

**Parameters**

**/db** *FileName*

This parameter specifies the database used to perform the security configuration.

**/cfg** *FileName*

This parameter specifies a security template to import into the database prior to configuring the computer. Security templates are created using the **Security Templates** snap-in.

**/overwrite**

This parameter specifies that the database should be emptied prior to importing the security template. If this parameter is not specified, the settings in the security template are accumulated in the database. If this parameter is not specified and there are conflicting settings in the database and the template being imported, the template settings take precedence.

**/areas** *Area1 Area2*

This parameter specifies the security areas to be applied to the system. If this parameter is not specified, all security settings defined in the database are applied to the system. To configure multiple areas, separate each area by a space. The following security areas are supported:

| Area name | Description |
|---|---|
| SECURITYPOLICY | This includes Account Policies, Audit Policy, Event Log settings, and Security Options. |
| GROUP_MGMT | This includes Restricted Groups settings. |
| USER_RIGHTS | This includes User Rights Assignment. |
| REGKEYS | This includes Registry permissions. |
| FILESTORE | This includes File System permissions. |
| SERVICES | This includes System Services settings. |

**/log** *FileName*

This parameter specifies a file in which to log the status of the configuration process. If not specified, configuration data is logged in the scesrv.log file, which is located in the %windir%\security\logs directory.

**/quiet**

This parameter specifies that the configuration process should take place without prompting the user.

**Examples**

The following are examples of how you can use this command:

**secedit /configure /db** *hisecws.sdb***/cfg***FileName*

**hisecws.inf /overwrite /log** *hisecws.log*

If **db***FileName* (database filename) doesn's exist, **secedit** creates a new database using the settings in **cfg***FileName* (template filename) and applies the configuration. If **db***FileName* exists, then **secedit** merges the settings into the database before applying the newly merged configuration. If you omit **cfg***FileName*, **secedit** applies the configuration using the settings already stored in the database.

**Secedit /export**

Running **secedit /export** allows you to export the security settings stored in the database.

**Syntax**

```
              secedit
              /export [/DBFileName] [/mergedpolicy] [/CFG FileName] [/areasArea1 Area2
...] [/logFileName] [/quiet]
```

**Parameters**
**/db** *FileName*

This parameter specifies the database used to configure security.

**/mergedpolicy**

This parameter merges and exports domain and local policy security settings.

**/CFG** *FileName*

This parameter specifies the template the settings will be exported to.

**/areas** *Area1 Area2*

This parameter specifies the security areas to be exported to a template. If an area is not specified, all areas are exported. Each area should be separated by a space. The following table lists the security areas that can be exported.

**Security Areas and Descriptions**

| Area name | Description |
|---|---|
| SECURITYPOLICY | This includes Account Policies, Audit Policy, Event Log settings, and Security Options. |
| GROUP_MGMT | This includes Restricted Groups settings. |
| USER_RIGHTS | This includes User Rights Assignment. |
| REGKEYS | This includes Registry permissions. |
| FILESTORE | This includes File System permissions. |
| SERVICES | This includes System Services settings. |

**/log** *FileName*

This parameter specifies a file in which to log the status of the export process. If not specified, the default is %windir%\security\logs\scesrv.log.

**/quiet**

This parameter specifies that the configuration process should take place without prompting the user.

**Examples**
The following is an example of how you can use this command:

**secedit /export /db *hisecws* .inf /log *hisecws* .log**

**Secedit /import**
Running **secedit /import** allows you to import a security template into a database so that the settings specified in the template can be applied to a system or analyzed against a system.

**Syntax**

```
secedit
/import
/db
FileName
.sdb
/cfg
FileName.inf [/overwrite] [/areasArea1 Area2 ...] [/logFileName] [/quiet]
```

**Parameters**
**/db** *FileName* **.sdb**

This parameter specifies the database to which the security template settings will be imported.

**/CFG** *FileName*

This parameter specifies a security template to import into the database. Security templates are created using the Security Templates snap-in.

**/overwrite** *FileName*

This parameter specifies that the database contents should be cleared prior to importing the security template. If this parameter is not specified, the settings in the security template are accumulated in the database. If this parameter is not specified and there are conflicting settings in the database and the template being imported, the template settings take precedence.

**/areas** *Area1 Area2*

This parameter specifies the security areas to be exported to a template, as listed in the following table. If an area is not specified, all areas are exported. Each area should be separated by a space.

| Area name | Description |
|---|---|
| SECURITYPOLICY | This includes Account Policies, Audit Policy, Event Log settings, and Security Options. |
| GROUP_MGMT | This includes Restricted Groups settings. |
| USER_RIGHTS | This includes User Rights Assignment. |
| REGKEYS | This includes Registry permissions. |
| FILESTORE | This includes File System permissions. |
| SERVICES | This includes System Services settings. |

**/log** *FileName*

This parameter specifies a file in which to log the status of the export process. If not specified, the default is %windir%\security\logs\scesrv.log.

**/quiet**

This parameter specifies that the configuration process should take place without prompting the user.

**Examples**
The following is an example of how you can use this command:

**secedit /import /db hisecws.sdb /cfg hisecws.inf /overwrite**

**Secedit /validate**
You can use **secedit /validate** to validate the syntax of a security template to be imported into a database for analysis or application to a system.

**Syntax**

```
secedit
/validate FileName
```

**Parameters**
*FileName*

This parameter specifies the file name of the security template you have created with Security Templates.

**Examples**
The following is an example of how you can use this command:

**secedit /validate /cfg filename**

**Secedit /GenerateRollback**
You can run **secedit / GenerateRollback** to generate a rollback template with respect to a configuration template. When applying a configuration template to a computer you have the option of creating rollback template which, when applied, resets the security settings to the values before the configuration template was applied.

**Syntax**

```
secedit /GenerateRollback
/CFG
FileName.inf /RBK SecurityTemplatefilename.inf [/logRollbackFileName.inf]
[/quiet]
```

**Parameters**
**/CFG** *FileName*

This parameter specifies the file name of the security template for which you want to create a rollback template of.

**/RBK** *FileName*

This parameter specifies the file name of the security template that will be created as the rollback template.

**Gpupdate**
You can use **gpupdate** to refresh local Group Policy settings and Group Policy settings that are stored in Active Directory, including security settings. This command supersedes the now obsolete **/refreshpolicy** option for the **secedit** command.

**Syntax**

```
gpupdate [/target:{computer | user}] [/force] [/wait:Value] [/logoff]
[/boot]
```

**Parameters**
**/target:{computer | user}**
This parameter specifies to processes only the *Computer* settings or the current *User* settings. By default, both the computer settings and the user settings are processed.

**/force**
Using this parameter ignores all processing optimizations and reapplies all settings.

**/wait:Value**
Indicates the number of seconds that policy processing must wait to finish. The default is 90 minutes with a randomized delay of up to 30 minutes — for a total maximum refresh interval of up to 120 minutes. 0 equals no wait, and -1 equals wait indefinitely.

**/logoff**
This parameter specifies that a user log off occurs after the refresh has completed. This is required for those Group Policy client-side extensions that do not process on a background refresh cycle but that do process when the user logs on, such as user Group Policy Software Installation and Folder Redirection. This option has no effect if there are no extensions called that require the user to log off.

**/boot**
Using this parameter restarts the computer after the refresh has completed. This is required for those Group Policy client-side extensions that do not process on a background refresh cycle but that do process when the computer starts up, such as computer Group Policy Software Installation. This option has no effect if there are no extensions called that require the computer to be restarted.

**/?**
Using this parameter displays help at the command prompt.

**Examples**
The following examples show how you can use the **gpupdate** command:

- **gpupdate**

  This command triggers a Group Policy refresh.

- **gpupdate /target:computer**

  This command triggers a Group Policy refresh of the Computer Settings policies only.

- **gpupdate /force /wait:100**

  This command triggers a Group Policy refresh, reapplies all policy settings, and indicates to wait 100 seconds for policy

to finish processing.

- **gpupdate /boot**

  This command triggers a Group Policy refresh and then causes the computer to restart.

**Security Settings Policies**

Security Settings include policy settings to control the following aspects of security:

- Account Policies
- Local Policies
- Event Log
- Restricted Groups
- System Services
- Registry
- File System

For a description of all security settings policies, see"Security Policy Settings" in the Security Collection.

**Related Information**

# IPSec Policy Extension Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Internet Protocol Security (IPSec) consists of a set of open standards designed to ensure private, secure communications over Internet Protocol (IP) networks, through the use of cryptographic security services.

IPSec uses policy-based management to define IPSec configuration options and security settings to enable two systems to agree on how to secure traffic between them. To configure IPSec security services, you create IPSec policies. An IPSec policy is a collection of settings and rules that determine IPSec behavior, including the types of network traffic IPSec examines, whether to permit or block traffic, whether to negotiate security, and how to authenticate an IPSec peer.

IPSec is included in the Microsoft Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; Windows Server 2003, Web Edition operating systems; the 64-bit editions of Windows Server 2003, and Windows 2000 Server and Windows 2000 Professional, Windows XP Professional, and Windows XP Home Edition operating systems (Kerberos authentication is not available in Windows XP Home edition).

# What Is IPSec Policy Extension?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is IP Security Policy Extension?**

**In this section**

- IPSec Policy Settings and Rules
- IPSec Policy Core Scenarios
- IPSec Policy Advantages
- Related Information

Internet Protocol Security (IPSec) is an architecture defined by the Internet Engineering Task Force (IETF) RFC 2401. This architecture involves several protocols that perform various functions in the architecture.

A network is not secure until servers can identify the computers communicating with them. IPSec enables secure, trusted communications between IP addresses. The system behind the IP address has an identity that is verified by using an authentication process. The only computers that must be aware of IPSec are the sending and receiving computers. Each computer handles security at its respective end, and assumes that the medium over which the communication takes place is not secure. Any computers that route data between the source and destination computer are not required to support IPSec.

You can deploy IPSec in several scenarios:

- A local area network (LAN) for client/server and server-to-server.
- A wide area network (WAN) for router-to-router and gateway-to-gateway.
- A remote network's dial-up clients and for Internet access from private networks.

Both the sending and the receiving computer require IPSec configuration (an IPSec policy) to specify options and security settings to enable the two systems to agree on how to secure traffic between them. The IP Security Policies extension of the Group Policy Object Editor snap-in is used to configure IPSec policies based on Active Directory. You can also configure IPSec policies on a computer that is not a domain member; however, it is more difficult to assign and manage IPSec policy configurations and trust relationships for computers that are not members of a trusted domain.

**IPSec Policy Settings and Rules**

An IPSec policy contains general IPSec policy settings that apply regardless of the rules that are configured, and one or more IPSec policy rules that determine IPSec behavior.

**General IPSec Policy Settings**

The general IPSec policy settings specify the name of the policy, its description for administrative purposes, polling interval for policy change, key exchange settings, and key exchange methods. The following table lists these general settings.

**General IPSec Policy Settings**

| Settings | Description |
|---|---|
| Name | The name for the policy. |
| Description | The optional text description used to describe the purpose of the IPSec policy. It is recommended that you complete and update this description to provide a summary of the settings and rules for the policy. |

| | |
|---|---|
| Policy change poll interval | Specifies the number of minutes between consecutive polls for changes in IPSec policies based on Active Directory. This polling does not detect a change in domain or organizational unit membership, or the assignment or removal of assignment of a new policy. These events are detected when the Winlogon service polls for changes in Group Policy, which occurs every 90 minutes by default. |
| Key exchange settings | Define the way in which new keys are derived and how often they are renewed. |
| Key exchange methods | Determine the ways in which identities are protected during the key exchange.<br><br>The default key exchange settings and methods are configured to work for most IPSec deployments. Unless there are special security requirements, default settings should not have to be changed. |

**IPSec Policy Rules**
IPSec policy rules specify settings such as the type of traffic IPSec examines, whether to permit or block traffic, whether to negotiate security, and how to authenticate an IPSec peer.

IPSec rules include a list of IP filters that specify a particular subset of inbound or outbound network traffic that should be secured. A filter is required to cover any traffic to which an associated IPSec rule applies. IPSec filters are inserted into the IP layer of the TCP/IP networking protocol stack on the computer so that they can filter all inbound or outbound IP packets.

**IP Filter Settings**
An IP filter contains the following settings:

**The source and destination address of the IP packet.**
You can specify any IP address assigned to the IPSec peer, a single IP address, IP addresses by DNS name, or groups of addresses to specify IP subnets.

**The protocol over which the packet is being transferred.**
By default, all protocols in the TCP/IP protocol suite are selected. However, you can specify an individual protocol for this filter to meet special requirements, including custom protocols.

**The source and destination port for TCP and UDP.**
By default, all TCP and UDP ports are selected, but you can select a specific TCP or UDP port.

**IPSec Rule Entries**
An IPSec rule contains the following configurable entries:

**Filter list.**
This list contains one or multiple predefined filters that specify IP addresses and the types of traffic to which an action (permit or block traffic, or negotiate security) is applied.

**Filter action.**
This entry specifies the security requirements for data transmission.

You can configure one of the following options for a filter action:

- **Permit.** Select this option to permit traffic. IPSec passes this traffic without modification or the requirement for security. This is appropriate for traffic from specific computers that are not IPSec-capable. Be sure to limit the IP filter list to a minimal scope when using this type of filter action, so you do not let traffic through which should be secured.

- **Block.** Select this option to block traffic. IPSec silently discards this traffic. Be sure to use an IP filter list that appropriately defines the scope of traffic when using a blocking filter action so that you do not block valid computers from communicating.

- **Negotiate security.** Select this option to negotiate IPSec parameters. IPSec requires the negotiation of security associations and the sending or receiving of IPSec-secured traffic. If you choose this option, you can also configure: security methods; allowance of initial incoming unsecured traffic (**Accept unsecured communication, but always respond using IPSec**); enabling of communication with non-IPSec-enabled computers (**Allow unsecured communication with non-IPSec-aware computer**); and generation of session keys from new keying material (**Use session key perfect forward secrecy (PFS)**).

**Authentication.**

This entry contains one or more authentication methods in order of preference that are used for protection during Internet Key Exchange (IKE) negotiations. The available authentication methods are the Kerberos v5 protocol, the use of a certificate issued from a specified certification authority, or a pre-shared key. The IKE protocol securely establishes a trust relationship between each computer, negotiates security options, and dynamically generates shared, secret cryptographic keying material.

**Tunnel endpoint.**
This entry contains settings that determine whether traffic is tunneled and, if it is, the tunnel endpoint. The tunnel endpoint is configured on the **Tunnel Setting** tab in the properties of an IPSec rule within an IPSec policy.

**Connection type.**
This entry contains a setting that specifies whether the rule applies to only local area network (LAN) connections, to only Point-to-Point Protocol (PPP)-based connections, or to both types of connections. The interface applicability is configured on the **Connection Type** tab in the properties of an IPSec rule within an IPSec policy.

For more detailed information about IPSec, see "What Is IPSec?" in the Networking collection.

**IPSec Policy Core Scenarios**
Corporate networks face various types of external and internal threats from untrusted computers, such as denial-of-service attacks, data corruption, and data theft. Network-based attacks on any application or service running on an internal corporate network server can result in:

- Loss of service through denial-of-service of the application, the service, or the network.
- Data corruption.
- Theft of information such as user credentials or data theft.
- Administrative control of the server or other network computers.

To protect network servers against network-based attacks, administrators can use IPSec. To provide enhanced security for networks against untrusted network attacks, you can require IPSec-authenticated, signed, and encrypted communication between computers.

You can use IPSec as part or your organization's security strategy to provide protection against network-based attacks from untrusted computers. IPSec is intended for use in environments where untrusted network access and attacks on network traffic are a realistic threat.

The features of IPSec (such as strong, cryptographic-based authentication and encryption) make it particularly useful for securing traffic that must traverse untrusted network paths such as the corporate intranet or the Internet. IPSec is also appropriate for securing traffic that uses protocols and applications that do not provide sufficient security for communications.

By using policy based on Active Directory, you can secure most communications for a group of servers. You can also use command-line tools to create, modify, and assign IPSec policies. The tools you use vary, depending on the operating system running on the computers. For more information about command-line tools, see the "IPSec Policy Extension Tools and Settings" section in this collection.

**IPSec Policy Advantages**
IPSec provides a key line of defense against private network and Internet attacks. IPSec keeps data intact as it is transmitted across the network and protects communications between private network computers, domains, sites, remote sites, extranets, and dial-up clients.

By using cryptographic protection services, security protocols, and dynamic key management, IPSec:

- Protects the content of IP packets.
- Provides a defense against active and passive network attacks by using packet filtering and the enforcement of trusted communication.

IPSec provides protection against the following types of attacks:

**Sniffers (lack of confidentiality).**
The Encapsulating Security Payload (ESP) protocol in IPSec encrypts the payload of IP packets to provide data confidentiality.

**Data modification.**
IPSec uses cryptography-based keys, shared only by the sending and receiving computers, to create a cryptographic checksum for each IP packet. Any modification to the packet data alters the checksum, indicating to the receiving computer that the packet was altered in transit.

**Identity spoofing, password-based, and application-layer attacks.**
IPSec permits the exchange and verification of identities without exposing that information to interpretation by an attacker. To establish trust between the communicating systems, and to ensure that only trusted systems can communicate with each other, IPSec uses mutual authentication. After identities are established, IPSec uses cryptography-based keys to create a cryptographic checksum for each IP packet. The checksum ensures that only the computers that have knowledge of the keys could have sent each packet.

**Man-in-the-middle attacks.**
IPSec combines mutual authentication with shared, cryptography-based keys to provide end-to-end data integrity and information hiding.

**Denial-of-service attacks.**
IPSec uses IP packet filtering methodology to determine whether communication is allowed, secured, or blocked, according to the IP address ranges, IP protocols, or specific TCP and UDP ports.

**IPSec Management with Group Policy**
To provide strong, cryptography-based security to protect data, and to reduce administrative costs, IPSec uses policy-based administration. You can configure IPSec policies to meet the security requirements of a computer, application, organizational unit, domain, site, or global enterprise. You can use the **IP Security Policies Management** snap-in provided in Windows XP, Windows 2000, and Windows Server 2003 to define IPSec policies for computers through Active Directory (for domain members), or on the local computer (for computers that are not members of a domain).

# How IPSec Policy Extension Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How IP Security Policy Extension Works**

**In this section**

- IPSec Policy Extension Architecture
- IPSec Policy Extension Processes and Interactions
- Related Information

An Active Directory deployment is recommended for central management and distribution of Internet Protocol Security (IPSec) policies. Deployment of IPSec policy in an Active Directory environment requires Windows Server 2003, Windows 2000 Server, and Windows 2000 Professional or Windows XP Professional clients. The IP Security Policies extension of Group Policy Object Editor is used for managing IPSec in Active Directory environments. Policy based on Active Directory is not supported for computers running Windows XP Home Edition.

For computers that are not members of a domain, you can use the IP Security Policy Management snap-in to manage the local computer.

To successfully deploy IPSec, the following conditions must also be met:

- Each computer that must establish IPSec-secured communications has an assigned IPSec policy. The assigned policy must be compatible with the IPSec policy that is assigned to other computers with which it must communicate.
- Authentication is configured correctly and an appropriate authentication method is selected in the IPSec policy, so that mutual authentication can occur between IPSec peers.
- Routers, firewalls, or other filtering devices are configured correctly on all parts of the corporate network to permit IPSec protocol traffic, if IPSec-secured traffic must pass through these devices.
- IPSec policy compatibility issues must be considered if computers are running different versions of the Windows operating system (Windows Server 2003, Windows XP, and Windows 2000).
- For client computers that need to establish IPSec-secured connections with servers, servers must be adequately sized to support those connections. If necessary, IPSec hardware offload network adapters can be used.

This section discusses how IPSec Policy Extensions work. It presents information about IPSec architecture and how IPSec policies are stored.

**IPSec Policy Extension Architecture**

The basic components of IPSec in Windows Server 2003 include the Policy Agent, the Internet Key Exchange (IKE) module, the IPSec driver, and the TCP/IP driver, as shown in the following figure.

**IPSec Policy Extension Architecture**

The following table describes the IPSec policy-related components.

**IPSec Policy-Related Components and Descriptions**

| Component | Description |
|---|---|
| IP Security Policy Management Snap-in | This is the administrative tool for configuring IPSec policies in Active Directory or on the local computer. When the IP Security Policy Management snap-in loads as part of a GPO, it appears in the **Computer Configuration\Security Settings** node of Group Policy Object Editor(displayed as IP Security Policies). IP Security policies set from a GPO that is linked to a site, domain, organizational unit (OU), or local computer follow GPO inheritance and filtering rules. |

| | |
|---|---|
| Policy Agent | The Policy Agent controls the retrieval and distribution of IPSec policy and maintains the most current configured policy data for the IPSec Driver and IKE module. The Service Control Manager starts the Policy Agent, which runs in the context of the local security authority (LSA). The Policy Agent performs the following tasks when it is started (when the Local Security Authority is initialized):<br>1. Starts the IKE module.<br>2. Retrieves IPSec policies.<br>3. Determines the filter list order.<br>4. Delivers IP filters to the IPSec driver.<br>5. Delivers both Phase 1 and Phase 2 settings to IKE.<br>6. Polls for policy updates.<br>For more information about the Policy Agent tasks, see *Process Flow*, later in this section. |
| Internet Key Exchange (IKE) Module | The IKE module is used to establish a combination of mutually agreeable policy settings and keys that define the security services, protection mechanisms, and cryptographic keys between communicating peers. This combination is called a security association (SA). The IPSec driver in Windows 2000 and Windows Server 2003 uses the IKE module to protect all corresponding network traffic.<br>To create an SA between the two computers, the IETF has established a standard method of SA and key exchange resolution, which combines the Internet Security Association and Key Management Protocol (RFC 2408) and the Oakley Key Determination Protocol (RFC 2412). This standard method is IKE and is described in RFC 2409. |
| IPSec Driver | The IPSec driver receives the active IP filter list from the IPSec Policy Agent, and then attempts to match every inbound and outbound packet against the filters in the list. If a packet matches a filter, the IPSec driver applies the filter action. If a packet does not match any filters, the packet is passed back without modification to the TCP/IP driver to be received or transmitted.<br>If the filter action permits transmission, the packet is received or sent with no modifications. If the action blocks transmission, the packet is discarded. If the action requires the negotiation of security, main mode and quick mode SAs are negotiated. |
| TCP/IP Driver | The TCP/IP driver is the Windows 2000 implementation of the TCP/IP protocol. It starts the IPSec driver. |
| Policy Store | This maintains both IPSec policy descriptions and interfaces to applications and other tools that provide for policy data management. The policy store accesses IPSec policy data stored in either the local registry or Active Directory. |
| Local Registry | The local registry stores the locally configured IPSec policies, the local cache, and other IPSec settings. |
| Local Cache | The local cache stores IPSec policies after they are pulled from an Active Directory domain controller. The local cache is part of the registry. |
| Windows Management Instrumentation (WMI) | WMI is a component of the Microsoft Windows operating system and is the Microsoft implementation of Web-Based Enterprise Management (WBEM), which is an industry initiative to develop a standard technology for accessing management information in an enterprise environment. WMI uses the Common Information Model (CIM) industry standard to represent systems, applications, networks, devices, and other managed components. You can use WMI to automate administrative tasks in an enterprise environment. |
| IP Security Container | Each domain OU has an internal system container in Active Directory. IPSec policies created with IP Security Policiesare stored in this location. |

**IPSec Policy Extension Processes and Interactions**

This section discusses how IPSec Policies are processed, assigned, and stored.

The sequence of events is as follows:

1. During computer startup, the TCP/IP driver starts the IPSec driver.

2. The Service Control Manager starts the IPSec Policy Agent. The Policy Agent service performs the following tasks when it is initialized:

   - In preparation for loading the IPSec policy from either Active Directory or the local registry, the Policy Agent initializes the policy state and polling interval.

   - The policy agent loads the IPSec policy from the appropriate store. If boot time security is enabled, the IPSec driver mode is changed from the boot mode (block or stateful) to normal operational mode.

   - The policy agent retrieves the appropriate IPSec policy (if one has been assigned) from the Active Directory directory store or from the registry.

     To determine if IPSec policies exist, the Policy Agent checks the local registry and the Active Directory domain or OU to which the computer belongs. The Policy Agent checks the registry for the value that indicates the location of the computer's IPSec policy in Active Directory. If the computer is a member of a domain and an IPSec policy exists, this value was set during computer initialization. The registry key checked is:

     **HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows\IPSec \GPTIPSECPolicy\DSIPSECPolicyPath**.

     If the computer is not a member of a domain, or if there is no IPSec policy in Active Directory, a value does not exist.

     If IPSec policies are found in Active Directory, in a Group Policy object, the Policy Agent retrieves the policies and stores them in the local cache. Note that the local Active Directory cache is not used for locally assigned policies. If IPSec policies are defined both locally and in Active Directory, the policies based on Active Directory override the local policies.

     If there are no IPSec policies in Active Directory or the registry, or if the IPSec Policy Agent cannot connect to Active Directory, the IPSec Policy Agent waits for policy to be assigned or activated.

3. The IKE module, which runs in the context of the local security authority (LSA) is started.

4. After the policy load process is completed, the Policy Agent begins a service loop.

   In Windows Server 2003, if an unexpected event occurs, the IPSec driver is put into Block mode and all network traffic is blocked. This is the network security component failing to a secure mode. This applies only to Windows Server 2003; Windows 2000 and Windows XP do not block traffic.

For more information about Windows Server 2003 IPSec, see "What Is IPSec?" in the *Networking Collection*.

**Assignment of IPSec Policy**

You can assign IPSec policy to a local computer and to computers in Active Directory sites, domains or organizational units. For computers that are not members of a domain, you can assign local IPSec policy.

The main method for building an IPSec policy is to use the **IP Security Policy Management** snap-in to create, modify, and activate IPSec policies, and then assign them to computers in either Active Directory (for domain members) or to the local computer (for computers that are not members of a domain).

When you assign an IPSec policy in a GPO, a Lightweight Directory Access Protocol (LDAP) pointer to the IPSec policy is recorded in the **IPSecOwnersReference** attribute of the GPO. When the GPO is applied to the computer, the IP Security Policies extension of Group Policy Object Editor reads the LDAP pointer from the GPO and writes it to the registry. When the IPSec service starts on the computer, it reads the LDAP pointer and queries Active Directory to obtain the IPSec policy settings. The IPSec service maintains a current local cache of the IPSec Policy by periodically polling for changes. The polling frequency

is based on a polling interval that is specified on the IPSec policy.

You can also create and assign persistent IPSec policy to secure a computer even if a local IPSec policy or an Active Directory IPSec policy cannot be applied. This policy adds to or overrides the local or Active Directory policy, and remains in effect regardless of whether other policies are applied. Persistent IPSec policies enhance security by providing a secure transition from computer startup to IPSec policy enforcement. Persistent policy also provides backup security in the event of an IPSec policy corruption, or if errors occur during the application of local or domain-based IPSec policy. To configure persistent policies, you must use the **netsh ipsec static set store location=persistent** command.

**Administering IPSec Policies with Group Policy Management Console**
IPSec policies are stored separately from the GPOs that have policies applied; therefore, administrators need to be aware of the following differences. Domain-based IPSec policies are stored in the IP Security Policiescontainer in the System container.

**Back-up and Restore of IPSec Policies**
Group Policy Management Console (GPMC) provides back-up and restore operations for Group Policy objects (GPOs). These operations help administrators maintain their Group Policy deployment in the event of a disaster. It is a recommended practice to regularly back up all GPOs. To provide consistency, when you use these tools, make sure that you include IPSec policies. However; GPMC tools do not store the IPSec policies themselves; therefore, you cannot use GPMC tools to back up and restore the actual IPSec policies. You can only back-up and restore information about whether the IPSec policies are assigned to Group Policy objects and, if so, to which Group Policy objects.

The IPSec policy objects in the IP Security Policies container in Active Directory can be backed up and restored by using the Export Policies and Import Policies commands in the IP Security Policiesconsole. The Export Policies command exports all IPSec policy objects from the policy store into one .IPSec file. The Import Policies command imports all IPSec policy objects in the .IPSec file into the destination policy store.

### Note

- Importing IPSec policy into Active Directory overwrites existing IPSec policy objects.

For information about GPMC, see "What Is Group Policy Management Console?" in this collection.

**Delegation of Rights to Manage IPSec Policies**
GPMC delegation of rights and security filtering permissions only apply to the GPO; they do not apply to the IPSec policy that is assigned in the GPO. Thus, delegation of edit rights in GPMC only enables a user to assign or unassign an existing IPSec policy in the specific GPO, and only if the user also has read access rights to the IPSec policy. To delegate rights to create, edit, or delete IPSec policies, administrators must perform the delegation on the IPSec policies container.

**Applied IPSec Policies**
You can use the GPMC Group Policy Results wizard to show which GPOs are applied to a computer, including the IPSec policy assignments. **Advanced View** in the computer node shows which IPSec policy is assigned to a specific computer.

On computers running Windows XP, IPSec does not provide Resultant Set of Policy (RSoP) information. GPMC Group Policy Results only shows the GPO being processed, but does not show which IPSec policy is assigned. To view the assigned IPSec policy, you can use **netdiag /test:ipsec.**

For information about netdiag, see "IPSec Policy Extension Tools and Settings."

**IPSec Order of Precedence**
Although most Group Policy settings are cumulative, you can assign only one IPSec policy to a computer at a time. If multiple IPSec policies have been assigned at different Active Directory levels, the last one applied is the one that takes effect. IPSec policy settings differ from other types of Group Policy settings in that IPSec policy settings from different OUs are not merged.

IPSec policy uses the same precedence sequence as other Group Policy settings, from lowest to highest. The following list outlines the default order in which policies are applied. You can override this order by using Group Policy options, including **Enforced**, **Block Policy Inheritance**, and the loopback policy processing option (the **User Group Policy loopback processing mode** policy setting):

- **Local GPO.** Each computer has one local GPO. If a computer is not a member of a domain, this is the only place where you can assign IPSec policy. You can assign an IPSec policy by editing the local GPO, but you can also assign a local policy directly in the IP Security Policy Management snap-in, outside of the Group Policy context, or by using the Netsh IPSec context. When IPSec policy assignments are made outside of the GPO context, the GPO cannot display the local IPSec policy that is assigned.

- **Site.** IPSec policies are infrequently assigned at the site level because this would require all computers within a site to

have the same security needs, which is unlikely. Furthermore, if the computer moves to another subnet — such as when a user travels to another location with a laptop that uses DHCP — different policies might be in effect, resulting in different security behaviors.

- **Domain.** Simple IPSec policies are often assigned at the domain level and then superseded by more specific IPSec policies, as required on various OUs.

- **OU.** Specific IPSec policies are assigned to groups of computers. This is the last policy applied under normal conditions and, therefore, the policy takes precedence. If an OU is nested within another OU, the IPSec policy assigned to the nested OU takes precedence.

**Persistence of IPSec Policy**
An IPSec policy that has been assigned might remain active (persist) even after a GPO to which it is assigned has been deleted. When you assign an IPSec policy in a GPO, a Lightweight Directory Access Protocol (LDAP) pointer to the IPSec policy is recorded in the IPSecOwnersReference attribute of the GPO. The IP Security Policies extension reads the LDAP pointer from the GPO and writes it to the registry when the GPO is applied to the computer. This registry entry can persist if you delete a GPO that contains an assigned IPSec policy. Although the IPSecOwnersReference LDAP pointer is updated when the GPO is deleted, it points to an unreadable object (the location of the deleted objects container), which IPSec services cannot access. As a result, IPSec policy fails and an error is logged.

To prevent an IPSec policy from persisting, you must unassign the IPSec policy in the GPO beforeyou delete the GPO. Unassigning the IPSec policy deletes the LDAP pointer from the GPO.

**Storage of IPSec Policy Settings**
Domain-based IPSec policy objects are stored in the IP Security Policies container in Active Directory, which is separate from the GPOs to which the IPSec policies are applied. The domain administrator must grant permissions to the IP Security Policies container for other delegated administrators to administer IPSec policies. Standard delegation tools cannot be used to delegate permissions to administer IPSec policies. Instead, domain administrators must use Active Directory Service Interfaces (ADSI) Edit for this purpose.

ADSIEdit is a Microsoft Management Console (MMC) snap-in that domain administrators can use to edit objects in the Active Directory database. When domain administrators delegate permissions to others to administer IPSec policies, the delegated administrators must have Full Control permissions to all IPSec policy objects in the IP Security Policies container. After an IPSec administrator creates an IPSec policy, a member of the Group Policy Creator Owners group or other delegated owner of the GPO can assign the IPSec policy to the appropriate GPOs.

### Note

- To modify ACLs on the IP Security Policies container, domain administrators should use the tools that are provided with the Windows 2000 or Windows Server 2003 operating system CD. When domain administrators modify ACLs on the IP Security Policies container, they must specify that all modifications are also propagated to all child objects. Incorrect modification of the ACLs on the IP Security Policies container, failure to propagate modifications to the child objects of this container, or both, can result in the failure of IPSec policy settings to be properly applied.

On standalone computers, IPSec policy is stored in the local registry.

ADSIEdit is one of the Windows Server 2003 Support Tools which are included on the Windows Server 2003 operating system CD. You install these tools separately by running the Support Tools Setup program, **Suptools.msi**, from the **\Support\Tools** folder.

For more information about permissions for the IPSec Policies container, see article 329194, “Permissions on the IPSec Policy Store” in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Baselink on the Web Resources page.

**IP Security Container Default Permissions**
In Windows Server 2003, the default discretionary access control lists (DACLs) for the IP Security container are described in the following tables. The IPSec container owner is the Domain Admin, and group membership is Domain Admin.

The following table lists access rights related to the IPSec container and describes their values.

### IPSec Container Access Rights Values and Descriptions

| Access Right Value | Description |
|---|---|

| | |
|---|---|
| **ADS_RIGHT_DS_READ_PROP** | The right to *read* properties of the object. The **ObjectType** member of an access control entry (ACE) can contain a GUID that identifies a property set or property. If **ObjectType** does not contain a GUID, the ACE controls the right to read all of the object properties. |
| **ADS_RIGHT_DS_WRITE_PROP** | The right to *write* properties of the object. The **ObjectType** member of an ACE can contain a GUID that identifies a property set or property. If **ObjectType** does not contain a GUID, the ACE controls the right to write all of the object properties. |
| **ADS_RIGHT_DS_CONTROL_ACCESS** | The right to perform an operation controlled by an extended access right. The **ObjectType** member of an ACE can contain a GUID that identifies the extended right. If **ObjectType** does not contain a GUID, the ACE controls the right to perform all extended right operations associated with the object. |
| **ADS_RIGHT_DS_LIST** | The right to list a particular object. If the user is not granted such a right, and the user does not have ADS_RIGHT_ACTRL_DS_LIST set on the object parent, the object is hidden from the user. This right is ignored if the third character of the **dSHeuristics** property is '0' or not set. |
| **ADS_RIGHT_DS_LIST_OBJECT** | The right to list a particular object. If the user is not granted such a right, and the user does not have ADS_RIGHT_ACTRL_DS_LIST set on the object parent, the object is hidden from the user. This right is ignored if the third character of the **dSHeuristics** property is '0' or not set. |
| **ADS_RIGHT_DS_CREATE_CHILD** | The right to create children of the object. The **ObjectType** member of an ACE can contain a GUID that identifies the type of child object whose creation is controlled. If **ObjectType** does not contain a GUID, the ACE controls the creation of all child object types. |
| **ADS_RIGHT_DS_DELETE_CHILD** | The right to delete children of the object. The **ObjectType** member of an ACE can contain a GUID that identifies a type of child object whose deletion is controlled. If **ObjectType** does not contain a GUID, the ACE controls the deletion of all child object types. |
| **ADS_RIGHT_READ_CONTROL** | The right to read data from the security descriptor of the object, not including the data in the SACL. |
| **ADS_RIGHT_WRITE_DAC** | The right to modify the discretionary access-control list (DACL) in the object security descriptor. |
| **ADS_RIGHT_WRITE_OWNER** | The right to assume ownership of the object. The user must be an object trustee. The user cannot transfer the ownership to other users. |
| **ADS_RIGHT_DELETE** | The right to delete the object. |
| **ADS_RIGHT_DS_DELETE_TREE** | The right to delete all children of this object, regardless of the permissions of the children. |
| **ADS_RIGHT_DS_SELF** | The right to perform an operation controlled by a validated write access right. The **ObjectType** member of an ACE can contain a GUID that identifies the validated write. If **ObjectType** does not contain a GUID, the ACE controls the rights to perform all valid write operations associated with the object. |

The following table lists the access control rights for the IPSec container.

**DACLs for IPSec Container**

| DACLs | Access Rights |
|---|---|

| | |
|---|---|
| Allow domain computers | **ADS_RIGHT_DS_READ_PROP**<br>**ADS_RIGHT_DS_LIST**<br>**ADS_RIGHT_DS_LIST_OBJECT**<br>**ADS_RIGHT_READ_CONTROL** |
| Allow Group Policy Creator Owner | **ADS_RIGHT_DS_READ_PROP**<br>**ADS_RIGHT_DS_LIST**<br>**ADS_RIGHT_DS_LIST_OBJECT**<br>**ADS_RIGHT_READ_CONTROL** |
| Allow Domain Admin | **ADS_RIGHT_DS_READ_PROP**<br>**ADS_RIGHT_DS_WRITE_PROP**<br>**ADS_RIGHT_DS_CONTROL_ACCESS**<br>**ADS_RIGHT_DS_LIST**<br>**ADS_RIGHT_DS_LIST_OBJECT**<br>**ADS_RIGHT_DS_CREATE_CHILD**<br>**ADS_RIGHT_DS_DELETE_CHILD**<br>**ADS_RIGHT_READ_CONTROL**<br>**ADS_RIGHT_WRITE_DAC**<br>**ADS_RIGHT_WRITE_OWNER**<br>**ADS_RIGHT_DS_SELF** |
| Allow Local SYSTEM | **ADS_RIGHT_DS_READ_PROP**<br>**ADS_RIGHT_DS_WRITE_PROP**<br>**ADS_RIGHT_DS_CONTROL_ACCESS**<br>**ADS_RIGHT_DS_LIST**<br>**ADS_RIGHT_DS_LIST_OBJECT**<br>**ADS_RIGHT_DS_CREATE_CHILD**<br>**ADS_RIGHT_DS_DELETE_CHILD**<br>**ADS_RIGHT_READ_CONTROL**<br>**ADS_RIGHT_WRITE_DAC**<br>**ADS_RIGHT_WRITE_OWNER**<br>**ADS_RIGHT_DELETE**<br>**ADS_RIGHT_DS_DELETE_TREE**<br>**ADS_RIGHT_DS_SELF** |

The following changes are implemented in Windows Server 2003, and they apply to both new and upgrade installations of Windows Server 2003:

- An inheritable DACL is included with the IP Security container.
- An empty DACL is included with the built-in IPSec policies. Because the DACL is empty, objects can inherit permissions

from the IP Security container and other parent containers in Active Directory.

- The default DACL for all IPSec objects is changed so that all new objects that you create have an empty DACL and can inherit permissions. As a result, IPSec policies that are created from Windows 2000, Windows XP or Windows Server 2003 management clients have the new permissions.

To view these ACLs, you can use the ADSIEdit.exe tool (described earlier in *Storage of IPSec Policy Settings*) or Ldp.exe. The Ldp.exe tool provides an interface to perform Lightweight Directory Access Protocol (LDAP) operations against Active Directory. Ldp.exe and ADSIEdit.exe are two of the Windows Server 2003 Support Tools, which are included in the Windows Server 2003 operating system CD. You can install these tools by running the Support Tools Setup program, Suptools.msi, from the **Support\Tools** folder.

For more information about delegating IPSec permissions, see "Delegating Permissions to Modify Active Directory Based IPSec Policy" in the *Using Microsoft Windows IPSec to Help Secure an Internal Corporate Network Server* article available at the Microsoft Download Center.

For more information about control access rights, search for "Control Access Rights" in the *Directory Services SDK Documentation* in the Microsoft Platform SDK on MSDN.

**IPSec Policy Polling Interval**

The general IPSec policy settings include a polling interval, **Policy change poll interval**, which specifies the number of minutes between consecutive polls for changes in IPSec policies based on Active Directory. The default value for the **Policy change poll interval** is 180 minutes. This polling does not detect a change in domain or organizational unit membership, or the assigning or unassigning of a new policy; these events are detected when the Winlogon service polls for changes in Group Policy, which occurs every 90 minutes by default.

To generate an immediate update of changes in IPSec policy settings, instead of waiting for the next polling period, you can use the **Gpupdate** command, by typing the following at the command prompt: **gpupdate /target:computer**.

**Related Information**

# IPSec Policy Extension Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP Security Policy Extension Tools and Settings**

**In this subject**

- Resultant Set of Policies
- Tools for Viewing IPSec Policy Assignment on Computers Running Windows Server 2003
- Tools for Viewing IPSec Policy Assignment on Computers Running Windows 2000
- Tools for Viewing IPSec Policy Assignment on Computers Running Windows XP
- Tools for Managing and Monitoring IPSec Policy
- Network Ports Used by IPSec
- Related Information

This section is an overview of IPSec tools, Resultant Set of Policies (RSoP) in particular, which are used to determine which IPSec policy settings are currently in effect for a computer or a user. RSoP is also used to assess how policy settings would affect computers or users if a specific Group Policy object were applied to them. This section also describes the Windows Server 2003 command-line tools for configuring and analyzing IPSec policy settings.

**Resultant Set of Policies**

Windows XP and the Windows Server 2003 family support an enhanced Group Policy infrastructure that utilizes Windows Management Instrumentation (WMI) to collect Group Policy-related data for planning and troubleshooting Group Policy. This structure is the Resultant Set of Policy (RSoP), a query engine that polls existing policy settings and planned policy settings, and then reports the results of those queries. RSoP polls existing policies based on site, domain, domain controller, and organizational unit. RSoP gathers this information from the Common Information Management Object Model (CIMOM) database (also known as CIM-compliant object repository) by using WMI.

Administrators can use RSoP in one of two modes. To determine which policy settings are in effect for a particular computer or user, administrators use Resultant Set of Policy (RSoP) Logging Mode; to evaluate how policy settings would affect a computer or user if a specific Group Policy object were applied to users or computers, they use Resultant Set of Policy (RSoP) Planning Mode.

In Windows Server 2003, you can use the **Group Policy Modeling** node in the Group Policy Management Console (GPMC) to access the RSoP Planning Mode capabilities of Windows Server 2003. By using this feature, administrators can simulate policy settings applied to users and computers with Group Policy before actually applying the policy settings. You can also use the **Group Policy Results** node of GPMC to access the RSoP Logging Mode capabilities. Group Policy Results represents the actual resultant set of policy that was applied to a given user and computer. This information is obtained by directly querying the target user or computer. Each subnode represents a different RSoP query for a given user/computer combination.

**RSOP_IPSECPolicySetting**

The **RSOP_IPSECPolicySetting** WMI class represents the policy data for the IPSec extension. The **RSOP_IPSECPolicySetting** class is derived from **RSOP_PolicySetting**, and is included in Windows Server 2003. This class was available starting with Windows Server 2003 family and might not be available in future versions of Windows.

For more detailed information about RSoP and WMI and to download SDKs, see the Microsoft Platform SDK page.

For more information about GPMC, see the Group Policy Management Console page.

**Tools for Viewing IPSec Policy Assignment on Computers Running Windows Server 2003**

IPSec provides support for RSoP to enhance deployment and troubleshooting of IPSec Policy in Windows Server 2003. You can run an RSoP Logging-Mode query or an RSoP Planning-Mode query to view detailed settings (the filter rules, filter actions, authentication methods, tunnel endpoints, and connection types) for the IPSec policy that is currently being applied, or would

be applied if you deployed that IPSec policy.

The RSoP console displays the following information for each Group Policy object (GPO) that contains an IPSec policy assignment: the name of the IPSec policy, the name of the GPO to which the IPSec policy is assigned, the IPSec policy precedence, and the name of the site, domain, and organizational unit to which the GPO containing the IPSec policy applies (that is, the scope of management for the GPO). The lower the number in the **Precedence** column, the higher the precedence of the IPSec policy. A precedence of 1 indicates the IPSec policy that is being applied.

To provide support for RSoP in Windows Server 2003, the **RSOP_IPSECPolicySetting** WMI class was created. For more information, see *RSOP_IPSECPolicySetting* earlier in this document.

**RSoP and the Group Policy Management Console**
If you have installed Group Policy Management Console (GPMC), you can find out which policies are currently applied to a specific computer, including the IPSec policy assignments, by using the **Group Policy Results** node in GPMC. This runs the GPMC **Group Policy Results** wizard, which replaces the Resultant Set of Policy (RSoP) Logging Mode capabilities. Running the wizard shows which IPSec policy is assigned to a specific computer by right-clicking on the computer node, and then selecting **Advanced View.**

GPMC is available as a download from the Microsoft Web site. For more information about GPMC, see the Group Policy Management Console page.

**Netsh Commands for IPSec**
**Netsh** is a command-line scripting utility that you can run on a local or remote computer to display or modify the network configuration of a computer that is currently running. **Netsh** also provides a scripting feature so you can run a group of commands in batch mode against a specified computer, and it can also save a configuration script in a text file for archival purposes or to help you configure other servers.

**Netsh** interacts with other operating system components using dynamic-link library (DLL) files. **Netsh** helper DLLs provide an extensive set of features called a context, which is a group of commands specific to a networking component. These contexts extend the functionality of **netsh** by providing configuration and monitoring support for one or more services, utilities, or protocols. For example, **Nshipsec.dll** provides **netsh** the context and set of commands necessary to configure and manage IPSec policies and state.

To run a **netsh** command, you must start **netsh** from the **Cmd.exe** prompt and change to the context that contains the command you want to use. The contexts that are available to you depend on which networking components you have installed.

For computers running members of the Windows Server 2003 family, you can use the **netsh** commands for Internet Protocol security (**netsh ipsec** context) as an alternative to the console-based management and diagnostic capabilities provided by the IP Security Policy Management and the IP Security Monitor snap-ins. By using the **netsh** commands for IPSec, you can script IPSec configuration, and change the IPSec configuration for troubleshooting. You can also use this command to extend the security and manageability of IPSec. For example, you can use the **netsh** commands for IPSec to enable IPSec driver event logging, set default traffic exemptions, and configure computer startup security.

**Note**

- For computers running Windows 2000, use **Ipsecpol.exe**, which is provided with the Windows 2000 Server Resource Kit.
- For more information about **Ipsecpol.exe**, see "*Ipsecpol.exe: Internet Protocol Security Policies Tool*" on the download site for Windows 2000 Server Resource Kit tools.

The **Netsh ipsec** command supports both static and dynamic mode:

**Netsh ipsec static mode commands.**
You can use the **netshipsec** static commands to perform the same management tasks that you can perform by using the IP Security Policy Management console. By using these commands, you can create, modify, and assign IPSec policies without immediately affecting the configuration of the active IPSec policy.

**Netsh ipsec dynamic mode commands.**
You can use the **netsh ipsec** dynamic commands to display the active state of IPSec and to immediately affect the configuration of the active IPsec policy. These commands directly configure the security policy database (SPD). Changes that you make to an IPSec policy while using these commands take effect only while the IPSec service is running. If the IPSec service is stopped, the dynamic policy settings are discarded. You can use the **netsh ipsec** dynamic mode commands to perform the monitoring tasks of the IPSec Monitor snap-in. The **netsh ipsec** dynamic command allows the active state of IPSec to be

displayed, and it also allows modification of the state (unlike the IPSec Monitor tool, which does not allow modification of the state).

You can run these commands from the Windows Server 2003 command prompt or from the command prompt for the **netsh ipsec** context. For these commands to work at the Windows Server 2003 command prompt, you must type **netsh ipsec** before typing ipsec commands (such as **add filter** or **add rule**) and parameters.

To find more information about **netsh ipsec**, see "Command Line References" in Tools and Settings.

**Gpupdate**
This command-line tool refreshes local Group Policy settings and Group Policy settings that are stored in Active Directory, including security settings. This command supersedes the now obsolete **/refreshpolicy** option for the **secedit** command.

**Syntax**

```
gpupdate [/target:{computer | user}] [/force] [/wait:Value] [/logoff]
[/boot]
```

**Parameters**
The following table lists the **Gpupdate** parameters.

**Gpupdate parameters**

| Parameter | Description |
|---|---|
| **/target:**{**computer** \| **user**} | Processes only the *Computer* settings or the current *User* settings. By default, both the computer settings and the user settings are processed. |
| **/force** | Ignores all processing optimizations and reapplies all settings. |
| **/wait:** *Value* | Number of seconds that policy processing waits to finish. The default is 600 seconds. 0 equals no wait, and -1 equals wait indefinitely. |
| **/logoff** | Logs off after the refresh has completed. This is required for those Group Policy client-side extensions that do not process on a background refresh cycle but that do process when the user logs on, such as user Group Policy Software Installation and Folder Redirection. This option has no effect if there are no extensions called that require the user to log off. |
| **/boot** | Restarts the computer after the refresh has completed. This is required for those Group Policy client-side extensions that do not process on a background refresh cycle but that do process when the computer starts up, such as computer Group Policy Software Installation. This option has no effect if there are no extensions called that require the computer to be restarted. |
| **/?** | Displays help at the command prompt. |

**Examples**
The following examples show how you can use the **gpupdate** command:

**gpupdate**

**gpupdate /target:computer**

**gpupdate /force /wait:**100

**gpupdate /boot**

**Tools for Viewing IPSec Policy Assignment on Computers Running Windows 2000**
On computers running Windows 2000, you can use the Group Policy Results tool, **Gpresult.exe,** to display information about how Group Policy affects both the currently logged-on user and the computer.

**Gpresult** displays Group Policy information regarding:

- The last time that Group Policy was applied and the domain controller that applied the Group Policy setting for the user and the computer.

- A list of all applied GPOs and their details, including a summary of the extensions that each GPO contains.

- Registry settings that are applied and the details.
- Folders that are redirected and their details.
- Disk quota information.
- Internet Protocol (IP) Security settings.
- Scripts.

**Gpresult.exe Syntax**

Gpresult.exe uses the following syntax:

```
gpresult [/v] [/s] [/c] [/u]
```

The following table lists the **Gpresult** parameters.

**Gpresult.exe parameters**

| Parameter | Explanation |
|---|---|
| **/v** | Use this parameter to run Gpresult.exe in verbose mode. When you use this parameter, the following information is displayed (in additional to the information that is typically displayed):<br>• A list of the user's security rights.<br>• GPO details including globally unique identifier (GUID), friendly name, version, and source.<br>• Details for the following Group Policy extensions:<br>1. Administrative Templates (registry-based policy settings)<br>2. Application management<br>3. Disk quotas<br>4. Folder redirection<br>5. IP Security<br>6. Scripts |
| **/s** | Use this parameter to run Gpresult.exe in super-verbose mode. When you use this parameter, the following information is displayed (in addition to the information that is typically displayed):<br>• Binary values of binary registry settings (when applicable)<br>• A detailed list of the programs that are displayed in the Add or Remove Programs tool in Control Panel<br>• The Group Policy container and Group Policy template version numbers of the GPO |
| **/c** | Use this parameter to display information about computer settings only. |

| | |
|---|---|
| **/u** | Use this parameter to display information about user settings only. |

The **Gpresults** command-line tool is available in the Windows 2000 Resource Kit. To download this tool, see Windows 2000 Server Resource Kit tools Web site.

**Gpotool.exe**

You can use Gpotool.exe on a domain controller to check Group Policy object integrity and monitor policy replication. GpoTool performs the following tasks:

- Checks Group Policy object consistency. The tool reads mandatory and optional directory services properties such as version, friendly name, extension globally unique identifiers (GUIDs), and SYSVOL data (Gpt.ini). GpoTool also compares directory services and SYSVOL version numbers and performs other consistency checks. If the extensions property contains any GUID, the functionality version must be 2 and the user/computer version must be greater than 0.

- Checks Group Policy object replication. The tool compares the Group Policy object instances from each domain controller.

- Displays information about a particular Group Policy object, including properties that cannot be accessed by means of the Group Policy snap-in, such as functionality version and extension GUIDs.

- Browses Group Policy objects. A command-line option can search based on either friendly name or GUID. A partial match is also supported for both name and GUID.

- Designates preferred domain controllers. By default, all available domain controllers in the domain are used, but this can be overwritten with a list of domain controllers supplied from the command line.

- Provides cross-domain support. You can use the command-line option to check Group Policy objects in different domains.

- Runs in verbose mode. If all the Group Policy objects are acceptable, the tool displays a validation message. If errors occur, the tool displays information about the corrupted Group Policy objects. A command-line option can turn on verbose information about each Group Policy object that is being processed.

**GpoTool Syntax**

```
gpotool [/gpo:GPO[,GPO]] [/domain:DNSname] [/dc:DC[,DC]] [/checkacl]
[/verbose] [/new:GPO[,GPO...]] [/del:GPO[,GPO...]] [/?] [/help]
```

Where:

**/gpo:** *GPO*[,*GPO*] processes preferred Group Policy objects *GPO*[,*GPO*]. Partial GUID and friendly name matches are accepted for *GPO*. If *GPO* is not specified, the tool processes all Group Policy objects in the domain.

**/domain:** *DNSname* specifies the DNS name for the domain hosting the Group Policy objects. If a name is not specified, the user's domain is used.

**/dc:** *DC*[,*DC*] finds the preferred list of domain controllers *DC*[,*DC*]. If not specified, finds all controllers in the domain.

**/checkacl** verifies the SYSVOL ACL. For faster processing, this step is skipped by default.

**/verbose** displays detailed information.

**/new:** *GPO*[,*GPO*...] create new Group Policy objects with the specified friendly names *GPO*[,*GPO*...].

**/del:** *GPO*[,*GPO*...] deletes Group Policy objects with the specified friendly names *GPO*[,*GPO*...].

**/?** or **/help** displays GpoTool syntax.

**Tools for Viewing IPSec Policy Assignment on Computers Running Windows XP**

On computers running Windows XP, IPSec does not provide RSoP information. GPMC **Group Policy Results** shows the GPO being processed, but it does not show which IPSec policy is assigned. To view the assigned IPSec policy, you must use the **netdiag /test:ipsec** command. **Netdiag.exe** is a command-line tool that you can use to display information about IPSec

policies and statistics, reports network configuration, and tests basic networking capabilities and domain-based functionality.

Specifically, **Netdiag.exe** displays information about IPSec policy assignments, including the name of the active IPSec policy, the name of the Group Policy object that assigned the policy, and the policy path.

For Windows XP, **Netdiag.exe** is available for installation from the Windows XP CD. You install it by running the **Setup.exe** file from the **\Support\Tools** folder, and choosing the **Complete** setup option.

**Netdiag.exe**
On computers running Windows XP, you can use **Netdiag.exe** to view information about IPSec policies and statistics, report network configuration, and test basic networking capabilities and domain-based functionality.

**Syntax**
**Netdiag** uses the following syntax:

```
netdiag [/q] [/v] [/l] [/debug] [/d:domain_name] [/fix] [/dcaccountenum]
[/test:test_name] [/skip:test_name]
```

**Parameters**
You can use the following parameters with **Netdiag**:

| Parameter | Explanation |
|---|---|
| **/q** | Use this parameter to specify quiet output and display errors only. |
| **/v** | Use this parameter to run Netdiag in verbose mode and display information about the actions that are performed. |
| **/l** | Use this parameter to write output to the Netdiag.log file. The Netdiag.log file is created in the same folder in which you run Netdiag. |
| **/debug** | Use this parameter to run Netdiag in debug mode. This parameter specifies a more verbose output than when you use the **/v** parameter. |
| **/d:domain_name** | Use this parameter to locate a domain controller in the specified domain. |
| **/fix** | Use this parameter to correct minor issues. |
| **/dcaccountenum** | Use this parameter to enumerate domain controller computer accounts. |

| | |
|---|---|
| **/test:** *test_name* | Use this parameter to specify the test or tests that you want to run, where *test_name* can be any of the following values:<br>• **Autonet**: Automatic Private IP Addressing (APIPA) address test<br>• **Bindings**: Bindings test<br>• **Browser**: Redir and Browser test<br>• **DcList**: Domain controller list test<br>• **DefGw**: Default gateway test<br>• **DNS**: Domain Name Service (DNS) test<br>• **DsGetDc**: Domain controller discovery test<br>• **IpConfig**: Internet Protocol (IP) address configuration test<br>• **IpLoopBk** : IP address loopback ping test<br>• **IPSec**: IP Security Protocol (IPSec) security test<br>• **IPX**: Internetwork Packet Exchange (IPX) test<br>• **Kerberos**: Kerberos Test<br>• **Ldap**: Lightweight Directory Access Protocol (LDAP) test<br>• **Member**: Domain membership test<br>• **Modem**: Modem diagnostics test<br>• **NbtNm**: NetBIOS over TCP/IP (NetBT) name test<br>• **Ndis**: Netcard queries test<br>• **NetBTTransports**: NetBT transports test<br>• **Netstat**: Netstat information test<br>• **NetWare**: NetWare test<br>• **Route**: Routing table test<br>• **Trust**: Trust relationship test<br>• **WAN**: Wide Area Network (WAN) configuration test<br>• **WINS**: Windows Internet Name Service (WINS) service test<br>• **Winsock**: Winsock test |

**Example**

To use **Netdiag** to display the currently active Internet Protocol security (IPSec) policy, type the following line:

**netdiag /test:ipsec /debug**

For more information about **Netdiag**, see the Microsoft Knowledge Base page, and search for Knowledge Base article number *321708 How to: Use the Network Diagnostics Tool (Netdiag.exe) in Windows 2000*.

**Tools for Managing and Monitoring IPSec**

This section describes tools for administering and monitoring IPSec policies:

- IP Security Policy Managementsnap-in. You can apply IPSec policies to domains, sites, organizational units, or any Group Policy object in Active Directory, as well as to the local computer. To create, modify, and assign IPSec policies, you can use the IP Security Policy Management snap-in.

- IP Security Monitorsnap-in. You can use this tool to view details about IPSec policy settings as they are applied to a computer.

**IP Security Policy Management**

Microsoft Windows XP and the Windows Server 2003 family provide the IP Security Policy Management snap-in, which you can use to define IPSec policies for computers through Active Directory (for domain members) or on the local computer (for computers that do not belong to domains). By using IP Security Policy Management, you can create IPSec policies to meet the security requirements of a computer, application, organizational unit, domain, site, or global corporation.

**IP Security Monitor**

On computers running Windows XP and the Windows Server 2003 family of operating systems, you can use the **IP Security Monitor** snap-in to view IPSec policy settings as they are applied to the computer. This tool monitors IPSec SAs, rekeys, negotiation errors, and other IPSec statistics.

### Note

- On computers running Windows 2000, you use the **Ipsecmon.exe** program to view IPSec policy settings.

You use IP Security Monitor to perform the following tasks:

- Monitor IPSec information for local computer and remote computers.

- View details about active IPSec policies, including the name, description, date last modified, store, path, organizational unit, and Group Policy object name.

- View the following IPSec details in main mode and quick mode:

  - Generic filters and specific filters

  - Statistics

  - Security associations

- Customize refresh rates, and use DNS name resolution for filter and security association output.

- Search for specific main mode or quick mode filters that match any source or destination IP address, a source or destination IP address on your local computer, or a specific source or destination IP address.

**Network Ports Used by IPSec**

IPSec uses the following ports:

| IPSec protocol | Uses |
|---|---|
| IPSec ESP | Protocol 50. |
| IPSec AH | Protocol 51. |

| | |
|---|---|
| ISAKMP | UDP port 500. |
| IPSec NAT-T | Source port of **Any** or UDP port 4500 (a source port of **Any** might be used because the network address translator might translate source port UDP 4500 to a different source port).<br><br>Destination port of UDP 4500. |

**Related Information**

The following resources contain additional information that is relevant to this section.

- "What Is IPSec?" in the Networking collection.
- For more information about RSoP and WMI and to download SDKs, see the Microsoft Platform SDK page.
- For more information about GPMC, see the Group Policy Management Console page.
- The Tools and Settings Collection.

# Software Restriction Policies Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft Windows XP and the Windows Server 2003 family include software restriction policies, a new Group Policy-based feature that identifies software programs running on computers in a domain, and controls the ability of those programs to run. Software restriction policies are part of the Microsoft security and management strategy to assist enterprises in increasing the reliability, integrity, and manageability of their computers.

**In this subject**

- What Are Software Restriction Policies?
- How Software Restriction Policies Work
- Software Restriction Policies Tools and Settings

# What Are Software Restriction Policies?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Are Software Restriction Policies?**

**In this section**

- Protecting Computer System Integrity
- Dependencies on Other Operating System Components
- Related Information

Software restriction policies provide administrators with a Group Policy-driven mechanism to identify software and control its ability to run on the local computer. These policies can be used to protect computers running Microsoft Windows XP Professional against known conflicts and safeguard the computers against security threats such as malicious viruses and Trojan horse programs. You can also use software restriction policies to create a highly restricted configuration for computers, in which you allow only specifically identified applications to run. Software restriction policies are integrated with Microsoft Active Directory and Group Policy. You can also create software restriction policies on stand-alone computers.

Software restriction policies are trust policies, which are regulations set by an administrator to restrict scripts and other code that is not fully trusted from running.

**Protecting Computer System Integrity**

Business users collaborate by using e-mail, instant messaging, and peer-to-peer applications. As these collaborations increase, especially with the use of the Internet in business computing, so do the threats from malicious code, such as worms, viruses, and malicious user or attacker threats.

Users might receive hostile code in many forms, ranging from native Windows executable files (.exe files), to macros in documents (such as .doc files), to scripts (such as .vbs files). Malicious users or attackers often use social engineering methods to get users to run code containing viruses and worms. (Social engineering is a term for tricking people into revealing their password or some form of security information.) If such code is activated, it can generate denial-of-service attacks on the network, send sensitive or private data to the Internet, put the security of the computer at risk, or damage the contents of the hard disk drive.

IT organizations and users must be able to determine which software is safe to run and which is not. With the large numbers and forms that hostile code can take, this becomes a difficult task.

To help protect their network computers from both hostile code and unknown or unsupported software, organizations can implement software restriction policies as part of their overall security strategy.

**Group Policy-Based Software Restrictions**

Administrators can use software restriction policies to define which applications are allowed or not allowed to run on a target computer. The configuration is deployed in Group Policy objects.

To help organizations address the problem of unknown code, administrators can use software restriction policies to perform the following tasks:

- Fight computer viruses
- Regulate which ActiveX controls can run
- Run only digitally signed scripts
- Enforce that only approved software is run on system computers
- Create a highly restricted configuration for a computer (for example, stipulate that only specific programs are allowed to run)

**Scenarios for Using Software Restriction Policies**
Administrators can use software restriction policies for the following tasks:

- Define what is trusted code
- Design a flexible Group Policy for regulating scripts, executable files, and ActiveX controls

Software restriction policies are enforced by the operating system and by applications (such as scripting applications) that comply with software restriction policies.

Specifically, administrators can use software restriction policies for the following purposes:

- Specify which software (executable files) can run on clients
- Prevent users from running specific programs on shared computers
- Specify who can add trusted publishers to clients
- Set the scope of the software restriction policies (specify whether policies affect all users or a subset of users on clients)
- Prevent executable files from running on the local computer, organizational unit (OU), site, or domain. This would be appropriate in cases when you are not using software restriction policies to address potential issues with malicious users.

**Advantages of Software Restriction Policies**
Using software restriction policies provides the following advantages:

**Administrators can enforce software restriction policies in domains or on the local computer.**
The software restriction policies can be implemented in a large enterprise with various types of computers and applications, and can also be applied in a stand-alone environment for computers that are not members of a domain. Software restriction policies leverage Active Directory and Group Policy for manageability. The software restriction policies are stored in a GPO. Administrators create the software restriction policy, and then define which applications are trusted and which are not. The software restriction policy is enforced at run time and users do not receive prompts allowing them to choose whether to run executable files.

**Software restriction policies apply to multiple types of files.**
Software restriction policies provide control over Microsoft Visual Basic Scripting Edition (VBScript), JScript, and other scripting languages. Software restriction policies also integrate with the Windows Installer feature to provide control over the types of software packages (.msi files) that can be installed on clients. This feature includes an application programming interface (API), which you can use to coordinate the software restriction policy run time with other run times.

**Software restriction policies provide flexibility.**
Administrators can prohibit unauthorized scripts from running, regulate Microsoft ActiveX controls, or lockdown client computers.

**Software restriction policies use strong cryptography to identify software.**
Software restriction policies can identify software by using a hash or a certificate.

**Dependencies on Other Operating System Components**
Software restriction policies rely on the following operating system components:

**Active Directory.**
The Windows-based directory service, Active Directory, stores information about objects on a network and makes this information available to administrators and users. By using Active Directory, you can view and manage network objects on the network from a single location, and users can access permitted network resources by using a single logon.

**Group Policy.**
The infrastructure within Active Directory, Group Policy, enables directory-based configuration management of user and computer settings on computers running Windows Server 2003, the Windows 2000 family, and the Microsoft Windows XP Professional operating systems. By using Group Policy, you can define configurations for groups of users and computers, including policy settings for Windows Server 2003 registry-based policies, software installation, scripts, folder redirection, Remote Installation Services, Microsoft Internet Explorer maintenance, and security.

**Windows Installer.**

Windows Installer is an installation and configuration service that reduces the total cost of ownership. Windows installer is included in Microsoft Windows Server 2003 family, Windows 2000, Windows XP, and Windows Millennium Edition (Windows Me). It is also provided as a service pack to Microsoft Windows NT version 4.0, Windows 98, and Windows 95. Windows Installer version 2.0 is integrated with Software Restriction Policies in Microsoft Windows XP and Windows Server 2003. The Windows Installer version 2.0 only installs packages allowed to run at the unrestricted level.

Patches or transforms must also be allowed to run at the unrestricted level. If a package, patch, or transform is not configured to run fully trusted (unrestricted), the Windows Installer displays an error message and logs an entry in the application event log. Software restriction policy is evaluated the first time an application is installed, when a new patch is applied, and when the installation package is re-cached.

Msiexec.exe is the executable program that interprets packages and installs products.

**Authenticode and WinVerifyTrust.**
These components are used to process signed executable files. Microsoft Authenticode, which is based on industry standards, allows developers to include information about themselves and their code with their programs through the use of digital signatures. The WinVerifyTrust function performs a trust verification action on a specified object.

The following figure illustrates the interactions of software restriction policies, Active Directory, and Group Policy.

# How Software Restriction Policies Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Software Restriction Policies Work**

**In this section**

- Software Restriction Policies Architecture
- Software Restriction Policies Overview
- Software Restriction Policies Processes and Interactions
- Related Information

Software restriction policies provide administrators with a policy-driven mechanism for identifying the software programs running on computers in a domain and for controlling the ability of those programs to run.

Deployment based on Active Directory requires Windows Server 2003, and Windows XP Professional clients, specifically:

- Windows Server 2003 with Active Directory installed and dynamic DNS properly configured.
- Windows XP client computers.
- The **Group Policy Object Editor** and the **Software Restriction Policies** extension of **Group Policy Object Editor**.

For Windows XP computers that are not participating in a domain, you can use the **Local Security Settings** snap-in to access **Software Restriction Policies**.

**Software Restriction Policies Architecture**

Software restriction policies provide a mechanism for the operating system and applications compliant with software restriction policies to restrict the runtime execution of software programs.

At a high level, software restriction policies consist of the following components:

- Software restriction policies (sometimes referred to as Safer) Application Programming Interfaces (APIs), which are used to create and configure the rules that constitute the software restriction policy. There also are software restriction policies APIs for querying, processing, and enforcing software restriction policies.
- A software restriction policies management tool. This consists of the **Software Restriction Policies** extension of the **Group Policy Object Editor** snap-in, which administrators use to create and edit the software restriction policies.
- A set of operating system APIs and applications that call the software restriction policies APIs to provide enforcement of the software restriction policies at runtime.
- Active Directory and Group Policy. Software restriction policies depend on the Group Policy infrastructure to propagate the software restriction policies from the Active Directory to the appropriate clients, and for scoping and filtering the application of these policies to the appropriate target computers.
- Authenticode and WinVerify Trust APIs which are used to process signed executable files.
- Event Viewer. Software restriction policies functions log events to the Event Viewer logs.
- Resultant Set of Policies (RSoP), which can aid in the diagnosing of the effective policy that will be applied to a client.

The following figure shows an example of the Group Policy Object Editor targeted on one of three different Group Policy objects (GPOs) that apply to a workstation. The Group Policy Object Editor is viewing a GPO containing software restriction policies, A1GPO, which is associated with the University domain. When the computer starts or the user logs on, the policies from A1GPO, A2GPO, and A3GPO are downloaded and applied.

**Software Restriction Policies, Group Policy and Active Directory**

After Group Policy downloads the software restriction policy, the policy is stored in the registry. This policy is processed during the calls to the software restriction policies (Safer) enforcement APIs. For example, when users double-click an executable file (.exe) in Windows Explorer, the enforcement API, **SaferIdentifyLevel**, is called to determine the rule details that are associated with that executable file. In this example, if the software restriction policy does not indicate that the program is fully trusted, the executable file does not run. **ShellExecute** calls **SaferIdentifyLevel** when a non-natively executable file is double-clicked (this is covered only by **Designated File Types**). For natively-executable files (a portable executable file or PE), **CreateProcess** calls **SaferIdentifyLevel**. See "Default Designated File Types," later in this section for more information.

Software restriction policies consist of the following components.

**Software Restriction Policies Components**

| Component | Description |
|---|---|
| Software Restriction Policies (Safer) API | This component is an API for creating and manipulating software restriction policies. The functions in this API are used to get and set the rules that constitute a software restriction policy. Safer APIs provide applications that launch programs from external sources the ability to query security policy for approval before an executable file is launched. |
| Management tools | These components include the **Group Policy Object Editor** snap-in, the **Software Restriction Policies** extension, and command line tools. The management tools use the Software Restriction Policies (Safer) APIs to allow the computer administrator to author and edit software restriction policies. |

| | |
|---|---|
| Safer Enforcement APIs | In Windows Server 2003, these components include functions (**SaferIdentifyLevel** and **SaferComputeTokenFromLevel**) that the operating system and applications compliant with software restriction policies use to enforce the software restriction policy. These functions can process the set of software restriction policies rules contained in the policy and return the most appropriate rule for a given program. |
| Operating system APIs and applications | A set of operating system APIs and applications, compliant with software restriction policies, which call into the Safer enforcement functions to provide enforcement of the policy at runtime. These include Microsoft Office Macros, a .DLL loader, Component Object Model (COM), and these APIs:<br>1. **ShellExecute.** Performs an operation on a specified file.<br>2. **CreateProcess.** Creates a new process and its primary thread. The new process runs the specified executable file in the security context of the calling process. |
| Microsoft Windows Script Host | Windows Script Host is not a component of Software Restriction Policies; however, it interacts with Software Restriction Policies. Windows Script Host calls into Software Restriction Policies to apply software restriction policies to scripts that are being run. Note that other script engines do not do this. If you want to perform script checking, you can only run script hosts that call software restriction policies.<br>Windows Script Host is a language-independent scripting host for Windows Script compatible scripting engines. It brings simple, powerful, and flexible scripting to the Windows 32-bit platform, enabling you to run scripts from both the Windows desktop and the command prompt. |
| Windows Installer | Windows Installer (Msiexec) is not a component of Software Restriction Policies, but it also interacts with Software Restriction Policies. Windows Installer calls into Software Restriction Policies to apply software restriction policies to scripts that are being installed. Windows Installer implements the Software Restriction Policies API. |
| Group Policy | Group Policy is a feature included in Windows XP, Windows 2000, and Windows Server 2003. Software restriction policies use the Group Policy's *Registry.pol* files.<br>The Administrative Templates extension of Group Policy saves information in Registry.pol files. These files contain the customized registry settings that you specify (by using Group Policy) to be applied to the computer or user portion of the registry. One Registry.pol file contains registry settings that are specific to the **HKEY_LOCAL_MACHINE** key; it is stored in the Group Policy Template folder, in the \Machine subfolder. The other Registry.pol file contains registry settings that are specific to the **HKEY_CURRENT_USER** key; it is stored in the Group Policy Template folder, in the \User subfolder.<br>Software restriction policies do not use a client side extension. Software restriction policies depend on Group Policy to propagate the policy from the Active Directory to the appropriate clients and use the appropriate filtering and scoping. |
| Event Viewer | Software restriction policies functions log events in the Event log. The **SaferRecordEventLogEntry** function saves messages to an event log. |
| Authenticode and WinVerifyTrust | These components are used to process signed executable files. Microsoft Authenticode, which is based on industry standards, enables developers to include information about themselves and their code with their programs through the use of digital signatures. The **WinVerifyTrust** function performs two actions: signature checking on a specified object and trust verification action. |
| Windows Management Instrumentation (WMI) | The Software Restriction Policies extension queries the registry policy by using WMI. WMI is a component of the Microsoft Windows operating system and is the Microsoft implementation of Web-Based Enterprise Management (WBEM), which is an industry initiative to develop a standard technology for accessing management information in an enterprise environment. WMI uses the Common Information Model (CIM) industry standard to represent systems, applications, networks, devices, and other managed components. You can use WMI to automate administrative tasks in an enterprise environment. |
| Resultant Set of Policy (RSoP) | RSoP is a Group Policy feature that aids in diagnosing effective policy settings that will be applied to a client. Software restriction policies provide support for RSoP. |

| | |
|---|---|
| Registry | Software restriction policies are stored in the registry. In **HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\Windows\Safer** or in **HKEY_CURRENT_USER\SOFTWARE\Policies\Microsoft\Windows**. |

For information about the Software Restriction Policies (Safer) functions, see the topic "Safer" in the Security section of the Microsoft Platform SDK on MSDN.

**Software Restriction Policies Overview**

A software restriction policy consists of a default rule that defines which programs can run, and a set of exceptions to the default rule.

You can set the default rule, which specifies whether software can run, to either **Unrestricted** (program can run) or **Disallowed** (program cannot run). If you set the default rule to **Unrestricted**, you can also define exceptions to specify a set of programs that are not allowed to run. The **Unrestricted** default setting is appropriate in an environment with lightly managed clients. For example, you can prevent users from installing a program that conflicts with existing programs by creating a rule to block that program.

For environments that require a more secure method of software control, you should set the default rule to **Disallowed** and then allow only a specific set of programs to run. If you use the **Disallowed** default setting, you have to identify all the software that users are permitted to run and create appropriate rules for them. The **Disallowed** default setting is the preferred default for securing Windows XP clients.

**Rules in Software Restriction Policies**

Software restriction policies use rules to identify one or more software applications, and to specify whether the software is permitted to run. By creating rules, administrators can identify software that is an exception to the default rule. Each rule can include descriptive text to indicate why the rule was created.

To identify software, software restriction policies support the following rules:

- **Hash.** A cryptographic fingerprint of the file
- **Certificate.** A software publisher certificate used to digitally sign a file
- **Path.** The local or universal naming convention (UNC) path of where the file is stored
- **Zone.** Internet Zone

**Hash Rule**

A hash is a cryptographic fingerprint that uniquely identifies a file regardless of its name or where it is accessed. With a hash rule, software can be renamed or moved into another location on a disk, but it will still match the hash rule because the rule is based on a cryptographic calculation involving file contents. Hash rules work effectively in a static environment. If the software in your clients is upgraded frequently, hash rules can become difficult to manage. Whenever a program executable is updated, the hash rule needs to be updated to support the new executable version.

For secure environments using a default level of **Disallowed**, hash rules are a very secure way to identify applications that you want to allow to run as **Unrestricted**. For environments using a default level of **Unrestricted**, hash rules allow you to specifically identify one particular version of an application to disallow.

A hash rule consists of three pieces of data, separated by colons:

- MD5 or SHA-1 hash value
- File length
- Hash algorithm ID

A hash rule uses the following format:

```
[MD5 or SHA1 hash value]:[file length]:[hash algorithm id]
```

Files that are digitally signed use the hash value contained in the signature, either SHA-1 or MD5. Files that are not digitally

signed use an MD5 hash.

For example, the following hash rule matches a file with a length of 126 bytes and with contents that match the MD5 (denoted by the hash algorithm identifier of 32771) hash of 7bc04acc0d6480af862d22d724c3b049:

```
7bc04acc0d6480af862d22d724c3b049:126:32771
```

**Certificate Rule**
A certificate rule specifies a code-signed software publisher's certificate. For example, a company can require that all scripts and ActiveX controls be signed with a particular set of publisher certificates. Certificates used in a certificate rule can be issued from a commercial certificate authority (CA) such as VeriSign, a Windows 2000 or Windows Server 2003 Public Key Infrastructure (PKI), or a self-signed certificate.

A certificate rule uses signed hashes contained in the signature of the signed file to match files regardless of name or location. If you want to make exceptions to a certificate rule, you can use a hash rule to identify the exceptions. Certificate rules provide more flexibility than hash rules. By using a certificate rule, you can allow (or deny) multiple applications at once. Certificate rules also allow low maintenance of the software restriction policies rule-set, but they can provide the security of hash rules.

**Path Rule**
A path rule can specify a folder or fully qualified path to a program. When a path rule specifies a folder, it matches any program contained in that folder and any programs contained in subfolders. Software restriction policies support local and Uniform Naming Convention (UNC) paths.

The administrator must define all directories for launching a specific application in the path rule. For example, if the administrator creates a shortcut on the desktop to launch an application, then in the path rule, the administrator must also grant the user Read access rights to both the executable file and the shortcut paths to run the application. If all the path information necessary for launching the application in the path rule is not defined, it can trigger the **Software Restricted** warning when the user attempts to run the application.

**Environment variables in path rules**
You can use environment variables in a path rule. Since path rules are evaluated in the client environment, the ability to use environment variables (for example, %Windir%) allows a rule to adapt to a particular user's environment.

### Note

- Environment variables are *not* protected by Access Control Lists (ACLs). There are two types of environment variables: **Users** and **System**. Users that are able to start a command prompt can redefine the **Users** environment variable to a different path. The reason for this is that if an administrator uses %Windir% in a path rule, then a user can run Cmd.exe, change the value of %Windir% to a directory where the user's .exe file is, run his or her .exe file, and then exit that shell or change %Windir% back. It is also possible for a user to make changes programmatically or by using the **System Properties** page in Control Panel. Only users in the Administrators group have permissions to change the **System** environment variable.

- If you need to provide enhanced security in your environment, use the registry-based path rules, which is the preferred method. See "Registry Path Rules," later in this section.

The following examples show instances of applying environment variables to a path rule:

- "%UserProfile%" matches C:\Documents and Settings\User and all subfolders under this directory.

- "%ProgramFiles%\Application" matches C:\Program Files\Application and all subfolders under this directory.

**Wildcards in path rules**
A path rule can incorporate the '?' and '*' wildcards, allowing rules such as "*.vbs" to match all Visual Basic Script files. The following examples illustrate the use of wildcards:

- "\\DC-??\login$" matches \\DC-01\login$, \\DC-02\login$

- "*\Windows" matches C:\Windows, D:\Windows, E:\Windows

- "c:\win*" matches c:\winnt, c:\windows, c:\windir

**Registry path rules**

Many applications store paths to their installation folders or application directories in the Windows registry. You can create a path rule to look up these registry keys. For example, some applications can be installed anywhere on the file system. These locations might not be easily identifiable by using specific folder paths, such as C:\Program Files\Microsoft Platform SDK, or environment variables, such as %ProgramFiles%\Microsoft Platform SDK. If the program stores its application directories in the registry, you can create a path rule that uses the value stored in the registry, such as **%HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\PlatformSDK\Directories\Install Dir%**. This type of path rule is called a registry path rule. Using registry path rules is a recommended practice because users cannot bypass the path rule by undermining the environment variable expansion.

The registry path format is:

**%[Registry Hive]\[Registry Key Name]\[Value Name]%**

**Note**

- A registry path rule suffix must not contain a backslash (\) character immediately after the last percent sign (%) in the rule. The registry hive name must be written out; abbreviations will not work.

The following conditions apply to registry paths rules:

- The registry path must be enclosed in percent signs (%).
- The registry value must be a **REG_SZ** or **REG_EXPAND_SZ**. You cannot use HKLM as an abbreviation for **HKEY_LOCAL_MACHINE**, or HKCU as an abbreviation for **HKEY_CURRENT_USER**.
- If the registry value contains environment variables, these will be expanded when the policy is evaluated.
- A registry path rule can also contain a suffix path such as **%HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Explorer\Shell Folders\Cache%OLK*.** This registry path rule identifies the folder that Microsoft Outlook XP uses to store attachments before launching them. The attachment folder always starts with the letters "OLK" so the rule uses wildcard matching. For example, this rule matches the following path: C:\Documents and Settings\username\Local Settings\Temporary Internet Files\OLK4.

**Note**

- When you set a path rule, you should check the access control list (ACL) entries on the path. If users have write access to a path, they can modify its contents. For example, if you allow C:\Program Files, any power user on the computer can copy software into the Program Files folder.

When the default rule is set to **Disallowed**, there are four registry paths that are setup so the operating system has access to system files for normal operation. These registry path rules are created as a safeguard against locking yourself and all other users out of the system. These registry rules are set to **Unrestricted**. Only advanced users should consider modifying or deleting these rules. The registry path rule settings are:

- **%HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\SystemRoot%**
- **%HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\SystemRoot%*.exe**
- **%HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\ CurrentVersion\SystemRoot%\System32*.exe**
- **%HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\ProgramFilesDir%**

**Path rule precedence**

When there are multiple matching path rules, the most specific matching rule takes precedence.

The following is a set of paths, from highest precedence (more specific match) to lowest precedence (more general match):

- Drive:\Folder1\Folder2\FileName.Extension
- Drive:\Folder1\Folder2*.Extension
- *.Extension
- Drive:\Folder1\Folder2\
- Drive:\Folder1\

**Zone Rule**
A rule can identify software from the Internet Explorer zone from which it is downloaded. These zones are:

- Internet
- Intranet
- Restricted Sites
- Trusted Sites
- My Computer

The current version of the Internet zone rule applies to only Windows Installer (*.msi) packages. This rule does not apply to software downloaded by using Internet Explorer. All other file types affected by zone rules are listed in the table on designated file types that appears under the "Default Designated File Types" heading, later in this section. There is one list of designated file types that is shared by all zone rules.

### Note

- Each rule is associated with a globally unique identifier (GUID). An example GUID is {f8c2c158-e1af-4695-bc93-07cbefbdc594}. Two identical rules, for example two **Disallowed**hash rules on the same program, have a different GUID associated with each. This GUID is stored in the registry along with the rule data.

**Rules Precedence**
Rules for software restriction policies are evaluated according to a specific order. The rules that more specifically match a program take precedence over rules that more generally match the same program. If two identical rules with differing security levels are established for the same software, the rule with the highest security level takes precedence. For example, if two hash rules, one with the security level **Disallowed** and one with the security level **Unrestricted**, are applied to the same software program, the rule with the security level **Disallowed** takes precedence, and the program will not run. The following ordered list defines the precedence order for the rules from the most specific (hash) to the least specific rule (default):

1. Hash rule
2. Certificate rule
3. Path rule
4. Zone rule
5. Default rule

**Policy Enforcement Options**
There are two policy enforcement options that influence the behavior of a software restriction policy. The following options define how software restriction policies are applied for all files, including signed files:

- **Apply software restriction policies to the following: All files**. This option includes dynamic-link libraries (DLLs).

- **Apply software restriction policies to the following users**: **All users except local administrators.** This option prevents the software restriction policies from applying to local administrators.

#### Including DLLs

Most programs consist of an executable file and many supporting DLLs. By default, software restriction policy rules are not enforced on DLLs. Not checking DLLs is the recommended option for most customers for the following reasons:

- Including DLLs degrades system performance because it has to check all libraries linked to the application. For example, if a user runs 10 programs during a logon session, the software restriction policy evaluates each program. When the **Apply software restriction policies to the following: All files** is selected, the software restriction policy evaluates each DLL load within each program. If each program uses 20 DLLs, this results in 10 executable program checks plus 200 DLL checks, so the software restriction policy must perform 210 evaluations. A program such as Internet Explorer consists of an executable file, iexplore.exe, and many supporting DLLs.

- Setting the default security level to **Disallowed** forces the system to identify both the main executable file andits supporting DLLs before the .exe file can run, which places added burden on the system.

### Note

- To provide the highest assurance possible for the programs running in environments that want the highest assurance possible when running programs, DLL Checking is the recommended option. DLL checking is recommended because while viruses primarily target executable files, some specifically target DLLs. To ensure that a program does not contain a virus, you can use a set of hash rules that identify the executable file and its constituent DLLs.

#### Excluding Administrators

An administrator might want to disallow programs from running for most users, but allow administrators to run all of them. For example, an administrator might have a shared computer that multiple user's connect to using terminal server. The administrator might want users to run only specific applications on the computer, but allow members in the local Administrators group to run any program. You can use the **Apply software restriction policies to the following users: All users except local administrators** enforcement option to do this.

If the software restriction policy is created in a GPO linked to an object in Active Directory, instead of using the **Skip Administrators** option, consider denying the **Apply Group Policy** permission on the GPO to the Administrators group. This approach consumes less network traffic because GPO settings that do not apply to administrators are not downloaded.

### Note

- Software restriction policy defined in local security policy objects cannot filter user groups. In this case, use the Skip Administrators option.

#### Default Designated File Types

Software restriction policy rules apply automatically to some types of executable files, regardless of their extension type. This includes the following types of files:

- Windows operating system executable files (.exe, .com, .dll)

- Windows scripting files (when processed by Windows Script Host, such as .vbs, and .wsh files)

- Command batch files (when processed by Windows CMD, such as .bat, .cmd)

- Installation packages when processed by Windows Installer (.msi)

You can apply software restriction policies rules to additional file types, even when they are handled by non-Microsoft programs. However, if the other program does not enforce software restriction policies itself, the software restriction policies restrictions will only apply when either Windows Explorer or Internet Explorer is used to open the file. Opening the other program and then opening the executable script from within that program circumvents software restriction policies. To resolve this issue, contact the software provider and request that they enforce software restriction policies when opening executable

scripts, or disallow execution of the other scripting host.

The file types are listed in the **Designated File Types Properties** dialog box. This dialog is accessible in the Group Policy Object Editor, in **Computer Configuration\Windows Settings\Security Settings\Software Restriction Policies**, under **Designated File Types** in the details pane. Additional file types to which you want to apply rules can be added to this list. For example, for Perl scripting files you might choose to add .pl and other file types associated with the Perl engine to the **Designated file types** list under the **General** tab of the **Designated File Types Properties** dialog box. Note that you can check only the initial script this way; if a Perl script calls another Perl script, there will be no software restriction policies check.

The following table lists what is considered to be executable code. This is in addition to standard program files such as .exe, .dll, and .vbs.

**Default Designated File Types**

| File Extension | File Description |
|---|---|
| .ade | Microsoft Access Project Extension |
| .adp | Microsoft Access Project |
| .bas | Visual Basic Class Module |
| .bat | Windows Batch File |
| .chm | Compiled HTML Help File |
| .cmd | Windows NT Command Script |
| .com | Application |
| .cpl | Control Panel extension |
| .crt | Security Certificate |
| .exe | Application |
| .hlp | Windows Help File |
| .hta | HTML Applications |
| .inf | Setup Information File |
| .ins | Internet Communication Settings |
| .isp | Internet Communication Settings |
| .lnk1 | Shortcut |
| .mdb | MDB File |
| .mde | Microsoft Access MDE Database |
| .msc | Microsoft Common Console Document |
| .msi | Windows Installer Package |
| .msp | Windows Installer Patch |
| .ocx | ActiveX Controls |
| .pcd | Photo CD Image |
| .pif | Shortcut to Program |
| .reg | Registration Entries |

| | |
|---|---|
| .scr | Screen Saver |
| .shs | Shell Scrap Object |
| .url | Internet Shortcut (Uniform Resource Locator) |
| .vb | VB File |
| .wsc | Windows Script Component |

[1] If you click a .lnk file (shortcut) in the UI, ShellExecute applies software restriction policies to it if the .lnk extension is included in Designated File Types. Otherwise, ShellExecute runs the target, where software restriction policies get applied in CreateProcess.

If the file type of the shortcut's (.lnk) target is not an executable file directly, such as a .doc file, and if .doc is included in **Designated File Types,** software restriction policies rules are applied to the .doc file. If .doc is not included in **Designated File Types,ShellExecute** runs the handler with specified options (such as running "WinWord filename.doc"). At this point, **CreateProcess** applies software restriction policies to the application, WinWord, and not to the filename.doc, which was the actual target of the .lnk.

#### Trusted Publishers

You can use the **Trusted Publishers Properties** dialog box to configure which users can select trusted publishers. You can also determine which, if any, certificate revocation checks are performed before trusting a publisher. With certificate rules enabled, software restriction policy will check a certificate revocation list (CRL) to ensure the software's certificate and signature are valid. This can decrease performance when starting signed programs. The options under the **General** tab of the **Trusted Publishers Properties** dialog box. You access this dialog in the **Group Policy Object Editor** snap-in, by navigating to **Computer Configuration\Windows Settings\Security Settings\Software Restriction Policies**, anddouble-clicking **Trusted Publishers** in the details pane.

### Note

- If you enable the Trusted Publishers option, you must also explicitly add the certificates of allowed ActiveX publishers to the Trusted Publisher certificate store. Adding the certificates is required to ensure that installation and other operations work properly and to maintain the appropriate system functions. If you don't add the certificates, ActiveX controls will not install, and some applications which perform signature validation might exhibit unexpected behavior. All trust validations using the default Authenticode policy fail unless the signing certificate is in the Trusted Publishers store. For example, Windows Update automatically validates its own signature and the signatures of downloaded files. The Trusted Publishers restrictions are only recommended for the most restrictive environments.

#### Default Settings for a Software Restriction Policy

The default settings for a software restriction policy include the following:

- Default **Security Level**: **Unrestricted**
- **Enforcement** options:
  - Apply to Files: All software files except libraries (such as DLLs)
  - Apply to Users: All users
- **Additional Rules**: none
- **Designated File Types**: These are defined in the "Default Designated File Types" section, earlier in this document.
- **Trusted Publishers**:
  - **Select Trusted Publishers**: End users
  - **Publisher** certificate revocation checking: Not selected

- **Timestamp** certificate revocation checking: Not selected

**Example: Applying Software Restriction Policies in a Highly Restricted Environment**
In some cases, you might want to manage all of the software that runs on a computer. For example, even when users have insufficient rights to replace system files or files in shared folders such as Program Files, if the user's have a place on the file system to which they can write, they could copy a program there and start it from that location.

Administrators can create a highly-restricted (locked down) configuration to prevent users from modifying the contents of the Program Files or Windows folders, and allow them to run only software that is installed by the administrator. In this case, you would also need to ensure that users are not administrators on their local computers.

The following policy can help prevent users from running malicious code:

- Default Security Level: Disallowed
- Apply software restriction policies to the following users: All users except administrators
- Path Rules:
    - %WINDIR% Unrestricted
    - %PROGRAMFILES% Unrestricted

This policy disallows all software on the users computer, except software that is installed in the Windows directory, Program Files directory, or their respective subfolders. The policy does not apply to administrators.

If all the programs a user needs are not installed in %WINDIR% or in %PROGRAMFILES%, or there are programs in those folders that the administrator does not want the user to run, the administrator can make additional exceptions as follows:

- Path Rules:
    - %WINDIR%\regedit.exe: Disallowed
    - %WINDIR%\system32\cmd.exe: Disallowed
    - \\CORP_DC_??\scripts: Unrestricted
    - %HKEY_LOCAL_MACHINE\SOFTWARE\ComputerAssociates \InoculateIT\6.0\Path\HOME%: Unrestricted

As a result of these exceptions, the following occurs:

- Both the command prompt (cmd.exe) and the registry editor (regedit.exe) are disallowed.
- An exception is created to allow login scripts to run on the users computer.
- The use of the question mark "?" wildcard allows the rule to match \\CORP_DC_01, \\CORP_DC_02, and others.
- A registry path rule is added that allows the anti-virus software on the computer to run.

**Software Restriction Policies Processes and Interactions**
This section discusses how software restriction policies are processed and stored, and also explains how software restriction policies are merged.

**Software Restriction Policies Processing**
Software restriction policy is distributed by using the normal Group Policy process. That is, software restriction policies are saved in Group Policy objects (GPOs), and the management tools use the Group Policy Interfaces (**IGroupPolicyObject**) to save and load the software restriction policies. GPOs are linked to sites, domains, or organizational units (OUs) in Active Directory. An administrator can use the standard Group Policy mechanisms to apply additional filtering options to a GPO to

have it apply to a select set of users or computers within an OU.

When a computer starts up or when a user logs on, the Group Policy engine queries Active Directory for any GPOs that apply to it. It downloads and applies these GPOs in a specific order (local, site, domain, and OU), where the closest OU to the user or computer object is the last GPO applied. If Group Policy fails to download any of the GPOs, the entire process is aborted and no GPOs are applied.

In regard to software restriction policies (also referred to as Safer), Group Policy processing essentially involves downloading a number of Registry.pol files from Active Directory. The Registry.pol files contain the registry keys and values set through the Safer policy APIs. The keys and values of each policy are then copied into the local user's registry in the **HKEY_LOCAL_MACHINE** or **HKEY_CURRENT_USER** registry hive as appropriate. This process is repeated for each GPO that contains a software restriction policy. Group Policy is periodically refreshed: on clients, security policy reapplies every 16 hours regardless of whether policy changes have occurred. If there is a policy change, it applies within 90 minutes of the change. All the policy distribution is handled by the Group Policy infrastructure and not by the software restriction policies extension directly. The Safer Enforcement APIs base their decisions on the effective policy, which is the result of combining the software restriction policies in the **HKEY_LOCAL_MACHINE** and **HKEY_CURRENT_USER** registry hives.

Software restriction policies do not implement a client side extension to Group Policy.

**Group Policy Processing Order**

By default, Group Policy is inherited and cumulative, and it affects all computers and users in an Active Directory container. Group Policy objects are processed according to the following order:

- **Local Group Policy object.** Each computer has one Group Policy object that is stored locally. This processes for both computer and user Group Policy processing. The local GPO can't be blocked by domain-based GPOs. However, settings in domain GPOs always take precedence because they are processed after the local GPO.

- **Site.** Any GPOs that have been linked to the site that the computer belongs to are processed next. They are processed in the order specified by the administrator, on the **Linked Group Policy Objects** tab for the site in the **Group Policy Management Console** (GPMC). The GPO with the lowest link order is processed last, and therefore has the highest precedence.

- **Domain.** Multiple domain-linked GPOs are processed in the order specified by the administrator, on the **Linked Group Policy Objects** tab for the domain in GPMC. The GPO with the lowest link order is processed last, and therefore has the highest precedence.

- **Organizational units.** GPOs that are linked to the OU that is highest in the Active Directory hierarchy are processed first. Then GPOs that are linked to its child OU are processed, and then any lower child OUs. Finally, the GPOs that are linked to the OU that contains the user or computer are processed.

This processing is subject to the following conditions:

- WMI or security filtering that has been applied to GPOs.

- A domain-based GPO can be enforced by using the **Enforce** option to ensure that it's policies cannot be overwritten. Because an Enforced GPO is processed last, no other settings can overwrite the settings in that GPO. If more than one Enforced GPO exist, its possible to set the same setting in each GPO to a different value, in which case, the link order of the GPOs determines which one contains the final settings.

- At any domain or OU, Group Policy inheritance can be selectively designated as **Block Inheritance.** However, because enforced GPOs are always applied and cannot be blocked, blocking inheritance does not prevent policy from **Enforced** GPOs from being applied.

**Group Policy Refresh Period**

By default, Group Policy is processed every 90 minutes plus a randomized offset of up to 30 additional minutes for a total maximum refresh interval of up to 120 minutes. For domain controllers, the default period is every 5 minutes. You can change the default values for computers by using the **Group Policy Refresh Interval for Computers** Group Policy setting under **Administrative Templates** in the **Default Domain Controllers** GPO. For domain controllers, the **Group Policy Refresh Interval for Domain Controllers** setting controls this default; it is available under **Computer Configuration\Administrative Templates\System\Group Policy**.

For computers, the **Gpupdate** command can also be used to trigger a background refresh of Group Policy on demand from the client.

**Merging for Multiple Software Restriction Policies**
Whenever two or more Group Policy objects apply to a user or computer, the policies are merged. When two or more software restriction policies are merged, the following occurs:

- The GPO with the highest precedence sets the following values:
    - Default Security Level
    - Designated File Types
    - Skip Administrators
    - DLL Checking
- The rules from multiple GPOs are always merged. Thus, all additional rules from all GPOs are preserved.

A software restriction policy can be set for user scope and computer scope. The following semantics are observed when merging user and computer scope:

- The more restrictive default security level is chosen.
- The list of designated file types in the computer policy, if present, is used. If not present, the list of designated file types in the user policy is used.
- The Skip Administrators value is always chosen from the computer policy.
- If DLL checking is enabled in either policy, then it is enabled.
- All the rules between user and computer policies are merged.

**Storage of Software Restriction Policies Settings**
After a software restriction policy is applied, the software restriction policy configuration is stored in the system registry. The security access control list (ACL) protecting these registry keys allows only members of the Administrators group and the SYSTEM account to change them.

Software restriction policies use these registry keys:
**HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\Windows\Safer** and
**HKEY_CURRENT_USER\Software\Policies\Microsoft\Windows.**

- **CodeIdentifiers**.
- **Default Level** (DWORD). 40000 for **Unrestricted**, 0 for **Disallowed**.
- **ExecutableTypes** (REG_MULTI_SZ). List of extensions for designated file types.
- **TransparentEnabled** (DWORD). Defines which files to include during rule evaluation. 0 means no enforcement, 1 indicates to exclude DLLs in evaluation, and 2 indicates to include all files in evaluation.
- **PolicyScope** (DWORD). Defines the scope of users to which this policy applies. 0 applies to all users, and 1 applies to all users except administrators. Note that this value is only valid for HKEY_LOCAL_MACHINE.
- **AuthenticodeEnabled** (DWORD). Defines if certificate rules should be applied, 0 means disabled, 1 indicates that certificate rules will be applied. Note that this value is only valid for HKEY_LOCAL_MACHINE.
- **LogFileName** (REG_SZ). An optional registry value that needs to be set manually. This value defines a path to the log file

that captures advanced logging. If this value is set, advanced logging is enabled and written to this log file. Note that this value is only valid for HKEY_LOCAL_MACHINE.

- The zero (**0**) key**.** Indicates a **SAFER_LEVELID_DISALLOWED** security level. Entries under this key are **Disallowed** rules.

    - **Hashes.** All hash rules are defined under this key.

      **{GUID}**. This is uniquely generated for each Rule defined.

      **Description** (REG_SZ). This is the administrator-defined description of the rule.

      **FriendlyName** (REG_SZ). This is the name of the hash.

      **HashAlg** (REG_DWORD). This is the type of hash that is stored in **ItemData**. For files that are not digitally signed or are signed with MD5, this value is defined as 0x8003 or CALG_MD5 or (ALG_CLASS_HASH | ALG_TYPE_ANY | ALG_SID_MD5).

      **ItemData** (REG_BINARY). The actual hash to the file. This value should always be 16 bytes and is generated with a call to **CodeAuthzpComputeImageHash()**.

      **ItemSize** (REG_QWORD). This is the actual file size of the target file. To evaluate this value, reverse the bytes. For example, if the value data was: 00 0A 01 00 00 00 00 00, the file size would actually be 010a00 or 68,096 bytes.

      **LastModified** (REG_QWORD). This is the date and time down to seconds of when this entry was last updated. Several utilities exits to extract this name into a readable format however just as the ItemSize data was reversed so should this value.

      **SaferFlags** (REG_DWORD). Not used and will always be set to zero.

- **Path.** All Path rules are defined under this key.

    - **{GUID}.** This is uniquely generated for each Rule defined.

    - **Description** (REG_SZ). This is an administrator defined description of the rule.

    - **ItemData** (REG_EXPAND_SZ Or REG_SZ). This is the path to be used for this rule. Note that if the data provided for this value includes any environment variables that must be expanded the value type will be REG_EXPAND_SZ otherwise it will be REG_SZ.

    - **LastModified** (REG_QWORD). This is the date and time down to seconds of when this entry was last updated. Several utilities exits to extract this name into a readable format however just as the ItemSize data was reversed so should this value.

    - **SaferFlags** (REG_DWORD). This is not used and will always be set to zero.

- **UrlZones**. All zone rules are defined under this key.

    - **{GUID}.** This is uniquely generated for each Rule defined.

    - **ItemData** (REG_BINARY). Defines the URLZone to which this rule is defined. URL Zones are defined in urlmon.h and are of type enum tagURLZONE. For example if a value of 0x3 appears in this value that evaluates to URLZONE_INTERNET.

    - **LastModified** (REG_QWORD). This is the date and time down to seconds of when this entry was last updated. Several utilities exits to extract this name into a readable format however just as the ItemSize data was reversed so should this value.

- **SaferFlags** (REG_DWORD). This is not used and will always be set to zero.

- **262144**. Indicates a **SAFER_LEVELID_FULLYTRUSTED** security level. Entries under this key are **Unrestricted** rules.

**Certificate Rules**
Certificate rules are stored in a separate key in the registry.

Certificate rules for user software restriction policies are stored in this registry key:

- **HKEY_CURRENT_USER\SOFTWARE\Policies\Microsoft\SystemCertificates**

Certificate rules for computer software restriction policies are stored in this registry key:

- **HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\SystemCertificates**

**Resultant Set of Policy**
To obtain information about policy stored in the registry, the Software Restriction Policies extension queries the registry policy by using WMI.

The **RSOP_RegistryPolicySetting** WMI namespace represents policy data for registry or administrative template extension. Policy settings in an administrative template file (.adm) involve setting values on registry keys that are abstracted by this namespace. Software Restriction Policies also store information in the registry.

To retrieve this registry data, the **IwbemServices** WMI interface's **ExecQuery** method is used to perform a query to retrieve objects from the **RSOP_RegistryPolicySetting** namespace.

# Software Restriction Policies Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Software Restriction Policies Tools and Settings**

**In this section**

- Software Restriction Policies Tools
- Software Restriction Policies Group Policy Settings
- Related Information

Administrators can use command line tools to refresh Group Policy settings, including software restriction policies, and to display the resulting set of policies that were enforced on the computer for a specified user at logon. To assess the policy settings that are in effect for a computer or user, administrators use the Resultant Set of Policy (RSoP) snap-in.

**Software Restriction Policies Tools**

The following tools are associated with Software Restriction Policies:

**Gpupdate.exe**

This tool is used for refreshing local and Active Directory policy settings on the computer from which you run the **gpupdate** command. For more information about this tool, see "Core Group Policy Tools and Settings" in this collection.

**Gpresult.exe**

This tool enables you to examine the Group Policy settings applied during a policy refresh. For more information about this tool, see "Core Group Policy Tools and Settings" in this collection.

**Resultant Set of Policy (RSoP)**

This tool polls for existing Group Policy settings and planned policy settings, and then reports the results of those queries. For more information about RSoP, see "What Is Resultant Set of Policy?" in this collection.

**Software Restriction Policies Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with software restriction policies.

**Software Restriction Policies Security Levels and Additional Rules**

| Security Levels | Description |
|---|---|
| Disallowed | Does not allow the specified software to run. |
| Unrestricted | Allows the specified software to run on the computer with the full rights of the currently logged on user. |

**Additional Rules**

| Security Levels | Description |
|---|---|
| Hash Rule | A series of bytes with a fixed length that uniquely identifies a software program or file. A hash (also called a message digest) is obtained by applying a one-way mathematical function (sometimes called a hash algorithm) to an arbitrary amount of data. If the input data changes, the hash changes. The hash can be used in many operations, including authentication and digital signing.<br><br>If you create a hash rule for a software program, software restriction policies calculate a hash of the program. When a user tries to open a software program, a hash of the program is compared to existing hash rules for software restriction policies. The hash of a software program is always the same, regardless of where the program is located on the computer. However, if any changes are made to the software program, its hash also changes, and it no longer matches the hash in the hash rule for software restriction policies. |

| | |
|---|---|
| Path Rule | Identifies a program according to a folder or its fully qualified path. Both URL and UNC paths are permitted. You can use the following in path rules: environment variables, wildcards (question mark "?" and asterisk "*"), and registry path rules. |
| Certificate Rule | Identifies software based on a signed certificate. You create a certificate rule that identifies software and then specify a security level to either allow or not allow the software to run. |
| Internet Zone Rule | Identifies software from a zone that is specified through Internet Explorer. The zones are Internet, Intranet, Restricted sites, Trusted sites, and My Computer. These rules apply only to Windows Installer packages (.msi files). |

The following table lists the software restriction policy options.

**Software Restriction Policy Options**

| Options | Description |
|---|---|
| Enforcement | Enforcement enables you to specify whether to turn on dynamic-link library (DLL) checking and skip administrators to prevent the software restriction policies from applying to local administrators.<br><br>Use the Apply software restriction policies to the following option to select one of the following:<br><br>• **All software files except libraries (such as DLLs).** This option specifies that the rules will not affect DLLs.<br><br>• **All software files.** This option applies software restriction policies to all files, including DLLs. This option turns on DLL checking.<br><br>Use the Apply software restriction policies to the following users option to select one of the following:<br><br>• **All users.** This option specifies that all the rules you define apply to all users.<br><br>**All users except local administrators.** This option prevents software restriction policies from applying to local administrators. This is used when administrators want to prevent most users from running certain programs, but allow local administrators to run any program. |
| Designated File Types | The Designated File Types dialog box lists the file types to which the software restriction policy applies. The list represents the types of files that are considered executable files. The rules you specify in a software restriction policy apply only to the file types listed in the Designated File Types list. If you want to be able to set rules on additional file types, add them to the Designated File Types list. |
| Trusted Publishers | The Trusted Publishers options enable you to configure settings related to ActiveX controls and other signed content. Trusted Publishers includes the following options:<br><br>• **Enterprise Administrators:** Use this option to allow only domain administrators to make decisions regarding signed active content.<br><br>• **Local computer Administrators:** Use this option to allow local computer administrators to make all decisions regarding signed active content.<br><br>• **End Users:** Use this option to allow any user to make decisions regarding signed active content.<br><br>• **Publisher:** Use this option to ensure that the certificate used by the software publisher has not been revoked.<br><br>• **Timestamp:** Use this option to ensure that the certificate used by the organization that time-stamped the active content has not been revoked. |

For more information about software restriction policies rules and enforcement options, see "How Software Restriction Policies Work" in this Collection.

# Scripts Extension Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft Windows 2000 Server and Windows Server 2003 use Group Policy settings to provide directory-based desktop configuration management. These Group Policy settings are stored in a Group Policy object (GPO). You can create and manage GPOs by using the Group Policy Object Editor.

General classes of Group Policy settings are implemented as extensions to the operating system. These extensions are packaged as dynamic-link libraries (DLLs), and exist as two types of extension:

- Server-side extension — A Microsoft Management Console (MMC) snap-in that is used for administration and configuration.
- Client-side extension (CSE) — An extension that runs on the client computer that interprets and applies the MMC type settings to the client computer, also known as the target computer.

The GPO settings are configured via the server side extension, and applied to individual computers and users, by the client-side extension (CSE). The Group Policy engine is the framework used to manage all client side extensions, including the Scripts client-side extension.

# What Is Scripts Extension?

Updated: December 13, 2010

Applies To: Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Vista

**What Is Scripts Extension?**

Active Directory domains use the Scripts extension to run scripts on client computers. The Scripts extension consists of two components; an MMC server-side snap-in and a client-side extension (CSE). A Group Policy CSE is a dynamic-link library (DLL) on the client (target) that interacts with the Group Policy infrastructure and that implements Group Policy scripts on the target. You can control how the Scripts CSE implements scripts by using the Group Policy Object Editor on the server. The following figure shows Group Policy Object Editor, a Microsoft Management Console (MMC) snap-in with the scripts node.

**Group Policy Object Editor**

Before the introduction of the GPO Scripts extension, user logon scripts were added to the user account object. Only one script was added to the object, and the script was a user script; no computer scripts were allowed.

The Scripts CSE now allows the following four script types, corresponding to four of the target events triggering the Scripts extension:

- User logon scripts
- User logoff scripts
- Computer startup scripts
- Computer shutdown scripts

Other Scripts extension trigger events are:

- User policy refresh event
- User policy force refresh event
- Computer policy refresh event
- Computer policy force refresh event

- Secedit tool or gpupdate

These events tell the computer which scripts need to be run at each script execution opportunity; these events do not run the scripts.

Scripts are added to the Group Policy object (GPO), and multiple scripts for each script type can be added to the GPO. A script can be written in any language supported by the client computer, with Windows Script Host (WSH) supported languages and command files being the most common. WSH languages include VBScript and JScript, which are the languages used for the sample scripts included with Group Policy Management Console (GPMC).

Script names and their command-line arguments are stored in the registry when script policy processes. You can specify Administrative Templates Group Policy settings that modify how Group Policy scripts behave by using the options shown in the following table. These settings are located under Computer Configuration|Administrative Templates|System|Scripts.

**Computer Configuration Script Options**

| Option | Description |
|---|---|
| Allow logon scripts when NetBIOS or WINS is disabled<br><br>This setting requires Windows Vista or later. | Enable this setting to allow user logon scripts to run if NetBIOS or WINS is disabled during logons across forests without the DNS suffixes being configured. |
| Run logon scripts synchronously | Enable this option to force the system to run the scripts synchronously, one after another. This option exists for computer and user configuration, which can have a different value. In case of conflict, the computer configuration setting prevails. |
| Run startup scripts asynchronously | The default setting is for scripts to run synchronously (and hidden). Use this option to optimize the startup/logon processes so users can logon before startup scripts have finished. |
| Run startup scripts visible | Enable this option to run startup scripts in a visible window. |
| Run shutdown scripts visible | Enable this option to run shutdown scripts in a visible window. |
| Maximum wait time for Group Policy scripts | Use this option to set the script timeout interval. The default interval is 600 seconds (10 minutes), and valid intervals range from 0 to 32000 seconds.<br><br>If the value of this setting is greater than 900 seconds (15 minutes), for computers running Windows 7 you need to raise the value under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\gpsvc for PreshutdownTimeout to a corresponding value that is slightly greater than the value of the "Maximum wait time for Group Policy scripts" value. For example, in order for "Maximum wait time for Group Policy scripts" to work with a value of 30 minutes, you should set the **gpsvc for PreshutdownTimeout** registry entry to a value of 1800000 (The registry setting value is in milliseconds). |

| | |
|---|---|
| Run Windows PowerShell scripts first at computer startup, shutdown<br><br>This setting requires Windows 7 or Windows Server 2008 R2. | Enable this option to run PowerShell scripts before non-PowerShell scripts at computer startup and shutdown. |
| Run Windows PowerShell scripts first at user logon, logoff<br><br>This setting requires Windows 7 or Windows Server 2008 R2. | Enable this option to run PowerShell scripts before non-PowerShell scripts at logon and logoff. |

You can specify user configuration Group Policy settings that modify how Group Policy scripts behave by using the options shown in the following table. These settings are located under User Configuration|Administrative Templates|System|Scripts

**User Configuration Script Options**

| Option | Description |
|---|---|
| Run logon scripts synchronously | Enable this option to force the system to run the script synchronously, one after another. This option also exists for Computer configuration, which can have a different value. In case of conflict, the computer configuration setting prevails. On computers running Windows XP, the explorer starts before scripts finish running. |
| Run legacy logon scripts hidden | Enable this option to run legacy, Windows NT version 4–type logon scripts hidden. By default these run visible and so can be canceled by users. |
| Run logon scripts visible | Enable this option to run logon scripts in a visible window. |
| Run logoff scripts visible | Enable this option to run logoff scripts in a visible window. |
| Run Windows PowerShell scripts first at user logon, logoff<br><br>This setting requires Windows 7 or Windows Server 2008 R2. | Enable this option to run PowerShell scripts before non-PowerShell scripts at logon and logoff. |

**Change History**

| Date | Revision |
|---|---|

| | |
|---|---|
| December 13, 2010 | Updated the topic so it applies to Windows Vista, Windows Server 2008, Windows 7, and Windows Server 2008 R2.<br><br>Added information about configuring the value of the **gpsvc for PreshutdownTimeout** registry entry for computers running Windows 7 when the Maximum wait time for the Group Policy scripts setting is greater than 900 seconds.<br><br>Added settings that require Windows Vista, Windows Server 2008, Windows 7, or Windows Server 2008 R2.<br><br>Deleted row that incorrectly listed Run logoff scripts synchronously. |

# How Scripts Extension Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Scripts Extension Works**

The Scripts extension is one of the Group Policy extensions that automate configuration of the Group Policy infrastructure. The Scripts extension consists of two parts. The server-side extension, a Microsoft Management Console (MMC) snap-in, enables administrators to make enterprise-wide script Group Policy settings. The Scripts client side extension (CSE) implements those settings on the client computer. A separate process, Userinit, actually runs the scripts.

### In this section

- Scripts Extension Architecture
- Scripts Extension Protocols
- Scripts Extension Physical Structure
- Scripts Extension Processes and Interactions
- Network Ports Used by Scripts Extension

**Scripts Extension Architecture**

The Group Policy Scripts client-side extension (CSE) is managed by the Group Policy core, which stores a list of Group Policy objects (GPOs) received from Active Directory. The GPO list is then passed into the Scripts CSE where the scripts.ini file of each GPO is read from the Sysvol folder. This information required for script processing is stored in the client registry. When Group Policy is finished processing, the WinLogon process retrieves the registry information, and then creates a Userinit process that actually runs the scripts. During logoff and shutdown, WinLogon again creates a Userinit process to run the relevant scripts. The Userinit process uses the ShellExecute command to run each script. The following figure shows the Scripts extension architecture and the client-server interaction of the two extension components.

### Scripts Extension Architecture

Components important to the Scripts extension, seen in the preceding figure, are described in the table below. Components not seen in the figure, but important to the process are also described.

### Scripts Logical Architecture Components

| Component | Description |
|---|---|

| | |
|---|---|
| Group Policy engine | The Framework that manages and implements the Group Policy settings and configurations, made by the admin, across all client-side extensions (CSE). Userinit actually executes the script; not the CSE. Userenv.dll is the Group Policy engine module. |
| Scripts client-side extension (CSE) | The Scripts CSE is the component that is called by the Group Policy engine, and that applies the scripts setting. The Scripts CSE writes the relevant script information into the registry. It does not run the scripts. |
| WinLogon | WinLogon is the service that contains the Group Policy engine. |
| Resultant Set of Policy (RSoP) snap-in | Displays the results of Group Policy, including what scripts have run and when they were last run. For more information about RSoP, see "What Is Resultant Set of Policy?." |
| Userinit | Called by Winlogon to run Group Policy scripts by calling ShellExecute. |
| Local GPO | Contains Group Policy settings for the local computer, including potential scripts policies. |

The CSE registration information is written at setup to the HKEY_LOCAL_MACHINE\Software\Microsoft\WindowsNT\CurrentVersion\Winlogon\ GPExtensions registry key. This registry key structure exists on both the target and on the domain controller systems.

#### Scripts Extension Protocols

The various protocols used within the Scripts extension architecture are summarized in the following table.

**Scripts Extension Protocols**

| Protocol | Description |
|---|---|
| Win32 | Windows API function call. |
| NTLM or Kerberos | Authentication protocol used by the client to authenticate with Active Directory. |
| Server Message Block (SMB) | SMB is a file access protocol used by Userinit to access the Sysvol folder. |
| Distributed Component Object Model (DCOM) | DCOM is used by CSEs to communicate with Windows Management Instrumentation (WMI). |

#### Scripts Extension Physical Structure

Most Group Policy settings are stored in the Group Policy template, part of the domain controller's file system. Group Policy templates are stored in the %systemroot%\SYSVOL\sysvol*domainname*\policiessubfolder. The root of each Group Policy template contains a Gpt.ini file. Each Group Policy template contains a Machine and User subfolder, both of which contain a Scripts subfolder that contains the Scripts.ini file. The Machine Scripts subfolder contains a Shutdown and a Startup subfolder. The User Scripts subfolder contains a Logoff and a Logon subfolder. These four subfolders contain their respective Group Policy scripts to be implemented on the target by the Scripts CSE.

Components important to the Scripts CSE are described in the following table.

**Scripts Physical Architecture Components**

| Component | Description |
|---|---|
| Sysvol folder | The Sysvol folder contains the set of folders shared on each domain controller that stores *file-system* domain information, as compared to *registry* domain information. The Sysvol folder is one of the locations that the Scripts.ini file is stored. The other location is the Local GPO. |
| Group Policy template | The Group Policy template is part of the GPO, and is the portion of Group Policy settings stored in the file system and shared between domain controllers. The Group Policy template makes up the majority of the Group Policy settings. Each Group Policy template folder is a subfolder of the Policies folder and has a globally unique identifier (GUID). |

| | |
|---|---|
| Gpt.ini | Gpt.ini is a file in the Group Policy template root folder that stores the GPO version number of the Group Policy template. The Group Policy CSEs use this version number to confirm that directory and file components are synchronized correctly. |
| ADM folder | The ADM folder stores the System.adm file, among others. |
| Machine folder | The Machine folder stores GPO Computer settings files. One of the subfolders is the Scripts folder. |
| User folder | The User folder stores GPO User settings files. One of the folders is the Scripts folder. |
| Scripts folder | The Scripts folder, a subfolder of both the Machine and User folders, stores the Scripts.ini file and references scripts to be run. |
| Scripts.ini file | The Scripts.ini file is stored on the Sysvol folder in the Scripts folder and stores the path to each script. |
| External Scripts server | A server, other than the domain controller, on which the actual scripts can be stored. |
| Scripts Server-side extension Snap-in | A snap-in that is a server side component that loads with Group Policy Object Editor. The snap-in displays a Scripts node under Windows Settings of both Computer Configuration and User Configuration. |
| Logon folder | A subfolder of the Sysvol folder containing any user logon scripts to be implemented by the Scripts CSE. |
| Logoff folder | A subfolder of the Sysvol folder containing any user logoff scripts to be implemented by the Scripts CSE. |
| Startup folder | A subfolder of the Sysvol folder containing any computer startup scripts to be implemented by the Scripts CSE. |
| Shutdown folder | A subfolder of the Sysvol folder containing any computer shutdown scripts to be implemented by the Scripts CSE. |

**Scripts Extension Processes and Interactions**

The Scripts CSE processes all applied GPOs. The Scripts CSE reads the command-line options for the scripts from the Scripts.ini file. If a full path is specified, the full path is stored in the registry. If only a name is specified, the CSE creates the full path to the file in the Sysvol folder, prior to storing it in the registry. On Windows XP and better, The Scripts CSE stores this information in the client's registry, in the following keys:

- HKEY_LOCAL_MACHINE\Software\Policies\Windows\System\Scripts
- HKEY_CURRENT_USER\Software\Policies\Windows\System\Scripts

The script type is stored as one of the following registry values:

- Logon
- Logoff
- Startup
- Shutdown

The Scripts CSE sorts scripts by using the following rules:

- By GPO priority
- By priority order within each GPO

Scripts are usually stored in the Startup and Shutdown subfolders of the Machine\Scripts folder or in the Logon and Logoff subfolders of the User\Scripts folder. Scripts can be stored in a different location, or on a different server. However, for the script to run, the script file must be available and accessible (read access) for it to be run. Note that the user must have read access for logon and logoff scripts and the computer must have access for startup and shutdown scripts. Both are members of the Authenticated Users group, so by default both have access to run their respective scripts. The script is run from the file path location stored in Scripts.ini and the script is not cached on the client computer. If the network is unavailable when scripts are set to run, they will not run.

**Network Ports Used by Scripts Extension**

The following table summarizes the network protocols and port numbers used by the Scripts CSE. The Scripts extension impersonates the user and computer for network communication.

**Port Assignments for Scripts CSE**

| Task | Port (Protocol) |
|---|---|
| Retrieve GPO list | TCP 398 (LDAP) |
| Retrieve Group Policy container | TCP 398 (LDAP) |
| Request Distributed File System (DFS) referral for the Sysvol folder on the domain controller | TCP 445 (SMB) |
| Determine Sysvol DFS replica location for the Sysvol folder on the domain controller | TCP 445 (SMB) |
| Open and read Gpt.ini | TCP 445 (SMB) |
| Open and read Group Policy template settings files | TCP 445 (SMB) |
| Return Group Policy template file | TCP 445 (SMB) |

# Scripts Extension Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Scripts Extension Tools and Settings**

This section contains references to tools associated with the Scripts Extension. This section also contains settings, Registry entries, WMI Classes, and Network information associated with the Scripts extension.

**In this section**

- Scripts Extension Group Policy Settings
- Related Information

**Scripts Extension Group Policy Settings**

You can use the Windows Settings\Scripts node under both Computer Configuration and User Configuration to specify scripts to be run. Note that the scripts server-side extension permits you to specify the path to the scripts that need to be run. It does not create the script. The following tables describe the Computer and User Configuration Windows Settings\Scripts node settings.

**Computer Configuration\Windows Settings\Scripts**

| Option | Description |
|---|---|
| Scripts (Startup\Shutdown) | Use this node to specify the script files to be run when the computer starts up and shuts down. You can add or delete script files by selecting the button to open the explorer window. Add or delete the script files using this window. |

**User Configuration\Windows Settings\Scripts**

| Option | Description |
|---|---|
| Scripts (Logon\Logoff) | Use this node to specify the script files to be run when the user logs on and logs off. You can add or delete script files by selecting the button to open the explorer window. Add or delete the script files using this window. |

You can also specify Administrative Templates Group Policy settings that modify how Group Policy scripts behave. There is an Administrative Templates node for both Computer Configuration and User Configuration in Group Policy Object Editor. The following tables summarize the Group Policy settings that are associated with Scripts Extension in a Windows 2000 or greater domain.

**Computer Configuration\Administrative Templates\System\Scripts**

| Option | Description |
|---|---|
| Run logon scripts synchronously | Enable this option to force the system to run the scripts synchronously, one after another. This option exists for computer and user configuration. Computer setting has precedence. |
| Run startup scripts asynchronously | Use this option to optimize the startup/logon processes so users can logon before startup scripts have finished. By default startup scripts run synchronously. |
| Run startup scripts visible | Enable this option to run startup scripts in a visible window. By default scripts run invisible, users are not able to interact or cancel scripts that run invisible. |
| Run shutdown scripts visible | Enable this option to run shutdown scripts in a visible window. By default scripts run invisible, users are not able to interact or cancel scripts that run invisible. |
| Maximum wait time for Group Policy scripts | Use this option to set the script timeout interval. The default interval is 600 seconds (10 minutes), and valid intervals range from 0 to 32000 seconds. This affects both computer and user scripts that run synchronously. |

**Computer Configuration\Administrative Templates\System\Group Policy**

| Option | Description |
|---|---|
| Scripts policy processing | When enabled, this changes how the scripts client-side extension processes scripts policy. (Note that this affects only the processing of scripts policy—it does not affect how or when scripts are run).<br><br>When enabled, options include:<br><br>• Processing scripts policy when on a slow link. (Note that this will not stop existing scripts from running scripts policy; it stops scripts from processing scripts policy).<br><br>• Processing scripts policy during periodic background refresh.<br><br>• Always process scripts policy, even if there were no changes detected. |

**User Configuration\Administrative Templates\System\Scripts**

| Option | Description |
|---|---|
| Run logon scripts synchronously | Enable this option to force the system to run the script synchronously, one after another. This option also exists for Computer configuration, which can have a different value. In case of conflict, the computer configuration setting prevails. On computers running Windows XP, the Windows Explorer starts before scripts finish running. |
| Run legacy logon scripts hidden | Enable this option to run legacy, Windows NT 4–type logon scripts hidden. By default these run visible and so can be canceled by users. |
| Run logon scripts visible | Enable this option to run logon scripts in a visible window. By default scripts run invisible, users are not able to interact or cancel scripts that run invisible. |
| Run logoff scripts visible | Enable this option to run logoff scripts in a visible window. By default scripts run invisible, users are not able to interact or cancel scripts that run invisible. |

There are policies that control which Microsoft Management Console (MMC) snap-ins can and cannot be run. By setting these policies, a user can be restricted from administering scripts policies by restricting the scripts MMC snap-in. These policies are shown in the following table.

**User Configuration\Administrative Templates\Windows Components\Microsoft Management Console\Restricted/Permitted snap-ins\Group Policy\Group Policy snap-in extensions**

| Option | Description |
|---|---|
| Scripts (Logon/Logoff) | The default setting is Not Configured, which causes the Restrict users to the explicitly permitted list of snap-ins setting to apply. Enabling Scripts (Logon/Logoff) permits the snap-in. Disabling the setting prohibits the snap-in. |
| Scripts (Startup\Shutdown) | The default setting is Not Configured, which causes the Restrict users to the explicitly permitted list of snap-ins setting to apply. Enabling Scripts (Startup\Shutdown) permits the snap-in. Disabling the setting prohibits the snap-in. |
| Restrict users to the explicitly permitted list of snap-ins | The default setting of Not Configured and Disabled permits any snap-in that is not explicitly prohibited. If this setting is Enabled, only explicitly Enabled snap-ins are permitted. |

For more information about Group Policy settings, see the Group Policy Settings Reference for Windows Server 2003.

# Wireless Network Policies Extension Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Wireless Network Policies Extension is a Group Policy extension that you can use to automate configuration of Wireless Network Group Policy settings. Configuration of Wireless Group Policy settings requires, at minimum, one domain controller running a Microsoft Windows Server 2003 operating system. The Wireless Network Policies Extension is supported on client computers running Windows XP Professional (Service Pack 1 and later) and using IEEE 802.11 access with IEEE 802.1x authentication in a wireless network.

# What Is Wireless Network Policies Extension?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Wireless Network Policies Extension?**
This section describes the Wireless Network Policies Extension. On computers running Microsoft Windows Server 2003 Active Directory, domain administrators use the Wireless Network Policies Extension to automate wireless Group Policy management. The Wireless Network Policies Extension is one of the Group Policy client-side extensions that "plug" into the Group Policy infrastructure.

Wireless Network Policies Extension is one of the general classes of Group Policy settings that are implemented as extensions to the operating system. These extensions are packaged as DLLs, and exist as two types of extensions:

- MMC snap-in—An administration and configuration extension that runs on the server.
- Client-Side Extension—An extension that interprets and applies the MMC type settings to the target system (client), and which runs on the client.

The following figure shows an overview of a wireless network. The MMC snap-in fits in the Directory box on the server, and the CSE fits in the Wireless Client box.

**Wireless Network Overview**

Organizations need a way to centrally manage wireless Group Policy configuration for multiple users. The administrator needs to make specific wireless Group Policy decisions, including:

- Group Policy object (GPO) application criteria.
- Number of GPOs required.
- Location of GPOs.
- Number of Wireless LAN (WLAN) profiles required.

The Wireless Network Policies Extension provides central wireless Group Policy management that includes:

- Active Directory-based group filtering to provide Wireless Network Policy to a single computer global group.

- A single GPO Wireless Network Policy.
- A single GPO created and applied from the ForestRootDomain object.
- A single WLAN profile configured for 802.1x-compliant organizations. For multiple profiles, you have the option to support a phased migration from a legacy production WLAN.

This solution implementation is seen in the following figure. The figure shows the Group Policy Object Editor for a GPO, named gpo_Name. The Wireless Network (IEEE 802.11) Policies node contains a single wireless policy, named GPfield. It is from this central location that you implement the above wireless Group Policy solution.

**Group Policy Object Editor for the gpo_Name GPO**

You can use the Wireless Network Policies Extension to configure Active Directory-based Group Policy configurations for client computers. Specifically, the Wireless Network Policies Extension enables you to:

- Make wireless network Group Policy settings to protect a wireless network from unauthorized access by client computers with a compatible WLAN adapter.
- Protect data transferred over the wireless network, based on Group Policy settings.
- Make wireless network Group Policy settings to implement either certificate-based or password-based authentication for client computers accessing the wireless network.
- Configure Group Policy to add User authentication to computer authentication, ensuring round-the-clock network availability.

This Group Policy affects wireless client interaction between wireless Access Points (AP), the RADIUS server, and other wireless networks.

# How Wireless Network Policies Extension Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Wireless Network Policies Extension Works**
This section discusses how the Wireless Network Policies Extension works.

**In this section**

- Wireless Network Policies Extension Architecture
- Wireless Network Policies Extension Protocols
- Wireless Network Policies Extension Physical Structure
- Network Protocols Used by Wireless Network Policies Extension

**Wireless Network Policies Extension Architecture**
The Wireless Network Policies Extension consists of two subsystems:

- Wireless MMC snap-in
- Wireless Client-Side Extension (CSE)

**Wireless MMC Snap-in**
The Wireless MMC snap-in is the server-side tool used by the administrator to make the wireless Group Policy settings into Group Policy objects (GPOs). The snap-in functionality for the GPO is accessible from **Edit** on the pop-up menu for the GPO within the Group Policy Management Console (GPMC). The following figure shows the snap-in for the GPO named **gpo_Name**, and shows the **Properties** dialog box for the policy named **GPfield**.

**Group Policy Object Editor MMC Snap-in**

**Wireless Client-Side Extension (CSE)**

Gptext.dll, located in the **systemroot%\system32** folder on the target, is the Client-Side Extension (CSE) component, which implements the settings made by the administrator on the server using the snap-in. The Wireless Extension downloads these settings from the domain controller to the target and stored in the registry. This must be done over a wired (cable) network initially, due to a certificate services requirement. This initial download cannot be done over a wireless connection. Subsequent Computer Configuration Group Policy settings can be downloaded to a wireless device after the initial download. There is no UI for the CSE on the target.

Wireless CSE settings are stored in a subkey under the following registry key on the target:

**HKLM\Software\Microsoft\Windows NT\CurrentVersion\Winlogon\GPExtensions**

The wireless CSE subkey name is a GUID and the wireless subkey and its values are seen in the figure below. The other GUID subkeys correspond to the other CSEs.

**Target Wireless CSE Registry Key and Values**

**Wireless Network Policies Extension Protocols**

The figure below shows the conceptual view of wireless network access. The Wireless Network Extension MMC snap-in sits, conceptually, in the Management "box" of infrastructure services. The CSE sits in the Wireless Client "box" of the WLAN Component.

**Wireless Network Overview**

Components and protocols significant to the Wireless Network Policies Extension are included in the following table:

**Wireless Network Policies Extension Components and Protocols**

| Component | Description |
|---|---|
| IEEE 802.11 | A shared, wireless local area network standard. |
| IEEE 802.1x | A Port-based Network Access Control standard. |
| IEEE 802.11i | A draft standard that specifies improvements to WLAN networking security. |
| Wi-Fi Protected Access (WPA) | An interim standard, agreed to by wireless vendors, that is used until IEEE 802.11i is ratified. |
| wireless Access Point (wireless AP) | The more general term is Network Access Service (NAS). This is a device defined by the 802.11 standard that bridges the wireless and wired networks. |
| Remote Authentication Dial-In User Service (RADIUS) | Performs authentication and authorization for many types of networks, including wireless. |
| Internet Authentication Service (IAS) | A Microsoft implementation of RADIUS. |
| Extensible Authentication Protocol (EAP) | An authentication protocol used by, and required by the IEEE 802.1x standard. |
| Protected Extensible Authentication Protocol (PEAP) | One of two EAP authentication protocols available in the Wireless extension. Both are supported by Windows XP Service Pack 1. |
| EAP-Transport Layer Security (EAP-TLS) | One of two EAP authentication protocols (PKI-based) supported by Windows XP Service Pack 1. EAP-TLS is the EAP type recommended for certificate-based client authentication. |
| Public key infrastructure (PKI) | PKI is an implementation of public-key cryptography. Public-key cryptography provides data privacy, robust user and computer authentication, and documentation of action taken; all in a distributed security model. |

| | |
|---|---|
| certificate | A credential used for authentication. |
| Transport Level Security (TLS) | TLS provides mutual authentication, negotiation, and endpoint key determination. |
| Microsoft Challenge-Handshake Authentication Protocol version 2 (MS-CHAP v2) | An authentication protocol. |
| PEAP-EAP-MSCHAP-v2 | The recommended EAP type for password-based client authentication. |
| Wired Equivalent Privacy (WEP) algorithm | An algorithm on which the IEEE 802.11 WLAN Standard authentication and encryption services are based. |

**Wireless Network Policies Extension Physical Structure**

The physical structure of the Wireless Network Policies Extension, and how it fits into a wireless infrastructure, is seen in the Wireless Network Overview figure in the Protocols section above. Settings made by the administrator in the server-side snap-in are transferred to the CSE during initial wired connection between target and domain. These settings are transferred based on target (Computer) identity. Many of the settings are stored in the CSE registry key seen in the Target Wireless CSE Registry Key and Values figure, above.

One of the settings stored in a different registry location is the EAP type. This setting is stored in the following registry key on the client, and on the domain controller:

- HKLM\SYSTEM\CurrentControlSet\Services\RasMan\PPP\EAP\[#]
    - [#] = 13 for Smart Card or other certificate
    - [#] = 25 for Protected EAP (PEAP)
    - [#] = 26 for Secured password (EAP-MSCHAP v2)
    - [#] = 4 for MD-5 Challenge (not configurable via Extension)

On the wireless client (target) at machine startup, all CSEs are managed by the Group Policy Engine (GPE). The GPE stores a list of all GPOs received from the Active Directory. The GPE passes the GPO list into the Wireless CSE.

Group Policy templates (GPTs), the file system portion of Group Policy Settings, are stored in the **[%systemroot%\SYSVOL]\sysvol\domainname\policies** subfolder of the sysvol tree. The root of each GPT contains a GPT.INI file. Each GPT contains a MACHINE and USER subfolder. Wireless policy is located in the MACHINE subfolder.

The GPT.ini file, stored on the domain controller SYSVOL, contains the GPO version number of the Group Policy template (GPT). The GptTmpl.inf file, stored in the MACHINE\Microsoft\Windows NT\SecEdit folder for each GPO, contains machine GPO settings including Wireless Network Policy Extension settings.

At client machine startup, when Group Policy is finished processing, Winlogon gets the CSE registry information, creates a Userinit process, and passes Userinit the Wireless CSE information. The GPE, running in the same process as Winlogon, calls Userinit; Winlogon doesn't call Userinit. The Wireless CSE is registered with Winlogon in the registry, as seen in the Target Wireless CSE Registry figure above. Other Wireless Network Group Policy settings are also stored in the registry, and are retrieved and applied at this time.

Windows XP and Windows Server 2003 stores computer and user authentication behavior settings in the AuthMode value in the following registry key:

HKLM\Software\Microsoft\EAPOL\Parameters\General\Global

Valid AuthMode registry values are:

- 0 for With user authentication
- 1 for With user re-authentication
- 2 for Computer only

The following table summarizes the components that interact during target startup.

**Physical Structure Components**

| Component | Description |
|---|---|
| Group Policy Engine | The Framework that manages and implements the Group Policy settings and configurations, made by the admin, across all Client Side Extensions (CSE). Userenv.dll is the GPE module. The GPE runs in the same process as Winlogon. It is from that process that Userinit is called. The component actually calling Userinit is the GPE, not Winlogon. |
| Wireless Client-Side Extension (CSE) | The Wireless CSE is the central communication point for the GPE, and is contained within gptext.dll located in the %systemroot%\system32 folder. This DLL runs on the client system that is responsible for interpreting and implementing the Group Policy Management Console wireless settings made by the administrator through the wireless snap-in. It also runs on the domain controller to provide the Group Policy Object Editor snap-in. |
| WinLogon | WinLogon is the component that calls the Wireless CSE at machine startup and timed intervals. Winlogon is the only system component that actively interacts with the Group Policy Engine. All CSEs are registered with WinLogon in the registry under the following registry key on both the domain controller and the client machine:<br><br>HKLM\Software\Microsoft\WindowsNT\CurrentVersion\Winlogon\GPExtensions<br><br>**Note**<br><br>Direct registry manipulation of CSE behavior is not recommended. Most behavior settings are available for modification in the Group Policy Object Editor. |
| Userinit | Called by the process in which both Winlogon and the GPE are running. |
| SYSVOL | The SYSVOL is the set of folders shared on each domain controller, which store *file-system* domain information, as compared to *registry* domain information. Sysvol is one of the locations in which the GPT.INI file is stored. |
| Group Policy template (GPT) | The GPT is part of the GPO, and is the portion of Group Policy Settings stored in the file system and shared between domain controllers. The GPT makes up the majority of the Group Policy settings. Each GPT folder is a subfolder of the Policies folder and has a GUID for a name. |
| GPT.INI | GPT.INI is a file in the GPT root folder that stores the GPO version number of the GPT. The Group Policy Client Side Extensions use this version number to confirm that directory and file components are synchronized correctly. |
| ADM (Adm) folder | The ADM folder stores the System.adm file, among others. |
| MACHINE folder | The Machine folder stores GPO Computer settings files. One of the subfolders is the SecEdit folder. |
| SecEdit folder | The SecEdit folder, a subfolder of the MACHINE folder, stores the GptTmpl.inf file. |

**Network Ports Used by Wireless Network Policies Extension**

The following table summarizes the network protocols and port numbers used by the Wireless Network Policies Extension.

**Port Assignments for Wireless Network Policies Extension**

| Task | Port (Protocol) |
|---|---|
| Retrieve GPO list | TCP 398 (LDAP) |
| Retrieve Group Policy container | TCP 398 (LDAP) |
| Request Distributed File System (DFS) referral for the Sysvol folder on the domain controller | TCP 445 (SMB) |

| | |
|---|---|
| Determine Sysvol DFS replica location for the Sysvol folder on the domain controller | TCP 445 (SMB) |
| Open and read Gpt.ini | TCP 445 (SMB) |
| Open and read Group Policy template settings files | TCP 445 (SMB) |
| Return Group Policy template file | TCP 445 (SMB) |
| RADIUS Messages | UDP 1812, 1813 |

# Wireless Network Policies Extension Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Wireless Network Policies Extension Tools and Settings**

**In this section**

- Wireless Network Policies Extension Tools
- Wireless Network Policies Extension Registry Entries
- Wireless Network Policies Extension Group Policy Settings
- Related Information

This section contains references to tools associated with the Wireless Extension. This section also contains settings, Registry entries, and Network information associated with the Wireless extension.

**Wireless Network Policies Extension Tools**

The following tools are associated with Wireless Network Policies Extension.

**Wlanmon.dll: Wireless Monitor**

**Category**

Wlanmon.dll is a Microsoft Management Console (MMC) snap-in.

**Version compatibility**

Wlanmon.dll runs only on Windows Server 2003.

Wlanmon.dll is used to monitor Access Point information and Wireless Client information.

**Wlsnp.dll: Wireless Group Policy Snap-In**

**Category**

Wlsnp.dll is an MMC snap-in.

**Version compatibility**

Wlsnp.dll runs only on Windows Server 2003.

Wlsnp.dll is used to create and edit Wireless policy on Windows Server 2003 operating systems.

**Wireless Network Policies Extension Registry Entries**

The following registry entries are associated with Wireless Network Policies Extension.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. You should not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**GPExtensions\ {0ACDD40C-75AC-47ab-BAA0-BF6DE7E7FE63} (Domain Controller and Target)**

**Registry path**

HKEY_CURRENT_USER\Software\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The Registry settings in this section are for a domain controller running Windows Server 2003 and a target running Windows XP SP1 or later.

This key contains Wireless Group Policy extension information.

For more information about this registry entry, see the Registry Reference for Windows Server 2003.

**GPExtensions\{0ACDD40C-75AC-47ab-BAA0-BF6DE7E7FE63} (Domain Controller and Target)**

**Registry path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**
The Registry settings in this section are for a domain controller running Windows Server 2003 and a target running Windows XP SP1 or later.

This key contains specific Wireless Group Policy extension information.

For more information about this registry entry, see the Registry Reference for Windows Server 2003.

**Wireless (Domain Controller and Target)**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\windows\

Note that Windows in the Registry path is "windows" for Windows Server 2003 and "Windows" for Windows XP.

**Version**
The Registry settings in this section are for a domain controller running Windows Server 2003 and a target running Windows XP SP1 or later.

This registry key stores specific wireless Group Policy settings.

For more information about this registry entry, see the Registry Reference for Windows Server 2003.

**Wireless Network Policies Extension Group Policy Settings**
You can specify Administrative Templates Group Policy settings that modify wireless Group Policy. You can also modify settings in the Wireless Group Policy Properties dialog box. The following two tables summarize Administrative Template settings.

**Computer Configuration\Administrative Templates\System\Group Policy**

| Group Policy Setting | Description |
|---|---|
| Wireless Policy Processing | Options are:<br>• Not Configured (default)<br>• Enabled<br>• Disabled |

**Computer Configuration\Administrative Templates\Network\Network Connections**

| Group Policy Setting | Description |
|---|---|
| Prohibit use of Internet Connection Sharing on your Domain Name System (DNS) domain network | Options are:<br>• Not Configured (default)<br>• Enabled<br>• Disabled |
| Prohibit use of Internet Connection Firewall on your DNS domain network | Options are:<br>• Not Configured (default)<br>• Enabled<br>• Disabled |

| | |
|---|---|
| Prohibit installation and configuration of Network Bridge on your DNS domain network | Options are:<br>• Not Configured (default)<br>• Enabled<br>• Disabled |
| IEEE 802.1x Certificate Authority for Machine Authentication | Options are:<br>• Not Configured (default)<br>• Enabled<br>• Disabled |

The remaining tables summarize settings from the various tabs on the Wireless Group Policy Properties dialog box.

**General Tab**

| Option | Description |
|---|---|
| Name | String of your choice |
| Description | String of your choice |
| Check for policy Changes every *x* minutes | 180 is the default |
| Networks to access | Drop-down list box choices are:<br>• Any available network (access point preferred) (default)<br>• Access point (infrastructure) networks only<br>• Computer-to-computer (ad hoc) networks only |
| Use Windows to configure wireless network settings for clients (check box) | Default is check box selected. Clearing the check box disables the option. |
| Automatically connect to non-preferred networks (check box) | Default is check box cleared. Selecting the check box enables the option. |

**Preferred Networks Tab**

| Option | Description |
|---|---|
| Networks: (list) | The list, by default, is empty. Adding a network to the list enables the Move Up and Move Down buttons. |
| Add, Edit and Remove buttons | The Add and Edit button dialog boxes are the same. |

**Network Properties Tab**

| Option | Description |
|---|---|

| | |
|---|---|
| Network Name (SSID) | String for network name. |
| Description | String for description |
| Wireless Network Key (WEP) (3 check boxes) | This network requires a key for the following:<br>• Data encryption (WEP-enabled) (default is selected)<br>• Network authentication (Shared mode) (default is cleared)<br>• The key is provided automatically (default is selected) |
| This is a computer-to-computer (ad hoc) network; wireless access points are not used. | Default is check box cleared. Selecting the check box enables the option. |

**IEEE 802.1x Tab**

| **Option** | **Description** |
|---|---|
| Enable network access control using IEEE 802.1x | Default is check box selected. Clearing the check box disables the option. |
| EAPOL-Start message | Drop-down list box choices are:<br>• Do not transmit<br>• Transmit (default)<br>• Transmit per IEEE 802.1x |
| Parameters (seconds) | Text Box settings are:<br>• Max start (default is 3)<br>• Start period (default is 60)<br>• Held period (default is 60)<br>• Authentication period (default is 30) |
| EAP type | Drop-down list box choices are:<br>• Smart Card or other certificate (default)<br>• Protected EAP (PEAP) |
| Authenticate as guest when user or computer information is unavailable | Default is check box cleared. Selecting the check box enables the option. |
| Authenticate as computer when computer information is available | Default is check box selected. Clearing the check box disables the option. |

| | |
|---|---|
| Computer authentication | Drop-down list box choices are:<br>• With user authentication<br>• With user re-authentication (default)<br>• Computer only |

**EAP type (Smart Card or other certificate) Settings Tab**

| Option | Description |
|---|---|
| When connecting | Option button choices are:<br>• Use my smart card<br>• Use a certificate on this computer (default)<br>  • Use simple certificate selection (Recommended) [(check box) (default is selected)] |
| Validate server certificate (check box) | Default is check box selected. Clearing the check box disables the option. |
| Connect to these servers (check box) | Default is check box cleared and list box disabled. Selecting the check box enables the text box, in which you enter the servers. |
| Trusted Root Certificate Authorities (list box) | Default is none of the check boxes in the list are selected. Selecting the check box enables the option. |
| Use a different user name for the connection (check box) | Default is check box is cleared. Selecting the check box enables the option. |

**EAP type (Protected EAP (PEAP)) Settings Tab**

| Option | Description |
|---|---|
| Validate server certificate (check box) | Default is check box selected. Clearing the check box disables the option. |
| Connect to these servers (check box) | Default is check box cleared and list box disabled. Selecting the check box enables the text box, in which you enter the servers. |
| Trusted Root Certificate Authorities (list box) | Default is none of the check boxes in the list are selected. Selecting the check box enables the option. |
| Select Authentication Method | Drop-down list box options are:<br>• Secured password (EAP-MSCHAP v2) [(default)]<br>• Smart Card or other certificate |
| Enable Fast Reconnect (check box) | Default is check box cleared. Selecting the check box enables the option. |

**Select Authentication Method (Secured Password (EAP-MSCHAP v2)) Properties Tab**

| Option | Description |
|---|---|

| | |
|---|---|
| When connecting: (check box) | Automatically use my Windows logon name and password (and domain if any) [(default is check box is selected)] |

**Select Authentication Method (Smart Card or other certificate) Properties Tab**

| Option | Description |
|---|---|
| When connecting | Option button choices are:<br>• Use my smart card<br>• Use a certificate on this computer (default)<br>  • Use simple certificate selection (Recommended) [(check box) (default is selected)] |
| Validate server certificate (check box) | Default is check box selected. Clearing the check box disables the option. |
| Connect to these servers (check box) | Default is check box cleared and list box disabled. Selecting the check box enables the text box, in which you enter the servers. |
| Trusted Root Certificate Authorities (list box) | Default is none of the check boxes in the list are selected. Selecting the check box enables the option. |
| Use a different user name for the connection (check box) | Default is check box cleared. Selecting the check box enables the option. |

# Folder Redirection Extension Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Folder Redirection is a feature of IntelliMirror that allows users and administrators to redirect the path of a folder to a new location. The new location can be a folder on the local computer or a shared directory on a network. Users have the ability to work with documents on a server as if the documents were located on the local hard disk. For example, if you redirect the My Documents folder, which is usually stored on the computer's local hard disk drive, to a network location, the documents in the folder will be available to the user from any computer on the network.

# What Is Folder Redirection Extension?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Benefits of Folder Redirection
- Common Folder Redirection Scenarios
- Folder Redirection Dependencies on or Interactions with Other Technologies
- Related Information

The Folder Redirection extension, a feature of IntelliMirror, enables an administrator to redirect the location of certain folders in the user profile to different path, such as a shared network location. When these redirected folders are accessed, either by the operating system or by applications, the operating system automatically redirects to the location on a network share specified by the administrator. From a user perspective, this feature is similar to a roaming profile because users have the same folder settings regardless of which computers they use. These settings remain on the network share and enable users to access their files from any computer they use to logon on to the network. The following figure illustrates the relationships and interactions of the Folder Redirection extension with other networking components and Group Policy features.

**Folder Redirection Extension Relationships and Interactions**

The following special folders can be redirected:

- Application Data
- Desktop
- My Documents
    - My Pictures
- Start Menu

**Note**

- My Pictures folder is no longer shown in the Folder Redirection Node. To simplify the user interface and to help support the best practice that the My Pictures folder should always follow the My Documents folder, the My Pictures folder is not shown in the Folder Redirection node for new GPO's. If you have previously redirected the My Pictures folder separately, the My Pictures node will still appear.

**Benefits of Folder Redirection**

When fully deployed, IntelliMirror uses Active Directory and Group Policy for policy-based management of user desktops. A Windows XP or Windows 2000 Professional desktop can be automatically configured to meet specific requirements of a user's business roles, group memberships, and location. Group Policy and the Active Directory are not necessary for every IntelliMirror feature. Some of the features can be set on the local level or through local polices. An organization can tailor IntelliMirror to meet its needs. When planning to use IntelliMirror, an organization should assess which features it needs and then implement the technology required.

By using IntelliMirror on both the server and client, administrators can protect and manage user data and settings. Non-recoverable data from local workstations can be copied to servers, where it can be easily backed up and centrally managed. Personalized data, applications, and settings can follow each user to different computers throughout the network. Administrators can easily replace faulty computers and restore all user data and settings on a new computer.

Previously, administrators who wanted to redirect folders to the network had to use logon scripts to change registry values. In Windows Server 2003 and Windows XP, the same task can be accomplished by using the Folder Redirection extension of Group Policy. For example, you could redirect a user's My Documents directory to \\Server\Share\%username%.

Folder Redirection provides the following benefits:

- **Improved Roaming User Profile performance.** You can use Folder Redirection to reduce the time it takes to log on to and log off from the network. The My Documents folder is part of the Roaming User Profile (RUP), which means that the My Documents folder and its contents are copied back and forth between the client computer and the server each time users log on and log off. Redirecting the My Documents folder to a location outside of the user profile can significantly decrease the amount of time it takes to log on and log off because not all of the data in the user profile is transferred to the desktop each time the user logs on — only the data that user requires is transferred.

- **User documents available from any computer.** To ensure that users' documents are available when they roam from one computer to another, you can use Folder Redirection to redirect user documents to a server location accessible from any computer connected to the domain.

- **User documents available when not connected to the corporate network.** Folder Redirection can be used with Offline Files technologies to make users' network-based My Documents folder available when they are disconnected from the corporate network. By default in Windows XP and Windows Server 2003, any redirected shell folders such as My Documents, Desktop, Start Menu, and Application Data are automatically made available Offline.

  **Note**

  - Offline Files are disabled by default in Windows Server 2003.

- **Increased security and availability of user data.** When you use Folder Redirection to redirect user data to a network location, the data stored on a shared network server can be backed up as part of routine system administration. This protects user data and requires no action on the part of the user.

- **Reduced support costs and user down-time.** If there are multiple hard disk drives in a user's computer, user data and files can be redirected to a hard disk on the user's local computer other than the one on which the operating system is installed. This protects the user's data if the operating system needs to be reinstalled or if computer hardware needs to be replaced.

- **Control allocation of disk space.** Administrators can use Group Policy to set disk quotas, which limit the amount of space taken up by users' folders.

**Common Folder Redirection Scenarios**

This section presents sample scenarios that illustrate some of the practical uses of Folder Redirection. Each of the scenarios fits into an entire picture or can be seen as a separate event. Each scenario also shows how the components of IntelliMirror benefit

the entire organization by reducing the time and effort associated with maintaining the computing environment.

**The new hire**
One of the most critical and time consuming IT tasks is setting up a computer for a new hire. In an organization that uses IntelliMirror, the new hire logs on to a new computer and finds documents and shortcuts already on the desktop. There are shortcuts to common files, URLs, and folders that are useful to all employees (for example, the employee handbook, shortcuts to the departmental shared documents store, and the user's departmental guidelines and procedures). Desktop options, application configurations, Internet settings, and so on, are all configured to the corporate standard, ensuring that if the user needs to call the help desk, the support staff knows what configuration the user started with.

In this example, the user gets a pre-configured user profile that was set up for all new users, and was configured before the new hire logged on to the network. The administrator configured a computer to look and behave according to the corporate standard, and then, using the User Profile utility built into the System Control Panel application, copied the user profile to a Default User folder on the domain controller's Netlogon share. When the new hire logged onto the network for the first time, Windows copied this default profile to the local computer and used this profile as the basis for the new hire's profile. In addition to configuring the default profile the user received, the administrator also used Group Policy to redirect the user's My Documents folder to a network location, so that the user's documents are safely stored on a network server and can be backed up regularly.

**The laptop user**
In this scenario, a laptop user working at the office creates several documents and saves them to his or her My Documents folder. After saving documents, the user logs off, unplugs the laptop computer from the network and takes it home. While at home and off the network, the user continues to edit the documents saved earlier in the My Documents folder.

The user returns to the office and logs on to the network. Since the user has worked offline, a dialog box appears advising the user that data in My Documents has changed and is being synchronized with the network copy.

In this scenario, the user's My documents folder has been redirected to a network server, the documents are transparently saved to the network location and also saved in the local computer's cache (because the network folder is setup to be available offline), so that they are available when the computer is disconnected from the network.

The whole process can be transparent to the user; the experience is no different than saving documents to the local hard disk.

As soon as the user reconnects to the network, IntelliMirror attempts to reconnect to the network location of the redirected folders. When IntelliMirror reconnects, it determines if there are differences in the data between the local copy of the folder and the network copy. In this scenario, the user has made modifications to a document on the local computer. IntelliMirror identifies this change and prompts the user to update the version stored on the network.

**Computer replacement**
In this scenario the computer that a user is working on suddenly stops working because of a complete hardware failure. The user calls the support line, and receives a new computer, loaded with only the Windows XP Professional operating system. Without waiting for technical assistance, the user plugs in the new computer, connects it to the network, and starts it. When the user logs on to the corporate network, he or she will find that the desktop has the same appearance as the original computer that it replaced. It will have the same color scheme, the user's preferred background picture on the screensaver, and all the application icons, shortcuts, and favorites. More importantly, all the user's data files will have been restored.

In a disaster recovery scenario, IntelliMirror assists in getting the user's computer replaced and running quickly with the minimum of support. In this example, because the user was configured to use roaming user profiles, a copy of the user's working environment was safely stored on a network server. When the new computer arrived, the user was able to log on and the server copy of the user's profile was downloaded to the new computer. An administrator could also have used Folder Redirection to redirect the user's key folders such as My Documents and Application Data, to ensure that the user's documents were safely stored on the server.

**A shared computer environment**
In this scenario, a user works in a department where the computer he or she uses might change from day to day—a call center or IT support environment, for example. The user is working on an important document late one night when the shift ends. The user saves the document and logs off the computer. When the user returns to work the next day, he or she logs onto the first available computer—a different computer from the one used the previous night. The user logs onto the network, and sees that the desktop has the same look and feel as the original computer. The user opens the My Documents folder on the desktop and finds the document exactly where he or she saved it and continues the work started the previous night.

In this example, the user was configured to use roaming user profiles, so that a copy of the user's working environment was stored on a network server. When the user logged onto the computer, the user's existing preferences, shortcuts and documents were copied to the local computer, so that the user could continue working as if using the original computer. A variation on this scenario is using roaming profiles in conjunction with Folder Redirection. Users can have the same work

environment and have access to the same documents on any computer. Changes made on one computer are synchronized with the other computer the next time the user logs on.

**Folder Redirection Dependencies**
The Folder Redirection extension is used most effectively when combined with other related Group Policy and Windows Server technologies, such as Roaming User Profiles, Offline Files, and Synchronization Manager.

**Folder Redirection with Roaming User Profiles**
You can also combine Folder Redirection and roaming user profiles to decrease logon and logoff times for roaming and mobile users. A common scenario is to redirect the My Documents and My Pictures folders, and allow the Application Data, Desktop, and Start Menu folders to roam with the profile. In addition to improved availability and administrative benefits from storing the data on the network, users also realize performance gains when using low-speed network connections and in subsequent logon sessions. Not all of the data in the user profile is transferred to the desktop each time the user logs on — only the data that user accesses during a session is transferred. Because only some documents are copied, performance is improved when the user's' profiles are copied from the server.

When you combine the use of Folder Redirection and roaming user profiles, you can also provide fast computer replacement. If a user's computer needs to be replaced, the user's data can quickly be copied from the server locations to a replacement computer. Combining Folder Redirection with roaming profiles gives the benefits of roaming profiles, while minimizing network traffic caused by synchronization of the profile.

### Note

- To decrease initial logon time to a new computer, you should redirect the location of the My Documents folder outside of the user's roaming profile.

**Local profiles**
Using Folder Redirection with local profiles can provide some of the benefits of roaming profiles (such as having a user's data available at any computer or maintaining data on the server) without the need to implement roaming profiles. Remember though, using Folder Redirection with a local profile would only result in the user's documents and files being available from all computers. To have settings and configurations move with the user, you would need to use roaming profiles.

**Folder Redirection with Offline Files**
By using Offline Files, users can continue to work with a cached copy of files stored on a network location, even when they are not connected to a network. If your organization has mobile users with portable computers, Offline Files gives them access to their files when they are not connected to the network, and ensures that they are always working with the current version of network files. Offline Files technology stores the data in the computer's cache to make network files available offline. The view of shared network items that you have made available offline remains as it is when connected, even if users lose a connection to or manually disconnect from the network. Users can continue to work with the Offline Files as they normally do when online. Users have the same access permissions to those files and folders as when they are connected to the network. When the network connection is restored, any changes they made while working offline are updated to the network so that both locations are synchronized.

Offline Files is a stand-alone technology, which means that you do not need to use it with Folder Redirection. However, using Offline Files with Folder Redirection allows for greater flexibility and availability of user files. For example, if a shortcut to a file is available offline, that file is made available offline, but if a shortcut to a folder is available offline, the contents of that folder are not available offline. If you pair the two technologies, Offline Files and Folder Redirection, both the shortcut and the folder are available offline.

Shared files or folders on a Windows Server 2003 or Windows XP-based network can be available offline. By default in Windows XP and Windows Server 2003, any redirected shell folders such as My Documents, Desktop, Start Menu, and Application Data are automatically made available offline. You can also make files available for offline use from any computer that is sharing files using server message block-based file and printer sharing, including Windows 2000, Windows 95, Windows 98, and Windows NT 4.0.

### Note

- Make sure that you turn off Offline Folders for shares where roaming user profiles are stored. If you do not turn off Offline Folders for a user's profile, you might experience synchronization problems since both Offline Folders and Roaming Profiles will try to synchronize the files in a user's profile.

**Synchronization Manager**
When using Offline Files and folders, users can synchronize all network resources by using the Synchronization Manager. The

Synchronization Manager can be set to automatically synchronize some or all resources. For example, users can set certain files and folders to be synchronized every time they log on or off the network. The Synchronization Manager quickly scans the system for any changes, and if it detects changes, the resources are automatically updated. Only resources that have changed are updated—vastly speeding up the synchronization process.

# How Folder Redirection Extension Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Folder Redirection Architecture
- Folder Interactions Processes and Interactions
- Related Information

Folder Redirection, a client-side extension (CSE) of Group Policy, enables an administrator of an organization to set policies that redirect users' folders to a different location, such as a shared network folder. When used in combination with Roaming User profiles and offline files, Folder Redirection enables administrators to centrally manage and protect user data and settings including policy-based management of user desktops.

Folder Redirection provides the greatest benefit when used with other components of IntelliMirror in an Active Directory environment. Folders can be redirected only from client computers running Windows 2000 or Windows XP.

**Folder Redirection Architecture**

The Folder Redirection client-side extension consists of a dynamic-linked library (DLL), fdeploy.dll, a redirection information file, {25537BA6-77A8-11D2-9B6C-0000F8080861}.ini, which includes information about Folder Redirection options specific to each user profile on the computer, and {1C08E84D-F112-4252-978B-EC82A225CC20}.ini which stores information about previous locations used for Folder Redirection.. Fdeploy.dll is loaded during the logon process by the Group Policy engine. The Folder Redirection policies are passed to fdeploy.dll, which then examines the policy settings and redirects user folders based on those settings.

The first step in Folder Redirection is to get a list of all Folder Redirection policies and evaluate them. The policies are handed down to the fdeploy.dll by the Group Policy engine through an API call into fdeploy.dll. The policies come in the form of two linked lists. The first list is a list of added policies. This refers to a list of Folder Redirection policies that are still applicable to the user. The second list is a list of deleted policies that refers to policies that used to be applicable to the user but are no longer applicable. The changes that result from Folder Redirection are then updated with the shell. The client-side cache, also referred to as offline files, is also updated to reflect the files moved by Folder Redirection.

**Folder Redirection Client-side Extension Architecture**

The following table describes the components that interact with Folder Redirection extension.

**Folder Redirection Components**

| Component | Description |
|---|---|

| | |
|---|---|
| Fdeploy.dll | Client-side extension DLL that processes policy settings for Folder Redirection. |
| {25537BA6-77A8-11D2-9B6C-0000F8080861}.ini | Locally cached redirection information file specific to each user profile. |
| {1C08E84D-F112-4252-978B-EC82A225CC20}.ini | A file indicating the status of the previous locations used for redirected folders. This file is used to detect server location changes and user name changes. |
| Server (domain controller) | In an Active Directory forest, the domain controller is a server that contains a writable copy of the Active Directory database, participates in Active Directory replication, and controls access to network resources. |
| Active Directory | Active Directory, the Windows-based directory service, stores information about objects on a network and makes this information available to users and network administrators. Administrators link Group Policy objects (GPOs) to Active Directory containers such as sites, domain, and organizational units (OUs) that include user and computer objects. In this way, policy settings can be targeted to users and computers throughout the organization. |
| Sysvol | The Sysvol is a set of folders containing important domain information that is stored in the file system rather than in the directory. The Sysvol folder is, by default, stored in a subfolder of systemroot folder (%\systemroot\sysvol\sysvol) and is automatically created when a server is promoted to a domain controller. The Sysvol contains the largest part of a GPO: the Group Policy template, which includes Administrative Template-based policy settings, security settings, script files, and information regarding applications that are available for software installation. It is replicated through the File Replication Service (FRS) between all domain controllers in a domain. |
| Group Policy object (GPO) | A GPO is a collection of Group Policy settings, stored at the domain level as a virtual object consisting of a Group Policy container and a Group Policy template. The Group Policy container, which contains information about the properties of a GPO, is stored in Active Directory on each domain controller in the domain. The Group Policy template contains the data in a GPO and is stored in the Sysvol in the /Policies subdirectory. GPOs affect users and computers that are contained in sites, domains, and OUs. |
| Local Group Policy object | The Local Group Policy object (Local GPO) is stored on each individual computer, in the hidden **Windows\System32\GroupPolicy** directory. Each computer running Windows 2000, Windows XP Professional, Windows XP 64-Bit Edition, Windows XP Media Center Edition, or Windows Server 2003 has exactly one Local GPO, regardless of whether the computers are part of an Active Directory environment.<br><br>Local GPOs are always processed, but are the least influential GPOs in an Active Directory environment, because GPOs based on Active Directory have precedence. |
| Winlogon | A component of the Windows operating system that provides interactive logon support, Winlogon is the service in which the Group Policy engine runs. |
| Group Policy engine | The Group Policy engine is the framework that handles common functionalities across registry-based settings and client-side extensions (CSEs). |
| Client-side extensions | CSEs run within dynamic-link libraries (DLLs) and are responsible for implementing Group Policy at the client computer.<br><br>The CSEs are loaded on an as-needed basis when a client computer is processing policy. |
| File system | The NTFS file system on client computers. |

| | |
|---|---|
| Registry | A database repository for information about a computer's configuration, the registry contains information that Windows continually references during operation, such as:<br>• Profiles for each user.<br>• The programs installed on the computer and the types of documents that each can create.<br>• Property settings for folders and program icons.<br>• The hardware on the system.<br>• Which ports are being used.<br><br>The registry is organized hierarchically as a tree, and it is made up of keys and their subkeys, hives, and entries.<br><br>Registry settings can be controlled through Group Policy, specifically, Administrative Templates (.adm files). Windows Server 2003 comes with a predefined set of Administrative Template files, which are implemented as text files (with an .adm extension), that define the registry settings that can be configured in a GPO. These .adm files are stored in two locations by default: inside GPOs in the Sysvol folder and in the **Windows\inf** directory on the local computer. |
| Event log | The Event log is a service, located in Event Viewer, that records events in the system, security, and application logs. |
| Help and Support Center | The Help and Support Center is a component on each computer that provides HTML reports on the policy settings currently in effect on the computer. |
| Resultant Set of Policy (RSoP) infrastructure | All Group Policy processing information is collected and stored in a Common Information Model Object Management (CIMOM) database on the local computer. This information, such as the list, content, and logging of processing details for each GPO, can then be accessed by tools using Windows Management Instrumentation (WMI). |
| WMI | WMI is a management infrastructure that supports monitoring and controlling of system resources through a common set of interfaces and provides a logically organized, consistent model of Windows operation, configuration, and status.<br><br>WMI makes data about a target computer available for administrative use. Such data can include hardware and software inventory, settings, and configuration information. For example, WMI exposes hardware configuration data such as CPU, memory, disk space, and manufacturer, as well as software configuration data from the registry, drivers, file system, Active Directory, the Windows Installer service, networking configuration, and application data. WMI filtering in Windows Server 2003 enables you to create queries based on this data. These queries (WMI filters) determine which users and computers receive all of the policy configured in the GPO where you create the filter. |
| SMB | Server Message Block (SMB) protocol is the primary method of file and print sharing. Folder Redirection client-side extension use SMB to access the Sysvol as well as back up and retrieve files to a remote file system. The client computer also uses SMB to read the Sysvol on the domain controller. |

The following table shows the location of the files used by Folder Redirection.

**Folder Redirection Component Locations**

| **Component** | **Location** |
|---|---|
| Fdeploy.dll | %windir%\system32 |
| {25537BA6-77A8-11D2-9B6C-0000F8080861}.ini | %USERPROFILE%\Local Settings\Application Data\Microsoft\Windows\File Deployment\ |
| Fdeploy.log | %windir%\debug\usermode\ |

**Locally Cached Redirection Information File**
Whenever a folder is redirected, fdeploy.dll saves the details of the redirection in a local file. This data is used later by fdeploy.dll to determine how to process redirected folders if a user's personal name (UPN) or security group membership changes. The file is also used with roaming user profiles.

The redirection information file is stored in the %USERPROFILE%\Local Settings\Application Data\Microsoft\Windows\File Deployment\ folder.

The file has one section per folder currently redirected through Folder Redirection policy. If there is no policy applicable for a particular folder, then that section is removed from this file. For each folder, the following information is maintained:

- **User Name.** The user name of the user when the redirection was performed. This information is used to handle UPN changes.
- **Path.** The path to which the folder is redirected.
- **Flags.** The flags describing the Folder Redirection settings.
- **Group.** The string representation of the SID for the security group that was responsible for that particular path to get chosen as the redirection destination.
- **GPO.** The GUID of the GPO that was responsible for redirection.

### An example cached redirection file:

```
[Desktop]
Username=username
Path=%USERPROFILE%\Desktop
Flags=31
Group=S-1-5-21-397955417-626881126-188441444-3038017
GPO={AFC36721-F1D5-46BA-981C-FC33BDE293D7}
```

**Folder Redirection Processes and Interactions**
Folder Redirection client-side extension interacts with the Group Policy engine as well as the shell.

Folder Redirection processing contains five steps:

1. Determine which user folders to redirect based on changes to Group Policy settings at time of logon.
2. Determine the target location specified for redirection and confirm the user has access rights to that location.
3. If the target folder does not exist, the folder is created and the appropriate access control list (ACL) rights are set.
4. If the folder exists, access rights and folder ownership are checked.
5. If desired, the files contained within specified folders are moved to the new location, which also deletes them from the source folder if the source folders are local.

If the policy for Folder Redirection does not specify that the user be granted exclusive access to the redirected location, fdeploy.dll confirms only that the destination folder exists. If the target folder does not exist, it is created. However, if the policy requires that the user be given exclusive access to the destination folder, fdeploy.dll does one of the following, depending on whether the destination folder already exists or not.

### Note

- With Windows XP SP1 the user must be the owner of the folder on the server. If not, the ownership check fails, and redirection fails unless a policy is set to ignore this. This was added in SP1.
- If the destination already exists, fdeploy.dll checks whether the user is the owner of the folder. If the folder is owned by the user, fdeploy.dll proceeds; otherwise it fails and aborts the redirection of that folder.

- If the destination does not exist, fdeploy.dll creates the folder and then sets ACLs on it so that only the user and the local system account have full access to it, but no other users have any access to it. Fdeploy.dll also ensures that the folder does not inherit any Access Control Entries (ACE) from its parent. Fdeploy.dll then sets the user as the owner of the folder. This is done because if the user belongs to the local administrators group on the destination server, the local administrators group becomes the owner of the group by default. By setting the user as the owner of the folder you can assure that any quota accounting for that user is done correctly. This also ensures that any subsequent redirections to the same location from other computers do not fail due to the ownership check performed on pre-existing folders described previously. If configuration of either ownership or Access Control Lists (ACL) fails, the process is aborted and redirection fails for the folder specified. If not, redirection proceeds and the files are copied to the redirected location.

Once this is done, fdeploy.dll deletes the files from the source. However, there is an exception to this. If the source is a network location and the destination is a local location, the files are not deleted from the source. This ensures that any subsequent redirection operations from other computers also get a copy of the files on the local computer as required by the policy.

**Folder Redirection Interaction with the Shell**
There are two main points of interaction with the shell. The first point is when fdeploy.dll determines the current location of a folder. For this, it uses the **SHGetFolderPath** API from shell32.dll. The second point of interaction is when fdeploy.dll needs to notify the shell about the new location of a folder after it applies redirection settings. For this, it uses the **SHSetFolderPath** API from shell32.dll.

In addition, there is one other point of interaction which is specific to redirection of the My Documents folder. In the Windows shell, the properties dialog box for the My Documents folder has a **Target** tab. Settings on the **Target** page enable a user to change the location of this folder. If the folder is redirected through policy, this functionality is not desirable and should be disabled. Therefore, fdeploy.dll needs to set the policy which disables this functionality. This is done by creating a DWORD value called **DisablePersonalDirChange** under the key HKLM\Software\Microsoft\Windows\CurrentVersion\Policies\Explorer.

**Folder Redirection and Environment Variables**
Environment variables can be used to define the path to the redirected location. Supported environment variables include %USERNAME% and %USERPROFILE%.

These are the only environment variables supported because other variables are not defined when the Folder Redirection extension is loaded by Winlogon. Note that fdeploy.dll does not do any sort of validation to ensure that only certain allowed variables are present in the paths. It merely expands the paths and if any variables are not defined, they stay as they are. Homedir redirection is an exception. Redirection to the home directory of the user is only allowed for the My Documents folder; fdeploy.dll does perform validation to ensure that other folders cannot be redirected to that location.

**Folder Redirection and Mapped Drives**
Because Folder Redirection is processed early in the logon process, drives mapped with logon scripts (including the homedrive for folders other than My Documents), the Folder Redirection client side extension is not able to redirect to these locations. At the time that redirection takes place, the drives do not exist hence redirection fails.

**Using Offline Files Settings**
Using offline files settings on a shared network folder where user data is stored is especially useful for users of portable computers. It is recommended that you use Folder Redirection in conjunction with offline files.

The offline files feature of Windows, also referred to as client-side caching, is designed to make network access of files more efficient by keeping a local copy of the files in the offline files cache. It also facilitates access to those files when the user is not connected to the network. Since Folder Redirection moves a user's files to and from network locations, it is important for it to move files within the local offline files cache to provide a seamless and transparent experience to the user. In most cases when you use Folder Redirection, you will combine it with offline files so that users can access cached copies of the redirected folders when disconnected from the network. The following table provides some recommended settings for redirecting folders.

### Note

- All redirected folders are pinned by default.

### Recommended Configuration for Offline Files

| Redirected Folder | Recommended Offline Folder Settings |
|---|---|

| | |
|---|---|
| My Documents | Auto-caching for documents or manual caching for documents (if you want users to have to manually make files and folders available offline). |
| My Pictures | Auto-caching for documents or manual caching for documents (if you want users to have to manually make files and folders available offline). |
| Application Data | Auto-caching for programs. |
| Desktop | Auto-caching for programs if the desktop is read-only. |

**Folder Redirection and Software Installation Policies**

When logon optimization is enabled, a user might need to log on to a computer twice before Folder Redirection policies and software installation policies are applied. This is because application of these types of policies requires the synchronous policy application. During a policy refresh (which is asynchronous), the system sets a flag that indicates that the application of Folder Redirection or a software installation policy is required. The flag forces synchronous application of the policy at the user's next logon.

Because background refresh is the default behavior in Windows XP, Folder Redirection and Software Installation might require as many as three logons to apply changes.

This behavior exists because Folder Redirection and Software Installation cannot apply during an asynchronous or background application of policy. Folder Redirection can be applied only when processed synchronously.

Here is a sample scenario showing how polices are applied:

- An administrator deploys a software package to User A.
- User A logs on fast and receives a background (asynchronous) application of policy.
- Because the policy application was asynchronous, the software that was set to be installed cannot be installed at this time. Instead the computer is tagged, indicating that software needs to be installed.
- The next time the user logs on, the computer instead logs on the user synchronously to allow the software package to be installed. (This is the same behavior as Windows 2000). This results in one extra logon for the software to be installed.
- In the case of Advanced Folder Redirection, because policy is evaluated based on security group membership three logons will be required: the first logon to update the cached user object (and security group membership), the second logon for policy to detect the change in security group membership and require a foreground policy application, and the third logon to actually apply Folder Redirection policy in the foreground.

  **Note**

  - When a client running Windows XP logs onto a Windows 2000 or Windows Server 2003 Active Directory, all Software Installation policy settings for Windows 2000 clients will be applied and work successfully on the Windows XP client.

# Folder Redirection Extension Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Folder Redirection Tools
- Folder Redirection Settings
- Folder Redirection Registry Keys
- Related Information

**Folder Redirection Tools**
The following is a list of tools available for supporting and configuring Folder Redirection.

**Folder Redirection Logging**
Errors and failures of Folder Redirection processing are logged as events in the Application Event log. In addition, Folder Redirection can provide a detailed log to aid troubleshooting. To create a detailed log file for Folder Redirection, add a value to the following registry key:

HKLM\Software\Microsoft\Windows NT\CurrentVersion\Diagnostics

Set: FdeployDebugLevel = Reg_DWORD 0x0f

A log file, Fdeploy.log, is created and stored in the *%windir%*\debug\usermode\ folder.

**Group Policy Administrative Tools**
The following Group Policy administrative tools are used to administer Group Policy components:

- Group Policy Management Console
- Group Policy Object Editor
- Resultant Set of Policy Snap-in

For more information about these tools, please see the "Group Policy Administrative Tools" section.

**Folder Redirection Settings**
There are two types of Folder Redirection. The type you choose to use depends on your network configuration and security considerations.

- **Basic.** This option redirects everyone's folder to the same location. All folders affected by this Group Policy object will be stored on the same network share.
- **Advanced.** This option specifies locations for various user groups. Folders are redirected to different network shares based on security group membership. For example, folders belonging to users in the Accounting group can be redirected to the Finance server, while folders belonging to users in the Sales group can be redirected to the Marketing server.

The following list describes the settings available for redirecting folders.

- **Grant the user exclusive rights to My Documents.** If selected, this sets the NTFS security descriptor for the %username% folder to Full Control for the user and local system only; this means that administrators and other users do not have access rights to the folder. This option is enabled by default. Rights to this folder can later be modified to enable administrators to access these folders.

- **Move the contents of My Documents to the new location.** This setting moves any file the user has in the local My Documents folder to the server share. This option is enabled by default.

- **Leave the folder in the new location when policy is removed.** This setting specifies that files remain in the new location when the Group Policy object no longer applies. This option is enabled by default.

- **Redirect the folder back to the local user profile location when policy is removed.** If enabled, this setting specifies for the folder to be copied back to the local profile location if the Group Policy object no longer applies.

There are two additional settings available only for My Pictures folder.

- **Make My Pictures a subfolder of My Documents.** If selected, when the My Documents folder is redirected, My Pictures remains a subfolder of My Documents. By default, My Pictures automatically follows the My Documents folder.

- **Do not specify administrative policy for My Pictures.** If selected, Group Policy does not control the location of My Pictures; this is determined by the user profile.

The following table outlines the behavior of redirected folders, and the files contained in them, when the policy for Folder Redirection is removed.

**Summary of Folder Redirection Policy Removal Settings**

| Move the contents of special folder to the new location setting | Setting selected for the Policy Removal option | When policy is removed |
|---|---|---|
| Enabled | Redirect the folder back to the user profile location when policy is removed. | The special folder returns to its user profile location.<br><br>The folder contents are copied back to the user profile location.<br><br>The contents are not deleted from the redirected location.<br><br>The user can continue to access the contents, but only on the local computer. |
| Disabled | Redirect the folder back to the user profile location when policy is removed. | The special folder returns to its user profile location.<br><br>Note**:** In this case, the folder contents are not copied or moved to the user profile location. As a result, the user can no longer see the contents. |
| Either Enabled or Disabled | Leave the folder in the new location when policy is removed. | The special folder remains at its redirected location.<br><br>The contents remain at the redirected location.<br><br>The user continues to have access to the contents at the redirected folder. |

**Note**

- Changing the redirection option to "Not Configured" does not redirect the folder to the local profile. This option means that Folder Redirection is not configured—if a folder was previously redirected it will continue to be redirected to the previous location. If administrators wish to return the folder to the local user profile they should use the **Redirect to the local user profile** setting.

**Folder Redirection Registry Keys**

The following registry entries are associated with Folder Redirection.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. You should not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in

unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**Note**

- Folder Redirection extension does not own the User Shell Folder keys, but simply manipulates them.

The following tables describe the registry settings associated with Folder Redirection.

**HKCU\Software\Microsoft\Windows\CurrentVersion\Explorer\User Shell Folders**

| Value Name | Type | Purpose | Platforms |
|---|---|---|---|
| Personal | REG_EXPAND_SZ | Populated with redirected path from policy. | W2K, WinXP |
| My Pictures | REG_EXPAND_SZ | Populated with redirected path from policy. | W2K, WinXP |
| Desktop | REG_EXPAND_SZ | Populated with redirected path from policy. | W2K, WinXP |
| AppData | REG_EXPAND_SZ | Populated with redirected path from policy. | W2K, WinXP |
| Start Menu | REG_EXPAND_SZ | Populated with redirected path from policy. | W2K, WinXP |
| Startup | REG_EXPAND_SZ | Populated with redirected path from policy. | W2K, WinXP |
| Programs | REG_EXPAND_SZ | Populated with redirected path from policy. | W2K, WinXP |

**HKCU\Software\Microsoft\Windows\CurrentVersion\Explorer\Shell Folders**

| Value Name | Type | Purpose | Platforms |
|---|---|---|---|
| Personal | REG_SZ | Populated with expanded redirected path from policy. | W2K, WinXP |
| My Pictures | REG_SZ | Populated with expanded redirected path from policy. | W2K, WinXP |
| Desktop | REG_SZ | Populated with expanded redirected path from policy. | W2K, WinXP |
| AppData | REG_SZ | Populated with expanded redirected path from policy. | W2K, WinXP |
| Start Menu | REG_SZ | Populated with expanded redirected path from policy. | W2K, WinXP |
| Startup | REG_SZ | Populated with expanded redirected path from policy. | W2K, WinXP |
| Programs | REG_SZ | Populated with expanded redirected path from policy. | W2K, WinXP |

**HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Diagnostics**

| Value Name | Type | Purpose | Platforms |
|---|---|---|---|
| FDeployDebugLevel | REG_DWORD | Determines the logging level of Folder Redirection. | W2K, WinXP |
| FDeployDebugBreak | REG_DWORD | Makes the Folder Redirection client break into the debugger at startup. | W2K, WinXP |

**HKLM\SOFTWARE\Microsoft\Windows\CurrentVersion\Policies\Explorer**

| Value Name | Type | Purpose | Platforms |
|---|---|---|---|
| DisablePersonalDirChange | REG_DWORD | Prevent users from changing the location of the My Documents folder through the UI on the My Documents properties sheet if the folder is redirected through policy. | W2K, WinXP |

**HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\GPExtensions\{25537BA6-77A8-11D2-9B6C-0000F8080861}**

(This is registration information from fdeploy.dll)

| Value Name | Type | Purpose | Platforms |
|---|---|---|---|
| DllName | REG_EXPAND_SZ | Name of the dll. | W2K, WinXP |
| EventSources | REG_MULTI_SZ | For event logging. | W2K, WinXP |
| GenerateGroupPolicy | REG_SZ | Entry point for planning mode RSoP. | WinXP |
| ProcessGroupPolicyEx | REG_SZ | Entry point for diagnostic mode RSoP and regular policy application. | WinXP |
| NoBackgroundPolicy | REG_DWORD | Disposition during background policy application. | W2K, WinXP |
| NoGPOListChanges | REG_DWORD | Disposition when the GPO list has not changed. | W2K, WinXP |
| NoMachinePolicy | REG_DWORD | Disposition when processing machine policies. | W2K, WinXP |
| NoSlowLink | REG_DWORD | Disposition when connected over slow link. | W2K, WinXP |
| PerUserLocalSettings | REG_DWORD | Determine if history should be maintained per-user per computer-. | W2K, WinXP |

# Internet Explorer Maintenance Extension Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Internet Explorer Maintenance Extension is used to manage Internet Explorer settings in a computing environment that uses Group Policy. The settings are grouped into the Browser User Interface, Connection Settings, Custom URLs, Security, and Program nodes.

Administrators can customize the appearance of the browser, preset and manage browser connection settings, set the default URLs displayed by the browser, and set the default programs used for each Internet service. Administrators can also preset the security zone, content rating, certification authority, and Authenticode settings.

The Internet Explorer Maintenance Extension of Group Policy is used to configure Internet Explorer only in domains using the Windows 2000 or Windows Server 2003 operating systems. It is possible to customize Internet Explorer before deployment and to manage Internet Explorer in other domain environments by using the Microsoft Internet Explorer Administration Kit (IEAK).

# What Is Internet Explorer Maintenance Extension?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Internet Explorer Maintenance Extension?**

**In this subject**

- Common Internet Explorer Maintenance Extension Scenarios
- Internet Explorer Maintenance Extension Dependencies on or Interactions with Other Technologies
- Related Information

The Internet Explorer Maintenance Extension is part of the Group Policy Object Editor, and it enables you to define an Internet Explorer configuration as part of a Group Policy Object (GPO). The GPOs are linked to Active Directory containers such as sites, domains, or organizational units, and enable administrators to manage the Internet Explorer configuration for multiple users on any computer joined to the domain.

The Internet Explorer Maintenance Extension uses two sets of extensions to accomplish its purpose: a snap-in extension to the Group Policy Object Editor, and a Client-Side Extension (CSE). The snap-in extension (ieaksie.dll) is used to configure Internet Explorer settings in a GPO. The Client-Side Extension (iedkcs32.dll) is a dynamic-link library (DLL) on the client computer that implements the Internet Explorer Maintenance Extension settings contained in the GPO.

The security risks inherent in exposure to the Internet for large computer networks require organizations to adopt a computer security policy. Users can accidentally compromise security for the entire network by misconfiguring their own, or a coworker's, computer. Providing users with information useful in solving problems or in accomplishing their jobs is not very effective if users are not familiar with the information, or if the information is difficult to access. The Internet Explorer Maintenance Extension enables administrators to stipulate custom favorites, links, security, interface, and other settings to specify an Internet Explorer configuration as part of a GPO. Administrators are able to enforce Internet-related security standards, and provide a common browser interface within the organization. Specifying custom links provides users easy access to useful information, and can aid in reducing end-user help calls.

**Common Internet Explorer Maintenance Extension Scenarios**

The Internet Explorer Maintenance Extension can be used to configure either mandatory or default settings for Internet Explorer.

**Mandatory Internet Explorer Settings**

Mandatory settings are used to enforce security, interface and other Internet Explorer settings by making users unable to change those settings. To configure mandatory settings, the settings are created while Internet Explorer Maintenance Extension is in Policy mode. When a GPO containing Policy mode settings is applied to a user configuration, the settings are reapplied only when Group Policy is forcefully reapplied to the target computer or changes are made to the GPO. Without further configuration using Group Policy Administrative Templates Extension settings, users are able to change their browser settings. There are two additional steps that must be completed to impose the mandatory status of the GPO:

- The `Computer Configuration\Administrative Templates\System\Group Policy\Internet Explorer Maintenance policy processing` setting must be configured to process settings even if they have not been changed.
- All of the settings in the `User Configuration\Administrative Templates\Windows Components\Internet Explorer\Internet Control Panel` node must be enabled.

**Default Internet Explorer Settings**

Internet Explorer Maintenance Extension can also be used to configure default settings for users the first time the GPO is applied to their computers. This provides users with the same starting configuration for their browsers, but enables them to personalize the configuration. To configure default settings, the settings are created while Internet Explorer Maintenance Extension is in Preference mode. Once a GPO containing Preference mode settings is applied to a user configuration, the settings are not reapplied unless there are changes to the GPO settings, even when Group Policy is forcefully reapplied to the target computer. Preference Mode also enables two additional groups of settings:

- **Corporate Settings.** These are used to configure temporary internet file settings, and download locations for ActiveX controls and Java code.

- **Internet Settings.** These are used to configure Internet Explorer link and text colors, AutoComplete settings, how often Internet Explorer checks for updates, and other advanced settings.

**Internet Explorer Maintenance Extension Settings**

The mode setting for Internet Explorer Maintenance Extension settings is exclusive within a GPO. Policy and Preference mode settings cannot coexist in the same GPO. The following table lists the available Internet Explorer Maintenance Extension Group Policy settings and their descriptions. It also notes if a setting is available in only Preference mode or Policy mode.

**Internet Explorer Maintenance Extension Configuration Settings**

| **Browser User Interface** | **Description** |
|---|---|
| Browser Title (Policy mode only) | This setting customizes the text that appears in the title bar of the Internet Explorer browser. The text is appended to the string "Microsoft Internet Explorer provided by." |
| Custom Logo (Policy mode only) | This setting replaces the static Internet Explorer logo in the upper-right corner of the Internet Explorer window with a custom static logo. It also replaces the animated Internet Explorer logo in the upper-right corner of the Internet Explorer window with a properly formatted custom animated logo. |
| Browser Toolbar Customizations | This setting customizes the background and buttons of the Internet Explorer toolbar. |
| **Connection** | **Description** |
| Connection Settings | This setting enables you to import connection settings from the Internet Control Panel Connections tab of an already-configured computer. It restricts how users can interact with connection settings through the System Policies and Restrictions page. It is not necessary to import current settings in order to set theses restrictions. Connections Settings is also used to remove old dial-up connection settings from users' computers. |
| Automatic Browser Configuration | Automatic Configuration (auto-config) is used to update a user's computer after deployment by specifying a URL to an .ins file, an auto-proxy URL, or both. You can set the interval in minutes for when auto-config will happen. If the interval value is left blank, or at zero, auto-config will happen only when the browser has been started and navigates to a page. |
| Proxy Settings | This setting specifies to which proxy servers, if any, users connect. |
| User Agent String (Policy mode only) | The user agent string is what the browser sends to visited servers to identify itself. It is often used to keep Internet traffic statistics. You can enter custom text that will be appended to the default Internet Explorer string. The default string is different for each platform. |
| **URLs** | **Description** |
| Favorites and Links | You can customize Favorites and Links by specifying the URLs. You can also specify the order of each folder, add an icon for each Favorite and Link, and import an existing folder structure. |
| Important URLs | You can specify a custom home page, search bar URL, and online support page. |
| **Security** | **Description** |
| Security Zones and Content Ratings | You can customize the settings of each security zone as well as customize the privacy settings. Content ratings enable you to prevent users from viewing sites with risky content. |

| | |
|---|---|
| Authenticode Settings | Authenticode enables you to designate software publishers as trustworthy. You can prevent users from adding new trusted publishers while using the browser. Enabling this lockdown does not prevent access to the Content control panel, but doing so is possible using the Administrative Templates Extension of Group Policy. |
| **Programs** | **Description** |
| Programs | You can import the current default programs settings. The programs selected specify which program Windows automatically uses for each Internet service. |
| **Advanced** | **Description** |
| Corporate Settings (Preference mode only) | These settings specify the location of a file containing settings used to make the browser work best for your corporation. These settings can be useful in reducing the cost of supporting applications in your corporation. Advanced features, as well as details of other features, can all be configured through these options. |
| Internet Settings (Preference mode only) | These settings specify the location of a file used to preset defaults for Internet Explorer settings that are not set through the IEAK Wizard. Most of these settings apply to defaults in the Internet Control Panel. |

**Internet Explorer Maintenance Extension Dependencies on or Interactions with Other Technologies**
Deployment of Internet Explorer Maintenance Extension settings requires Group Policy in a Windows 2000 or Windows 2003 Active Directory environment, and Windows 2000 Professional or Windows XP clients running Internet Explorer.

The Internet Explorer Maintenance Extension leverages the Internet Explorer Administration Kit (IEAK) management infrastructure, a part of Internet Explorer, in order to configure Internet Explorer. IEAK is an application used to deploy and manage customized Internet Explorer software packages. The packages can be used to configure Internet Explorer, just like the Internet Explorer Maintenance Extension, or to install completely customized versions.

**Internet Explorer Maintenance Extension and Internet Explorer Enhanced Security Configuration**
Another Technology the Internet Explorer Maintenance Extension interacts with is the Internet Explorer Enhanced Security Configuration component of Windows Server 2003. Internet Explorer Enhanced Security Configuration, also known as Microsoft Internet Explorer Hardening, reduces a server's vulnerability to attacks from Web content by applying more restrictive Internet Explorer security settings. You can deploy Internet Explorer Enhanced Security Configuration settings to target computers through Internet Explorer Maintenance only if Internet Explorer Enhanced Security Configuration is enabled on the target computer. This is because the Internet Explorer Maintenance CSE stores these settings on the target computer in the equivalent registry location from where they were imported. Those registry keys are read only by Windows Server 2003 because it is currently the only operating system that supports Internet Explorer Hardening.

If Internet Explorer Enhanced Security Configuration is enabled on your computer, the sites list is read from and written to **HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Internet Settings\ZoneMap\ESCDomains**.

If Internet Explorer Enhanced Security Configuration is disabled on your computer, or if your computer is running an earlier version of Windows, the sites list is read from and written to **HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Internet Settings\ZoneMap\Domains**.

Internet Explorer Enhanced Security Configuration settings (as imported by the computer when editing the GPO) can be applied only to computers on which Internet Explorer Enhanced Security Configuration is already enabled. Likewise, if Internet Explorer Enhanced Security Configuration is disabled on your computer, you can deploy security settings and trusted sites to other servers running with Internet Explorer Enhanced Security Configuration disabled. These variables are shown in the following table.

**Expected Behaviors on Target Computers for HKEY_CURRENT_USER Preferences with Internet Explorer Maintenance**

| Computer Importing Settings to the GPO (Your administrative computer) | Windows Server 2003 with Internet Explorer Enhanced Security Configuration enabled | Windows Server 2003 with Internet Explorer Enhanced Security Configuration disabled | Windows 2000 Server |
|---|---|---|---|

| | | | |
|---|---|---|---|
| | (writes to HKCU\...\ESCDomain) | (writes to HKCU\...\Domain | (reads HKCU\...\Domain) |
| Windows Server 2003 with Internet Explorer Enhanced Security Configuration enabled<br><br>(writes to HKCU\...\ESCDomain) | Security settings and trusted sites | No security settings or trusted sites | No security settings or trusted sites |
| Windows Server 2003 with Internet Explorer Enhanced Security Configuration disabled (writes to HKCU\...\Domain) | No security settings or trusted sites | Security settings and trusted sites | Security settings and trusted sites |
| Windows 2000 Server<br><br>(writes to HKCU\...\Domain) | No security settings or trusted sites | Security settings and trusted sites | Security settings and trusted sites |

# How Internet Explorer Maintenance Extension Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Internet Explorer Maintenance Extension Works**

**In this section**

- Internet Explorer Maintenance Extension Architecture
- Internet Explorer Maintenance Extension Physical Structure
- Internet Explorer Maintenance Extension Processes and Interactions
- Related Information

The Internet Explorer Maintenance Extension of the Group Policy Object Editor enables administrators to define an Internet Explorer configuration as part of a Group Policy Object (GPO). The GPO is linked to Active Directory containers such as sites, domains, or organizational units (OUs), and enables management of the Internet Explorer configuration for multiple users on any computer joined to the domain that is capable of using Group Policy.

Deployment of Internet Explorer Maintenance Extension settings requires Group Policy in a Windows 2000 or Windows 2003 Active Directory environment, and Windows 2000 Professional or Windows XP clients.

**Internet Explorer Maintenance Extension Architecture**

The following figure illustrates the components important to the Internet Explorer Maintenance Extension.

**Internet Explorer Maintenance Extension Architecture**

These components are described in the following table. Components not seen in the figure, but important to the process, are also described.

**Internet Explorer Maintenance Extension Logical Architecture Components**

| Component | Description |
|---|---|
| Group Policy engine | This component is the framework that manages and implements the Group Policy settings and configurations, made by the admin, across all client-side extensions (CSE). Userenv.dll is the Group Policy engine module. |
| Internet Explorer Maintenance Client-Side extension (CSE) | The Internet Explorer Maintenance CSE is the component that is called by the Group Policy engine, and that applies the Internet Explorer Maintenance settings. The Internet Explorer Maintenance CSE writes the relevant information into the registry. |
| WinLogon | WinLogon is the service that contains the Group Policy engine. |

| | |
|---|---|
| Resultant Set of Policy (RSoP) snap-in | This component displays the results of Group Policy, including what Group Policy settings have been applied and when they were last applied. For more information about RSoP, see "What Is Resultant Set of Policy?." |
| Local GPO | Contains Group Policy settings for the local computer, including potential Internet Explorer Maintenance policies. |

The CSE registration information is written at setup to the HKEY_LOCAL_MACHINE\Software\Microsoft\WindowsNT\CurrentVersion\Winlogon\ **GPExtensions** registry key. This registry key structure exists on both the target and domain controller systems.

**Internet Explorer Maintenance Extension Physical Structure**

Understanding where Internet Explorer Maintenance Extension policy settings are stored and how they are structured can help you troubleshoot problems you might encounter when you implement Internet Explorer Maintenance. Although GPOs can be linked to sites, domains, and OUs, they are stored only in the domain. See the "How Core Group Policy Works" topic in this collection for more information about how Group Policy stores its data.

The following table lists the setting types and the locations where Internet Explorer Maintenance Extension policy configuration files are stored on both the local computer and the domain.

**Physical Structure Components**

| Setting Type | Policy File Name |
|---|---|
| Browser Title | install.ins |
| Custom Bitmaps | Install.ins<br>\Branding\Logo\<<small logo file name>><br>\Branding\Logo\<<big logo file name>><br>\Branding\Animbmp (empty folder created) |
| Toolbar Customization | \install.ins<br>\Branding\Btoolbar\<<color logo file name>><br>\Branding\Btoolbar\<<grayscale logo file name>><br>\Branding\Toolbmp\<<toolbar bmp file name >> |
| Connection Settings | \install.ins<br>\Branding\cs\connect.set<br>\Branding\cs\cs.dat |
| Automatic Browser Configuration | \install.ins |
| Proxy Settings | \install.ins |
| User Agent String | \install.ins |
| Favorites and Links | \install.ins |
| Important URLs | \install.ins |
| Security Zones | \install.ins<br>\Branding\Zones\seczones.inf<br>\Branding\Zones\seczrsop.inf |

| | |
|---|---|
| Content Ratings | \install.ins<br>\Branding\Ratings\ratings.inf<br>\Branding\Ratings\ratrsop.inf |
| Authenticode Settings | \install.ins<br>\Branding\Authcode\authcode.inf |
| Programs | \install.ins<br>\Branding\Programs\programs.inf |
| Corporate Settings | \Branding\Adm\inetcorp.adm<br>\Branding\Adm\inetcorp.inf |
| Internet Settings | \Branding\Adm\inetset.adm<br>\Branding\Adm\inetset.inf |

Domain policy settings use the Fully Qualified Domain Name (FQDN) to reference GPOs. There are two main paths where the configuration files are stored:

- Domain policy files are stored in the folder `\\FQDN\Sysvol\FQDN\Policies\<GPOGUID>\User\Microsoft\IEAK`
- Local Machine policy files are stored in the folder `%windir%\System32\GroupPolicy\User\Microsoft\IEAK`

The following figure shows the files used by the Internet Explorer Maintenance Extension and where they are stored on both the domain controller and client computers.

**Internet Explorer Maintenance Extension File Storage**

**Internet Explorer Maintenance Extension Processes and Interactions**

When working with Internet Explorer Maintenance settings, you can use one of two interfaces. To configure Internet Explorer Maintenance Extension settings, use the Group Policy Object Editor. Use the Group Policy Management Console (GPMC) to view the Internet Explorer Maintenance Extension settings contained within a GPO.

**Using Group Policy Object Editor with Internet Explorer Maintenance**

To configure Internet Explorer Maintenance settings, an Administrator sets up Internet Explorer on a client computer with the settings to be included in the GPO. The Administrator then uses the Group Policy Object Editor to import the settings for the Security Zones, Content Ratings, Authenticode Settings, Programs, and Connection Settings, areas of the Internet Explorer Maintenance Extension and saves them as part of a GPO. The following figure shows the Internet Explorer Maintenance Extension interface used to import Connection Settings into a GPO.

**Importing Internet Explorer Settings**

**Configuring and Importing Internet Explorer Maintenance Settings to a GPO**

Administrators import settings from the appropriate settings dialog boxes in the Internet Explorer Maintenance extension of Group Policy Object Editor. The following things occur when the settings are imported:

- The IEAK Engine (ieakeng.dll) hosts the Internet Options Control Panel (inetcpl.cpl), which then reads the current settings from the registry.
- The Administrator then modifies the settings using the user interface of inetcpl.cpl.
- When the settings are saved, they are written back to the registry by inetcpl.cpl. Ieakeng.dll then imports them to the appropriate GPO files.

The following figure illustrates the process of importing Internet Explorer Maintenance Extension settings.

**Importing Internet Explorer Settings in XP**

**Note**

- If an administrator tries to view the settings in a GPO by clicking **Modify Settings**, the current settings from the registry, instead of the GPO, are immediately imported. Clicking **OK** then overwrites the settings stored in the GPO with the settings in effect on the client, deleting the settings previously contained in the GPO. In this event, the administrator

cannot view the GPO to find out what the previous settings were. It then becomes difficult to reconfigure the settings.

**Using the Group Policy Management Console to View a GPO**

To avoid overwriting the Internet Explorer Maintenance settings in a GPO, use GPMC to view the Internet Explorer Maintenance settings. GPMC runs on Windows XP Professional SP1 and Windows Server 2003 computers, and can manage Group Policy in either Windows 2000 or Windows Server 2003 domains. To see the settings contained in a GPO using GPMC, an Administrator views the **Settings** tab of the GPO as shown in the following figure.

**Viewing Internet Explorer Maintenance Settings in GPMC**

**Applying GPO Settings to a Client Computer**

The Internet Explorer Maintenance Extension uses the Internet Explorer Administration Kit (IEAK) infrastructure for both storage of settings and application to the client system.

When Group Policy is applied, Client-Side Extensions process the GPO. Internet Explorer Maintenance settings are handled by the Internet Explorer branding DLL (iedkcs32.dll). The Group Policy CSE invokes iedkcs32.dll, and two things happen:

1. The Group Policy CSE copies all IEAK settings files created using Internet Explorer Maintenance, listed in the previous **Physical Structure Components** table, to the following locations:

   Documents and Settings\<<username>>\Application Data\Microsoft\Internet Explorer\Custom Settings\Custom0\

   And

   Documents and Settings\<<username>>\Application Data\Microsoft\Network\Connections\pbk\Rasphone.pbk (for connection settings)

   Note that the policy's directory structure shown in the previous Physical Structure Components table is not replicated.

2. The Branding DLL then applies the settings from the downloaded files to the registry on the client system. There are four possible locations for the registry settings:

   - HKLM\Software\Policies (preferred)

- HKLM\Software\Microsoft\Windows\CurrentVersion\Policies
- HKCU\Software\Policies (preferred)
- HKCU\Software\Microsoft\Windows\CurrentVersion\Policies

These locations have security permissions that a standard user cannot modify in order to change applied policy settings. These keys are created the first time a GPO `configures` them.

Because the IEAK settings files are stored in the user's profile, the user has full-access permissions and can modify their contents. When the GPO is updated, the files are copied from the policy's directory structure back to the user profile and any changes the user might have made are overwritten. Although users can modify files in their own profile, attempting to execute the .inf file will give them an Access is denied error if they attempt to write settings to a key located in the secure registry branches previously specified.

If the user has a roaming profile, the IEAK settings files in the profile can be applied when roaming. This will happen if a roaming profile user logs on to the network from a computer that can't use Group Policy, or from one that isn't linked to a GPO containing Internet Explorer Maintenance Extension settings. If a user has manually changed the Internet Explorer Maintenance Extension settings located in their user profile, the user's settings will be applied to the computer. This has the potential of circumventing browser and security settings configured by the administrator. However, any settings appropriately locked-down in the registry (such as security and connection settings) will not have this problem.

# Internet Explorer Maintenance Extension Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Explorer Maintenance Extension Tools and Settings**

**In this section**

- Internet Explorer Maintenance Extension Tools
- Internet Explorer Maintenance Registry Entries
- Internet Explorer Maintenance Group Policy Settings
- Related Information

This section summarizes the tools and settings associated with the Group Policy Internet Explorer Maintenance Extension.

**Internet Explorer Maintenance Extension Tools**

The following tools are associated with the Internet Explorer Maintenance Extension:

- The Microsoft Internet Explorer Administration Kit (IEAK)
- Group Policy Management MMC snap-in (GPMC)
- Resultant Set of Policy (RSoP)
- Group Policy Object Editor

This topic discusses the Microsoft Internet Explorer Administration Kit (IEAK) and the settings associated with the Internet Explorer Maintenance Extension.

GPMC, the Group Policy Object Editor, and RSoP are described in the "Group Policy Administrative Tools" topic in this collection. GPMC is documented in full at the Group Policy Management Console page, and in the "What Is Group Policy Management Console?" topic in this collection.

Additional command-line tools for managing Group Policy are described in the "Core Group Policy Tools and Settings" topic in this collection.

**Microsoft Internet Explorer Administration Kit**

The Microsoft Internet Explorer Administration Kit (IEAK) is a set of tools that provide administrators with powerful, easy-to-use options designed to save time and money in deploying and managing Web solutions for organizations and internet service providers (ISPs).

**Category**

To download a tool kit for customizing and distributing Microsoft Internet Explorer, see the Microsoft Internet Explorer Administration Kit (IEAK) Web site for Internet Explorer 6 Service Pack 1. To download the IEAK for previous versions of Internet Explorer, use the site's navigation to find the **Downloads** page.

The programs and tools in the IEAK 6 Service Pack 1 (SP1) simplify deploying and managing custom browser software packages. The features and resources include:

- **IEAK Toolkit.** The IEAK Toolkit contains tools, programs, and sample files, such as the animated bitmap tools, a sample sign-up and add-ons. The toolkit also includes the IExpress Wizard; administrators can use it to control setup options and to integrate command-line switches, which control how custom browser packages are installed.
- **IEAK Profile Manager.** After deploying Internet Explorer, the IEAK Profile Manager enables administrators to change browser settings and restrictions automatically.

- **Internet Explorer Customization Wizard.** The Internet Explorer Customization Wizard breaks browser customization into five stages. Step-by-step screens guide the administrator through the process of creating custom browser packages. When these packages are installed on clients' desktops, clients receive customized versions of Internet Explorer with the settings and options that the administrator selected.

- **IEAK Help.** The IEAK Help includes many conceptual and procedural topics viewable through **Index**, **Contents**, and **Search** tabs. Topics from the IEAK Help can also be printed.

**Version compatibility**
The IEAK is designed to manage Internet Explorer on any Windows operating system. Internet Explorer 6 is a core component of Windows XP and Windows Server 2003.

**IEdkcs32.dll**
**Category**
IEdkcs32.dll is an extension that provides settings for Group Policy Internet Explorer Maintenance.

**Version compatibility**
IEdkcs32.dll is compatible with Windows XP1 and Windows Server 2003.

**Internet Explorer Maintenance Extension Registry Entries**
The following registry entries are associated with the Internet Explorer Maintenance Extension.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. You should not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**ConnectionSettings**
**Registry path**
HKCU\Software\Microsoft\IEAK\BrandedFeatures\ConnectionSettings

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key stores the names of all network connections assigned to the computer using the Internet Explorer Maintenance Extension. The ConnectionSettings key contains a REG_MULTI_SZ entry named **NamesList**, which holds a list of the connection names.

**Button GUID**
**Registry path**
HKCU\Software\Microsoft\Internet Explorer\Extensions\<*Button GUID*>

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key stores configuration data for each button added to the Internet Explorer toolbar using Internet Explorer Maintenance Extension. The key name is variable, and is assigned by the Internet Explorer Maintenance Client-Side Extension (CSE) when the button is created. The **Button GUID** registry key contains the following Internet Explorer Maintenance Extension configured entries:

- **ButtonText** – The toolbar caption for the button.

- **Exec** – The program or action associated with the button.

- **HotIcon** – The toolbar button shown when the button is selected or the mouse pointer is over it.

- **Icon** – The standard toolbar button.

- **Default Visible** – Specifies whether or not the button is visible on the toolbar.

**Help_Menu_URLs**
**Registry path**
HKCU\Software\Microsoft\Internet Explorer\Help_Menu_URLs

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key stores the URL associated with the Online Support choice located on Internet Explorer's Help menu. The **Online_Support** entry contains the configured URL.

**Main**
**Registry path**
HKCU\Software\Microsoft\Internet Explorer\Main

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key stores configuration data for the home page, search bar, and the browser title. The **Main** registry key contains the following Internet Explorer Maintenance Extension configured entries:

- **Window Title** – This entry contains the test string displayed in the Internet Explorer title bar. Text entered in the Internet Explorer Maintenance Extension interface is appended to the string "Microsoft Internet Explorer provided by" and is then stored in this registry key entry.
- **Start Page** – This entry stores the URL for the assigned browser home page.
- **Search Bar** – This entry stores the URL displayed in the search toolbar pane when a user clicks the search button.
- **Use Custom Search URL** – This entry specifies whether or not the browser uses the custom search page located in the Search Bar entry.

**Toolbar**
**Registry path**
HKCU\Software\Microsoft\Internet Explorer\Toolbar

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key stores configuration data used to customize the Internet Explorer toolbar background, and the animated and static logos. The **Toolbar** registry key contains the following Internet Explorer Maintenance Extension configured entries:

- **BackBitmapIE5** – This entry specifies the bitmap used to customize the background for the Internet Explorer toolbar.
- **SmallBitmap** – This entry specifies the bitmap used for the small static logo.
- **BigBitmap** – This entry specifies the bitmap used for the large static logo.
- **SmBrandBitmap** – This entry specifies the bitmap used for the small animated logo.
- **BramdBitmap** – This entry specifies the bitmap used for the large animated logo.

**Default**
**Registry path**
HKCU\Software\Microsoft\RAS\AutoDial\Default

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key is used to specify the default internet connection. The **DefaultInternet** entry contains the name of the default

connection used to access the Internet.

**Internet Settings**
The following registry entries are located under HKCU\Software\Microsoft\Windows\CurrentVersion\Internet Settings.

**Automatic Configuration script**
**Registry path**
HKCU\Software\Microsoft\Windows\CurrentVersion\Internet Settings

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

The **AutoConfigURL** entry is used to specify where Internet Explorer checks for a configuration script. The configuration script is used to update the Internet Explorer setup.

**Proxy Server Location**
**Registry path**
HKCU\Software\Microsoft\Windows\CurrentVersion\Internet Settings

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key stores configuration data used to specify the proxy servers Internet Explorer uses. The following registry entries are configured for the Proxy Server Location by the Internet Explorer Maintenance Extension:

- **ProxyEnable** – This entry specifies whether or not the proxy server is currently enabled.
- **ProxyOverride** – This entry specifies the Web sites Internet Explorer bypasses the proxy server to access.
- **ProxyServer** – This entry specifies the URL and port number for the proxy server.

**Dial -up and VPN settings**
**Registry path**
HKCU\Software\Microsoft\Windows\CurrentVersion\Internet Settings\Connections

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key stores configuration data used to specify the configuration of dial-up and VPN connections. The following registry entries are configured for Dial-up and VPN Settings by the Internet Explorer Maintenance Extension:

- **<Connection Name> –** This entry is dependent on the name of the connection, and specifies the connection name displayed on the Internet Properties Connections tab.
- **DefaultConnectionSettings** – This entry specifies the configuration of the default connection used by Internet Explorer.
- **SavedLegacySettings** – This entry specifies the configuration used by network connections other than the default connection.

**Zone Map Domains**
**Registry path**
HKCU\Software\Microsoft\Windows\CurrentVersion\Internet Settings\ZoneMap\Domains\<*Domain or UNC*>

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

These registry keys specify which domain names have been configured within a security zone. Each domain or UNC that has an entry within a security zone has its own registry key in this path. The <*protocol*> entry takes its name from the corresponding protocol type (http, ftp, and so on). The contained entry specifies which zone the domain with protocol is part of.

**Protocol**
**Registry path**
HKCU\Software\Microsoft\Windows\CurrentVersion\Internet Settings\ZoneMap\Domains\<*Domain or UNC*>\<*protocol*>

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key specifies which protocols within a domain name have been placed in a security zone. There are no entries associated with this registry key.

**User Agent String**
**Registry path**
HKCU\Software\Microsoft\Windows\CurrentVersion\Internet Settings\User Agent\PostPlatform

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key contains the Internet Explorer Maintenance Extension settings specifying the user agent string. The name of the entry used to specify the string is the same as the string itself.

**Ratings**
The following registry entries are located under HKLM\Software\Microsoft\Windows\CurrentVersion\policies\Ratings.

**Password Hint and Encrypted Password**
**Registry path**
HKLM\Software\Microsoft\Windows\CurrentVersion\policies\Ratings

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key contains the settings for Internet Explorer ratings. The Hint entry contains the clue used to help someone remember the Ratings password, and the **Key** entry contains the encrypted Ratings password.

**Rating Policy**
**Registry path**
HKLM\Software\Microsoft\Windows\CurrentVersion\policies\Ratings\PICSRules\.Default\0\PRPolicy\<#>

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

The <#> registry key contains information about the Ratings of a domain or UNC. The registry key is a variable number generated in the order the **Ratings** entry was created. The **PRPolicyAttribute** entry specifies whether the entry is approved or restricted.

**Rating Policy Configuration**
**Registry path**
HKLM\Software\Microsoft\Windows\CurrentVersion\policies\Ratings\PICSRules\.Default\0\PRPolicy\<#>\PRPolicySub\0

**Version**
The registry settings in this section are for Windows 2000 Professional or Windows XP Professional clients, or for Windows Server 2003 without the Internet Explorer Enhanced Security Configuration enabled.

This registry key contains the Ratings configuration of a Domain or UNC. The following entries specify the Ratings configuration:

- **PRBUHost** – Specifies the rating's configured Domain or UNC name.
- **PRBUPort** – Specifies which port is used.
- **PRBUScheme** – Specifies which rating level the domain or UNC is configured to use.
- **PRBUUrl** – Specifies the URL for the specified Ratings Service's Web site.

**Internet Explorer Maintenance Extension Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with the Internet Explorer Maintenance Extension.

**Internet Explorer Maintenance Extension Configuration Settings**

| **Browser User Interface** | **Description** |
|---|---|
| Browser Title (Policy mode only) | This setting customizes the text that appears in the title bar of the Internet Explorer browser. The text is appended to the string "Microsoft Internet Explorer provided by." |
| Custom Logo (Policy mode only) | This setting replaces the static Internet Explorer logo in the upper-right corner of the Internet Explorer window with a custom static logo. It also replaces the animated Internet Explorer logo in the upper-right corner of the Internet Explorer window with a properly formatted custom animated logo. |
| Browser Toolbar Customizations | This setting customizes the background and buttons of the Internet Explorer toolbar. |
| **Connection** | **Description** |
| Connection Settings | These setting allow importing connection settings from the Internet Control Panel Connections tab of an already configured computer. They restrict how users can interact with connection settings through the System Policies and Restrictions page. It is not necessary to import current settings in order to set theses restrictions. They are also used to remove old dial-up connection settings from users' computers. |
| Automatic Browser Configuration | Automatic Configuration (auto-config) is used to update a user's computer after deployment by specifying a URL to an .ins file, an auto-proxy URL, or both. You can set the interval in minutes for when auto-config will happen. If the interval value is left blank, or at zero, auto-config will only happen when the browser has been started and navigates to a page. |
| Proxy Settings | These settings specify to which proxy servers, if any, user's connect. |
| User Agent String (Policy mode only) | The user agent string is what the browser sends to visited servers to identify itself. It is often used to keep Internet traffic statistics. You can enter custom text that will be appended to the default Internet Explorer string. The default string is different for each platform. |
| **URLs** | **Description** |
| Favorites and Links | You can customize Favorites and Links by specifying the URLs. You can also specify the order of each folder, add an icon for each Favorite and Link, and import an existing folder structure. |
| Important URLs | You can specify a custom home page, search bar URL, and online support page. |
| **Security** | **Description** |
| Security Zones and Content Ratings | You can customize the settings of each security zone as well as customizing the privacy settings. Content ratings let you prevent users from viewing sites with risky content. |
| Authenticode Settings | Authenticode enables you to designate software publishers as trustworthy. You can prevent users from adding new trusted publishers while using the browser. Enabling this lockdown does not prevent access to the Content control panel, but doing so is possible using the Administrative Templates Extension of Group Policy. |
| **Programs** | **Description** |
| Programs | You can import the current default programs settings. The programs selected specify which program Windows automatically uses for each Internet service. |
| **Advanced** | **Description** |

| | |
|---|---|
| Corporate Settings (Preference mode only) | These setting specify the location of a file containing settings used to make the browser work best for your corporation. These settings can be useful in reducing the cost of supporting applications in your corporation. Advanced features, as well as details of other features, can all be configured through these options. |
| Internet Settings (Preference mode only) | These settings specify the location of a file used to preset defaults for Internet Explorer settings which are not set through the IEAK Wizard. Most of these settings apply to defaults in the Internet Control Panel. |

- For more information about Group Policy settings, see the Group Policy Settings Reference in the Tools and Settings Collection.

# Remote Installation Services Extension Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft Windows 2000 Server and Windows Server 2003 use Group Policy settings to provide directory-based desktop configuration management. These Group Policy settings are stored in a Group Policy object (GPO). You can create and manage GPOs by using the Group Policy Object Editor.

General classes of Group Policy settings are implemented as extensions to the operating system, and can exist as two types of extensions:

- **Server-side extension (SSE).** A Microsoft Management Console (MMC) snap-in that is used for administration and configuration.
- **Client-side extension (CSE).** An extension that runs on the client computer and interprets and applies the MMC-type settings to the client computer. The client computer is also known as the target computer.

The GPO settings are configured through the server-side extension, and are applied to individual computers and users by the Group Policy engine and the client-side extension (CSE). The Group Policy engine is the framework used to manage client side-extensions.

Remote Installation Services (RIS) is different from most other Group Policy extensions. RIS has no CSE or dynamic-link library (DLL) providing a CSE because RIS is used by the client before the client has an operating system installed.

# What Is Remote Installation Services Extension?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Remote Installation Services Extension?**

**In this section**

- Remote Installation Services Extension Overview
- Remote Installation Services Extension Core Scenarios
- Remote Installation Services Extension Dependencies
- Related Information

Remote Installation Services (RIS), originally introduced as an optional component with Windows 2000 Server, is an optional component of Windows Server 2003 family. RIS enables administrators or users to remotely install a copy of the Windows Server 2003, Windows XP Professional, or Windows 2000 operating system. Administrators use Remote Installation Services Extension to specify which options are presented to users by the Client Installation Wizard.

**Remote Installation Services Extension Overview**

Administrators who install multiple client operating systems on “bare-metal” computers—computers that do not have an operating system—one at a time from the installation CD, can spend a lot of time at each computer. This takes administrators away from their other responsibilities. Customizing and configuring each newly installed operating system to meet organization needs is susceptible to errors and takes even more time. Having an inexperienced end user install the operating system from the CD can be frustrating for the end user, result in installation errors, and increase the number of technical support service calls.

With Windows Server 2003, Microsoft provides two features to help administrators deploy Windows clients and servers over a network. These two features are RIS and Automated Deployment Services (ADS). Administrators can use ADS for deploying server farms. For more information about ADS, see AutomatedDeploymentServicesSupportResources under ManagementServices on Windows Server 2003 Support Center.

You can use RIS to:

Provide an operating system to users on demand.

Provide an operating system image that includes specific settings and applications.

Create automated installation images of products in the Windows Server 2003 family, Windows XP, and Windows 2000.

You can also combine RIS with IntelliMirror features such as user documents and settings, Software Installation, and Group Policy. This combination can improve the efficiency of computer management in your organization, and reduce the number of technical support service calls.

The following figure shows the Remote Installation Services node of the Group Policy Object Editor, which is used to configure RIS policy settings. This figure shows the RIS server-side extension user interface, provided by rigpsnap.dll. There is no RIS client-side extension.

**Group Policy Object Editor**

The settings you make in the RIS SSE determine which of the four options the user sees in the Client Installation Wizard of the target computer, as seen in the following figure.

**Client Installation Wizard**

This figure shows each of the options that are presented to the user on the target computer during a remote installation of an operating system. Because all four settings are enabled in the SSE, all four settings appear in the wizard. Maintenance and Troubleshooting in the wizard corresponds to Tools in the SSE.

**Remote Installation Services Extension Core Scenarios**

The core scenario for Remote Installation Services is operating system installation with no involvement of the administrator during client installation. By using the Remote Installation Services Extension node in the Group Policy Object Editor to configure RIS policy settings, the administrator can predetermine the options presented to users during installation. This saves the administrator time, and ensures consistent deployment of client computers across the organization.

**Remote Installation Services Extension Dependencies**
You can edit Remote Installation Group Policy settings on any computer that has the Group Policy Object Editor with the Remote Installation Services node (rigpsnap.dll). However, note the following about Remote Installation Services:

The Microsoft version of Active Directory is required.

The client computer using RIS to install an operating system must have a network card that:

- Supports Pre-boot Execution Environment (PXE), or
- Is supported by the RIS remote boot floppy disk.

Windows XP Professional must have Windows Server 2003 Administration Tools Pack installed to show RIS settings in Group Policy Object Editor.

RIS Help is not available by default in the Group Policy Management Console (GPMC) running on Windows XP Professional. Install Windows Help from the Windows Server 2003 CD onto the computer running Windows XP Professional.

RIS is not included in the Windows Server 2003, Web Edition operating system.

RIS installation image files must be located on a Windows NT File System (NTFS) partition not containing the system or boot files.

**Related Information**
The following contains additional information that is relevant to this section.

# How Remote Installation Services Extension Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Remote Installation Services Extension Works**

**In this section**

- Remote Installation Services Extension Architecture
- Remote Installation Services Extension Protocols
- Remote Installation Services Extension Physical Structure
- Remote Installation Services Extension Processes and Interactions
- Network Ports Used by Remote Installation Services Extension

Administrators configure Remote Installation Services Extension using the Remote Installation Services (RIS) server-side extension (SSE), accessed from the Group Policy Object Editor. There is no RIS client-side extension (CSE). This section describes how RIS Policy is configured in the SSE, and how those settings affect Remote Installation Services.

**Remote Installation Services Extension Architecture**

The following figure shows the high-level architecture of Remote Installation Services.

**Remote Installation Services Extension Architecture**

In the figure, RIS SSE is the Remote Installation Services (RIS) server-side extension (SSE). This is the Remote Installation Services node in the Group Policy Object Editor for the GPO.

Components significant to RIS are summarized in the following table.

**Remote Installation Services Extension Architecture Components**

| Component | Description |
|---|---|

| | |
|---|---|
| Group Policy Object Editor | The Group Policy Object Editor is an MMC server-side extension packaged as the dynamic-link library (DLL) named Gpedit.dll. Each of the nodes in the Group Policy Object Editor, including the Remote Installation Services node, is itself an extension. |
| Remote Installation Services (RIS) server-side extension (SSE) | The RIS SSE is a Group Policy Object Editor extension, packaged as the DLL named rigpsnap.dll. Administrators use the RIS extension to configure the Remote operating system Installation options presented to target users. |
| Rigpsnap.dll | Rigpsnap.dll is the RIS SSE component. |
| Lightweight Directory Access Protocol (LDAP) | LDAP is a communication protocol used to query Active Directory directory services. |
| Server Message Block (SMB) | SMB is a communication protocol used for file access between the RIS extension and Active Directory. |
| Group Policy Container | A Group Policy Container is a location in Active Directory where GPOs and their properties are stored. |
| Group Policy Template (GPT) | The GPT is the part of the GPO that consists of the domain controller file system, and in which most Group Policy settings are stored. |
| Sysvol | The Sysvol folder contains the subset of folders shared on each domain controller. These folders store *file-system* domain information, as compared to *registry* domain information. |
| Pre-Boot Execution Environment (PXE) | PXE is a combination of standardized protocols and services that enables remote startup of computers over a network. Remote Installation Services uses PXE. |
| Boot Information Negotiation Layer (BINL) service | BINL is a service that runs on the RIS Server. BINL handles client requests, authenticates clients with Active Directory, and confirms that correct policy and settings are applied to the client during remote installation. |
| Trivial File Transfer Protocol (TFTP) service (daemon) | TFTP is a RIS Server service that downloads the OSChooser, Client Installation Wizard (CIW) files, and other boot files during the RIS process. |
| Client Installation Wizard (CIW) | CIW is the graphical user interface that guides the user of a client computer through the remote installation of an operating system. CIW consists of screens and a program called OSChooser that displays the screens. |
| Single Instance Store (SIS) service | SIS is a pair of components used to save disk and main memory file cache space when two or more files share content. Other attributes of the files might be different, such as path, owner, access control lists, and so on. Writes to one file don't necessarily affect the other files. SIS saves space by providing links that are semantically identical to independent files. |
| SIS filter | The SIS filter is one of the SIS components. The SIS filter is a kernel-level file system filter driver that implements links for identical files. |
| SIS Groveler service | The SIS groveler service is one of the SIS components that detects identical files and reports them to the SIS filter for link creation. |
| DHCP | Dynamic Host Configuration Protocol is the communication protocol used between the client and the RIS server (and the DHCP server). RIS uses DHCP, which follows the PXE architecture, to bootstrap the client computer. |
| Bootp | Bootp is the RIS Server. |

**Remote Installation Services Extension Protocols**

Protocols used by Remote Installation Services are shown in the previous RIS Architecture figure, and are described in the following table.

**Remote Installation Services Protocols**

| Protocols | Description |
|---|---|
| Trivial File Transfer Protocol (TFTP) | TFTP is the service that hosts file download from the RIS Server to the client during remote operating system installation. |
| Lightweight Directory Access Protocol (LDAP) | LDAP is a communication protocol used by the RIS SSE on the Administrator computer to query Active Directory directory services. |
| Server Message Block (SMB) | SMB is a protocol used by the Administrative computer to access the Sysvol on the Domain Controller. SMB is the primary file and print sharing protocol. |
| NTLM v1 | Windows 2000 uses NTLM v1 for encryption. |
| NTLM v2 | Windows Server 2003 uses NTLM v2 for encryption. |
| DHCP | The client uses Dynamic Host Configuration Protocol (DHCP) to send out a DHCP discover asking for an IP address and a PXE boot server. The RIS Server and DHCP server respond using DHCP. |

**Remote Installation Services Extension Physical Structure**
The following figure shows the RIS file structure.

**RIS Policy Files**

The following table summarizes the files used by Remote Installation Services and the RIS extension.

**Remote Installation Services Policy Physical Structure Components**

| Component | Description |
|---|---|

| | |
|---|---|
| Setup Installation Files (.sif) | The RIS Server uses Setup Installation Files to communicate the installation options to the RIS client. These files have the .sif extension. |
| .osc files | The RISetup.exe tool, used to setup the RIS Server, installs a default set of Client Installation Wizard files. These files have an .osc extension, and are stored in the \OSChooser\English folder on the RIS Server. These files are text files formatted in OSCML, and can be modified. |
| Client Installation Wizard (CIW) files | CIW files are .osc files that guide the user through a remote operating system installation on the client. |
| Winnt.sif | Winnt.sif is a Setup Installation File downloaded from the RIS Server to the client and used to detect the client hardware abstraction layer (HAL) type. |
| Ntldr | Ntldr is the executable that starts the CIW. Ntldr is on the client, and is the same as the oschoice.exe file on the RIS Server, copied and saved as Ntldr on the client. |
| Startrom.com file | Startrom.com is a file located in the \\RIS_server_name\REMINST\oschooser\i386 folder on the RIS server. Startrom.com is the first file downloaded by Ntldr to start the client boot process. |
| Welcome.osc file | The Welcome.osc file provides the first Client Installation Wizard screen presented to the client during the Client Installation Wizard. |
| Choice.osc file | The Choice.osc file stores all possible remote operating system installation choices that can be presented to the client user. |
| Oscfilter.ini | The Oscfilter.ini file stores settings made in the RIS SSE, and it determines which of the possible operating system installation options in Choice.osc, are presented to the client. |
| Oschoice.osc | The Oschoice.osc file stores the remote operating system installation list (if more than one) presented to the client user as determined by the oscfilter.ini file and choice.osc file combination. |

**Remote Installation Services Extension Processes and Interactions**
A high-level overview of the remote installation of an operating system follows.

**How a Remote Operating System Installation Works**
The RIS Server and the RIS Client both must be connected to the wired network. Wireless connection to the network is not supported.

When the client user presses the F12 key, the client's BIOS initiates a PXE boot by sending a DHCP discover and implementing PXE option tags. The BinL service on the RIS Server, which monitors port 4011, receives the DHCP discover from the client. The server downloads the startrom.com file image to the client using TFTP. The server loads the network driver on the client using the Uniform Network Device Interface (UNDI). The client transmits the client's GUID/MAC to the server, which records the GUID/MAC. The server sends the Ntldr (oschoice.exe saved as Ntldr on the client) to the client using TFTP, and the client starts Ntldr/OSChoice.exe.

The server downloads the winnt.sif file to the client to detect the hardware abstraction layer (HAL) type. The client and server negotiate an OSC connection on port 401. Ntldr presents Client Installation Wizard (CIW) screens for user entry. Settings in Active Directory, the Registry, and files on the RIS Server determine the content of these screens.

One of the CIW screens is the Installation Choices screen. The RIS server queries the Active Directory Sysvol to determine the remote operating system installation options to display in this screen. The Active Directory Sysvol stores operating system choice settings in the oscfilter.ini file. You can determine the settings in the oscfilter.ini file using the Remote Installation Services node in the GPO editor. The Remote Installation Services node provides an interface for you to control the remote operating system installation options displayed on this one screen in the CIW. You can manually edit the oscfilter.ini file in Notepad to obtain the same result.

### Note

- You can also control the client installation process by manually editing the .osc and .sif files on the RIS server. For more information, see the Remote Installation Services help, which is available from the Windows Server 2003 family Group Policy Object Editor.

Depending on which of the remote operating system installation choices the client user makes, OSChoice receives the name of the next application to start, and sets the fully qualified path to the RIS server. The name of the loader is set, and a soft TFTP restart occurs. OSChoice passes the TFTP restart block, which is a local packet of information, to the setup loader. The restart block is an in-memory location for X86 computers and is passed using launch arguments in EFI architecture.

**RIS SSE Impact on Remote O/S Installation**

The settings you make in the RIS SSE are saved in the oscfilter.ini file, which is located in the \WINDOWS\SYSVOL\sysvol\<domain>\Policies<gpo_guid>\User\Microsoft\RemoteInstall folder on the domain controller. The oscfilter.ini file has the following structure:

```
[Choice]
OSAUTO=0
CUSTOM=1
RESTART=0
TOOLS=0
```

Your three options for each of the four settings in the RIS SSE, and their impact on the settings in the oscfilter.ini file are:

- **Not Configured.** This removes the choice and value from the oscfilter.ini file.
- **Enabled.** This sets the value for the choice to 1.
- **Disabled.** This sets the value for the choice to 0.

The choice.osc file on the RIS server is not edited by your settings in the RIS SSE; it remains unchanged. Only the oscfilter.ini file is edited. The Choice.osc file is formatted in OSChooser Markup Language (OSCML) which is HTML 2.0. You can manually edit this file to customize the login options presented to the client user. The following code shows the default Choice.osc file.

```
<OSCML>

**Network Ports Used by Remote Installation Services Extension**

The following table lists port assignments for Remote Installation Services extension.

**Port Assignments for Remote Installation Services**

| Service Name | UDP | TCP |
|---|---|---|
| DHCP | n/a | 67, 68 |
| RPC | Dynamically assigned | Dynamically assigned |
| LDAP | n/a | 398 |
| SMB | n/a | 445 |
| COM | Dynamically assigned | Dynamically assigned |
| DCOM | Dynamically assigned | Dynamically assigned |

# Remote Installation Services Extension Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote Installation Services Extension Tools and Settings**

**In this section**

- Remote Installation Services Extension Tools
- Remote Installation Services Extension Registry Entries
- Remote Installation Services Extension Group Policy Settings
- Related Information

This section includes Tools and Settings associated with Remote Installation Services Extension.

**Remote Installation Services Extension Tools**

The following tools are associated with Remote Installation Services.

**DSA.msc: Active Directory Users and Computers**

**Category**

DSA.msc is the Active Directory Users and Computers snap-in used by Administrators to manage Active Directory in Windows 2000 and Windows Server 2003 domains.

**Version compatibility**

DSA.msc runs on Windows 2000 Server, Windows XP SP1 with the Windows Server 2003 Administration Tools Pack installed, and Windows Server 2003.

DSA.msc ships with Windows 2000 and Windows Server 2003.

**GPMC.msc: Group Policy Management Console**

**Category**

GPMC.msc is a snap-in used by Administrators to manage Group Policy in Windows 2000 and Windows Server 2003 domains. Remote Installation Services policy can be configured from GPMC.

**Version compatibility**

GPMC.msc runs on Windows XP SP1, and Windows Server 2003.

For GPMC download information, see the Group Policy Management Console link on the Web Resources page.

**Remote Installation Services Extension Registry Entries**

The following registry entries are associated with Remote Installation Services Extension.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. You should not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**BINLSVC**

**Registry path**

HKEY_LOCAL_MACHINE \System\CurrentControlSet\Services\

**Version**

Windows Server 2003.

This key and its sub-keys store Remote Installation Service settings for the BinL service used by Remote Installation Services (RIS).

For more information about this registry entry, see the Registry Reference for Windows Server 2003.

**Groveler**
**Registry path**
HKEY_LOCAL_MACHINE \SYSTEM\CurrentControlSet\Service\

**Version**
Windows Server 2003.

This key and its sub-keys store Remote Installation Service settings for the Groveler service used by RIS.

For more information about this registry entry, see the Registry Reference for Windows Server 2003.

**SIS**
**Registry path**
HKEY_LOCAL_MACHINE \SYSTEM\CurrentControlSet\Service\

Version

**Windows Server 2003.**
This key and its sub-keys store Remote Installation Service settings for the SIS service used by RIS.

For more information about this registry entry, see the Registry Reference for Windows Server 2003.

**TFTPD**
**Registry path**
HKEY_LOCAL_MACHINE \SYSTEM\CurrentControlSet\Service\

**Version**
Windows Server 2003.

This key and its sub-keys store Remote Installation Service settings for the TFTPD service used by RIS.

For more information about this registry entry, see the Registry Reference for Windows Server 2003.

**Remote Installation Services Extension Group Policy Settings**
You can use the following four general settings to configure Remote Installation Services options:

- Group Policy Settings
    - Remote Installation Services node
    - Administrative Templates
- RIS Server Authorization (DHCP MMC)
- Authorized RIS Server Properties (ADUC MMC)
- Discretionary Access Control Lists (DACLs)

**Group Policy Settings**
This section summarizes the two types of Group Policy settings.

**Remote Installation Services Node Settings**
The following tables list and describe Group Policy settings that are associated with Remote Installation Services Extension.

### Remote Installation Services Node Policy Settings

| Group Policy Setting | Description |
|---|---|

| | |
|---|---|
| Automatic Setup | Automatic Setup is one of the four installation options. When Automatic Setup is the only installation choice, users on the client are not offered installation choices. Automatic Setup settings are:<br>• Not Configured (Default)<br>• Enabled<br>• Disabled |
| Custom Setup | Custom Setup is one of the four installation options, with settings of:<br>• Not Configured (Default)<br>• Enabled<br>• Disabled |
| Restart Setup | Restart Setup is one of the four installation options, with settings of:<br>• Not Configured (Default)<br>• Enabled<br>• Disabled |
| Tools (Maintenance and Troubleshooting) | Tools is one of the four installation options, with settings of:<br>• Not Configured (Default)<br>• Enabled<br>• Disabled |

**Administrative Templates Settings**

RIS template settings are found at the following node in Group Policy Object Editor:

- **User Configuration\Administrative Templates\Windows Components\MMC\Restricted/Permitted snap-ins\Group Policy\Group Policy snap-in extensions**

The setting is **Remote Installation Services** and the setting options are:

- Not Configured (Default)
- Enabled
- Disabled

**RIS Server Authorization (DHCP MMC) Settings**

RIS settings are also available from the Dynamic Host Configuration Protocol MMC, and the setting is **RIS Authorization**. You use this option to specify which RIS Servers are allowed to run on your network. RIS Servers are disabled by default, and you must specifically authorize a RIS Server.

**Authorized RIS Server Properties (ADUC MMC) Settings**

Once RIS servers are authorized in the DHCP MMC, the RIS server has settings accessible from the Active Directory Users and Computers (ADUC) MMC. These settings are located on tabs in the **Properties** dialog box for the RIS Server. The RIS server also has a New Answer File wizard.

The following table summarizes the Remote Install Tab settings.

**Remote Install Tab Settings**

| Setting | Description |
|---|---|
| Respond to client computers requesting service | You use this option to pre-stage a client. You pre-stage a client by adding the computer name to Active Directory, and then adding that name to this setting list. This setting is disabled by default. |
| Do not respond to unknown client computers | You use this option to prevent/allow clients that are not pre-staged to install a remote operating system. This setting is disabled by default. |

The next table shows the settings for the **New Clients Tab**.

**New Clients Tab**

| Setting | Description |
|---|---|
| Generate client computer names using | Options for this setting are:<br>• First initial, Last name<br>• Last name, First initial<br>• First name, Last initial<br>• Last initial, First name<br>• User name (default)<br>• NP plus MAC<br>• Custom |
| Where client account is created | Option button choices are:<br>• Default directory service location (Computers)<br>• Same location as that of the user setting up the client computer<br>• The following directory service location (Browse) |

The next table shows the settings for the **Images Tab**.

**Images Tab**

| Setting | Description |
|---|---|

| | |
|---|---|
| Images | This option lists installation images installed on the RIS Server, with no images listed as the default. The following actions are available for this option:<br>• Add (starts Add Wizard)<br>• Remove<br>• Properties<br>• Refresh |

The next table shows the settings for the **Tools Tab**.

**Tools Tab**

| Setting | Description |
|---|---|
| Tools | This option provides maintenance and troubleshooting tools that are installed on the RIS Server, with no tools listed as the default. The following actions are available for this option:<br>• Remove<br>• Properties<br>• Refresh |

The next table shows the settings for the **Security Tab**.

**Security Tab**

| Setting | Description |
|---|---|
| Group or user names | You use this option to add or remove users and groups to the list. |
| Permissions for *<user or group selected>* | You use this option to allow or deny the permission for the selected user or group, for the following permissions:<br>• Full Control<br>• Read<br>• Write<br>• Create All Child Objects<br>• Delete All Child Objects<br>• Special Permissions<br>• Advanced button |

The next table shows the settings for the **New Answer File Wizard**.

**New Answer File Wizard**

| Setting | Description |
|---|---|

| | |
|---|---|
| Associate a new answer file to an existing image (option button) | When you select this option and click the Next button, your options are:<br>• Windows image sample files<br>• Another remote installation server<br>• An alternate location |
| Add a new installation image (option button) | When you select this option and click the Next button, the Add Installation Image Wizard displays, which you can use to set:<br>• Path to image<br>• Folder name<br>• Friendly Description<br>• Help Text<br>• CIW screen options |

**Discretionary Access Control List Setting**

The following table shows the Discretionary Access Control List setting for the RIS server.

**Discretionary Access Control List (DACL) Setting**

| Setting | Description |
|---|---|
| OS image availability to users in CIW | Available to all users by default. |

For more information about Group Policy settings, see the Group Policy Settings Reference for Windows Server 2003.

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Related Information**

The following resources contain additional information that is relevant to this section.

# Group Policy Administrative Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group Policy Administrative Tools**

There are three primary tools used to administer Group Policy: Microsoft Group Policy Management Console (GPMC), Group Policy Object Editor, and Resultant Set of Policy (RSoP) snap-in. Each of these tools is a Microsoft Management Console (MMC). Administrators use GPMC for the bulk of Group Policy management tasks. Group Policy Object Editor is for editing Group Policy objects. Although administrators can still use the RSoP snap-in for reporting and planning the effects of Group Policy, much of its functionality has been subsumed into GPMC.

**Group Policy Administrative Tools Architecture**

The diagram below illustrates the relationship between the domain controller, client, and the three primary tools used to administer Group Policy.

**Group Policy Administrative Tools Architectural Diagram**

**Components of Group Policy Administrative Tools Architectural Diagram**

| Component | Description |
|---|---|
| Group Policy Object Editor | The Group Policy Object Editor is used to edit GPOs. It was previously known as the Group Policy snap-in, Group Policy Editor, or Gpedit. A notable feature of the Group Policy Object Editor is its extensibility. Developers can extend the server-side snap-ins that ship with Group Policy Object Editor or they can develop completely new extensions for implementing Group Policy.<br><br>The Group Policy Object Editor is capable of read and write access to Active Directory, Sysvol, and the Local GPO. |
| Server-Side Snap-Ins | The nodes of the Group Policy Object Editor are MMC snap-ins. These snap-ins include Administrative Templates, Scripts, Security Settings, Software Installation, Folder Redirection, Remote Installation Services, and Internet Explorer Maintenance. Snap-ins may in turn be extended. For example, the Security Settings snap-in includes several extension snap-ins. Developers can also create their own MMC extension snap-ins to the Group Policy Object Editor to provide additional policy settings. Extensions are capable of read and write access to the Local GPO. |

| | |
|---|---|
| Group Policy Management Console (GPMC) | GPMC makes Group Policy much easier to manage by providing a view of GPOs, sites, domains, and organizational units (OU) across an enterprise. GPMC can be used to manage either Windows Server 2003 or Windows 2000 domains.<br><br>GPMC simplifies the management of Group Policy by providing a single place for managing core aspects of Group Policy, such as scoping, delegating, filtering, and manipulating inheritance of GPOs. You can also back up GPOs to the file system as well as restore GPOs from backups. GPMC includes features that enable an administrator to predict how GPOs are going to affect the network as well as to determine how GPOs have actually changed settings on any particular computer or user.<br><br>GPMC is capable of read and write access to the Sysvol using the SMB protocol. It is also capable of read and write access to Active Directory via the LDAP protocol. In addition, GPMC is capable of read access to the event log and RSoP infrastructure. |
| Resultant Set of Policy (RSoP) snap-in | The Resultant Set of Policy snap-in is an MMC used to determine which policy settings are in effect for a given User or Computer, or to predict the effect of applied policy.<br><br>The snap-in itself is contained within the same binary as the Group Policy Object Editor snap-in (gpedit.dll). The user interface is mostly a read-only view of the same information available in the Group Policy Object Editor. However there is one important difference: While the Group Policy Object Editor can show only a single GPO setting at a time, the RSoP snap-in shows the cumulative effect of many GPOs.<br><br>For RsoP functionality it is recommended to use GPMC, which includes its own integrated RsoP features.<br><br>The RSoP snap-in is capable of read access to the Active Directory, Sysvol, Event Log, RSoP infrastructure, and Local GPO. Although the RSoP snap-in is capable of read only access to the Active Directory and Sysvol, most of the work of predicting or reporting Group Policy is done using RPC/COM communication with the RSoP provider, either on the client or the domain controller. |
| Domain Controller (Server) | In an Active Directory forest, the domain controller is a server that contains a writable copy of the Active Directory database, participates in Active Directory replication, and controls access to network resources. GPOs are stored in two parts of domain controllers: The Active Directory database and the Sysvol share. |
| Client | In an Active Directory forest, settings from GPOs are applied to clients. GPMC and the RSoP snap-in query the client to determine how policy has been applied to a particular user or computer. |
| Active Directory | Active Directory, the Windows-based directory service, stores information about objects on a network and makes this information available to users and network administrators. Administrators link GPOs to Active Directory containers such as sites, domains, and OUs that include user and computer objects. In this way, policy settings can be targeted to users and computers throughout the organization. |
| Sysvol | Sysvol is a shared directory that stores the server copy of the domain's public files, which are replicated among all domain controllers in the domain. The Sysvol contains the largest part of a GPO: the Group Policy template (GPT), which includes Administrative Template-based policy settings, security settings, and script files. File Replication Service (FRS) replicates this information throughout the network. |
| RsoP infrastructure | All Group Policy processing information is collected and stored in a Common Information Model Object Management (CIMOM) database on the local computer. This information, such as the list of GPOs that have been processed, as well as content and logging of processing details for each GPO, can then be accessed by tools using Windows Management Instrumentation (WMI).<br><br>With Group Policy Results in GPMC, or logging mode for the RSoP snap-in, the RSoP service is used to query the CIMOM database on the target computer; it receives information about the policies that were applied and displays the resulting information in GPMC or the RSoP snap-in.<br><br>With Group Policy Modeling in GPMC, or planning mode for the RSoP snap-in, the RSoP service simulates the application of policy using the Group Policy Directory Access Service (GPDAS) on a Domain Controller. GPDAS simulates the application of GPOs and passes them to virtual client-side extensions on the Domain Controller. The results of this simulation are stored in a local CIMOM database on the domain controller before the information is passed back and displayed in either GPMC or the RSoP snap-in. |

**Group Policy Administrative Tools Components**

The following is a list of Group Policy administrative tools.

**Group Policy Management Console**
In the past, administrators have been required to use several Microsoft tools to manage Group Policy, such as the Active Directory Users and Computers, Active Directory Sites and Services, Group Policy Object Editor and Resultant Set of Policy snap-ins. With the introduction of Group Policy Management Console (GPMC), most administrative tasks have been integrated into a single, unified console that also offers several new capabilities.

**Group Policy Object Editor**
Group Policy Object Editor is an MMC snap-in used to edit the policy settings in Group Policy objects (GPOs). Like all MMC snap-ins, its functionality can be customized or extended by means of MMC snap-in extensions. When you use Group Policy Object Editor, various extensions are included by default, including Administrative Templates, Scripts, Security Settings, Software Installation, Folder Redirection, Remote Installation Services, and Internet Explorer Maintenance. Snap-ins may in turn be extended. For example, the Security Settings snap-in includes several extension snap-ins. Developers can also create their own MMC extension snap-ins to the Group Policy Object Editor to provide additional policy settings.

**Resultant Set of Policy Snap-in**
Resultant Set of Policy (RSoP) snap-in is an MMC used to predict the effect of GPOs on the network as a whole, or to determine the effect Group Policy has had on a specific user or computer. Although administrators can use the RSoP snap-in, much of its functionality has been subsumed into GPMC.

**Group Policy Administrative Tools Deployment Scenarios**
The following is a list of common scenarios supported by each of the Group Policy Administrative Tools.

**Group Policy Management Console**
An administrator uses GPMC to manage Group Policy in an Active Directory environment. Although the majority of computers on the network might be running Windows 2000 server or Windows 2000 professional, the administrator might download and install GPMC on a machine running Windows XP SP1 or later. GPMC requires Windows XP or later.

GPMC offers the administrator a persistent view of the Group Policy environment on the network, including icons that represent GPOs, GPO links, sites, domains, and organizational units (OU) in the selected forest. With GPMC, an administrator can do any of the administrative tasks previously only available from the Group Policy tab of the Active Directory administrative tools.

GPMC can also be used to generate RSoP data that either predicts the cumulative effect of GPOs on the network, or reports the cumulative effect of GPOs on a particular user or computer. In addition, the administrator can use GPMC to perform GPO operations never possible before, like backing up and restoring a GPO, copying a GPO, or even migrating a GPO to another forest. Reading or generating HTML or XML reports of GPO settings is also possible.

**Group Policy Object Editor**
An administrator uses Group Policy Object Editor to manipulate settings in a GPO. Typically an administrator accesses Group Policy Object Editor by electing to edit a GPO from within GPMC. The Group Policy Object Editor opens, allowing the administrator to change settings for that GPO. If the administrator had two GPOs linked to an OU and wanted to manage settings in both, he would have to open them one at a time. This is because Group Policy Object Editor can only display settings for GPOs one at a time. To see how settings for multiple GPOs might affect an OU, the administrator would use a different tool — either GPMC or the RSoP snap-in.

**Resultant Set of Policy snap-in**
An administrator uses Resultant Set of Policy snap-in to predict the cumulative effect of GPOs on the network, or report the cumulative effect of GPOs on a particular user or computer. With the advent of GPMC, the administrator can generate reports with most of the information formerly only available through the RSoP snap-in. The RSoP snap-in does provide some information that GPMC does not. For example, when multiple GPOs attempt to set the same Group Policy setting differently, both GPMC and RSoP snap-in report how the setting is ultimately set and which GPO is responsible for the setting, but only RSoP snap-in can report all the GPO(s) that attempted and failed to manipulate the setting.

# Group Policy Management Console Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group Policy Management Console Technical Reference**
In the past, administrators have been required to use several Microsoft tools to manage Group Policy, such as the Active Directory Users and Computers, Active Directory Sites and Services, Group Policy Object Editor and Resultant Set of Policy snap-ins. With the introduction of Group Policy Management Console (GPMC), most administrative tasks have been integrated into a single, unified console that also offers several new capabilities.

# What Is Group Policy Management Console?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Group Policy Management Console?**

**In this section**

- Group Policy Management Console Core Scenarios
- Group Policy Management Console Dependencies
- Related Topics

The Group Policy Management Console (GPMC) is a new and comprehensive administrative tool for Group Policy management.

Prior to GPMC, administrators used property pages in various Active Directory administrative tools to manage Group Policy. For example, an administrator who wanted to implement policy for users might open the Active Directory Users and Computers snap-in, find an appropriate Organizational Unit (OU) and open its property page to access the Group Policy tab. On the Group Policy tab, the administrator might do any of a dozen or so administrative tasks, like creating Group Policy object links or manipulating their order to achieve the desired results. Whatever the tasks, when the administrator leaves the Group Policy tab, access to a visual representation of Group Policy ends and a view that focuses on Active Directory's user and computer objects appears.

GPMC integrates the existing Group Policy functionality of the property pages on the Active Directory administrative tools into a single, unified console dedicated to Group Policy management tasks; GPMC also expands management capabilities with new features. Administrators still use Active Directory administrative tools to manage Active Directory, but GPMC replaces the Group Policy management functionality of those tools with its own.

**Group Policy Management Console Core Scenarios**

There are many core scenarios for GPMC. Administrators use GPMC to perform all Group Policy management tasks, with the exception of configuring individual policy settings in Group Policy Objects themselves, which is done with Group Policy Object Editor. The scenarios below describe how an administrator uses GPMC to manage Group Policy.

**Creating and Editing GPOs**

Administrators use GPMC to create a GPO with no initial settings. An administrator can also create a GPO and linking it to an Active Directory container at the same time. To configure individual settings within a GPO, an administrator edits the GPO from within GPMC and Group Policy Object Editor appears with the GPO loaded. An administrator can use either GPMC or Group Policy Object Editor to disable or enable computer, user, or both computer and user nodes within a GPO.

**Scoping GPOs**

An administrator can use GPMC to link GPOs to sites, domains, or OUs in the Active Directory. Administrators must link GPOs to apply settings to users and computers in Active Directory Containers. Linking GPOs is the primary mechanism by which administrators apply Group Policy settings.

In addition to linking, an administrator can manipulate permissions on GPOs to manage how Group Policy applies. Prior to GPMC, an administrator would have to manually manipulate access control entries (ACE) to modify the scope of the GPO. For example, the administrator might remove **Read** and **Apply Group Policy** from the Authenticated Users group for GPO1. This effectively disables GPO1, since users in the Authenticated Users group require both **Read** and **Apply Group Policy** permissions to process Group Policy. To apply the settings in GPO1 to select network users or computers, the administrator would add a new security principal (typically a security group containing the target users or computers) to the ACL on the GPO and set **Read** and **Apply Group Policy** permissions. This is known as security filtering.

With GPMC, security filtering has been simplified. The administrator adds the security principal to the GPO, and GPMC automatically sets the **Read** and **Apply Group Policy** permissions.

Administrators can also use GPMC to link WMI Filters to GPOs. WMI Filters allow an administrator to dynamically determine the scope of GPOs based on attributes (available through WMI) of the target computer. A WMI filter consists of one or more queries that are evaluated to be either true or false against the WMI repository of the target computer. The WMI filter is a separate object from the GPO in the directory.

**Manipulating Inheritance**
Group Policy can be applied to users and computers at the site, domain, or OU level. GPOs from parent containers are inherited by default. When multiple GPOs apply to these users and computers, the settings in the GPOs are aggregated. For most policy settings, the final value of a given policy setting is set only by the highest precedent GPO that contains that setting. (However, the final value for a few settings will actually be the combination of values across GPOs.)

Group Policy determines precedence of GPOs by the order of processing for the GPOs. GPOs processed last have highest precedence. GPOs follow the SDOU rule for processing; site first, then domain, and then followed by OU, including nested OUs. A nested OU is one that has another OU as its parent. In the case of nested OUs, GPOs associated with parent OUs are processed prior to GPOs associated with child OUs. In this processing order, sites are applied first but have the least precedence. OUs are processed last and have the highest precedence.

When a container has multiple GPO links, administrators can use GPMC to manipulate the link order for every container. GPMC assigns each link a Link Order number; the GPO link with Link Order of 1 has highest precedence on that container.

Administrators can use GPMC to Block Inheritance. This is the ability to prevent an OU or domain from inheriting GPOs from any of its parent container. Note that Enforced GPO links (see below) will always be inherited.

Administrators can use GPMC to set GPO links to Enforced (previously known as No Override). This is the ability to specify that a GPO should take precedence over any GPOs that are linked to child containers. Enforcing a GPO link works by moving that GPO to the end of the processing order.

An administrator can also use GPMC to enable or disable a GPO link. If an administrator enables a GPO link, Group Policy processes the linked GPO. If the link is not enabled, Group Policy does not process the linked GPO.

**GPO Operations**
GPO operations refer to the ability to backup (export), restore, import, and copy GPOs. Backing up a GPO consists of making a copy of GPO data to the file system. Note that the Backup function also serves as the export function for GPOs. Backed up GPOs can be used either in conjunction with Restore or Import operations.

Restoring a GPO takes an existing GPO backup and re-instantiates it back in the domain. The purpose of a restore is to reset a specific GPO back to the identical state it was in when it was backed up. This restoration does not include GPO links. This is because the links are a property of the container the GPO is linked to, not the GPO itself. Since a restore operation is specific to a particular GPO, it is based on the GUID and domain of the GPO. Therefore, a restore operation cannot be used to transfer GPOs across domains.

Importing a GPO allows you to transfer settings from a backed up GPO to an existing GPO. You can perform this operation within the same domain, across domains, or across forests. This allows for many interesting capabilities such as staging of a test GPO environment in a lab before importing into a production environment.

Restoring and Importing a GPO will remove any existing settings already in the target GPO. Only the settings in the backup will be in the GPO when these operations are complete.

Copying a GPO is similar to an export/import operation only the GPO is not saved to a file system location first. In addition, a copy operation creates a new GPO as part of the operation, whereas an import uses an existing GPO as its destination.

**Reporting of GPO Settings**
GPMC can display a report of the defined settings in a given GPO. This report can be generated by any user with read access to the GPO. Without GPMC, users that did not have write access to a GPO could not read and view the settings in that GPO. This is because the Group Policy Object Editor requires the user to have read and write permissions to the GPO to open it. Some examples of users that might need to read and view but not edit a GPO include security audit teams that need to read but not edit GPO settings, helpdesk personnel that are troubleshooting a Group Policy issue, and OU administrators that may need to read and view the settings from inherited GPOs. With GPMC these users now have read access to the settings.

The HTML reports also make it easy for the administrator to view settings that are contained in a GPO at a glance. Alternatively, administrators can expand and contract individual sections within the report by clicking the heading for each section.

GPMC also solves some common reporting requirements including the ability to document all the settings in a GPO to a file for printing or viewing. Using a context menu, users can either print the reports, or save them to a file in either HTML or XML format.

**Search for GPO**
GPMC provides extensive capabilities to search for GPOs within a domain or across all domains in a forest. This search feature allows an administrator to search for GPOs based on the following criteria:

- Display name of the GPO.

- Whether or not a specific domain has containers that link to the GPO.
- The permissions set on the GPO.
- The WMI filter that is linked to the GPO.
- The type of policy settings that have been set in the User Configuration or Computer Configuration in the GPO, such as folder redirection or security settings. Note that you cannot search based on the individual settings configured in a GPO.
- GUID of the GPO.

**Group Policy Modeling**
Windows Server 2003 has a powerful new Group Policy management feature that allows the user to simulate a policy deployment that would be applied to users and computers before actually applying the policies. This feature, known in Windows Server 2003 as Resultant Set of Policy (RSoP) Planning Mode, is integrated into GPMC as Group Policy Modeling. This feature requires a domain controller that is running Windows Server 2003 in the forest, because the simulation is performed by a service that is only present on Windows Server 2003 domain controllers. However, with this feature, you can simulate the resultant set of policy for any computer in the forest, including those running Windows 2000.

**Group Policy Results**
This feature allows administrators to determine the resultant set of policy that was applied to a given computer and (optionally) the user that logged on to that computer. The data that is presented is similar to Group Policy Modeling data, however, unlike Group Policy Modeling, this data is not a simulation. It is the actual resultant set of policy data obtained from the target computer. Unlike Group Policy Modeling, the data from Group Policy Results is obtained from the client, and is not simulated on the DC. The client must be running Windows XP, Windows Server 2003 or later. It is not possible to get Group Policy Results data for a Windows 2000 computer. (However, with Group Policy Modeling, you can simulate the RSoP data).

**GPMC Scripting**
The GPMC user interface is based on a set of COM interfaces that accomplish all of the operations performed by GPMC. These interfaces are available to Windows scripting technologies like JScript and VBScript, as well as programming languages such as Visual Basic and VC++. An administrator can use these interfaces to automate many Group Policy management tasks.

These interfaces are discussed in detail in the GPMC software development kit (SDK) located in the **%programfiles%\gpmc\scripts\gpmc.chm** Help file on systems where GPMC has been installed. The contents of the GPMC SDK are also available in the Platform SDK.

For more information about GPMC interfaces, see MSDN.

**Group Policy Management Console Dependencies**
Group Policy Management Console requires the MMC infrastructure to function. In addition, GPMC has its own set of system installation requirements, as well as requirements for certain GPMC features to function.

**GPMC System Installation Requirements**
Although GPMC can manage both Windows 2000 and Windows Server 2003 domains with Active Directory, the tool itself must be installed on a computer running Windows Server 2003 or Windows XP Professional (with Windows XP Service Pack 1 (or later) and the Microsoft .NET Framework). Note that when installing GPMC on Windows XP Professional SP1, a hotfix is required. This hotfix (Q326469) is included with GPMC. GPMC Setup prompts you to install Windows XP QFE Q326469 if it is not already present.

**GPMC Feature Requirements**
GPMC exposes features that are available in the underlying operating system. Because new features have been added to Group Policy since Windows 2000, certain features will only be available in GPMC depending on the operating system that has been deployed on the domain controllers and clients. This section describes these dependencies. In general, there are four key issues that determine whether a feature is available in GPMC:

- Windows Server 2003 Active Directory schema must be available to delegate Group Policy Modeling or Group Policy Results.
- Windows Server 2003 domain controller must be available to run Group Policy Modeling.
- Windows Server 2003 domain configuration (ADPrep /DomainPrep) must be available to use WMI Filters.

- Clients must be running Windows XP or Windows Server 2003 in order to generate Group Policy Results data.

GPMC dependencies upon Windows and Active Directory platform appear below:

**GPMC Dependencies on Windows and Active Directory**

| Dependency | Feature | Reason |
|---|---|---|
| Windows Server 2003 Active Directory Schema | Delegation of Group Policy Modeling and Group Policy Results | The Generate Resultant Set of Policy (Logging) and Generate Resultant Set of Policy (Planning) permissions needed for this operation are only available with the Windows Server 2003 Active Directory schema. |
| Windows Server 2003 Domain Controller in the forest | Group Policy Modeling | The simulation is performed by the Resultant Set of Policy Service which is only available on domain controllers running Windows Server 2003. |
| Windows Server 2003 domain configuration (DomainPrep) | WMI Filters | ADPREP /DomainPrep configures the domain for Windows 2003 Active Directory including configuration for WMI Filters. |
| Clients must be running Windows XP or Windows Server 2003 | Group Policy Results | Clients must be instrumented to log Group Policy Results data when policy is processed. This capability is only available on the listed systems. |

There is no dependency from the Group Policy perspective on whether a domain is in native mode or mixed mode.

**Related Information**

The following resource contains additional information that is relevant to this section:

- GPMC Interfaces on MSDN.

# How Group Policy Management Console Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Group Policy Management Console Works**

Administrators use Group Policy Management Console (GPMC) to manage Group Policy. An administrator must have an Active Directory environment to use GPMC to manage Group Policy. In an ideal environment, the clients are running Windows XP while the servers are running Windows 2003. However, GPMC can also be used to manage Windows 2000 domains.

- Related Information

**Group Policy Management Console Architecture**

GPMC is one of three administrative tools used to manage Group Policy. The following diagram shows all three of those tools, as well as the domain controller and a client. In addition, the diagram describes the different communication protocols being used by each tool (LDAP, SMB, RPC/COM, DNS), the interactions between the tool, the domain controller and the client, and whether those interactions are READ (lines with a single arrow head) or READ/WRITE (lines with double arrow heads).

**Group Policy Management Console Architectural Diagram**

**Components of Group Policy Management Console Architectural Diagram**

| Component | Description |
|---|---|

| | |
|---|---|
| Group Policy Management Console (GPMC) | GPMC makes Group Policy much easier to manage by providing a view of GPOs, sites, domains, and OUs across an enterprise. GPMC can be used to manage either Windows Server 2003 or Windows 2000 domains.<br><br>GPMC simplifies the management of Group Policy by providing a single place for managing core aspects of Group Policy, such as scoping, delegating, filtering, and manipulating inheritance of GPOs. You can also back up GPOs to the file system as well as restore GPOs from backups. GPMC includes features that enable an administrator to predict how GPOs are going to affect the network as well as to determine how GPOs have actually changed settings on any particular computer or user.<br><br>GPMC is capable of read and write access to the Sysvol using the SMB protocol. It is also capable of read and write access to Active Directory via the LDAP protocol. In addition, GPMC is capable of read access to the event log and RSoP infrastructure. |
| Server (Domain Controller) | In an Active Directory forest, the domain controller is a server that contains a writable copy of the Active Directory database, participates in Active Directory replication, and controls access to network resources. GPOs are stored in two parts of domain controllers: The Active Directory database and the Sysvol.<br><br>In addition to storing the GPOs used in normal policy processing, GPMC and the RSoP snap-in use the domain controller and the RSoP infrastructure to simulate the application of policy across the network. |
| Active Directory | Active Directory, the Windows-based directory service, stores information about objects on a network and makes this information available to users and network administrators. Administrators link GPOs to Active Directory containers such as sites, domains, and OUs that include user and computer objects. In this way, policy settings can be targeted to users and computers throughout the organization. Prior to GPMC, administrators used property pages in various Active Directory administrative tools to manage Group Policy. |
| Sysvol | The Sysvol is a shared directory that stores the server copy of the domain's public files, which are replicated among all domain controllers in the domain. The Sysvol contains the largest part of a GPO: the Group Policy template (GPT), which includes Administrative Template-based policy settings, security settings, script files, and information regarding applications that are available for software installation. File Replication Service (FRS) replicates this information throughout the network. |
| DNS/WINS | Domain Name Service (DNS) and Windows Naming Service (WINS) are network name services. Network name services are used to translate IP addresses to domain names. GPMC can use either DNS or WINS to locate domain controllers. |
| LDAP Protocol | Lightweight Directory Access Protocol (LDAP) is the protocol used by the Active Directory directory service. GPMC uses LDAP to access the directory store on the domain controller. The client computer on which Group Policy is processed also uses LDAP to read the directory store on the domain controller. |
| SMB Protocol | The Server Message Block (SMB) protocol is the primary protocol used for file and print sharing. SMB can also be used for named pipes and mail slots. GPMC uses SMB to access the Sysvol as well as back up and retrieve files to a remote file system. The client also uses SMB to read the sysvol on the domain controller. |
| DNS protocol /WINS protocol | Domain Name Service (DNS) protocol and Windows Internet Name Service (WINS) protocol are used for locating computers on a network by using hostnames instead of IP addresses. GPMC can use either to locate domain controllers. |
| RPC/COM | RPC (Remote Procedure Call), DCOM (Distributed Component Object Model) and COM (Component Object Model) enable data exchange between different processes. The different process can be on the same machine, on the local area network, or across the Internet.<br><br>The various binary files that make up the GPMC components primarily use COM calls to communicate. The GPMC COM interfaces are also all scriptable so that an administrator can automate Group Policy Management.<br><br>DCOM and RPC are used by GPMC for communication with the RSoP provider on the client or domain controller for Group Policy Results and Group Policy Modeling reports. |

| | |
|---|---|
| WMI | WMI is a management infrastructure that supports monitoring and controlling of system resources through a common set of interfaces and provides a logically organized, consistent model of Windows operation, configuration, and status.<br><br>WMI makes data about a target computer available for administrative use. Such data can include hardware and software inventory, settings, and configuration information. For example, WMI exposes hardware configuration data such as CPU, memory, disk space, and manufacturer, as well as software configuration data from the registry, drivers, file system, Active Directory, the Windows Installer service, networking configuration, and application data. WMI Filtering in Windows Server 2003 allows you to create queries based on this data. These queries (also called WMI filters) determine which users and computers receive the policy configured in the GPO. |
| RsoP infrastructure | Group Policy processing information is collected and stored in a Common Information Model Object Management (CIMOM) database on the local computer. This information, such as the list of GPOs, as well as the content and logging of processing details for each GPO, can then be accessed by tools using WMI.<br><br>With Group Policy Results in GPMC, or logging mode for the RSoP snap-in, the RSoP service is used to query the CIMOM database on the target computer; it receives information about the policies and displays it in GPMC or the RSoP snap-in.<br><br>With Group Policy Modeling in GPMC, or planning mode for the RSoP snap-in, the RSoP service simulates the application of policy using the Group Policy Directory Access Service (GPDAS) on a Domain Controller. GPDAS simulates the application of GPOs and passes them to virtual client-side extensions on the Domain Controller. The results of this simulation are stored to a local CIMOM database on the domain controller before the information is passed back and displayed in either GPMC or the RSoP snap-in. |
| Group Policy Engine | The Group Policy Engine is a framework that handles common functionality across client-side extensions. GPMC does not communicate directly with the Group Policy Engine. For more information about the Group Policy Engine, see Core Group Policy Technical Reference. |
| Client-Side Extensions | Client-side extensions (CSEs) consist of one or more dynamic-link libraries (DLLs) that are responsible for implementing Group Policy at the client computer. CSEs typically correspond to snap-ins: Administrative Templates, Scripts, Security Settings, Software Installation, Folder Redirection, Remote Installation Services, and Internet Explorer Maintenance. GPMC does not communicate directly with the Client-side extensions. For more information about client-side extensions, see Group Policy Components. |
| File System | GPMC can write to the file system of the local machine or any remote machine. GPMC writes to the file system for GPO operations, such as backups or copy, and for saving HTML/XML reports. |
| Event Log | The Event log is a service that records events in the various logs on the computer. GPMC is capable of read and write access to the Event Log on client computers and domain controllers. |
| Local Group Policy object | The local Group Policy object (local GPO) is stored on each individual computer, in the hidden **%systemroot%\System32\GroupPolicy** directory. Each computer running Windows 2000, Windows XP Professional, Windows XP 64-Bit Edition, or Windows Server 2003 has exactly one local GPO, regardless of whether the computers are part of an Active Directory environment.<br><br>GPMC does not offer access to the local GPO. For more information about the local Group Policy Object, see Core Group Policy Technical Reference. |

**Group Policy Management Console Interfaces**

GPMC includes a set of programmable interfaces designed for use by administrators writing scripts, as well as programmers using languages such as Visual Basic or C++.

The following is a comprehensive list of all the Group Policy Management Console (GPMC) interfaces.

**Comprehensive List of GPMC Interfaces**

| Interface | Description |
|---|---|
| **IGPM** | Accesses GPMC interfaces to retrieve GPMC information and to create objects. Manages and queries Group Policy objects (GPOs) and GPO links. Queries scope of management (SOM) objects. |

| | |
|---|---|
| **IGPMAsyncCancel** | Cancels an asynchronous GPMC operation, such as a backup, restore, import, copy, or report generation. The GPMC function called by the client will asynchronously return a pointer to the **IGPMAsyncCancel** interface. **IGPMAsyncCancel** is not available through scripting. |
| **IGPMAsyncProgress** | Enables client notification about the progress of an operation. Implemented by the client and passed as a parameter to GPMC methods that can run asynchronously. **IGPMAsyncProgress** is not available through scripting. |
| **IGPMBackup** | Retrieves properties of **GPMBackup** objects. Deletes **GPMBackup** objects |
| **IGPMBackupCollection** | Accesses a collection of GPO backups. |
| **IGPMBackupDir** | Queries GPO backups and GPO backup collections. |
| **IGPMClientSideExtension** | Queries client-side extension properties such as ID and display name. |
| **IGPMConstants** | Retrieves the values of GPMC constants. |
| **IGPMCSECollection** | Accesses a collection of client-side extension objects. |
| **IGPMDomain** | Queries SOM objects. Creates, restores, and queries GPOs. Creates and queries WMI filters. WMI filter queries use WMI Query Language (WQL). |
| **IGPMGPO** | Manages an individual GPO. Deletes, copies, imports, or backs up a GPO. Enables or disables user and computer configuration options. Sets security information. Retrieves multiple GPO properties for a given GPO and generates reports of the settings in the GPO. |
| **IGPMGPOCollection** | Accesses a collection of GPOs. |
| **IGPMGPOLink** | Manages a GPO link from a SOM. Sets and retrieves properties of GPO links, such as the link order or whether a link is enabled or enforced. |
| **IGPMGPOLinksCollection** | Accesses a collection of GPO links. |
| **IGPMPermission** | Retrieves permission properties. |
| **IGPMResult** | Retrieves status message information while performing GPMC operations on GPOs, such as restore, import, backup and copy. |
| **IGPMRSOP** | Queries Resultant Set of Policy (RSoP) in logging or planning mode. Generates RSoP reports. |
| **IGPMSearchCriteria** | Defines the criteria for search operations. |
| **IGPMSecurityInfo** | Defines the set of permissions that exist on a SOM, GPO or WMI filter. Removes or adds permissions. |
| **IGPMSitesContainer** | Queries SOM objects for particular sites in a forest. |
| **IGPMSOM** | Creates and retrieves GPO links for a SOM. Sets and retrieves security attributes and properties for a SOM. |
| **IGPMSOMCollection** | Accesses a collection of SOMs. |
| **IGPMStatusMessage** | Retrieves properties of status messages of GPO operations. |
| **IGPMStatusMsgCollection** | Accesses a collection of status messages. |
| **IGPMTrustee** | Retrieves information about a trustee that is a user, group, or computer in the domain. |
| **IGPMWMIFilter** | Sets or retrieves security attributes and properties of a WMI filter. |
| **IGPMWMIFilterCollection** | Accesses a collection of WMI filters. |
| **IGPMMapEntry** | Retrieves map entries. |

| | |
|---|---|
| **IGPMMapEntryCollection** | Accesses a collection of map entries. |
| **IGPMigrationTable** | Accesses a migration table. |

For more information about GPMC interfaces, see MSDN.

**Group Policy Management Console Processes and Interactions**

This section defines how GPO operations are handled by GPMC, as well as important differences between how GPMC and Group Policy Object Editor handle Administrative template files.

**GPO Operations in Group Policy Management Console**

With Group Policy Management Console (GPMC) administrators can back up, restore, import, or copy Group Policy objects (GPOs). When copying or importing GPOs across domains, an administrator can use migration tables to facilitate the copy or import operation.

**Backups**

Backing up a Group Policy object (GPO) copies the data in the GPO to the file system. The backup function also serves as the export capability for GPOs. A GPO backup can be used to restore the GPO to the backed-up state, or to import the settings in the backup to another GPO. Because each backup is identified by a unique backup ID, multiple backups of the same or different GPO can be stored in the same file system location. The collection of backups in a given file system location can be managed using the GPMC or through the scriptable interfaces. When you open **Manage Backups** from the **Group Policy Objects** node in GPMC, the view is automatically filtered to show only backups of GPOs from that domain. When opened from the **Domains** node, all backups are displayed, regardless of which domain they are from.

**Information saved in a backup**

Backing up a GPO saves all information that is stored inside the GPO to the file system. This includes the following information:

- GPO globally unique identifier (GUID) and domain.
- GPO settings.
- Discretionary access control list (DACL) on the GPO.
- WMI filter link, if there is one, but not the filter itself.
- Links to IP Security Policies, if any.
- XML report of the GPO settings, which can be viewed as HTML from within GPMC.
- Date and time stamp of when the backup was taken.
- User-supplied description of the backup.

**Information not saved in a backup**

Backing up a GPO only saves data that is stored inside the GPO. Data that is stored outside the GPO is not available when the backup is restored to the original GPO or imported into a new one. This data that becomes unavailable includes the following information:

- Links to a site, domain, or organizational unit.
- WMI filter.
- IP Security policy.

**Restore**

Restoring a Group Policy object (GPO) re-creates the GPO from the data in the backup. A restore operation can be used in both of the following cases: the GPO was backed up but has since been deleted, or the GPO is live and you want to roll back to a known previous state. The end effect is the same in either case, except as noted below in some cases for GPOs that contain software installation settings.

GPMC identifies the GPO by its domain and globally unique identifier (GUID). The purpose of a restore operation is to return the GPO to its original state, so the restore operation retains the original GUID even if it is recreating a deleted GPO. This is a key difference between the restore operation and the import or copy operations. You cannot use restore to transfer GPOs to different domains or forests. That capability is provided by import and copy.

**Information replaced in a restore**
A restore operation replaces the following components of a GPO:

- GPO settings.
- The Discretionary Access Control List (DACL) on the GPO.
- WMI filter links (but not the filters themselves).

**Information not replaced in a restore**
The restore operation does not restore objects that are not part of the GPO. This includes the following:

- Links to a site, domain, or organizational unit. Links are an attribute of the site, domain, or organizational unit, not the GPO. Any existing links in these containers will continue to be used, for example, when restoring an existing GPO to a previous state. However, if you have deleted a GPO and all links to the GPO, you must add these links back after restoring the GPO.
- WMI filters. A GPO only contains a link to the WMI filter. If the WMI filter does not exist at the time of restore, the link will be dropped, otherwise the link will be restored.
- IPSec Policies. A GPO only contains a link to the IPSec policy. If the IPSec policy does not exist at the time of restore, the link will be dropped, otherwise the link will be restored.

**Permissions required to restore a GPO from backup**
The permissions necessary to perform a restore of a GPO vary, depending on whether you are restoring an existing GPO or if you are restoring a GPO that has been deleted since it was backed up. Version numbers for the GPO are handled differently as well. The following table summarizes the situation for existing and deleted GPOs:

**Permissions Required to Restore GPOs from Backup**

| GPO state | Permission needed to restore GPO from backup | GPO version number |
|---|---|---|
| Existing GPO | The user must have Edit settings, delete, and modify permissions on the GPO, as well as read access to the file system location where the backup is stored. This does NOT require GPO creation rights. | Incremented by 1, which will trigger client refreshes of settings from the GPO. |
| Deleted GPO | The user must have the right to create GPOs in the domain, as well as read access to the file system location where the backup is stored. | Retained unchanged from the backed-up GPO. |

**Restoring GPOs with software installation settings**
When restoring a deleted GPO that contains Software Installation settings, some side effects are possible depending on the circumstances under which the GPO is restored.

When restoring a GPO that contains software installation settings, it is possible that:

- Cross-GPO upgrade relationships that upgrade applications in the GPO being restored, if any, are not preserved after restore. A cross-GPO upgrade is one in which the administrator has specified that an application should upgrade another application, and the two applications are not in the same GPO. Note that upgrade relationships are preserved when applications — in the GPO being restored — upgrade applications in other GPOs.
- If the client computer has not yet detected that the GPO has been deleted (either because the user has not logged on again or rebooted since the deletion of the GPO), and the application was deployed with the option to **Uninstall this application when it falls out of scope of management** then the next time the user logs on:
    - Published applications that the user has previously installed will be removed.

- Assigned applications will be uninstalled before re-installation.

This issue can be avoided if all of the following conditions are met:

- You perform the restore on a Windows Server 2003 domain controller instead of a Windows 2000 domain controller.
- The user performing the restore has permissions to re-animate tombstone objects in the domain.
- The time elapsed between deletion and restoration of the GPO does not exceed the tombstone lifetime specified in Active Directory.

Tombstone re-animation is a new feature of Windows Server 2003 Active Directory. By default, only Domain Admins and Enterprise Admins have this permission but you can delegate this right to additional users at the domain level using the ACL editor.

As a general rule, if you deploy software using Group Policy, it is recommended that you perform the restoration of GPOs that contain application deployments using a domain controller running Windows Server 2003 and that you grant the tombstone re-animation right to the users who will be performing restoration of those GPOs.

Finally, when restoring a GPO that contains software installation settings, if you are using categories to classify applications, the application in the restored GPO will appear in its original category only if the category exists at the time of restoration. Note that the category definition is not part of the GPO.

**Import**
The Import operation transfers settings into an existing GPO in Active Directory using a backed-up GPO in the file system location as its source. Import operations can be used to transfer settings from one GPO to another GPO within the same domain, to a GPO in another domain in the same forest, or to a GPO in a domain in a different forest. The import operation always places the backed-up settings into an existing GPO. It erases any pre-existing settings in the destination GPO. Import does not require trust between the source domain and destination domain. Therefore it is useful for transferring settings across forests and domains that don't have trust. Importing settings into a GPO does not affect its discretionary access control list (DACL), links on sites domains or organizational units to that GPO, or a link to a WMI filter.

When using import to transfer GPO settings to a GPO in a different domain or different forest, you might want to use a migration table in conjunction with the import operation. A migration table allows you to facilitate the transfer of references to security groups, users, computers, and UNC paths in the source GPO to new values in the destination GPO.

**Copy**
A copy operation allows you to transfer settings from an existing Group Policy object (GPO) in Active Directory directly into a new GPO. The new GPO created during the copy operation is given a new globally unique identifier (GUID) and is unlinked. You can use a copy operation to transfer settings to a new GPO in the same domain, another domain in the same forest, or a domain in another forest. Because a copy operation uses an existing GPO in Active Directory as its source, trust is required between the source and destination domains. Copy operations are suited for moving Group Policy between production environments, and for migrating Group Policy that has been tested in a test domain or forest to a production environment, as long as there is trust between the source and destination domains.

Copying is similar to backing up followed by importing, but there is no intermediate file system step, and a new GPO is created as part of the copy operation. The import operation, in contrast with the copy operation, does not require trust.

**Specifying the discretionary access control list (DACL) on the new GPO**
You have two options for specifying the DACL to use on the new GPO:

- Use the default permissions that are used when creating new GPOs.
- Preserve the DACL from the source GPO. For this option, you can specify a migration table, used to facilitate the transfer of references to security groups, users, computers, and UNC paths in the source GPO to new values in the destination GPO. If you specify a migration table for the copy operation, and you choose the option to preserve the DACL from the source GPO, the migration table will apply to any security principals in the DACL.

**Copying within a domain compared with copying to another domain**

Copying a GPO to another domain is slightly different from copying it to the same domain.

When copying a GPO within the same domain, you have a simple choice of two options, just described, for choosing the DACL. However, for copy operations to another domain, GPMC presents a wizard to facilitate the operation. The wizard guides you through the following choices:

- Choice of DACL for the new GPO, as described earlier.
- Specification of migration table, if applicable. A migration table allows you to facilitate the transfer of references to security groups, users, computers, and UNC paths in the source GPO to new values in the destination GPO.

When copying a GPO within the same domain, any link to a WMI filter is preserved. However, when copying a GPO to a new domain, the link is dropped because WMI filters can only be linked to GPOs within the same domain.

**Migration Tables**
When you copy or import a Group Policy object (GPO) from one domain to another, you can use a migration table to tell Group Policy Management Console (GPMC) how domain-specific data should be treated.

The key challenge when migrating GPOs from one domain to another is that some information in the GPO is actually specific to the domain where the GPO is defined. When transferring the GPO to a new domain, it may not always be desirable, or even possible, to use the exact same settings. Items that can be specific to a domain include references to security principals such as users, groups, and computers as well as UNC paths. The solution is to modify these references in the GPO that are domain-specific, during the import or copy operation, so that the settings in the destination GPO are written with the appropriate information for the destination domain. GPMC supports this capability using migration tables.

A migration table is a file that maps references to users, groups, computers, and UNC paths in the source GPO to new values in the destination GPO. A migration table consists of one or more mapping entries. Each mapping entry consists of a type, source reference, and destination reference. If you specify a migration table when performing an import or copy, each reference to the source entry will be replaced with the destination entry when writing the settings into the destination GPO.

The migration table will apply to any references in the settings within a GPO, whether you are performing an import or copy operation. In addition, during a copy operation, if you choose the option to preserve the discretionary access control list (DACL) on the GPO, the migration table will also apply to both the DACL on the GPO and the DACLs on any software installation settings in the GPO.

Migration tables store the mapping information as XML, and have their own file name extension, .migtable. You can create migration tables using the Migration Table Editor (MTE). The MTE is a convenient tool for viewing and editing migration tables without having to work in, or be familiar with, XML. The MTE is associated with the .migtable extension so that when you double-click a migration table, it opens in the MTE. The MTE is installed with GPMC. You can also create and edit migration tables using any XML editor or using the GPMC scripting interfaces.

**Settings impacted by migration tables**
There are two types of settings that may not transfer well across domains:

- Users, groups, and computers (security principals) that are referenced in the following places: the settings of the GPO, in the ACL for the GPO itself, and the ACL for any software installation settings in the GPO. Security principals do not transfer well for several reasons. For instance, domain local groups are invalid in external domains but other groups are valid if there is trust in place. Even with a trust between domains, it may not always be appropriate to use the exact same group in the new domain. If there is no trust, then none of the security principals in the source domain will be available in the destination domain.
- UNC paths. When you are migrating GPOs across domains that do not have trust, such as from test to production environments, users in the destination domain may not have access to paths in the source domain.

The following items can contain security principals and can be modified using a migration table:

- Security policy settings of the following types:
    - User rights assignment
    - Restricted groups

    - Services
    - File system
    - Registry
- Advanced folder redirection policies.
- The GPO discretionary access control list (DACL), if you choose to preserve it during a copy operation.
- The DACL on software installation objects. This is only preserved if the option to copy the GPO DACL is specified. Otherwise the default DACL is used.

  **Note**

    - Security Principals referenced in Administrative Templates settings cannot be migrated using a migration table.

The following items can contain UNC paths and can be modified using a migration table:

- Folder redirection policies.
- Software installation policies (for software distribution points).
- Pointers to scripts deployed through Group Policy (such as startup and shutdown scripts) that are stored outside the GPO. Note that the script itself is not copied as part of the GPO copy operation, unless the script is stored inside the source GPO.

**Options for specifying migration tables**
Migration tables are specified when performing import and copy operations. There are three options for using migration tables with import and copy:

- Do not use a migration table. This option copies the GPO exactly as it is. All references to security principals and UNC paths are copied identically.
- Use a migration table. This option maps any references in the GPO that are in the migration table. References that are not contained in the migration table are copied as is.
- Use a migration table exclusively. This option requires that all references to security principals and UNC paths that are referenced in the source GPO be specified in the migration table. If a security principal or UNC path is referenced in the source GPO and is not included in the migration table, the import or copy operation fails.

In addition, cross-domain copy operations will apply the migration table to the DACL on the GPO (and any software installation settings) if you choose the option **Preserve or migrate the existing permissions**.

When performing a copy or import, the wizard scans the source GPO to determine if there are any references to security principals or UNC paths in the GPO. If there are, you have the opportunity to specify a migration table. During cross-domain copy operations, if you specify the option **Preserve or migrate the permissions on the GPO**, the wizard will always present the opportunity to specify a migration table, because a DACL by definition contains security principals.

**Contents of Migration tables**
A migration table consists of one or more mapping entries. Each mapping entry has three pieces of information: type, source and destination. The following sections describe these categories in more detail.

**Source Types**
Source types describe the type of domain-specific information for the source GPO. Migration tables support the following types of source types:

### XML Elements of Source Types

| Source Type | How This Type Appears in XML Editor |
|---|---|
| User | <Type>User</Type> |
| Computer | <Type>Computer</Type> |
| Domain Local Group | <Type>LocalGroup</Type> |
| Domain Global Group | <Type>GlobalGroup</Type> |
| Universal Group | <Type>UniversalGroup</Type> |
| UNC Path | <Type>UNCPath</Type> |
| Free Text or security identifier (SID). This category is only for use with security principals that are specified as free text and raw SIDs. | <Type>Unknown</Type> |

**Note**

- Built-in groups such as Administrators and Account Operators have the same SID in all domains. If references to built-in groups are stored in the GPO using their resolved format (based on the underlying SID), they cannot be mapped using migration tables. However, if references to built-in groups are stored as free text, you can map them using a migration table, and in this case, you must specify source type=Free Text or SID.

**Source Reference**

A source reference is the specific name of the User, Computer, Group or UNC Path referenced in the source GPO. For example, **\\server1\publicshare** is a specific example of a UNC path. The type of the source reference must match whatever source type has been specified in the migration table.

**Source Reference Syntax**

| Source Reference | Syntax |
|---|---|
| UPN | someone@example.com |
| SAM | example\someone |
| DNS | example.com\someone |
| Free text | someone (must be specified as the unknown type) |
| SID | S-1-11-111111111-111111111-1111111111-1112 (must be specified as the unknown type.) |

**Destination Name**

The destination name specifies how the name of the User, Computer, Group or UNC Path in the source GPO should be treated upon transfer to the destination GPO.

**Destination Name Options**

| Destination Name | Description |
|---|---|
| Same as source | Copy without changes. Equivalent to not putting the source value in the migration table at all.<br><br>MTE value: <Same As Source><br><br>XML tag:<DestinationSameAsSource /> |
| None | Removes the User, Computer or Group from the GPO. This option cannot be used with UNC paths<br><br>MTE value: <None><br><br>XML tag: <DestinationNone /> |

| | |
|---|---|
| Map by relative name | For example, map SourceDomain\Group1 to TargetDomain\Group1. This option cannot be used with UNC paths.<br><br>MTE value: <Map by Relative name><br><br>XML tag: <DestinationByRelativeName /> |
| Explicitly specify value | In the destination GPO, replace the source value with the exact literal value you specify.<br><br>MTE value: <exact name to use in target><br><br>XML tag: <Destination>Exact Name to use in Destination</Destination> |

**Note**

- Administrators can specify security principals for destination names using any of the syntactical formats described in source references, with the exception of using a raw SID. A raw SIDs can never be used for the destination name.

#### Default Entries

Valid migtable files must contain the following entries, which identifies the namespace used by migtables. If you are creating migtables by hand, you need to add this. Otherwise MTE does this for you.

```
<?xml version="1.0" encoding="utf-16"? >
<MigrationTable
xmlns="http://www.microsoft.com/GroupPolicy/GPOOperations/MigrationTable">
```

Each mapping entry appears in the following format:

```
<Mapping>
<Type>Type</Type>
<Source>Source</Source>
<Destination>Destination</Destination>
</Mapping>
```

#### The Migration Table Editor

The Migration Table Editor (MTE) is provided with Group Policy Management Console (GPMC) to facilitate the editing of migration tables. Migration tables are used for copying or importing Group Policy objects (GPOs) from one domain to another, in cases where the GPOs include domain-specific information that must be updated during copy or import.

MTE displays three columns of information:

### Migration Table Editor columns

| Source Name | Source Type | Destination Name |
|---|---|---|
| Name of the user, computer, group, or UNC path, referenced in the source GPO. | The type of the reference named in the Source Name column. For example, Domain Global Group. | The new value, after copy or import to the new GPO; or the method used to calculate the new value. |

Note that you do not specify Destination Type. The Destination Type is determined during the import or copy operation by checking the actual reference identified in the Destination Name.

#### Migration Table Editor features

- You can edit text fields using Cut, Copy, and Paste options, for example when you right-click an item in **the Source Name** column.
- You can add computers, users, and groups, for source and destination names, by using a **Browse** dialog box.
- You can fill in **Source Type** fields by using a drop-down menu.
- MTE provides automatic syntax checking to make sure the XML file is properly populated and also ensures that only compatible entries are entered in the table. For example, \\server1\share1 is not a valid security group name name, and

server1 is not a valid UNC path so MTE prompts the user to correct those entries.

- You can validate the overall migration table using MTE, in addition to basic syntax checking using the **Validate Table** option. The **Validate Table** option checks to ensure:

  - The existence of destination security principals and UNC paths. This is important to know before you copy or import a GPO, because if there are unresolvable entries in the migration table, then the copy or import operation might fail.

  - Source entries with UNC paths do not have destinations of MapByRelative name or NoDestination.

  - Type of the destination entry in the table matches the real type in the destination source.

- You can auto-populate a migration table by scanning one or more GPOs or backups to extract all references to security principals and UNC paths, and then enter these items into the table as source name entries. This capability is provided by the **Populate from GPO** and **Populate from Backup** options available on the **Tools** menu. To complete the migration table, you only need to adjust the destination values. By default, the destination name for each entry will be set to Same as source when you use either of the Populate options.

  **Note**

  - With either auto-populate option, when the source GPO or backup contains references to built-in groups such as Administrators or Backup Operators, these references will not be entered into the migration table if the references are stored in the source GPO or backup in their resolved format [based on security identifier (SID)]. This is because built-in groups have the same SID in all domains and therefore cannot be mapped to new values using a migration table. However, if references to built-in groups are stored as free text, they will be captured by the auto-populate options. In this case, you can map them as long as you specify the source type as Free Text or SID.

**Administrative Templates in GPMC and Group Policy Object Editor**

Administrators using Group Policy Management Console need to understand that Administrative template files are handled differently, depending upon whether they are working with Group Policy Management Console or Group Policy Object Editor. How each of the tools handles Administrative template files can be manipulated using Group Policy, but it is important to understand first the differences between the two.

**Administrative Templates**

Administrative templates, or .adm files, enable administrators to control registry settings using Group Policy. Windows comes with a predefined set of Administrative template files, which are implemented as text files (with an .adm extension), that define the registry settings that can be configured in a GPO. These .adm files are stored in two locations by default: inside GPOs in the **Sysvol** folder and in the **%windir%\inf** directory on the local computer.

Windows Server 2003 includes the following .adm files: System.adm, Inetres.adm, Conf.adm, Wmplayer.adm, and Wuau.adm, which contain all the settings initially displayed in the **Administrative Templates** node.

### Default Administrative Templates

| Administrative Template File | Contains | For Use on | Description |
|---|---|---|---|
| System.adm | Settings to configure the Operating System | Windows 2000 or Windows Server 2003 | Loaded by default. |
| Inetres.adm | Settings to configure Internet Explorer | Windows 2000 or Windows Server 2003 | Loaded by default |
| Conf.adm | Settings to configure NetMeeting v3 | Windows 2000 or Windows Server 2003. Note: This tool is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. | Loaded by default. |

| | | | |
|---|---|---|---|
| Wmplayer.adm | Settings to configure Windows Media Player | Windows XP, Windows Server 2003.<br><br>**Note:** This tool is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. | Loaded by default. |
| Wuau.adm | Settings to configure Windows Update | Windows 2000 SP3, Windows XP SP1, Windows Server 2003 | Loaded by default. |

**Handling Administrative Template Files in GPMC**

GPMC uses .adm files to display the friendly names of policy settings when generating HTML reports for GPOs, Group Policy Modeling, and Group Policy Results.

By default, GPMC uses the local .adm file, regardless of time stamp. If the file is not found, then GPMC will look in the GPO's directory on Sysvol.

The user can specify an alternate path for where to find .adm files. If specified, this takes precedence over the previous locations.

GPMC never copies the .adm file to the Sysvol.

**Handling Administrative Template Files in Group Policy Object Editor**

Group Policy Object Editor uses .adm files to display available registry-based policy settings in the Administrative Templates section of a GPO. This includes Group Policy for the Windows Server 2003 operating system and its components and for applications.

By default, it attempts to read .adm files from the GPO (from the Sysvol on the domain controller). Alternatively, the .adm file can be read from the local workstation computer. This behavior can be controlled by a policy setting.

By default, if the version of the .adm file found on the local computer is newer (based on the time stamp of the file) than the version on the Sysvol, the local version is copied to the Sysvol and is then used to display the settings. This behavior can be controlled by a policy setting.

If the GPO contains registry settings for which there is no corresponding .adm file, these settings cannot be seen in Group Policy Object Editor. However, the policy settings are still active and will be applied to users or computers targeted by the GPO.

Policy settings pertaining to a user who logs on to a given workstation or server are written to the **User** portion of the registry database under **HKEY_CURRENT_USER**. Computer-specific settings are written to the **Local Machine** portion of the registry under **HKEY_LOCAL_MACHINE**.

# Group Policy Management Console Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group Policy Management Console Tools and Settings**

**In this section**

- Group Policy Management Console Tools
- Group Policy Management Console Group Policy Settings
- Related Information

This section describes tools and settings that are associated with Group Policy Management Console (GPMC) Service Pack 1 (SP1).

**Group Policy Management Console Tools**

The following tools are associated with Group Policy Management Console (GPMC) SP1.

**Group Policy Management Console**

**Category**

The GPMC SP1 is a Microsoft Management Console (MMC) snap-in used to administer Group Policy for Windows 2000 and Windows Server 2003-based domains.

**Version compatibility**

GPMC runs on both Windows Server 2003 and on Windows XP SP1 with the Microsoft .NET Framework v1 and later, and with QFE Q326469 applied. QFE Q326469 is automatically installed by gpmc.msi on computers with English as the default language. GPMC can be used to manage both Windows 2000 and Windows Server 2003 domain Group Policy.

For more information about GPMC, see the What Is Group Policy Management Console? topic in this collection.

**Migration Tool Editor**

**Category**

The Migration Table Editor (MTE) is provided with GPMC to facilitate the editing of migration tables. Migration tables are used for copying or importing Group Policy objects (GPOs) from one domain to another, in cases where the GPOs include domain-specific information that must be updated during copy or import. When transferring the GPO to a new domain, it might not always be desirable, or even possible, to use the exact same settings. Items that can be specific to a domain include references to security principals such as users, groups, and computers as well as Universal Naming Convention (UNC) paths.

**Version compatibility**

The Migration Table Editor is provided with GPMC.

**Group Policy Management Console Group Policy Settings**

You can permit or prohibit use of GPMC through an Administrative Templates policy setting, as shown in the following table.

| Administrative Templates Policy Setting | Description |
|---|---|
| Group Policy Management<br><br>USER\Administrative Templates\Windows Components\Microsoft Management Console\Restricted/Permitted snap-ins\Group Policy | This setting permits or prohibits the use of this snap-in. If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited. If this setting is not configured, the setting of the Restrict users to the explicitly permitted list of snap-ins setting determines whether this snap-in is permitted or prohibited. |

For a complete reference of all Administrative Templates policy settings, see Group Policy Settings Reference for Windows Server 2003.

# Group Policy Object Editor Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group Policy Object Editor Technical Reference**
Group Policy Object Editor is a Microsoft Management Console (MMC) snap-in used to edit the policy settings in Group Policy objects (GPOs). Like all MMC snap-ins, its functionality can be customized, or extended, by means of MMC snap-in extensions. When you use Group Policy Object Editor, various extensions are included by default.

# What Is Group Policy Object Editor?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Group Policy Object Editor Core Scenarios
- Group Policy Object Editor Dependencies

Group Policy Object Editor is a Microsoft Management Console (MMC) snap-in used for configuring and modifying Group Policy settings within Group Policy objects (GPOs).

Administrators need to be able to quickly modify Group Policy settings for multiple users and computers throughout a network environment. The Group Policy Object Editor provides administrators with a hierarchical tree structure for configuring Group Policy settings in GPOs. These GPOs can then be linked to sites, domains, and organizational units (OU) containing computer or user objects.

Group Policy Object Editor consists of two main sections: **User Configuration**, which holds settings that are applied to users (at logon and periodic background refresh), and **Computer Configuration**, which holds settings that are applied to computers (at startup and periodic background refresh). These sections are further divided into the different types of policies that can be set, such as Administrative Templates, Security, or Folder Redirection.

To work efficiently, administrators need to have immediate access to information about the function and purpose of individual policy settings. For Administrative Templates policy settings, Group Policy Object Editor provides information about each policy setting directly in the Web view of the console. This information is called explain text. Explain text shows operating system requirements, defines the policy setting, and includes any specific details about the effect of enabling or disabling the policy setting.

In addition, developers should be able to quickly and easily add Group Policy support to their software products. The Group Policy Object Editor is designed to be extensible. The easiest way for developers to extend Group Policy Object Editor for their applications is to write custom Administrative Template files that "plug in" to Group Policy Object Editor.

**Group Policy Object Editor Core Scenarios**
There are two core scenarios for Group Policy Object Editor: editing GPOs, and extending the user interface (UI) to accommodate new applications or features. Both of these scenarios are described in detail in the following section.

**Editing Group Policy Objects**
Group Policy Object Editor is the primary tool used for configuring policy settings within a GPO. Group Policy Object Editor operates as an extension to Group Policy Management Console (GPMC). When an administrator elects to edit a GPO from within GPMC, Group Policy Object Editor appears, displaying the settings for that particular GPO. If GPMC is not available, Group Policy Object Editor operates as an extension to Active Directory management tools, such as the Active Directory Users and Computers snap-in or the Active Directory Sites and Services snap-in. Regardless of the tool an administrator uses to call Group Policy Object Editor, the primary function of Group Policy Object Editor is to edit settings within GPOs.

In addition to editing Active Directory-based GPOs, Group Policy Object Editor can also edit the local Group Policy object (local GPO). There is a local GPO stored on each computer running Windows 2000, Windows XP Professional, Windows XP 64-Bit Edition, or Windows Server 2003, regardless of whether the computers are part of an Active Directory environment. Local GPOs are always processed, but are the least influential GPOs in an Active Directory environment, because Active Directory-based GPOs have precedence.

Local GPOs do not support certain extensions, such as Folder Redirection or Group Policy Software Installation. Local GPOs do support many security settings, but the Security Settings extension of Group Policy Object Editor does not support remote management of local GPOs.

**Extending Group Policy Object Editor**
The Group Policy Object Editor is designed so that it can be extended. This architecture enables developers to create applications and features that can be administered with Group Policy. All of the nodes in the Group Policy Object Editor are themselves MMC snap-in extensions. These extensions include Administrative Templates, Scripts, Security Settings, Software Installation, Folder Redirection, Remote Installation Services, and Internet Explorer Maintenance. Extension snap-ins can in turn be extended. For example, the Security Settings snap-in includes several snap-in extensions.

Writing Group Policy extensions allows developers to use their own data store for policy settings, create a richer UI through the Group Policy Object Editor, or implement their own client-side processing for Group Policy. Developers can provide any one or all of the previous elements, or combine them with existing parts of the Group Policy infrastructure. For example, a developer could write a server-side extension snap-in to the Group Policy Object Editor that provides a UI on the server and a corresponding client-side extension that processes your data on the client. Alternately, a developer could write only a client-side extension and allow an existing Group Policy Object Editor extension to provide the UI, or vice versa.

**Extending Registry-Based Policy**

Registry-based policy is the least complex method to implement policy, and for administrators, registry-based policy settings are easy to configure and deploy. In addition, registry-based policy settings managed through administrative template (.adm) files automatically support Resultant Set of Policy (RSoP) capabilities.

Registry-based policy settings work by modifying the registry on the client computer. They utilize the Administrative Templates node of Group Policy Object Editor for a UI, and the default client side extension for registry-based policy to implement settings on the client. In addition to these components, registry-based policy settings also utilize an administrative template file. Written by the developer, an .adm file is a text file that specifies the registry-based policy that users modify through the Group Policy Object Editor. This file is then loaded into the Group Policy Object Editor. The Group Policy Object Editor displays the information contained in loaded .adm files as administrators navigate through the Administrative Templates node.

**Group Policy Object Editor Dependencies**

You must have edit rights on a GPO in order to open it in Group Policy Object Editor.

# How Group Policy Object Editor Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Group Policy Object Editor Architecture
- Group Policy Object Editor Processes and Interactions

Administrators use Group Policy Object Editor to manipulate the settings in Group Policy objects (GPOs). The ideal environment contains:

- Windows Server 2003 with Active Directory installed
- Windows XP client computers

In this environment, an administrator can work with GPOs stored on the server. For these types of GPOs, all of the extensions to Group Policy Object Editor are functional. If Active Directory is not installed on your network, Group Policy Object Editor can be used only to edit the local GPO on individual client computers. For the local GPO, some of the extensions to Group Policy Object Editor are not functional.

**Group Policy Object Editor Architecture**

The Group Policy Object Editor is one of three administrative tools used to manage Group Policy. The following diagram shows all three of the tools as well as the domain controller and a client. In addition, the diagram describes the different communication protocols being used by each tool (LDAP, SMB, RPC/COM, DNS), the interactions between the tool, the domain controller and the client, and whether those interactions are READ or READ/WRITE.

**Group Policy Object Editor Architecture**

**Component Descriptions of the Group Policy Object Editor Architectural Diagram**

| Component | Description |
|---|---|

| | |
|---|---|
| Group Policy Object Editor | The Group Policy Object Editor is the Microsoft Management Console (MMC) snap-in used to edit GPOs. It was previously known as the Group Policy snap-in, Group Policy Editor, or Gpedit. The most notable feature of the Group Policy Object Editor is its extensibility. Administrators can extend the server-side snap-ins that ship with Group Policy Object Editor or they can develop completely new extensions for implementing Group Policy.<br><br>The Group Policy Object Editor is capable of read and write access to Active Directory, Sysvol, and the Local GPO. |
| Server Side Snap-ins | The nodes of the Group Policy Object Editor are also MMC server-side snap-ins. These snap-ins include Administrative Templates, Scripts, Security Settings, Software Installation, Folder Redirection, Remote Installation Services, and Internet Explorer Maintenance. Snap-ins can, in turn, be extended. For example, the Security Settings snap-in includes several extension snap-ins. Developers can also create their own MMC extension snap-ins to the Group Policy Object Editor to provide additional policy settings. Extensions are capable of read and write access to the Local GPO. |
| Server (Domain Controller) | In an Active Directory forest, the domain controller is a server that contains a writable copy of the Active Directory database, participates in Active Directory replication, and controls access to network resources. GPOs are stored in two parts of domain controllers: The Active Directory database and the Sysvol. |
| Active Directory | Active Directory, the Windows-based directory service, stores information about objects on a network and makes this information available to users and network administrators. Administrators link GPOs to Active Directory containers such as sites, domain, and OUs that include user and computer objects. In this way, policy settings can be targeted to users and computers throughout the organization. |
| Sysvol | Sysvol is a shared directory that stores the server copy of the domain's public files, which are replicated among all domain controllers in the domain. The Sysvol contains the largest part of a GPO, the Group Policy template (GPT), which includes Administrative Template-based policy settings, security settings, script files, and information regarding applications that are available for software installation. File Replication Service (FRS) replicates this information throughout the network.<br><br>Group Policy Object Editor uses .adm files to display available registry-based policy settings in the Administrative Templates section of a GPO. By default it attempts to read .adm files from the Sysvol on the domain controller. Alternatively, the .adm file can be read from the local workstation computer. This behavior can be controlled by a policy setting.<br><br>By default, if the time stamp of the .adm file found on the local computer is newer than the version on the Sysvol, the local version is copied to the Sysvol and is then used to display the settings. This behavior can be controlled by a policy setting.<br><br>If the GPO contains registry settings for which there is no corresponding .adm file, these settings cannot be seen in the Group Policy Object Editor. |
| LDAP Protocol | LDAP (Lightweight Directory Access Protocol) is the protocol used by the Active Directory directory service. Group Policy Object Editor uses LDAP to access the directory store on the domain controller. The client also uses LDAP to read the directory store on the domain controller. |
| SMB Protocol | SMB (Server Message Block) protocol is the primary method of file and print sharing. SMB can also be used for abstractions such as named pipes and mail slots. Group Policy Object Editor uses SMB to access the Sysvol as well as back up and retrieve files to a remote file system. The client also uses SMB to read the sysvol on the domain controller. |
| Group Policy Engine | The Group Policy Engine is a framework that handles common functionalities across client side extensions. |
| Client Side Extensions | Client-side extensions (CSEs) are dynamic-link libraries (DLLs) that are responsible for implementing Group Policy at the client computer. CSEs correspond to server-side snap-ins: Administrative Templates, Scripts, Security Settings, Software Installation, Folder Redirection, Remote Installation Services, and Internet Explorer Maintenance.<br><br>The client-side extensions are loaded on an as-needed basis when a client computer is processing policy. The client computer first gets a list of Group Policy objects. Next, it loops through all the client-side extensions and determines whether each client-side extension has any data in any of the GPOs. If a client-side extension has data in a GPO, the client-side extension is called with the list of Group Policy objects that it should process. If the client-side extension does not have any settings in any of the GPOs, it is not called. |

| | |
|---|---|
| Local Group Policy object | The local Group Policy object (local GPO) is stored on each individual computer, in the hidden **%systemroot%\System32\GroupPolicy** directory. Each computer running Windows 2000, Windows XP Professional, Windows XP 64-Bit Edition, or Windows Server 2003 has exactly one local GPO, regardless of whether the computers are part of an Active Directory environment.<br><br>Local GPOs do not support certain extensions, such as Folder Redirection or Group Policy Software Installation. Local GPOs do support many security settings, but the Security Settings extension of the Group Policy Object Editor does not support remote management of local GPOs. Local GPOs are always processed, but are the least influential GPOs in an Active Directory environment, because Active Directory-based GPOs have precedence. |

**Group Policy Object Editor Processes and Interactions**

Administrators using Group Policy Object Editor need to understand that Administrative template files are handled differently, depending upon whether they are working with Group Policy Object Editor or Group Policy Management Console. The way each of the tools handles Administrative template files can be manipulated using Group Policy, but it is important to understand the differences between the two.

**Administrative Templates in Group Policy Object Editor and GPMC**

Administrative templates, or .adm files, enable administrators to control registry settings using Group Policy. Windows comes with a predefined set of Administrative template files, which are implemented as text files (with an .adm extension), that define the registry settings that can be configured in a GPO. These .adm files are stored in two locations by default: inside GPOs in the Sysvol folder and in the %windir%\inf directory on the local computer.

Windows Server 2003 includes the following .adm files: System.adm, Inetres.adm, Conf.adm, Wmplayer.adm, and Wuau.adm. These files contain all the settings initially displayed in the Administrative Templates node.

### Default Administrative Templates

| .Adm file | Contains | For Use on | Description |
|---|---|---|---|
| System.adm | Settings to configure the Operating System. | Windows 2000 or Windows Server 2003. | Loaded by default. |
| Inetres.adm | Settings to configure Internet Explorer. | Windows 2000 or Windows Server 2003. | Loaded by default. |
| Conf.adm | Settings to configure NetMeeting v3. | Windows 2000 or Windows Server 2003. Note: This tool is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. | Loaded by default. |
| Wmplayer.adm | Settings to configure Windows Media Player. | Windows XP, Windows Server 2003. Note: This tool is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. | Loaded by default. |
| Wuau.adm | Settings to configure Windows Update. | Windows 2000 SP3, Windows XP SP1, Windows Server 2003. | Loaded by default. |

**Handling .Administrative Template Files in Group Policy Object Editor**

Group Policy Object Editor uses .adm files to display available registry-based policy settings in the Administrative Templates section of a GPO. These settings include registry-based Group Policy for the Windows Server 2003 operating system and its components and for applications.

By default Group Policy Object Editor attempts to read .adm files from the GPO (from the Sysvol on the domain controller). Alternatively, the .adm file can be read from the local workstation computer. This behavior can be controlled by a policy setting.

By default, if the version of the .adm file found on the local computer is newer (based on the time stamp of the file) than the version on the Sysvol, the local version is copied to the Sysvol and is then used to display the settings. This behavior can be controlled by a policy setting.

If the GPO contains registry settings for which there is no corresponding .adm file, these settings cannot be seen in the Group Policy Object Editor. However, the policy settings are still active and will be applied to users or computers targeted by the GPO.

Policy settings pertaining to a user who logs on to a given workstation or server are written to the User portion of the registry database under **HKEY_CURRENT_USER**. Computer-specific settings are written to the Local Machine portion of the registry

under **HKEY_LOCAL_MACHINE**.

**Handling Administrative Template Files in GPMC**

GPMC uses .adm files to display the friendly names of policy settings when generating HTML reports for GPOs, Group Policy Modeling, and Group Policy Results.

By default, GPMC uses the local .adm file, regardless of time stamp. If the file is not found, then GPMC will look in the GPO's directory on Sysvol.

The user can specify an alternate path for where to find .adm files. If specified, this takes precedence over the previous locations.

GPMC never copies the .adm file to the Sysvol.

**In this section**

- Group Policy Object Editor Tools
- Group Policy Object Editor Group Policy Settings
- Related Information

This section describes the tools and settings that are associated with the Group Policy Object Editor server-side extension (SSE) when accessed from the Group Policy Management Console (GPMC) with Service Pack (SP) 1 applied. The Group Policy Object Editor SSE is a Microsoft Management Console (MMC) snap-in that administrators use to edit policy settings for Group Policy Objects (GPOs).

**Group Policy Object Editor Tools**
The following tools are associated with the Group Policy Object Editor.

**Gpedit.dll: Group Policy Object Editor**
**Category**
The Group Policy Object Editor is contained in gpedit.dll. Group Policy Object Editor is an MMC snap-in installed with Windows 2000, Windows XP, and Windows Server 2003. Gpedit.dll also contains the Resultant Set of Policy (RSoP) snap-in.

**Version compatibility**
You can access the Group Policy Object Editor from the Active Directory Users and Computers on Windows 2000, on Windows XP with the Windows Server 2003 Administration Tools Pack installed, and on Windows Server 2003. Administrators use the Group Policy Object Editor to edit policy settings in Group Policy objects (GPOs).

For a discussion of RSoP features provided by Gpedit.dll, see the What Is Resultant Set of Policy? topic in this collection. For more information about Group Policy Object Editor, see the What Is Group Policy Object Editor? topic in this collection.

**MMC.exe**
**Category**
MMC.exe provides a common host environment for snap-ins such as the Group Policy Object Editor and the GPMC.

**Version compatibility**
See MMC.exe documentation for version compatibility.

MMC.exe supplies programmatic interfaces that integrate snap-ins with the console. MMC.exe itself provides no management behavior. All management behavior is supplied by the snap-in. MMC interfaces deal only with user interface extensions.

**Group Policy Object Editor MMC Extensions**
The remaining tools in this section are Microsoft Management Console (MMC) snap-ins that are Group Policy server-side extensions. They extend the Group Policy Object Editor (gpedit.dll).

**Gptext.dll**
**Category**
Gptext.dll is an MMC extension to gpedit.dll that provides settings for Scripts, IP Security, and Wireless Group Policy.

**Version compatibility**
Gptext.dll is compatible with Windows XP SP1 and Windows Server 2003.

For more information about the Scripts, IP Security, and Wireless extensions, see the What Is Scripts Extension?, What Is Security Settings Extension?, and What Is Wireless Network Policies Extension? topics in this collection.

**Fdeploy.dll**
**Category**
Fdeploy.dll is an MMC extension to gpedit.dll that provides settings for Folder Redirection Group Policy.

**Version compatibility**
Fdeploy.dll is compatible with Windows XP SP1 and Windows Server 2003.

For more information about the Folder Redirection extension, see the What Is Folder Redirection Extension? topic in this collection.

**Scecli.dll**
**Category**
Scecli.dll is an MMC extension to gpedit.dll that provides settings for Security Settings Group Policy.

**Version compatibility**
Scecli.dll is compatible with Windows XP SP1 and Windows Server 2003.

For more information about the Security Settings extension, see the What Is Security Settings Extension? topic in this collection.

**Dskquota.dll**
**Category**
Dskquota.dll is an MMC extension to gpedit.dll that provides settings for Disk Quota Group Policy.

**Version compatibility**
Dskquota.dll is compatible with Windows XP1 and Windows Server 2003.

**Iedkcs32.dll**
**Category**
Iedkcs32.dll is an MMC extension to gpedit.dll that provides settings for Internet Explorer Maintenance Group Policy.

**Version compatibility**
Iedkcs32.dll is compatible with Windows XP SP1 and Windows Server 2003.

For more information about the Internet Explorer Maintenance extension, see the What Is Internet Explorer Maintenance Extension? topic in this collection.

**Appmgmts.dll**
**Category**
Appmgmts.dll is an MMC extension to gpedit.dll that provides settings for Software Installation Group Policy.

**Version compatibility**
Appmgmts.dll is compatible with Windows XP SP1 and Windows Server 2003.

For more information about the Software Installation extension, see the What Is Group Policy Software Installation Extension? topic in this collection.

**Group Policy Object Editor Group Policy Settings**
You can permit or prohibit use of Group Policy Object Editor through an Administrative Templates policy setting, as shown in the following table. MMC has policies that will prevent snap-ins from running. The list of snap-ins, including the Group Policy server side extension snap-ins, can be viewed in the results pane by selecting the tree-view node.

| Administrative Templates Policy Setting | Description |
|---|---|
| Group Policy Object Editor<br><br>USER Configuration\Administrative Templates\Windows Components\Microsoft Management Console\Restricted/Permitted snap-ins\Group Policy | Permits or prohibits use of this snap-in. If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited. If this setting is not configured, the setting of the Restrict users to the explicitly permitted list of snap-ins setting determines whether this snap-in is permitted or prohibited. |

For a complete reference of all Administrative Templates policy settings, see Group Policy Settings Reference for Windows Server 2003.

**Related Information**
The following resources contain additional information that is relevant to this section.

# What Is Resultant Set of Policy?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Resultant Set of Policy?**

**In this section**

- Resultant Set of Policy Snap-in Core Scenarios
- Similar Technologies for Viewing Resultant Set of Policy Data
- Resultant Set of Policy Snap-in Dependencies

One challenge of Group Policy administration is to understand the cumulative effect of a number of Group Policy objects (GPOs) on any given computer or user, or how changes to Group Policy, such as reordering the precedence of GPOs or moving a computer or user to a different organizational unit (OU) in the directory, might affect the network. The Resultant Set of Policy (RSoP) snap-in offers administrators one solution. Administrators use the RSoP snap-in to see how multiple Group Policy objects affect various combinations of users and computers, or to predict the effect of Group Policy settings on the network.

**Resultant Set of Policy Snap-in Core Scenarios**

There are two core scenarios for the Resultant Set of Policy (RSoP) snap-in: reporting the effect of policy on various combinations of users and computers, and predicting the affect of policy. The reporting functionality of RSoP snap-in is known as logging mode. The predictive functionality is known as planning mode. Both of these scenarios are described in detail in the following respective sections.

Whether in logging or planning mode, an administrator typically accesses the RSoP snap-in by opening an empty Microsoft Management Console (MMC), adding the RSoP snap-in to the console, and then using the Resultant Set of Policy Wizard to collect data from various computers on the network for either logging or planning mode.

**Logging Mode**

An administrator uses logging mode to report on the current state of Group Policy settings. The scope of reports can include Group Policy settings for various targets, including a computer, a user, or both. The administrator selects combinations of targets in the Resultant Set of Policy Wizard.

When the administrator finishes with the wizard, the RSoP snap-in queries the Windows Management Instrumentation (WMI) repository on the client computer for information about the Group Policy settings for the targets. RSoP snap-in displays these settings.

Logging mode in the RSoP snap-in is useful for troubleshooting Group Policy. The RSoP snap-in lists each policy setting, and from which GPO the displayed setting came. GPO precedence is also available, as is any error information that was logged by either the Group Policy engine or any of the Group Policy client side extensions. Using this information, an administrator can determine which GPOs are applying a Group Policy setting and which GPOs are not.

In addition to using an empty MMC to access RSoP snap-in, there is another scenario an administrator is just as likely to use for troubleshooting Group Policy settings. An administrator can run RSOP.msc from the command prompt on a client computer to report on the current computer with the current user logged on. In this manner, the administrator avoids having to select targets in the Resultant Set of Policy Wizard.

**Planning Mode**

An administrator uses planning mode to perform “what if” scenarios with Group Policy. Like logging mode, the end result is a report of Group Policy settings. However, unlike logging mode, this report contains simulated data.

The administrator uses RSoP snap-in and a Windows Server 2003 domain controller. First, the administrator must use the Resultant Set of Policy Wizard to define the scope of the report. This is done by selecting various targets. In planning mode these targets must include both user information and computer information; however, the administrator can select either a particular user or computer or an Active Directory container for users or computers.

After specifying the scope of the plan, the administrator uses the wizard to specify a simulated Group Policy settings environment. Because these Group Policy environment settings are simulated, an actual client computer might behave differently in live tests. It is not possible for a domain controller to accurately determine how a particular client computer will actually behave.

The following simulated environment settings are available:

- A slow network connection
- Loopback processing (merge mode and replace mode)
- Site-based policy implementation
- Security group memberships for the user, the computer, or both
- WMI Filters that are linked to the user, the computer, or both

The administrator can elect to simulate any, all, or none of the environment variables. Whatever the choices, when the wizard finishes, the RSoP snap-in requests a simulation of policy from the domain controller. The domain controller uses Resultant Set of Policy Provider to simulate the application of GPOs. This service passes the GPO settings to virtual client-side extensions on the domain controller. The results of the simulation are stored in the WMI repository on the domain controller before the information is passed back to the RSoP snap-in for analysis. It is important to remember that the results displayed in the RSoP snap-in are not actual Group Policy settings, but simulated Group Policy based on the settings created using the wizard. If a custom client side extension exists on a client but does not exist on the domain controller, then any Group Policy settings this custom client side extension might create would not appear in the simulation results.

Planning mode in the RSoP snap-in is useful for planning Group Policy. The RSoP snap-in lists each GPO from which the displayed setting came as well as any other lower priority GPOs that attempted to configure settings. Using this information, an administrator can determine which GPOs are applying a policy setting and which GPOs are not.

**Similar Technologies for Viewing Resultant Set of Policy Data**
Although administrators can use the RSoP snap-in for reporting and planning the effects of Group Policy, much of its functionality has been subsumed into Group Policy Management Console (GPMC), which provides a much better experience for the network administrator.

The following table gives the equivalent names of GPMC and RSoP snap-in features that utilize the RSoP infrastructure.

**Equivalent Names and Descriptions of GPMC and RSoP Snap-in Features**

| GPMC feature | RSoP snap-in feature | Description |
|---|---|---|
| Group Policy Results | Logging Mode | Reports the effect of policy on a computer or user |
| Group Policy Modeling | Planning Mode | Predicts the affect of policy on the network |

Although GPMC provides functionality that subsumes most of the reporting features of RSoP snap-in, there is some Group Policy information that can only be reported on using RSoP snap-in. For example, RSoP snap-in lists each GPO from which the displayed setting came as well as any other lower priority GPOs that attempted to configure settings. Using this information, an administrator can determine which GPOs are applying a policy setting and which GPOs are not. In these cases, an administrator can use GPMC to open the RSoP snap-in by electing to view advanced information about a Group Policy Results or Group Policy Modeling report.

**Resultant Set of Policy Snap-in Dependencies**
Resultant Set of Policy snap-in has the following dependencies.

- Resultant Set of Policy snap-in is an MMC console; as such, it requires MMC infrastructure to function.
- Resultant Set of Policy infrastructure was introduced in Windows XP. Therefore, you cannot run gather RSoP data for a computer running Windows 2000 or lower.
- To run RSoP on a remote computer, you must be logged on as a member of the local Administrators group, or be delegated **Generate Resultant Set of Policy (logging)** rights for logging mode, or **Generate Resultant Set of Policy (planning)** rights for planning mode.
- To run RSoP planning mode, you must have a Windows Server 2003 domain controller.

- For planning mode involving security group membership, the administrator needs access to see membership of security groups.

# How Resultant Set of Policy Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Resultant Set of Policy Works**

**In this section**

- Resultant Set of Policy Snap-in Architecture
- Related Topics

Administrators can use the Resultant Set of Policy (RSoP) snap-in for two purposes: to predict the cumulative effect of Group Policy objects (GPOs), or to determine the actual result of Group Policy settings on a particular computer, user, or user on a computer.

Although administrators can use the RSoP snap-in for reporting and planning the effects of Group Policy, much of its functionality has been subsumed into Group Policy Management Console (GPMC), which provides a much better experience for the network administrator.

In an ideal environment, administrators are encouraged to use the GPMC features for simulating Group Policy or determining the effect of Group Policy on a particular user or computer.

**Resultant Set of Policy Snap-in Architecture**

The RSoP snap-in is one of three administrative tools used to manage Group Policy. The following diagram shows all three of the tools, as well as the domain controller and a client computer. In addition, the diagram describes the different communication protocols being used by each tool (LDAP, SMB, RPC/COM); the interactions between RSoP, the domain controller, and the client; and whether those interactions are READ or READ/WRITE.

**Resultant Set of Policy Snap-in Architectural Diagram**

**Component Description of Resultant Set of Policy Snap-in Architectural Diagram**

| Component | Description |
|---|---|

| | |
|---|---|
| Resultant Set of Policy snap-in | The RSoP snap-in is an MMC used to determine which policy settings are in effect for a given computer, user, or user on a computer, or to predict the effect of applied policy.<br><br>The RSoP snap-in itself is contained within the same binary as the Group Policy Object Editor. Thus, the user interface is a read-only view of the same information available in Group Policy Object Editor. However, there is one important difference: while Group Policy Object Editor can show all settings from a single GPO at a time, the RSoP snap-in can show the cumulative effect of many GPOs.<br><br>For RSoP snap-in functionality, administrators can use GPMC, which includes its own integrated RSoP infrastructure reporting features.<br><br>RSoP snap-in is capable of read access to the Active Directory, Sysvol, Event Log, RSoP infrastructure, and Local GPO on the target computer. Although RSoP is capable of read-only access to the Active Directory and Sysvol, most of the work of predicting or reporting Group Policy is done using RPC/COM communication with the RSoP provider, either on the client or the domain controller. |
| Domain Controller (Server) | In an Active Directory forest, the domain controller is a server that contains a writable copy of the Active Directory database, participates in Active Directory replication, and controls access to network resources. GPOs are stored in two parts of domain controllers: The Active Directory database (sometimes called Group Policy Container) and the Sysvol (known as the Group Policy template). |
| Active Directory | Active Directory, the Windows-based directory service, stores information about objects on a network and makes this information available to users and network administrators. Administrators link GPOs to Active Directory containers such as sites, domain, and OUs that include user and computer objects. In this way, policy settings can be targeted to users and computers throughout the organization. |
| Sysvol | Sysvol is a shared directory that stores the server copy of the domain's public files, which are replicated among all domain controllers in the domain. The Sysvol contains the largest part of a GPO: the Group Policy template, which includes Administrative Template-based policy settings, security settings, script files, and information regarding applications that are available for software installation. File Replication Service (FRS) replicates this information throughout the network. |
| LDAP Protocol | LDAP (Lightweight Directory Access Protocol) is the protocol used by the Active Directory directory service. RSoP snap-in uses LDAP for authentication and delegation checks. The client also uses LDAP to read the directory store on the domain controller. |
| SMB Protocol | SMB (Server Message Block) protocol is the primary method of file and print sharing. SMB can also be used for abstractions such as named pipes and mail slots. RSoP snap-in and the client use SMB to access the Sysvol on the domain controller. |
| RPC/COM | RPC (Remote Procedure Call), DCOM (Distributed Component Object Model) and COM (Component Object Model) enable data exchange between different processes. The different process can be on the same computer, on the local area network, or across the Internet.<br><br>COM and RPC are used by the RSoP snap-in for communication with the RSoP provider on the client or domain controller. |
| WMI | WMI is a management infrastructure that supports the monitoring and controlling of system resources through a common set of interfaces and provides a logically organized, consistent model of Windows operation, configuration, and status.<br><br>WMI makes available data about a target computer for administrative use. Such data can include hardware and software inventory, settings, and configuration information. For example, WMI exposes hardware configuration data such as CPU, memory, disk space, and manufacturer, as well as software configuration data from the registry, drivers, file system, Active Directory, the Windows Installer service, networking configuration, and application data. WMI Filtering in Windows Server 2003 allows you to create queries based on this data. These queries (also called WMI filters) determine which users and computers receive all of the policy configured in the GPO where you create the filter. |

| | |
|---|---|
| RSoP infrastructure | All Group Policy processing information is collected and stored in a namespace in WMI. This information, such as the list, content and logging of processing details for each GPO, can then be accessed by tools using WMI.<br><br>In logging mode, RSoP snap-in queries the database on the target computer, receives information about the policies and displays it in the RSoP snap-in.<br><br>In planning mode, RSoP snap-in simulates the application of policy using the Resultant Set of Policy Provider on a Domain Controller. This simulates the application of GPOs and passes them to Group Policy client-side extensions on the Domain Controller. The results of this simulation are stored to a local WMI database on the domain controller before the information is passed back and displayed in the RSoP snap-in. |
| Event Log | The Event log is a service that records events in various logs. The RSoP snap-in reads the Event Log on client computers and domain controllers in order to provide information about error events. |
| Local Group Policy object | The local Group Policy object (local GPO) is stored on each individual computer, in the hidden **%systemroot%\System32\GroupPolicy** directory. Each computer running Windows 2000, Windows XP Professional, Windows XP 64-Bit Edition, or Windows Server 2003 has exactly one local GPO, regardless of whether the computers are part of an Active Directory environment.<br><br>Local GPOs do not support certain extensions, such as Folder Redirection or Group Policy Software Installation. Local GPOs do support many security settings, but the Security Settings extension of the Group Policy Object Editor does not support remote management of local GPOs. Local GPOs are always processed, but can be overridden by domain policy in an Active Directory environment, because GPOs linked to Active Directory containers have precedence. |

# Resultant Set of Policy Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resultant Set of Policy Tools and Settings**

**In this section**

- Resultant Set of Policy Tools
- Resultant Set of Policy Group Policy Settings
- Resultant Set of Policy WMI Classes
- Related Information

This section describes the tools and settings that are associated with Resultant Set of Policy (RSoP), a Microsoft Management Console (MMC) snap-in that administrators use to report and plan cumulative effects of Group Policy.

**Resultant Set of Policy Tools**

The following tools are associated with Resultant Set of Policy.

**RSoP Extension**

**Category**

The Resultant Set of Policy (RSoP) extension is an MMC snap-in included in the same binary as the Group Policy Object Editor (gpedit.dll). The RSoP extension consists of a planning mode service, and a logging mode service. These two services correspond to the Group Policy Modeling and Group Policy Results nodes, respectively, in Group Policy Management Console (GPMC).

**Version compatibility**

The RSoP feature, which consists of two services, requires a Windows Server 2003 domain controller for the planning mode, but requires only a Windows Server 2003 schema for remote logging delegation. A Windows Management Instrumentation (WMI) namespace, Web Based Enterprise Management (WBEM), on which each computer policy has processed, is required for logging mode. This namespace is present in Windows XP and later.

The RSoP snap-in displays RSoP data provided by one or both of its two services, depending on domain controller operating system and forest schema. The RSoP snap-in requires Windows XP or later. RSoP logging is always processed on the targeted client computer. For remote logging, the RSoP data is generated on the remote computer and displayed on the client computer running the RSoP snap-in.

For more information about Resultant Set of Policy, see the What Is Resultant Set of Policy? topic in this collection.

**Gpresult.exe: Group Policy Results**

**Category**

This command line tool displays RSoP for a user or computer. You can use gpresult to see what policy is in effect and to troubleshoot problems on computers running Windows XP and later.

**Version compatibility**

The gpresult.exe that ships with Windows XP and Windows Server 2003 family is completely different than the original version of gpresult.exe that shipped in the Windows 2000 Resource Kit. The newer version cannot be used to view policy information for computers running Windows 2000.

For more information about Group Policy Tools and Settings, see the Core Group Policy Tools and Settings topic in this collection.

**Resultant Set of Policy Group Policy Settings**

This section describes Resultant Set of Policy specific settings. Using these settings, the administrator can determine which MMC snap-ins and RSoP services are permitted for the GPO. For a complete reference of these settings, see Group Policy Settings Reference for Windows Server 2003.

### Group Policy Settings Associated with RSoP

| Group Policy Setting | Description |
| --- | --- |
| Resultant Set of Policy Provider (Computer Configuration/Windows Settings/Security Settings/System Services) | This setting controls enabling/disabling the RSoP service. |
| Turn off RSoP logging (Computer Configuration/Administrative Templates/System/Group Policy) | This setting allows you to enable or disable Resultant Set of Policy (RSoP) logging on a client computer. |
| Disallow Interactive Users from generating RSoP data (Computer and User Configuration/Administrative Templates/System/Group Policy) | This setting controls the ability of users to view their Resultant Set of Policy (RSoP) data.<br><br>If this setting is enabled, interactive users cannot generate RSoP data.<br><br>If this setting is not configured or disabled, interactive Users can generate RSoP. |
| Resultant Set of Policy snap-in (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the “Restrict users to the explicitly permitted list of snap-ins” setting determines whether this snap-in is permitted or prohibited. |
| Administrative Templates (Computers) (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy/RSoP snap-in extensions) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the “Restrict users to the explicitly permitted list of snap-ins” setting determines whether this snap-in is permitted or prohibited. |
| Administrative Templates (Users) (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy/RSoP snap-in extensions) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the “Restrict users to the explicitly permitted list of snap-ins” setting determines whether this snap-in is permitted or prohibited. |
| Folder Redirection (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy/RSoP snap-in extensions) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the “Restrict users to the explicitly permitted list of snap-ins” setting determines whether this snap-in is permitted or prohibited. |
| Internet Explorer Maintenance (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy/RSoP snap-in extensions) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the “Restrict users to the explicitly permitted list of snap-ins” setting determines whether this snap-in is permitted or prohibited. |

| | |
|---|---|
| Scripts (Logon/Logoff) (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy/RSoP snap-in extensions) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the "Restrict users to the explicitly permitted list of snap-ins" setting determines whether this snap-in is permitted or prohibited. |
| Scripts (Startup/Shutdown) (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy/RSoP snap-in extensions) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the "Restrict users to the explicitly permitted list of snap-ins" setting determines whether this snap-in is permitted or prohibited. |
| Security Settings (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy/RSoP snap-in extensions) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the "Restrict users to the explicitly permitted list of snap-ins" setting determines whether this snap-in is permitted or prohibited. |
| Software Installation (Computers) (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy/RSoP snap-in extensions) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the "Restrict users to the explicitly permitted list of snap-ins" setting determines whether this snap-in is permitted or prohibited. |
| Software Installation (Users) (User Configuration/Administrative Templates/Windows Components/MMC/Restricted/Permitted snap-ins/Group Policy/RSoP snap-in extensions) | This setting permits or prohibits use of this snap-in.<br><br>If you enable this setting, the snap-in is permitted. If you disable the setting, the snap-in is prohibited.<br><br>If this setting is not configured, the setting of the "Restrict users to the explicitly permitted list of snap-ins" setting determines whether this snap-in is permitted or prohibited. |

For more information about Group Policy settings, see the Group Policy Settings Reference for Windows Server 2003.

**Resultant Set of Policy WMI Classes**

There are two categories of WMI namespaces: computer and user. Each user has its own RSoP namespace based on the user's Security Identifier (SID). Administrators can automate RSoP using scripting and WMI classes. The following table lists the WMI classes associated with RSoP.

**RSoP WMI Classes**

| Class Name | Namespaces | Version Compatibility |
|---|---|---|
| RsopLoggingModeProvider | ROOT\RSOP | Windows XP<br><br>Windows Server 2003 |
| RsopPlanningModeProvider | ROOT\RSOP | Windows XP<br><br>Windows Server 2003<br><br>(Windows Server 2003 Domain Controller Required) |

In addition, administrators can automate RSoP using the **IGPMRSOP** interface included with GPMC interfaces. The **IGPMRSOP** interface provides methods that support making RSoP queries in both logging and planning mode.

# High Availability and Scalability Collection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**High Availability and Scalability Collection**
In a competitive environment, enterprises are required to have computer systems that are both highly available and easily scalable. High availability is essential to both customer satisfaction and employee productivity. Scalability is vital in responding to spikes in business and supporting the rapid rollout of new products and services.

The following technologies provide for high availability and scalability in a Microsoft Windows Server 2003 environment:

- Clustering Technologies
- Resource and Memory Management Technologies

High availability is the ability to provide user access to a service or application for a high percentage of scheduled time by attempting to reduce unscheduled outages and mitigate the impact of scheduled downtime for particular servers. A solution is highly available if it meets the organization's scheduled uptime goals. Included in the Windows Server 2003 family of operating systems are two technologies used to improve availability, server clusters and Network Load Balancing.

Scalability is the ability to increase or decrease computing capacity almost instantly, while delivering on value. Scalability is delivered through two methods: scale up and scale out. Typically, both scale up and scale out technologies are employed by organizations to address the capacity needs of Web applications, databases, and business applications. The scaling method used, scale out or scale up, depends on the types of applications being used and on the type of functionality needed. The scale up technologies included in the 32-bit versions of Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, are: 4-gigabyte tuning (4GT), Physical Address Extension (PAE) X86, and Windows System Resource Manager. Available in all versions of the Windows Server 2003 family of products is Network Load Balancing, which can be used to not only improve availability, but also as a scale out solution.

High availability and scale up and scale out technologies are designed to respond to the changing requirements demanded of today's enterprise, regardless of where changes occur in the architecture. Whether it is handling Web site traffic, query processing, or large-scale database applications, high availability and scaling flexibility provide support for the most demanding Information Technology (IT) environments. By using these technologies, administrators can provide a highly available IT infrastructure that can incrementally scale as needed, without having to over-buy computing power.

### Notes

- Although not currently described in this Technical Reference, Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, also support Cache Coherent Non-Uniform Memory Architecture (ccNUMA) and Large Symmetric Multiprocessing (Large SMP). These two scale up technologies enhance and optimize processing in large multi-CPU servers.
- Also not discussed in this collection of technologies, the 64-bit versions of Windows Server 2003 provide scale up capabilities as well. Because of the inherent capabilities of the 64-bit operating system, the scale up technologies described in this collection are not required on the 64-bit versions of the Windows Server 2003 family.

**Clustering Technologies**
Availability is the percentage of time that a system is available for users. Availability is increased by reducing the amount of time that a system is down for any reason, such as maintenance, upgrades, or recovery from a failure. Server clusters and Network Load Balancing can improve availability by removing the physical server as a single point of failure. A server cluster is a group of independent computer systems that work together as a single system. If one of the servers in the cluster becomes unavailable, another server in the cluster can automatically replace the unavailable server and continue to provide users access to the system.

Network Load Balancing combines up to 32 servers running any product in the Windows Server 2003 family into a single cluster. Each server can run an identical set of processes and applications. If one of the servers becomes unavailable, network requests can automatically be redirected to other servers in the Network Load Balancing cluster thus eliminating any loss of system availability.

### Note

- Maintaining highly available systems requires not only good choices in technology, but careful attention to design and operational practices. Implementing server clusters and Network Load Balancing will not ensure high availability. Many other factors, not covered in this technical reference, must also be considered and addressed.

**Resource and Memory Management Technologies**
Scaling up refers to incrementally adding system hardware resources (processors and memory) to increase overall system performance. Two of the resource and memory management technologies described in this technical reference used for scaling up, 4-gigabyte tuning (4GT) and Physical Address Extension (PAE) X86, are key components of the scale up capabilities. Further, Windows System Resource Manager provides for the effective management of the powerful servers used in scale up scenarios. Windows System Resource Manager makes it possible to assign, manage, and guarantee system resources for applications. Windows System Resource Manager also provides resource utilization statistics.

### Note

- Not only must the hardware and operating system be able to effectively scale up, but to gain the benefits of scale up capability, applications must be designed to scale up as well.

**Clustering Technologies**
The two clustering technologies described here are server clusters and Network Load Balancing. Both of these technologies provide a means for two or more computers to work together to provide a higher level of availability than can be obtained by using a single computer.

A brief description of these technologies is provided in the following sections.

For more information about clustering technologies, see "Clustering Technologies."

**Server Clusters**
A server cluster is a group of independent computer systems running Microsoft Windows Server 2003, Enterprise Edition, or Microsoft Windows Server 2003, Datacenter Edition, and working together as a single system to ensure that critical applications and resources remain available to clients. The servers in a cluster remain in constant communication through the exchange of periodic messages. If one of the servers becomes unavailable as a result of failure or maintenance, another server immediately begins providing service (a process known as failover). Server clusters also allow users and administrators to access and manage the servers as a single system rather than as separate computers.

**Network Load Balancing**
Network Load Balancing improves availability by clustering multiple servers running identical services and applications. The servers in the cluster can concurrently respond to different client requests, even multiple requests from the same client. Similar to server clusters, the servers in a Network Load Balancing cluster remain in constant communication through the exchange of periodic messages. If one of the servers becomes unavailable, the other servers in the cluster can continue to respond to client requests with no loss of availability. For more information about Network Load Balancing, see "Network Load Balancing Technical Reference."

**Resource and Memory Management Technologies**
4GT and PAE X86 increase the amount of RAM available to applications. Windows System Resource Manager makes it possible to assign, manage, and guarantee system resources for applications. Windows System Resource Manager also provides resource utilization statistics.

A brief description of these technologies is provided in the following sections.

For more information about scale up technologies, see "Resource and Memory Management Technologies."

### Notes

- Although not currently described in this Technical Reference, Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, also support Cache Coherent Non-Uniform Memory Architecture (ccNUMA) and Large Symmetric Multiprocessing (Large SMP). These two scale up technologies enhance and optimize processing in large multi-CPU servers.

- Also not discussed in this collection of technologies, the 64-bit versions of Windows Server 2003 provide scale up capabilities as well. Because of the inherent capabilities of the 64-bit operating system, the scale up technologies described in this collection are not required on the 64-bit versions of the Windows Server 2003 operating system.

**4-gigabyte Tuning (4GT)**
Additional RAM is often added to servers as they are scaled up to meet increasing demands. Applications can benefit from accessing this additional memory. 4GT can make more of the computer's RAM available to applications by making less virtual memory available to the operating system. 4GT allows applications to address 3 gigabytes (GB) of virtual memory instead of the 2 GB normally allocated for user mode processes. This is a 50 percent increase in virtual memory for the applications, allowing more data to be cached and potentially increasing performance. For more information about 4GT, see "4GT Technical Reference."

**Physical Address Extension (PAE) X86**
As even more physical memory is added to servers, the operating system must be specifically enabled to access any memory beyond 4 GB. PAE X86 provides access to this additional memory. PAE X86 allows software that uses the Address Windowing Extensions (AWE) API set and runs on computers with more than 4 GB of physical memory to map more physical memory into the application's virtual address space. Applications not using the AWE API set can also benefit from PAE X86 because the operating system uses the larger physical memory to reduce paging and thus increase performance. For more information about PAE X86, see PAE X86 Technical Reference."

**Windows System Resource Manager**
Windows System Resource Manager (WSRM) is a tool used to manage server resources such as processor cycles and memory utilization. Using policies, Windows System Resource Manager allocates specific amounts of resources to applications or processes. These policies allow system administrators to set usage limits based on a percentage of available CPU resources as well as set affinities between managed applications and certain CPUs in the case of multi-processor servers. For more information about Windows System Resource Manager, see "Windows System Resource Manager Technical Reference."

**High Availability and Scalability Scenarios**
Each of the technologies described in this collection can be used in multiple ways for multiple scenarios. However, certain technologies are better suited for particular situations, as described in the following sections.

Additional deployment scenarios for 4GT, PAE X86, Windows System Resource Manager, and Network Load Balancing are described in the Technical Reference section for each technology.

**High availability**
Applications servicing customers as well as line-of-business applications such as databases, messaging servers, enterprise resource planning (ERP) applications and core file and print services are central to a company's operations and profitability. It is essential that these applications remain highly available. While both server clusters and Network Load Balancing can be used to improve the availability of many of these applications, each technology is better suited for certain scenarios. Server clusters are particularly valuable for messaging applications, database applications, and file and print services. Network Load Balancing is most commonly used with Web and File Transfer Protocol (FTP) servers, proxy servers and firewall services, such as computers running Microsoft Internet Security and Acceleration (ISA) Server, virtual private network (VPN) servers, servers running Windows Media technologies player, and terminal servers.

**Scale up**
Many of the same applications requiring high availability also present the need for scalability. Applications such as transaction processing applications and databases are architected to perform best on a single, monolithic server requiring scale up capabilities. The scale up technologies 4GT, PAE X86, and Windows System Resource Manager, are typically used in server consolidation scenarios and other enterprise systems that make use of these large servers with large amounts of memory and multiple CPUs. Some examples of scale up usage models include:

- Back-end database systems that drive ERP
- Customer relationship management (CRM) applications
- Decision support and data mining

**Scale out**
Scale out scenarios are ones in which applications are architected for distributed processing or that might need incremental hardware additions. Scale out scenarios also require the ability for centralized management of multiple servers. The same applications that can benefit from improved availability using Network Load Balancing can also often be scaled out with Network Load Balancing as well. As described earlier, these are Web and File Transfer Protocol (FTP) servers, proxy servers and firewall services, such as computers running Internet Security and Acceleration (ISA) Server, virtual private network (VPN) servers, servers running Windows Media technologies player, and terminal servers.

# Clustering Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Clustering Technologies**

The clustering technologies in products in the Microsoft Windows Server 2003 operating system are designed to help you achieve high availability and scalability for applications that are critically important to your business. These applications include corporate databases, e-mail, and Web-based services such as retail Web sites. By using appropriate clustering technologies and carefully implementing good design and operational practices (for example, configuration management and capacity management), you can scale your installation appropriately and ensure that your applications and services are available whenever customers and employees need them.

High availability is the ability to provide user access to a service or application for a high percentage of scheduled time by attempting to reduce unscheduled outages and mitigate the impact of scheduled downtime for particular servers. Scalability is the ability to easily increase or decrease computing capacity. A cluster consists of two or more computers working together to provide a higher level of availability, scalability, or both than can be obtained by using a single computer. Availability is increased in a cluster because a failure in one computer results in the workload being redistributed to another computer. Scalability tends to be increased, because in many situations it is easy to change the number of computers in the cluster.

Windows Server 2003 provides two clustering technologies: server clusters and Network Load Balancing (NLB). Server clusters primarily provide high availability; Network Load Balancing provides scalability and at the same time helps increase availability of Web-based services.

Your choice of cluster technologies (server clusters or Network Load Balancing) depends primarily on whether the applications you run have long-running in-memory state:

- **Server clusters** are designed for applications that have long-running in-memory state or frequently updated data. These are called stateful applications. Examples of stateful applications include database applications such as Microsoft SQL Server 2000 and messaging applications such as Microsoft Exchange Server 2003.

  Server clusters can combine up to eight servers.

- **Network Load Balancing** is intended for applications that do not have long-running in-memory state. These are called stateless applications. A stateless application treats each client request as an independent operation, and therefore it can load-balance each request independently. Stateless applications often have read-only data or data that changes infrequently. Web front-end servers, virtual private networks (VPNs), and File Transfer Protocol (FTP) servers typically use Network Load Balancing. Network Load Balancing clusters can also support other TCP- or UDP-based services and applications.

  Network Load Balancing can combine up to 32 servers.

In addition, with Microsoft Application Center 2000 Service Pack 2, you can create another type of cluster, a Component Load Balancing cluster. Component Load Balancing clusters balance the load between Web-based applications distributed across multiple servers and simplify the management of those applications. Application Center 2000 Service Pack 2 can be used with Web applications built on either the Microsoft Windows 2000 or Windows Server 2003 operating systems.

**Multitiered Approach for Deployment of Multiple Clustering Technologies**

Microsoft does not support the configuration of server clusters and Network Load Balancing clusters on the same server. Instead, use these technologies in a multitiered approach.

**Clustering Technologies Architecture**

A cluster consists of two or more computers (servers) working together. For server clusters, the individual servers are called nodes. For Network Load Balancing clusters, the individual servers are called hosts.

**Basic Architecture for Server Clusters**

The following diagram shows a four-node server cluster of the most common type, called a single quorum device cluster. In this type of server cluster, there are multiple nodes with one or more cluster disk arrays (often called the cluster storage) and a connection device (bus). Each of the disks in the disk array are owned and managed by only one node at a time. The quorum resource on the cluster disk array provides node-independent storage for cluster configuration and state data, so that each

node can obtain that data even if one or more other nodes are down.

**Four-Node Server Cluster Using a Single Quorum Device**

**Basic Architecture for Network Load Balancing Clusters**

The following diagram shows a Network Load Balancing cluster with eight hosts. Incoming client requests are distributed across the hosts. Each host runs a separate copy of the desired server application, for example, Internet Information Services. If a host failed, incoming client requests would be directed to other hosts in the cluster. If the load increased and additional hosts were needed, you could add them dynamically to the cluster.

**Network Load Balancing Cluster with Eight Hosts**

**Clustering Technologies Scenarios**

This section describes the most common scenarios for using server clusters and Network Load Balancing.

**Scenarios for Server Clusters**

This section provides brief descriptions of some of the scenarios for server cluster deployment. The scenarios cover three different aspects of server cluster deployment:

- The applications or services on the server cluster.
- The type of storage option: SCSI, Fibre Channel arbitrated loops, or Fibre Channel switched fabric.
- The number of nodes and the ways that the nodes can fail over to each other.

**Applications or Services on a Server Cluster**

Server clusters are usually used for services, applications, or other resources that need high availability. Some of the most common resources deployed on a server cluster include:

- **Printing**
- **File sharing**
- **Network infrastructure services**. These include the DHCP service and the WINS service.

- **Services that support transaction processing and distributed applications**. These services include the Distributed Transaction Coordinator (DTC) and Message Queuing.

- **Messaging applications**. An example of a messaging application is Microsoft Exchange Server 2003.

- **Database applications**. An example of a database application is Microsoft SQL Server 2000.

#### Types of Storage Options

A variety of storage solutions are currently available for use with server clusters. As with all hardware that you use in a cluster, be sure to choose solutions that are listed as compatible with Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition. Also be sure to follow the vendor's instructions closely.

The following table provides an overview of the three types of storage options available for server clusters running Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition:

**Storage Options for Server Clusters**

| Storage Option | Maximum Number of Supported Nodes |
|---|---|
| SCSI | Two |
| Fibre Channel arbitrated loop | Two |
| Fibre Channel switched fabric | Eight |

#### Number of Nodes and Failover Plan

Another aspect of server cluster design is the number of nodes used and the plan for application failover:

- **N-node Failover Pairs**. In this mode of operation, each application is set to fail over between two specified nodes.

- **Hot-Standby Server /N+I**. Hot-standby server operation mode reduces the overhead of failover pairs by consolidating the "spare" (idle) node for each pair into a single node, providing a server that is capable of running the applications from each node pair in the event of a failure. This mode of operation is also referred to as active/passive.

  For larger clusters, N+I mode provides an extension of the hot-standby server mode where N cluster nodes host applications and I cluster nodes are spare nodes.

- **Failover Ring**. In this mode of operation, each node in the cluster runs an application instance. In the event of a failure, the application on the failed node is moved to the next node in sequence.

- **Random**. For large clusters running multiple applications, the best policy in some cases is to allow the server cluster to choose the fail over node at random.

#### Scenarios for Network Load Balancing

This section provides brief descriptions of some of the scenarios for deployment of Network Load Balancing. The scenarios cover three different aspects of Network Load Balancing deployment:

- The types of servers or services in Network Load Balancing clusters.

- The number and mode of network adapters on each host.

#### Types of Servers or Services in Network Load Balancing Clusters

In Network Load Balancing clusters, some of the most common types of servers or services are as follows:

- Web and File Transfer Protocol (FTP) servers.

- ISA servers (for proxy servers and firewall services).

- Virtual private network (VPN) servers.
- Windows Media servers.
- Terminal servers.

**Number and Mode of Network Adapters on Each Network Load Balancing Host**

Another aspect of the design of a Network Load Balancing cluster is the number and mode of the network adapter or adapters on each of the hosts:

| **Number and Mode of Network Adapters on Each Host** | **Use** |
|---|---|
| Single network adapter in unicast mode | A cluster in which ordinary network communication among cluster hosts is not required and in which there is limited dedicated traffic from outside the cluster subnet to specific cluster hosts. |
| Multiple network adapters in unicast mode | A cluster in which ordinary network communication among cluster hosts is necessary or desirable. It is also appropriate when you want to separate the traffic used to manage the cluster from the traffic occurring between the cluster and client computers. |
| Single network adapter in multicast mode | A cluster in which ordinary network communication among cluster hosts is necessary or desirable but in which there is limited dedicated traffic from outside the cluster subnet to specific cluster hosts. |
| Multiple network adapters in multicast mode | A cluster in which ordinary network communication among cluster hosts is necessary and in which there is heavy dedicated traffic from outside the cluster subnet to specific cluster hosts. |

# Server Clusters Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server Clusters Technical Reference**
With the Microsoft Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, operating systems you can use server clusters to ensure that users have constant access to important server-based resources. With clustering, you create several cluster nodes that appear to users as one server. If one of the nodes in the cluster fails, another node begins to provide service (a process known as failover). In this way, server clusters can increase the availability and scalability of critical applications and resources.

Server clusters are based on one of the two clustering technologies in Windows Server 2003. The other clustering technology is Network Load Balancing. Server clusters are designed for applications that have long-running in-memory state or frequently updated data. Typical uses for server clusters include file servers, print servers, database servers, and messaging servers. Network Load Balancing is intended for applications that do not have long-running in-memory state. Typical uses for Network Load Balancing include Web front-end servers, virtual private networks (VPNs), and File Transfer Protocol (FTP) servers.

# What Is a Server Cluster?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is a Server Cluster?**

**In this section**

- Introduction to Server Clusters
- Types of Server Clusters
- Related Information

A server cluster is a group of independent servers running Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition, and working together as a single system to provide high availability of services for clients. When a failure occurs on one computer in a cluster, resources are redirected and the workload is redistributed to another computer in the cluster. You can use server clusters to ensure that users have constant access to important server-based resources.

Server clusters are designed for applications that have long-running in-memory state or frequently updated data. Typical uses for server clusters include file servers, print servers, database servers, and messaging servers.

**Introduction to Server Clusters**

A cluster consists of two or more computers working together to provide a higher level of availability, reliability, and scalability than can be obtained by using a single computer. Microsoft cluster technologies guard against three specific types of failure:

- **Application and service failures,** which affect application software and essential services.
- **System and hardware failures,** which affect hardware components such as CPUs, drives, memory, network adapters, and power supplies.
- **Site failures in multisite organizations,** which can be caused by natural disasters, power outages, or connectivity outages.

The ability to handle failure allows server clusters to meet requirements for high availability, which is the ability to provide users with access to a service for a high percentage of time while reducing unscheduled outages.

In a server cluster, each server owns and manages its local devices and has a copy of the operating system and the applications or services that the cluster is managing. Devices common to the cluster, such as disks in common disk arrays and the connection media for accessing those disks, are owned and managed by only one server at a time. For most server clusters, the application data is stored on disks in one of the common disk arrays, and this data is accessible only to the server that currently owns the corresponding application or service.

Server clusters are designed so that the servers in the cluster work together to protect data, keep applications and services running after failure on one of the servers, and maintain consistency of the cluster configuration over time.

**Dependencies on Other Technologies**

Server clusters require network technologies that use IP-based protocols and depend on the following basic elements of network infrastructure:

- The Active Directory directory service (although server clusters can run on Windows NT, which does not use Active Directory).
- A name resolution service, that is, Windows Internet Name Service (WINS), the Domain Name System (DNS), or both. You can also use IP broadcast name resolution. However, because IP broadcast name resolution increases network traffic, and is ineffective in routed networks, within this Technical Reference we assume that you are using WINS or DNS.

In addition, for IP addressing for clients, Dynamic Host Configuration Protocol (DHCP) is often used.

**Note**

- The Cluster service does not support the use of IP addresses assigned from a DHCP server for the cluster administration address (which is an IP address resource associated with the cluster name) or any other IP address resources. If possible, we recommend that you use static IP addresses for all cluster systems.

**Types of Server Clusters**

There are three types of server clusters, based on how the cluster systems, called nodes, are connected to the devices that store the cluster configuration and state data. This data must be stored in a way that allows each active node to obtain the data even if one or more nodes are down. The data is stored on a resource called the quorum resource. The data on the quorum resource includes a set of cluster configuration information plus records (sometimes called checkpoints) of the most recent changes made to that configuration. A node coming online after an outage can use the quorum resource as the definitive source for recent changes in the configuration.

The sections that follow describe the three different types of server clusters:

- Single quorum device cluster, also called a standard quorum cluster
- Majority node set cluster
- Local quorum cluster, also called a single node cluster

**Single Quorum Device Cluster**

The most widely used cluster type is the single quorum device cluster, also called the standard quorum cluster. In this type of cluster there are multiple nodes with one or more cluster disk arrays, also called the cluster storage, and a connection device, that is, a bus. Each disk in the array is owned and managed by only one server at a time. The disk array also contains the quorum resource. The following figure illustrates a single quorum device cluster with one cluster disk array.

**Single Quorum Device Cluster**

Because single quorum device clusters are the most widely used cluster, this Technical Reference focuses on this type of cluster.

**Majority Node Set Cluster**

Windows Server 2003 supports another type of cluster, the majority node set cluster. In a majority node set cluster, each node maintains its own copy of the cluster configuration data. The quorum resource keeps configuration data consistent across the nodes. For this reason, majority node set clusters can be used for geographically dispersed clusters. Another advantage of majority node set clusters is that a quorum disk can be taken offline for maintenance and the cluster as a whole will continue to operate.

The major difference between majority node set clusters and single quorum device clusters is that single quorum device clusters can operate with just one node, but majority node set clusters need to have a majority of the cluster nodes available for the server cluster to operate. The following figure illustrates a majority node set cluster. For the cluster in the figure to continue to operate, two of the three cluster nodes (a majority) must be available.

**Majority Node Set Cluster**

This Technical Reference focuses on the single quorum device cluster.

**Local Quorum Cluster**

A local quorum cluster, also called a single node cluster, has a single node and is often used for testing. The following figure illustrates a local quorum cluster.

**Local Quorum Cluster**

This Technical Reference focuses on the single quorum device cluster, which is explained earlier in this section.

**Related Information**

The following sources provide information that is relevant to this section.

- "Planning Server Deployments" in the Windows Server 2003 Deployment Kit on the Microsoft Web site for information about planning for high availability and scalability, choosing among the different types of clustering technology, and designing and deploying server clusters.

- Network Load Balancing Technical Reference

# How a Server Cluster Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How a Server Cluster Works**

**In this section**

- Server Cluster Architecture
- Server Cluster API
- Server Cluster Processes
- Related Information

A server cluster is a collection of servers, called nodes that communicate with each other to make a set of services highly available to clients. Server clusters are based on one of the two clustering technologies in the Microsoft Windows Server 2003 operating systems. The other clustering technology is Network Load Balancing. Server clusters are designed for applications that have long-running in-memory state or frequently updated data. Typical uses for server clusters include file servers, print servers, database servers, and messaging servers.

This section provides technical background information about how the components within a server cluster work.

**Server Cluster Architecture**

The most basic type of cluster is a two-node cluster with a single quorum device. For a definition of a single quorum device, see "What Is a Server Cluster?." The following figure illustrates the basic elements of a server cluster, including nodes, resource groups, and the single quorum device, that is, the cluster storage.

**Basic Elements of a Two-Node Cluster with Single Quorum Device**

Applications and services are configured as resources on the cluster and are grouped into resource groups. Resources in a resource group work together and fail over together when failover is necessary. When you configure each resource group to include not only the elements needed for the application or service but also the associated network name and IP address, then that collection of resources runs as if it were a separate server on the network. When a resource group is configured this way,

clients can consistently get access to the application using the same network name, regardless of which node the application is running on.

The preceding figure showed one resource group per node. However, each node can have multiple resource groups. Within each resource group, resources can have specific dependencies. Dependencies are relationships between resources that indicate which resources need to come online before another resource can come online. When dependencies are configured, the Cluster service can bring resources online or take them offline in the correct order during failover.

The following figure shows two nodes with several resource groups in which some typical dependencies have been configured between resources. The figure shows that resource groups (not resources) are the unit of failover.

**Resource Dependencies Configured Within Resource Groups**

**Cluster Service Component Diagrams and Descriptions**

The Cluster service runs on each node of a server cluster and controls all aspects of server cluster operation. The Cluster service includes multiple software components that work together. These components perform monitoring, maintain consistency, and smoothly transfer resources from one node to another.

Diagrams and descriptions of the following components are grouped together because the components work so closely together:

- Database Manager (for the cluster configuration database)
- Node Manager (working with Membership Manager)
- Failover Manager
- Global Update Manager

Separate diagrams and descriptions are provided of the following components, which are used in specific situations or for specific types of applications:

- Checkpoint Manager
- Log Manager (quorum logging)
- Event Log Replication Manager
- Backup and Restore capabilities in Failover Manager

**Diagrams of Database Manager, Node Manager, Failover Manager, Global Update Manager, and Resource Monitors**

The following figure focuses on the information that is communicated between Database Manager, Node Manager, and Failover Manager. The figure also shows Global Update Manager, which supports the other three managers by coordinating updates on other nodes in the cluster. These four components work together to make sure that all nodes maintain a consistent view of the cluster (with each node of the cluster maintaining the same view of the state of the member nodes as the others) and that resource groups can be failed over smoothly when needed.

**Basic Cluster Components: Database Manager, Node Manager, and Failover Manager**

The following figure shows a Resource Monitor and resource dynamic-link library (DLL) working with Database Manager, Node Manager, and Failover Manager. Resource Monitors and resource DLLs support applications that are cluster-aware, that is, applications designed to work in a coordinated way with cluster components. The resource DLL for each such application is responsible for monitoring and controlling that application. For example, the resource DLL saves and retrieves application properties in the cluster database, brings the resource online and takes it offline, and checks the health of the resource. When failover is necessary, the resource DLL works with a Resource Monitor and Failover Manager to ensure that the failover happens smoothly.

**Resource Monitor and Resource DLL with a Cluster-Aware Application**

**Descriptions of Database Manager, Node Manager, Failover Manager, Global Update Manager, and Resource Monitors**
The following descriptions provide details about the components shown in the preceding diagrams.

**Database Manager**
Database Manager runs on each node and maintains a local copy of the cluster configuration database, which contains information about all of the physical and logical items in a cluster. These items include the cluster itself, cluster node membership, resource groups, resource types, and descriptions of specific resources, such as disks and IP addresses. Database Manager uses the Global Update Manager to replicate all changes to the other nodes in the cluster. In this way, consistent configuration information is maintained across the cluster, even if conditions are changing such as if a node fails and the administrator changes the cluster configuration before that node returns to service.

Database Manager also provides an interface through which other Cluster service components, such as Failover Manager and Node Manager, can store changes in the cluster configuration database. The interface for making such changes is similar to the interface for making changes to the registry through the Windows application programming interface (API). The key difference is that changes received by Database Manager are replicated through Global Update Manager to all nodes in the cluster.

**Database Manager functions used by other components**
Some Database Manager functions are exposed through the cluster API. The primary purpose for exposing Database Manager functions is to allow custom resource DLLs to save private properties to the cluster database when this is useful for a particular clustered application. (A private property for a resource is a property that applies to that resource type but not other resource types; for example, the SubnetMask property applies for an IP Address resource but not for other resource types.) Database Manager functions are also used to query the cluster database.

**Node Manager**
Node Manager runs on each node and maintains a local list of nodes, networks, and network interfaces in the cluster. Through regular communication between nodes, Node Manager ensures that all nodes in the cluster have the same list of functional nodes.

Node Manager uses the information in the cluster configuration database to determine which nodes have been added to the cluster or evicted from the cluster. Each instance of Node Manager also monitors the other nodes to detect node failure. It does this by sending and receiving messages, called heartbeats, to each node on every available network. If one node detects a communication failure with another node, it broadcasts a message to the entire cluster, causing all nodes that receive the message to verify their list of functional nodes in the cluster. This is called a regroup event.

Node Manager also contributes to the process of a node joining a cluster. At that time, on the node that is joining, Node Manager establishes authenticated communication (authenticated RPC bindings) between itself and the Node Manager component on each of the currently active nodes.

### Note

- A down node is different from a node that has been evicted from the cluster. When you evict a node from the cluster, it is removed from Node Manager's list of potential cluster nodes. A down node remains on the list of potential cluster nodes even while it is down; when the node and the network it requires are functioning again, the node joins the cluster. An evicted node, however, can become part of the cluster only after you use Cluster Administrator or Cluster.exe to add the node back to the cluster.

**Membership Manager**
Membership Manager (also called the Regroup Engine) causes a regroup event whenever another node's heartbeat is interrupted (indicating a possible node failure). During a node failure and regroup event, Membership Manager and Node Manager work together to ensure that all functioning nodes agree on which nodes are functioning and which are not.

**Cluster Network Driver**
Node Manager and other components make use of the Cluster Network Driver, which supports specific types of network communication needed in a cluster. The Cluster Network Driver runs in kernel mode and provides support for a variety of functions, especially heartbeats and fault-tolerant communication between nodes.

**Failover Manager and Resource Monitors**
Failover Manager manages resources and resource groups. For example, Failover Manager stops and starts resources, manages resource dependencies, and initiates failover of resource groups. To perform these actions, it receives resource and system state information from cluster components on the node and from Resource Monitors. Resource Monitors provide the execution environment for resource DLLs and support communication between resources DLLs and Failover Manager.

Failover Manager determines which node in the cluster should own each resource group. If it is necessary to fail over a resource group, the instances of Failover Manager on each node in the cluster work together to reassign ownership of the resource group.

Depending on how the resource group is configured, Failover Manager can restart a failing resource locally or can take the failing resource offline along with its dependent resources, and then initiate failover.

**Global Update Manager**
Global Update Manager makes sure that when changes are copied to each of the nodes, the following takes place:

- Changes are made atomically, that is, either all healthy nodes are updated, or none are updated.

- Changes are made in the order they occurred, regardless of the origin of the change. The process of making changes is coordinated between nodes so that even if two different changes are made at the same time on different nodes, when the changes are replicated they are put in a particular order and made in that order on all nodes.

Global Update Manager is used by internal cluster components, such as Failover Manager, Node Manager, or Database Manager, to carry out the replication of changes to each node. Global updates are typically initiated as a result of a Cluster API call. When an update is initiated by a node, another node is designated to monitor the update and make sure that it happens on all nodes. If that node cannot make the update locally, it notifies the node that tried to initiate the update, and changes are not made anywhere (unless the operation is attempted again). If the node that is designated to monitor the update can make the update locally, but then another node cannot be updated, the node that cannot be updated is removed from the list of functional nodes, and the change is made on available nodes. If this happens, quorum logging is enabled at the same time, which ensures that the failed node receives all necessary configuration information when it is functioning again, even if the original set of nodes is down at that time.

**Diagram and Description of Checkpoint Manager**
Some applications store configuration information locally instead of or in addition to storing information in the cluster configuration database. Applications might store information locally in two ways. One way is to store configuration information in the registry on the local server; another way is to use cryptographic keys on the local server. If an application requires that locally-stored information be available on failover, Checkpoint Manager provides support by maintaining a current copy of the local information on the quorum resource.

The following figure shows the Checkpoint Manager process.

### Checkpoint Manager

Checkpoint Manager handles application-specific configuration data that is stored in the registry on the local server somewhat differently from configuration data stored using cryptographic keys on the local server. The difference is as follows:

- For applications that store configuration data in the registry on the local server, Checkpoint Manager monitors the data while the application is online. When changes occur, Checkpoint Manager updates the quorum resource with the current configuration data.

- For applications that use cryptographic keys on the local server, Checkpoint Manager copies the cryptographic container to the quorum resource only once, when you configure the checkpoint. If changes are made to the cryptographic container, the checkpoint must be removed and re-associated with the resource.

Before a resource configured to use checkpointing is brought online (for example, for failover), Checkpoint Manager brings the locally-stored application data up-to-date from the quorum resource. This helps make sure that the Cluster service can recreate the appropriate application environment before bringing the application online on any node.

**Note**

- When configuring a Generic Application resource or Generic Service resource, you specify the application-specific configuration data that Checkpoint Manager monitors and copies. When determining which configuration information must be marked for checkpointing, focus on the information that must be available when the application starts.

Checkpoint Manager also supports resources that have application-specific registry trees (not just individual keys) that exist on the cluster node where the resource comes online. Checkpoint Manager watches for changes made to these registry trees when the resource is online (not when it is offline). When the resource is online and Checkpoint Manager detects that changes have been made, it creates a copy of the registry tree on the owner node of the resource and then sends a message to the owner node of the quorum resource, telling it to copy the file to the quorum resource. Checkpoint Manager performs this function in batches so that frequent changes to registry trees do not place too heavy a load on the Cluster service.

**Diagram and Description of Log Manager (for Quorum Logging)**

The following figure shows how Log Manager works with other components when quorum logging is enabled (when a node is down).

**Log Manager and Other Components Supporting Quorum Logging**

When a node is down, quorum logging is enabled, which means Log Manager receives configuration changes collected by other components (such as Database Manager) and logs the changes to the quorum resource. The configuration changes logged on the quorum resource are then available if the entire cluster goes down and must be formed again. On the first node coming online after the entire cluster goes down, Log Manager works with Database Manager to make sure that the local copy of the configuration database is updated with information from the quorum resource. This is also true in a cluster forming for the first time — on the first node, Log Manager works with Database Manager to make sure that the local copy of the configuration database is the same as the information from the quorum resource.

**Diagram and Description of Event Log Replication Manager**

Event Log Replication Manager, part of the Cluster service, works with the operating system's Event Log service to copy event log entries to all cluster nodes. These events are marked to show which node the event occurred on.

The following figure shows how Event Log Replication Manager copies event log entries to other cluster nodes.

**How Event Log Entries Are Copied from One Node to Another**

The following interfaces and protocols are used together to queue, send, and receive events at the nodes:

- The Cluster API
- Local remote procedure calls (LRPC)
- Remote procedure calls (RPC)
- A private API in the Event Log service

Events that are logged on one node are queued, consolidated, and sent through Event Log Replication Manager, which broadcasts them to the other active nodes. If few events are logged over a period of time, each event might be broadcast individually, but if many are logged in a short period of time, they are batched together before broadcast. Events are labeled to show which node they occurred on. Each of the other nodes receives the events and records them in the local log. Replication of events is not guaranteed by Event Log Replication Manager — if a problem prevents an event from being copied, Event Log Replication Manager does not obtain notification of the problem and does not copy the event again.

**Diagram and Description of Backup and Restore Capabilities in Failover Manager**

The Backup and Restore capabilities in Failover Manager coordinate with other Cluster service components when a cluster node is backed up or restored, so that cluster configuration information from the quorum resource, and not just information from the local node, is included in the backup. The following figure shows how the Backup and Restore capabilities in Failover Manager work to ensure that important cluster configuration information is captured during a backup.

**Backup Request on a Node That Does Not Own the Quorum Resource**

**DLLs Used by Core Resource Types**

A number of DLLs that are used by core resource types are included with server clusters in Windows Server 2003. The resource DLL defines and manages the resource. The extension DLL (where applicable) defines the resource's interaction with Cluster Administrator.

**Core Resource Types and Their Associated DLLs**

| Resource Types | DLLs |
|---|---|
| Physical Disk<br><br>Internet Protocol (IP) Address<br><br>Network Name<br><br>Print Spooler<br><br>File Share<br><br>Generic Application<br><br>Generic Script<br><br>Generic Service<br><br>Local Quorum<br><br>Majority Node Set | Resource DLL: Clusres.dll<br><br>Extension DLL: Cluadmex.dll |
| Volume Shadow Copy Service Task | Resource DLL: VSSTask.dll<br><br>Extension DLL: VSSTskEx.dll |

| | |
|---|---|
| DHCP Service<br><br>WINS Service | Resource DLL: Clnetres.dll<br><br>Extension DLL: Clnetrex.dll |
| Distributed Transaction Coordinator (DTC) | Resource DLL: Mtxclu.dll<br><br>Extension DLL: not applicable |
| Message Queuing | Resource DLL: Mqclus.dll<br><br>Extension DLL: not applicable |

**Cluster Service Files**

The following table lists files that are in the cluster directory (*systemroot*\cluster, where *systemroot* is the root directory of the server's operating system).

**Cluster Service Files in *Systemroot* \Cluster**

| File | Description |
|---|---|
| Cladmwiz.dll | Cluster Administrator Wizard |
| Clcfgsrv.dll | DLL file for Add Nodes Wizard and New Server Cluster Wizard |
| Clcfgsrv.inf | Setup information file for Add Nodes Wizard and New Server Cluster Wizard |
| Clnetres.dll | Resource DLL for the DHCP and WINS services |
| Clnetrex.dll | Extension DLL for the DHCP and WINS services |
| Cluadmex.dll | Extension DLL for core resource types |
| Cluadmin.exe | Cluster Administrator |
| Cluadmmc.dll | Cluster Administrator MMC extension |
| Clusres.dll | Cluster resource DLL for core resource types |
| Clussvc.exe | Cluster service |
| Debugex.dll | Cluster Administrator debug extension |
| Mqclus.dll | Resource DLL for Message Queuing |
| Resrcmon.exe | Cluster Resource Monitor |
| Vsstask.dll | Resource DLL for Volume Shadow Copy Service Task |
| Vsstskex.dll | Extension DLL for Volume Shadow Copy Service Task |
| Wshclus.dll | Winsock helper for the Cluster Network Driver |

The following table lists log files for server clusters.

**Log Files for Server Clusters**

| Log File | Folder Location | Description |
|---|---|---|
| cluster.log (default name) | *systemroot*\Cluster | Records the activity of the Cluster service, Resource Monitor, and resource DLLs on that node. The default name of this log can be changed by changing the System environment variable called **ClusterLog**. |
| cluster.oml | *systemroot*\Cluster | Records the creation and deletion of cluster objects and other activities of the Object Manager of the cluster; useful for a developer writing a tool for analyzing the translation of GUIDs to friendly names in the cluster. |

| | | |
|---|---|---|
| clcfgsrv.log | *systemroot*\system32\LogFiles\Cluster | Records activity of Cluster configuration wizards; useful for troubleshooting problems during cluster setup. |
| clusocm.log | *systemroot*\system32\LogFiles\Cluster | Records cluster-related activity that occurs during an operating system upgrade. |
| cluscomp.log | *systemroot*\system32\LogFiles\Cluster | Records the activity that occurs during the compatibility check at the start of an operating system upgrade on a cluster node. |

The following table lists files that are in *systemroot*\system32, *systemroot*\inf, or subfolders in *systemroot*\system32.

**Additional Cluster Service Files**

| File | Folder | Description |
|---|---|---|
| clusapi.dll | *systemroot*\system32 | Server Cluster API |
| clusocm.dll | *systemroot*\system32\Setup | Cluster extension for the Optional Component Manager |
| clusocm.inf | *systemroot*\inf | Cluster INF file for the Optional Component Manager |
| clussprt.dll | *systemroot*\system32 | A DLL that enables the Cluster service on one node to send notice of local cluster events to the Event Log service on other nodes |
| cluster.exe | *systemroot*\system32 | Cluster command-line interface |
| msclus.dll | *systemroot*\system32 | Cluster Automation Server |
| Resutils.dll | *systemroot*\system32 | Utility routines used by resource DLLs |
| Clusnet.sys | *systemroot*\system32\drivers | Cluster Network Driver |
| Clusdisk.sys | *systemroot*\system32\drivers | Cluster Disk Driver |

The following table lists files that have to do with the quorum resource and (for a single quorum device cluster, the most common type of cluster) are usually in the directory *q*:*mscs*, where *q* is the quorum disk drive letter and *mscs* is the name of the directory.

**Files Related to the Quorum Resource**

| File | Description |
|---|---|
| Quolog.log | The quorum log, which contains records of cluster actions that involve changes to the cluster configuration database. |
| Chk*.tmp | Copies of the cluster configuration database (also known as checkpoints). Only the latest one is needed. |
| {GUID} | Directory for each resource that requires checkpointing; the resource GUID is the name of the directory. |
| {GUID}*.cpt | Resource registry subkey checkpoint files. |
| {GUID}*.cpr | Resource cryptographic key checkpoint files. |

**Server Cluster API**

With the Server Cluster application programming interface (API), developers can write applications and resource DLLs for server clusters. The following table lists Server Cluster API subsets.

**Subsets in the Server Cluster API**

| API Subset | Description |
|---|---|
| Cluster API | Works directly with cluster objects and interacts with the Cluster service. |
| Resource API | Manages resources through a Resource Monitor and a resource DLL. |

| | |
|---|---|
| Cluster Administrator Extension API | Enables a custom resource type to be administered by Cluster Administrator. |

For more information, see Server Cluster APIson MSDN.

**Server Cluster Processes**

The following sections provide information about the following processes:

- How nodes form, join, and leave a cluster.
- How heartbeats, regroup events, and quorum arbitration work in a cluster. These processes help the cluster to keep a consistent internal state and maintain availability of resources even when failures occur.
- How resource groups are brought online, taken offline, failed over, and failed back.

**How Nodes Form, Join, and Leave a Cluster**

Nodes must form, join, and leave a cluster in a coordinated way so that the following are always true:

- Only one node owns the quorum resource at any given time.
- All nodes maintain the same list of functioning nodes in the cluster.
- All nodes can maintain consistent copies of the cluster configuration database.

**Forming a Cluster**

The first server that comes online in a cluster, either after installation or after the entire cluster has been shut down for some reason, forms the cluster. To succeed at forming a cluster, a server must:

- Be running the Cluster service.
- Be unable to locate any other nodes in the cluster (in other words, no other nodes can be running).
- Acquire exclusive ownership of the quorum resource.

If a node attempts to form a cluster and is unable to read the quorum log, the Cluster service will not start, because it cannot guarantee that it has the latest copy of the cluster configuration. In other words, the quorum log ensures that when a cluster forms, it uses the same configuration it was using when it last stopped.

The sequence in which a node forms a cluster is as follows:

1. The node confirms that it can start the Cluster service.
2. The node reviews the information stored in the local copy of the cluster configuration database.
3. Using information from the local copy of the cluster configuration database, the node confirms that no other nodes are running.

   If another node is running, then the node that started most recently joins the cluster instead of forming it.
4. Using information from the local copy of the cluster configuration database, the node locates the quorum resource.
5. The node confirms that it can acquire exclusive ownership of the quorum resource and that it can read from the quorum resource. If it can, the node takes ownership.
6. The node compares the sequence numbers on the copy of the cluster configuration database on the quorum resource and the sequence numbers on the quorum log against the sequence numbers on the node's local copy of the cluster configuration database.

7. The node updates its local copy of the cluster configuration database with any newer information that might be stored on the quorum resource.

8. The node begins to bring resources and resource groups online.

**Joining a Cluster**
The sequence in which a server joins an existing cluster is as follows:

1. The node confirms that it can start the Cluster service.

2. The node reviews the information stored in the local copy of the cluster configuration database.

3. The node that is joining the cluster tries to locate another node (sometimes called a sponsor node) running in the cluster. The node goes through the list of other nodes in its local configuration database, trying one or more until one responds.

   If no other nodes respond, the node tries to form the cluster, starting by locating the quorum resource.

4. Node Manager on the sponsor node authenticates the new node. If the joining node is not recognized as a cluster member, the request to join the cluster is refused.

5. Node Manager on the joining node establishes authenticated communication (authenticated RPC bindings) between itself and the Node Manager component on each of the currently active nodes.

6. Database Manager on the joining node checks the local copy of the configuration database. If it is outdated, Database Manager obtains an updated copy from the sponsor node.

**Leaving a Cluster**
A node can leave a cluster when the node shuts down or when the Cluster service is stopped. When a node leaves a cluster during a planned shutdown, it attempts to perform a smooth transfer of resource groups to other nodes. The node leaving the cluster then initiates a regroup event.

Functioning nodes in a cluster can also force another node to leave the cluster if the node cannot perform cluster operations, for example, if it fails to commit an update to the cluster configuration database.

**Heartbeats, Regroup Events, and Quorum Arbitration**
When server clusters encounter changing circumstances and possible failures, the following processes help the cluster to keep a consistent internal state and maintain availability of resources:

- Heartbeats

- Regroup events

- Quorum arbitration

**Heartbeats**
Heartbeats are single User Datagram Protocol (UDP) packets exchanged between nodes once every 1.2 seconds to confirm that each node is still available. If a node is absent for five consecutive heartbeats, the node that detected the absence initiates a regroup event to make sure that all nodes reach agreement on the list of nodes that remain available.

Server cluster networks can be private (node-to-node communication only), public (client-to-node communication), or mixed (both node-to-node and client-to-node communication). Heartbeats are communicated across all networks; however, the monitoring of heartbeats and the way the cluster interprets missed heartbeats depends on the type of network:

- On private or mixed networks, which both carry node-to-node communication, heartbeats are monitored to determine whether the node is functioning in the cluster.

  A series of missed heartbeats can either mean that the node is offline or that all private and mixed networks are offline; in either case, a node has lost its ability to function in the cluster.

- On public networks, which carry only client-to-node communication, heartbeats are monitored only to determine whether a node's network adapter is functioning.

**Regroup Events**
If a node is absent for five consecutive heartbeats, a regroup event occurs. (Membership Manager, described earlier, starts the regroup event.)

If an individual node remains unresponsive, the node is removed from the list of functional nodes. If the unresponsive node was the owner of the quorum resource, the remaining nodes also begin the quorum arbitration process. After this, failover begins.

**Quorum Arbitration**
Quorum arbitration is the process that occurs when the node that owned the quorum resource fails or is unavailable, and the remaining nodes determine which node will take ownership. When a regroup event occurs and the unresponsive node owned the quorum resource, another node is designated to initiate quorum arbitration. A basic goal for quorum arbitration is to make sure that only one node owns the quorum resource at any given time.

It is important that only one node owns the quorum resource because if all network communication between two or more cluster nodes fails, it is possible for the cluster to split into two or more partial clusters that will try to keep functioning (sometimes called a "split brain" scenario). Server clusters prevent this by allowing only the partial cluster with a node that owns the quorum resource to continue as the cluster. Any nodes that cannot communicate with the node that owns the quorum resource stop working as cluster nodes.

**How Clusters Keep Resource Groups Available**
This section describes how clusters keep resource groups available by monitoring the health of resources (polling), bringing resource groups online, and carrying out failover. Failover means transferring ownership of the resources within a group from one node to another. This section also describes how resource groups are taken offline as well as how they are failed back, that is, how resource groups are transferred back to a preferred node after that node has come back online.

Transferring ownership can mean somewhat different things depending on which of the group's resources is being transferred. For an application or service, the application or service is stopped on one node and started on another. For an external device, such as a Physical Disk resource, the right to access the device is transferred. Similarly, the right to use an IP address or a network name can be transferred from one node to another.

Resource-related activities in server clusters include:

- Monitoring the health of resources (polling).
- Bringing a resource group online.
- Taking a resource group offline.
- Failing a resource group over.
- Failing a resource group back.

The administrator of the cluster initiates resource group moves, usually for maintenance or other administrative tasks. Group moves initiated by an administrator are similar to failovers in that the Cluster service initiates resource transitions by issuing commands to Resource Monitor through Failover Manager.

**Resource Health Monitoring (Polling)**
Resource Monitor conducts two kinds of polling on each resource that it monitors: Looks Alive (resource appears to be online) and Is Alive (a more thorough check indicates the resource is online and functioning properly).

When setting polling intervals, it can be useful to understand the following:

- If a Generic Application resource has a long startup time, you can lengthen the polling interval to allow the resource to finish starting up. In other words, you might not require a custom resource DLL to ensure that the resource is given the necessary startup time.
- If you lengthen the polling intervals, you reduce the chance that polls will interfere with each other (the chance for lock contention).

- You can bypass Looks Alive polling by setting the interval to 0.

**How a Resource Group Comes Online**
The following sequence is used when Failover Manager and Resource Monitor bring a resource group online.

1. Failover Manager uses the dependency list (in the cluster configuration) to determine the appropriate order in which to bring resources online.

2. Failover Manager works with Resource Monitor to begin bringing resources online. The first resource or resources started are ones that do not depend on other resources.

3. Resource Monitor calls the **Online** entry point of the first resource DLL and returns the result to Failover Manager.

    - If the entry point returns ERROR_IO_PENDING, the resource state changes to **OnlinePending**. Resource Monitor starts a timer that waits for the resource either to go online or to fail. If the amount of time specified for the pending timeout passes and the resource is still pending (has not entered either the Online or Failed state), the resource is treated as a failed resource and Failover Manager is notified.

    - If the Online call fails or the **Online** entry point does not move the resource into the Online state within the time specified in the resource DLL, the resource enters the Failed state, and Failover Manager uses Resource Monitor to try to restart the resource, according to the policies defined for the resource in its DLL.

    - When the resource enters the Online state, Resource Monitor adds the resource to its list of resources and starts monitoring the state of the resource.

4. The sequence is repeated as Failover Manager brings the next resource online. Failover Manager uses the dependency list to determine the correct order for bringing resources online.

After resources have been brought online, Failover Manager works with Resource Monitor to determine if and when failover is necessary and to coordinate failover.

**How a Resource Group Goes Offline**
Failover Manager takes a resource group offline as part of the failover process or when an administrator moves the group for maintenance purposes. The following sequence is used when Failover Manager takes a resource group offline:

1. Failover Manager uses the dependency list (in the cluster configuration) to determine the appropriate order in which to bring resources offline.

2. Failover Manager works with Resource Monitor to begin taking resources offline. The first resource or resources stopped are ones on which other resources do not depend.

3. Resource Monitor calls the **Offline** entry point of the resource DLL and returns the result to Failover Manager.

    - If the entry point returns ERROR_IO_PENDING, the resource state changes to **OfflinePending**. Resource Monitor starts a timer that waits for the resource either to go offline or to fail. If the amount of time specified for the pending timeout passes and the resource is still pending (has not entered either the Offline or Failed state), the resource is treated as a failed resource and Failover Manager is notified.

    - If the Offline call fails or the **Offline** entry point does not move the resource into the Offline state within the time specified in the resource DLL, Failover Manager uses Resource Monitor to terminate the resource and the resource enters the Failed state.

    - If the Offline call succeeds, Resource Monitor takes the resource off its list and stops monitoring the resource.

4. The sequence is repeated as Failover Manager brings the next resource offline. Failover Manager uses the dependency list to determine the correct order for taking resources offline.

**How Failover Occurs**

Group failover happens when the group or the node that owns the group fails. Individual resource failure causes the group to fail if you configure the **Affect the group** property for the resource.

Failover takes two forms, as described in the sections that follow:

- Resource failure and group failure (without node failure)
- Node failure or loss of communication between nodes

**Resource Failure and Group Failure (Without Node Failure)**

When a resource fails, the following process occurs:

1. Resource Monitor detects the failure, either through Looks Alive or Is Alive polling or through an event signaled by the resource. Resource Monitor calls the **IsAlive** entry point of the resource DLL to confirm that the resource has failed.

2. If **IsAlive** fails, the state of the resource changes to Failed.

   If you configured the resource to be restarted on failure, Failover Manager attempts to restart the resource by trying to bring it online. If the attempts to bring the resource online fail more than is allowed by the restart **Threshold** and **Period** properties, Resource Monitor stops polling the resource.

3. Through Resource Monitor, Failover Manager calls the **Terminate** entry point of the resource DLL.

   The rest of this process concerns how the group fails over.

4. If the resource is set to **Affect the group**, the sequence continues. Otherwise, it ends without further action. If the resource is set to **Affect the group**, Failover Managers on the cluster nodes work together to reassign ownership of the group.

5. On the node on which the resource failed, Failover Manager terminates the resource that failed and the resources that depend on it, and then Failover Manager takes the remaining resources in the dependency tree offline in order of dependencies.

6. Failover Manager on the node on which the resource failed notifies Failover Manager on the node that will take ownership of the resource (and also notifies Failover Manager on other nodes about the changes that are happening).

7. If any of the resources have been configured so that application-specific configuration information (registry subkeys) for that resource is checkpointed, Checkpoint Manager restores the saved registry subkeys for those resources from the quorum resource.

8. The destination node Failover Manager brings the resources online one by one, using the dependency list to determine the correct order.

9. The node that now owns the group turns control of the group's resources over to their respective Resource Monitors.

**Node Failure or Loss of Communication Between Nodes**

Failover that occurs when a node fails is different from failover that occurs when a resource fails. For the purposes of clustering, a node is considered to have failed if it loses communication with other nodes.

As described in previous sections, if a node misses five heartbeats, this indicates that it has failed, and a regroup event (and possibly quorum arbitration) occurs. After node failure, surviving nodes negotiate for ownership of the various resource groups. On two-node clusters the result is obvious, but on clusters with more than two nodes, Failover Manager on the surviving nodes determines group ownership based on the following:

- The nodes you have specified as possible owners of the affected resource groups.
- The order in which you specified the nodes in the group's Preferred Owners list.

**Note**

- When setting up a preferred owners list for a resource group, we recommend that you list *all* nodes in your server cluster and put them in priority order.

**How Failback Occurs**

Failback is the process by which the Cluster service moves resource groups back to their preferred node after the node has failed and come back online. You can configure both *whether* and *when* failback occurs. By default, groups are not set to fail back.

The node to which the group will fail back initiates the failback. Failover Manager on that node contacts Failover Manager on the node where the group is currently online and negotiates for ownership. The instances of Failover Manager on the two nodes work together to smoothly transfer ownership of the resource group back to the preferred node.

You can test failback configuration settings by following procedures in Help and Support Center.

**Related Information**

The following sources provide information that is relevant to this section.

- "Planning Server Deployments" in the Windows Server 2003 Deployment Kit on the Microsoft Web site for more information about failover policies, choices for cluster storage, and ways that applications can operate within a server cluster.
- What Is a Server Cluster?

# Server Cluster Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server Cluster Tools and Settings**

**In this section**

- Server Cluster Tools
- Server Cluster WMI Classes
- Related Information

The information in this section is helpful for learning about tools to administer, diagnose, and recover server clusters. It also provides information about tools for configuring disks and for migrating a clustered print server to Windows Server 2003 operating systems. In addition, this section provides information about WMI classes associated with server clusters.

**Server Cluster Tools**

The following tools are associated with server clusters.

**Cluadmin.exe: Cluster Administrator**

**Category**

Tool included in Windows Server 2003, Standard Edition, Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, operating systems. The tool is also included in the Windows Server 2003 Administration Tools Pack.

**Version Compatibility**

Cluster Administrator can run on computers running Windows Server 2003, Standard Edition, Windows Server 2003, Enterprise Edition, Windows Server 2003, Datacenter Edition, and Windows XP Professional with Windows Server 2003 Administration Tools Pack installed.

Cluster Administrator can target server cluster nodes running Windows Server 2003, Enterprise Edition, Windows Server 2003, Datacenter Edition, Windows 2000 Advanced Server, Windows 2000 Datacenter Server, and Windows NT Server 4.0, Enterprise Edition.

Cluster Administrator is the graphical user interface (GUI) for server clusters. It displays information about the cluster and its nodes, resources, and groups. With Cluster Administrator, you can do a variety of tasks, including joining nodes to a cluster, managing cluster objects, establishing groups, initiating failover, monitoring cluster activity, and other tasks.

**Cluster.exe**

**Category**

Tool included in Windows Server 2003, Standard Edition, Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, operating systems. The tool is also included in the Windows Server 2003 Administration Tools Pack.

**Version Compatibility**

Cluster.exe can run on computers running Windows Server 2003, Standard Edition, Windows Server 2003, Enterprise Edition, Windows Server 2003, Datacenter Edition, and Windows XP Professional with Windows Server 2003 Administration Tools Pack installed.

Cluster.exe can target server cluster nodes that are running Windows Server 2003, Enterprise Edition, Windows Server 2003, Datacenter Edition, Windows 2000 Advanced Server, Windows 2000 Datacenter Server, and Windows NT Server 4.0, Enterprise Edition.

- Cluster.exe is the command-line interface for server clusters. Cluster.exe provides all the functionality of Cluster Administrator, the graphical user interface (GUI), plus several additional functions:
- The **cluster resource** command includes the **/private** option, which can be used to view or change a resource's private properties in the cluster configuration database.
- The **cluster** command includes the **/changepass** option, which can be used to change the Cluster service account password.

- The **cluster resource** command (with no options) can provide information about a cluster resource when Cluster Administrator does not display information quickly, which sometimes happens if a resource is in a pending state.

- Commands can be put together into scripts that can be run routinely, possibly by staff members less highly trained than those who wrote the scripts.

For more information about Cluster.exe, see "Command line reference A-Z" on the Microsoft TechNet Web site.

**Clusdiag.msi: Cluster Diagnostics and Verification Tool**
**Category**
Tool included in the Windows Server 2003 Resource Kit. An updated version of this tool is available.

**Version Compatibility**
The Cluster Diagnostics tool can run on computers running Windows Server 2003, Windows 2000, and Windows XP Professional.

The updated version of the tool can target server clusters running Windows Server 2003, Enterprise Edition, Windows Server 2003, Datacenter Edition, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

The original version of the tool can target server clusters running Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition.

The Cluster Diagnostics tool provides a graphical user interface (GUI) for performing diagnostic tests on a preproduction cluster, as well as an interface for viewing multiple log files to aid in troubleshooting cluster failures. The tool can generate various cluster-related reports from the information gathered during testing. An example of a report that the tool can generate is a diagram showing resource dependencies.

To find more information about Clusdiag.msi, see Resource Kit Tool Updates in the Tools and Settings Collection.

**Clusterrecovery.exe: Server Cluster Recovery Utility**
**Category**
Tool included in the Windows Server 2003 Resource Kit.

**Version Compatibility**
The Server Cluster Recovery Utility can be installed on computers running Windows Server 2003 and Windows XP Professional.

The Server Cluster Recovery Utility can target server clusters running Windows Server 2003, Enterprise Edition, Windows Server 2003, Datacenter Edition, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

The Server Cluster Recovery Utility is primarily intended for:

- Restoring resource checkpoint files.

- Replacing a failed disk or recovering from disk signature changes.

- Migrating data to a different disk on the shared bus.

To find more information about Clusterrecovery.exe, see Resource Kit Tools Help in the Tools and Settings Collection.

**Confdisk.exe: Disk Configuration Tool**
**Category**
Tool included in the Windows Server 2003 Resource Kit.

**Version Compatibility**
The Disk Configuration Tool can be installed on computers running Windows Server 2003 and Windows XP Professional.

The Disk Configuration Tool can target server clusters running Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition.

The Disk Configuration Tool restores a disk signature from an Automated System Recovery (ASR) set.

To find more information about Confdisk.exe, see Resource Kit Tools Help in the Tools and Settings Collection.

**Printmig.exe: Print Migrator 3.1 Tool**
**Category**
Tool is available at the Download Center at the Microsoft Web site.

**Version Compatibility**
The tool supports moving printers, including clustered print servers, from Windows NT 4.0 to Windows 2000 or Windows Server 2003 operating systems. The tool also supports the conversion of LPR ports to standard TCP/IP ports.

For more information about print servers and Print Migrator 3.1, see the Microsoft Web site. To download this tool, see Print Migrator 3.1 at the Microsoft Web site.

**Server Cluster WMI Classes**
With Windows Server 2003, you can take advantage of new support for managing server clusters through Windows Management Instrumentation (WMI). You can also continue to use Cluster Automation Server, the cluster management interface that was first available in Windows NT Server 4.0, Enterprise Edition. However, Cluster Automation Server is an interface specific to server clusters. In contrast, the WMI interface has the advantage of being a standardized, current interface in Windows operating systems.

The following tables list and describe the WMI classes that are associated with server clusters. The WMI classes are grouped as follows:

- Classes for the cluster and its elements
- Association classes
- Event classes

**WMI Classes for Server Clusters—Classes for the Cluster and Its Elements**

| Class Name | Name-space | Version Compatibility |
|---|---|---|
| MSCluster_Cluster | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_Network | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_NetworkInterface | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_Node | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_Property | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_Resource | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ResourceGroup | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ResourceType | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_Service | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |

**WMI Classes for Server Clusters—Association Classes**

| Class Name | Name-space | Version Compatibility |
|---|---|---|

| | | |
|---|---|---|
| MSCluster_ClusterToNetwork | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ClusterToNetworkInterface | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ClusterToNode | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ClusterToQuorumResource | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ClusterToResource | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ClusterToResourceGroup | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ClusterToResourceType | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_NetworkToNetworkInterface | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_NodeToActiveGroup | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_NodeToActiveResource | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_NodeToHostedService | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_NodeToNetworkInterface | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ResourceGroupToPreferredNode | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ResourceGroupToResource | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ResourceToDependentResource | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ResourceToPossibleOwner | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_ResourceTypeToResource | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |

**WMI Classes for Server Clusters—Event Classes**

| **Class Name** | **Name-space** | **Version Compatibility** |
|---|---|---|
| MSCluster_Event | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_EventGroupStateChange | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_EventObjectAdd | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |

| | | |
|---|---|---|
| MSCluster_EventObjectRemove | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_EventPropertyChange | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_EventResourceStateChange | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| MSCluster_EventStateChange | MSCluster | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |

For information about Cluster Automation Server and descriptions of many WMI classes, see the SDK documentation on MSDN.

**Related Information**

The following source provides information that is relevant to this section.

For information about command syntax for Cluster.exe and about backing up server clusters, see Help and Support Center in Windows Server 2003, Standard Edition, Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition operating systems.

# Network Load Balancing Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Load Balancing Technical Reference**
Network Load Balancing is a network driver that distributes the load for networked client/server applications across multiple cluster servers. It is part of the Windows scale out functionality and is one of three Windows Clustering technologies. Server clusters, ideal for applications requiring stateful connections, and Component Load Balancing, ideal for stateless COM+ applications, are the other two technologies. Component Load Balancing is a feature of Microsoft Application Center 2000. It is not a feature of the Microsoft Windows Server 2003 family.

Network Load Balancing distributes client requests across a set of servers. It is particularly useful for ensuring that stateless applications, such as a Web server running Internet Information Services (IIS), can be scaled out by adding additional servers as the load increases. Network Load Balancing allows you to easily replace a malfunctioning server or add a new server, which provides scalability.

Network Load Balancing clusters provide scalability for services and applications based on Transmission Control Protocol (TCP) and User Data Protocol (UDP) by combining up to 32 servers running the following operating systems into a single cluster:

- Windows Server 2003, Standard Edition
- Windows Server 2003, Enterprise Edition
- Windows Server 2003, Datacenter Edition
- Windows Server 2003, Web Edition

By using Network Load Balancing to build a group of identical, clustered computers, you can enhance the scalability of the following servers over your corporate local area network (LAN):

- Web and File Transfer Protocol (FTP) servers
- Proxy servers and firewall services, such as computers running Internet Security and Acceleration (ISA) Server
- Virtual private network (VPN) servers
- Servers running Windows Media technologies player
- Terminal servers

The sections in this subject include an overview of Network Load Balancing, an in-depth description of how it works, and information about tools and settings.

# What Is Network Load Balancing?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Network Load Balancing?**

**In this section**

- Common Scenarios for Network Load Balancing
- Technologies Related to Network Load Balancing
- Interacting with Other Technologies
- Related Information

For most Information Technology (IT) departments, Internet servers must support applications and services that run 24 hours a day, 7 days a week, such as financial transactions, database access, and corporate intranets. In addition, network applications and servers need the ability to scale performance to handle large volumes of client requests without creating unwanted delays.

Network Load Balancing clusters enable you to manage a group of independent servers as a single system for greater scalability, increased availability, and easier manageability. You can use Network Load Balancing to implement enterprise-wide scalable solutions for the delivery of Transmission Control Protocol/Internet Protocol (TCP/IP) based services and applications.

Network Load Balancing has many advantages over other load balancing solutions that can introduce single points of failure or performance bottlenecks. Because there are no special hardware requirements for Network Load Balancing, you can use any industry standard compatible computer in a Network Load Balancing cluster.

Network Load Balancing works by distributing client requests across a set of servers. It is particularly useful for ensuring that stateless applications, such as Web pages from a server running Internet Information Services (IIS), are highly available and can be scaled out by adding additional servers as the load increases. The ease with which Network Load Balancing allows you to replace a malfunctioning server or add a new server provides scalability.

Network Load Balancing offers the following benefits:

**Scalability**
Network Load Balancing supports up to 32 computers in a single cluster. Hosts can be added and removed without interrupting cluster availability.

**Load balancing**
Load-balances multiple server requests, from either the same client, or from several clients, across multiple hosts in the cluster.

**Increased availability**
Automatically detects and recovers from a failed or offline computer and balances the network load when hosts are added or removed. Recovers and redistributes the workload within seconds.

Many enterprise solutions must address client access to services and applications that are based on connections to selected TCP/IP addresses, protocols, and port numbers. For example, IIS provides service to clients on IP (TCP, 80). If this single IP host were to fail or become overloaded, client access to the service or application may be prevented or fall below a designated performance level.

Configuring multiple hosts to increase scalability and availability for applications and services is one solution. However, this solution may involve specialized network hardware, complex network configuration, and management of individual hosts. For example, multiple hosts functioning as Web servers, each with an individual IP address, could be resolved by multiple entries in round robin DNS. Each server is independent and if a server fails, the static load balancing provided by round robin DNS may prevent clients from accessing their Web application.

To resolve client connection problems, Network Load Balancing allows multiple computers or hosts, configured in a logical group called a network load balancing cluster, to respond to client connection requests made to a single virtual IP address.

**Network Load Balancing Driver**
Network Load Balancing is a driver, Wlbs.sys, which you must load on each host in the cluster. Wlbs.sys includes a statistical

mapping algorithm that the hosts of the cluster collectively use to determine which host handles each incoming request.

You install the driver on each of the cluster hosts, and you configure the cluster to present a virtual IP address to client requests. The client requests go to all of the hosts in the cluster, but only the mapped host accepts and handles the request. All of the other hosts in the cluster drop the request.

**Network Load Balancing Cluster Configuration**
After the driver is installed, it must be configured before the host can join a cluster. You must configure three groups of information about each host: cluster parameters, host parameters, and port rules, before it is possible to create or join a cluster. Configuring the driver allows you to:

- Select the cluster virtual IP address option.
- Customize the cluster according to the various hosts' capacities and sources of client requests.
- Specify that one host handles all of the client requests with the others serving as failover alternatives.
- Divide the load of incoming client requests among the hosts evenly or according to a specified load partitioning weight.

**Common Scenarios for Network Load Balancing**
This section includes scenarios representing common implementations of Network Load Balancing.

**IIS Server (Web Farm)**
An IIS Server Web farm is the most common scenario for Network Load Balancing. Below are two examples of how Network Load Balancing can be used to service a Web farm.

**Servicing Multiple Web Sites**
A Network Load Balancing cluster can be used to host multiple Web sites with different IP addresses. To do this, enter the additional IP addresses as you create the cluster. Additional IP addresses can also be added to an existing cluster.

The virtual cluster feature for Network Load Balancing (available in Windows Server 2003) makes it simpler to service multiple Web sites. Using this feature, you can define port rules that apply to only one of the specific IP addresses that you add to the cluster or to all of the IP addresses.

**Servicing a Web Site with Active Server Pages**
Web sites that use Active Server Pages (ASP) can maintain session state across client connections. Network Load Balancing helps preserve client access to session information by ensuring that all TCP/IP connections from a single client are directed to the same cluster host.

There are, however, situations in which a client can connect with one cluster host, and then have subsequent connections load-balanced to different hosts. Such situations include the following:

- A host is added to the cluster, and Network Load Balancing load-balances new connections from this client to the host.
- Multiple client-side proxy servers cause multiple connections from the same client to originate from different IP addresses.

If either of the preceding situations arises, ASP applications must provide a means to retrieve and manage session state even if a client connects to multiple cluster hosts as part of a single session. The following are two strategies for addressing this issue:

- Use a means at the ASP level, such as a cookie, to retrieve the ASP client state across the Network Load Balancing cluster hosts.
- Encapsulate in a client-side cookie the state from a specific client request. The cookie gives the server the context for subsequent client requests. This solution works only if there is a relatively small amount of state associated with each client transaction. As state grows larger, it becomes increasingly difficult to have the client forward a large cookie to the server with every request.

**Virtual Private Network**
Network Load Balancing can be used with virtual private network (VPN) servers to load-balance PPTP clients. To ensure compatibility with clients running earlier versions of Windows, such as Windows 98 and Windows NT 4.0, it is important to

configure the TCP/IP properties correctly. To do this, assign only a single virtual IP address (the cluster's primary IP address) to the network adapter used by Network Load Balancing. Do not assign a dedicated IP address on any network adapter on this subnet. This restriction does not apply for Windows 2000 or Windows Server 2003 clients. Assigning only a single virtual IP address to the network adapter used by Network Load Balancing ensures that network traffic returning from the host to the client originates from the virtual IP address to which the client sent the request.

**Single-Server Failover Support**
Although you can use Network Load Balancing to provide failover support for applications, using a server cluster is the preferred solution for this scenario. However, if you choose to achieve failover support with Network Load Balancing, this section describes how to do this.

You must first start the application on every host in the cluster. Network Load Balancing does not restart an application on failover. It assumes that an instance of the application is running on each host in the cluster.

In order for Network Load Balancing to provide failover support for a specific application, the files that the application uses must be simultaneously accessible to all hosts that run the application. To achieve this, these files should reside on a back-end file server.

Some applications open shared files only on client request. For these applications, using Network Load Balancing for failover is possible. However, other applications require that these files be continuously open exclusively by one instance of the application. Because this is not possible with Network Load Balancing, you must instead use server clusters to provide failover support for these types of applications.

**Technologies Related to Network Load Balancing**
Network Load Balancing is one of three Windows Clustering technologies. In addition to Network Load Balancing, there are server clusters and Component Load Balancing.

**Server clusters**
Server clusters are used to ensure that stateful applications such as a database, for example, SQL Server, can be kept highly available by failing over the application from one server to another in the event of a failure. Multiple servers (nodes) in a cluster remain in constant communication. If one of the nodes in a cluster is unavailable as a result of failure or maintenance, another node immediately begins providing service (a process known as failover). Users who access the cluster are constantly connected to server-based resources.

With Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, you can configure server clusters in one of three available cluster models, depending on your requirements.

Network Load Balancing load-balances requests between front-end Web servers and server clusters does the same thing for back-end database access. Network Load Balancing and server clusters cannot both be active on the same computer since both technologies control and configure network adapters and they may interfere with one another. By joining Network Load Balancing and server clusters together, an overall clustering scheme is created, as shown in the following diagram:

**Integrated Clustering Scheme Using Network Load Balancing and Server Clusters**

**Component Load Balancing**
Component Load Balancing is the dynamic load balancing feature of COM+. It enables the creation of 8-node application clusters behind a Component Load Balancing router, enabling the COM+ applications to scale while also ensuring their constant availability. Component Load Balancing is ideal for stateless COM+ applications. Component Load Balancing is a feature of Microsoft Application Center 2000. It is not a feature of the Windows Server 2003 family.

**Interacting with Other Technologies**
Network Load Balancing interacts with the following technologies:

**Terminal server clusters**
Network Load Balancing can be used to load-balance terminal server clusters. Load balancing pools the processing resources of several servers using the TCP/IP networking protocol. You can use this service with a cluster of terminal servers to scale the performance of a single terminal server by distributing sessions across multiple servers. Session Directory (included in Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition) keeps track of disconnected sessions on the cluster, and ensures that users are reconnected to those sessions.

**DNS resolution**
Network Load Balancing does not support dynamic Domain Name System (DNS) resolution, where the name of the cluster is automatically registered by the host when the host starts. This functionality must be disabled on the Network Load Balancing interface for both DNS and Windows Internet Name Service (WINS); otherwise, each host's computer name will be registered with the cluster IP address. When using Network Load Balancing with DNS, you will need to directly configure the DNS server to register the name. Also, Dynamic Host Configuration Protocol (DHCP) should not be used on the network interface to which Network Load Balancing is bound; however, DHCP can be used on other interfaces.

**L2TP/IPSec**
Network Load Balancing in Windows Server 2003 supports both Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP) virtual private network (VPN) sessions. However, Network Load Balancing must be configured in single affinity mode.

**Kerberos authentication**
Network Load Balancing supports Kerberos with applications it load-balances.

**.NET Framework remoting**
Network Load Balancing supports .NET Framework remoting, which uses method invocations from client to server over a single TCP connection. This means that once a connection is established, it is reused for subsequent method invocations and is closed only after the connection remains idle for a pre-configured amount of time. Network Load Balancing can load-balance these connections, but load balancing will likely be uneven because it is the TCP connection that is load-balanced and not the method invocation. Since one client gets "pinned" to a specific server, the load will be well distributed only if you have many clients connected to the cluster at the same time. Each client will get load-balanced, but the connection will stay open for a long period of time.

**Related Information**

- Network Load Balancing Architecture
- Network Load Balancing Protocols
- Application Compatibility with Network Load Balancing
- Network Load Balancing for Scalability
- Scaling Network Load Balancing Clusters
- Performance Impact of Network Load Balancing

When Network Load Balancing is installed as a network driver on each of the member servers, or hosts, in a cluster, the cluster presents a virtual Internet Protocol (IP) address to client requests. The client requests go to all the hosts in the cluster, but only the host to which a given client request is mapped accepts and handles the request. All the other hosts drop the request. Depending on the configuration of each host in the cluster, the statistical mapping algorithm, which is present on all the cluster hosts, maps the client requests to particular hosts for processing.

**Basic Diagram for Network Load Balancing Clusters**

The following figure shows two connected Network Load Balancing clusters. The first cluster is a firewall cluster with two hosts and the second cluster is a Web server cluster with four hosts.

**Two Connected Network Load Balancing Clusters**

**Network Load Balancing Terms and Definitions**

Before you review the Network Load Balancing components and processes, it is helpful to understand specific terminology. The following terms are used to describe the components and processes of Network Load Balancing.

**affinity**

For Network Load Balancing, the method used to associate client requests to cluster hosts. When no affinity is specified, all network requests are load-balanced across the cluster without respect to their source. Affinity is implemented by directing all client requests from the same IP address to the same cluster host.

**convergence**

The process of stabilizing a system after changes occur in the network. For routing, if a route becomes unavailable, routers send update messages throughout the network, reestablishing information about preferred routes.

For Network Load Balancing, a process by which hosts exchange messages to determine a new, consistent state of the cluster and to elect the default host. During convergence, a new load distribution is determined for hosts that share the handling of

network traffic for specific Transmission Control Protocol (TCP) or User Datagram Protocol (UDP) ports.

**dedicated IP address**
The IP address of a Network Load Balancing host used for network traffic that is not associated with the Network Load Balancing cluster (for example, Telnet access to a specific host within the cluster). This IP address is used to individually address each host in the cluster and therefore is unique for each host.

**default host**
The host with the highest host priority for which a **drainstop** command is not in progress. After convergence, the default host handles all of the network traffic for Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) ports that are not otherwise covered by port rules.

**failover**
In server clusters, the process of taking resource groups offline on one node and bringing them online on another node. When failover occurs, all resources within a resource group fail over in a predefined order; resources that depend on other resources are taken offline before, and are brought back online after, the resources on which they depend.

**heartbeat**
A message that is sent at regular intervals by one computer on a Network Load Balancing cluster or server cluster to another computer within the cluster to detect communication failures.

Network Load Balancing initiates convergence when it fails to receive heartbeat messages from another host or when it receives a heartbeat message from a new host.

**multicast media access control (MAC) address**
A type of media access control address used by multiple, networked computers to receive the same incoming network frames concurrently. Network Load Balancing uses multicast MAC addresses to efficiently distribute incoming network traffic to cluster hosts.

**multihomed computer**
A computer that has multiple network adapters or that has been configured with multiple IP addresses for a single network adapter.

Network Load Balancing supports multihomed servers by allowing multiple virtual IP addresses to be assigned to the cluster adapter.

**throughput**
A performance measure defined as the number of client requests processed by a Network Load Balancing cluster per unit of time.

**virtual cluster**
A Network Load Balancing cluster that you create by assigning specific port rules to specific virtual IP addresses. With virtual clusters, you can use different port rules for different Web sites or applications hosted on the cluster, provided each Web site or application has a different virtual IP address.

**virtual IP address**
An IP address that is shared among the hosts of a Network Load Balancing cluster. A Network Load Balancing cluster might also use multiple virtual IP addresses, for example, in a cluster of multihomed Web servers.

**Network Load Balancing Architecture**
Network Load Balancing runs as a network driver logically beneath higher-level application protocols, such as HTTP and FTP. On each cluster host, the driver acts as a filter between the network adapter's driver and the TCP/IP stack, allowing a portion of the incoming network traffic to be received by the host. This is how incoming client requests are partitioned and load-balanced among the cluster hosts. To maximize throughput and availability, Network Load Balancing uses a fully distributed software architecture, and an identical copy of the Network Load Balancing driver that runs in parallel on each cluster host. The figure below shows the implementation of Network Load Balancing as an intermediate driver in the Windows Server 2003 network stack.

### Typical Configuration of a Network Load Balancing Host

The following table describes the principal components related to the Network Load Balancing architecture.

**Components of the Network Load Balancing Architecture**

| Component | Description |
|---|---|
| Nlb.exe | The Network Load Balancing control program. You can use Nlb.exe from the command line to start, stop, and administer Network Load Balancing, as well as to enable and disable ports and to query cluster status. |
| Nlbmgr.exe | The Network Load Balancing Manager control program. Use this command to start Network Load Balancing Manager. |
| Wlbs.exe | The former Network Load Balancing control program. This has been replaced by Nlb.exe. However, you can still use Wlbs.exe rather than Nlb.exe if necessary, for example, if you have existing scripts that reference Wlbs.exe. |
| Wlbsprov.dll | The Network Load Balancing WMI provider. |
| Nlbmprov.dll | The Network Load Balancing Manager WMI provider. |
| Wlbsctrl.dll | The Network Load Balancing API DLL. |
| Wlbs.sys | The Network Load Balancing device driver. Wlbs.sys is loaded onto each host in the cluster and includes the statistical mapping algorithm that the cluster hosts collectively use to determine which host handles each incoming request. |

**Application and Service Environment**

When a Web server application maintains state information about a client session across multiple TCP connections, it is important that all TCP connections for the client are directed to the same cluster host.

Network Load Balancing can load-balance any application or service that uses TCP/IP as its network protocol and is associated with a specific TCP or UDP port. The distributed algorithm, which is used to determine which host responds to a TCP connection request or incoming UDP packet, can include the port rule in the decision. Including the port rule in the decision means that for any client, different members of the Network Load Balancing cluster may service connection requests or packets addressed to different port rule on the virtual IP address.

**Note**

- While configuring a Network Load Balancing cluster, consider the type of application or service that the server is providing, and then select the appropriate configuration for Network Load Balancing hosts.

**Client State**

A discussion of Network Load Balancing clusters requires clarification of two kinds of client states, application data state and session state, because they are essential to configuring Network Load Balancing.

**Application data state**

In terms of application data, you must consider whether the server application makes changes to the data store and whether the changes are synchronized across instances of the application (the instances that are running on the Network Load Balancing cluster hosts). An example of an application that does not make changes to the data store is a static Web page supported by an IIS server.

Means must be provided to synchronize updates to data state that need to be shared across servers. One such means is use of

a back-end database server that is shared by all instances of the application. An example would be an Active Server Pages (ASP) page that is supported by an IIS server and that can access a shared back-end database server, such as a SQL Server.

**Session state**
Session state (or intraclient state) refers to client data that is visible to a particular client for the duration of a session. Session state can span multiple TCP connections, which can be either simultaneous or sequential. Network Load Balancing assists in preserving session state through client affinity settings. These settings direct all TCP connections from a given client address or class of client addresses to the same cluster host. This allows session state to be maintained by the server application in the host memory.

Client/server applications that embed session state within "cookies" or push it to a back-end database do not need client affinity to be maintained.

An example of an application that requires maintaining session state is an e-commerce application that maintains a shopping cart for each client.

**Network Load Balancing Parameters**
By setting port rules, cluster parameters, and host parameters, you gain flexibility in configuring the cluster, which enables you to customize the cluster according to the various hosts' capacities and sources of client requests. Cluster parameters apply to the entire cluster, while the host parameters apply to a specific host.

**Port rules**
The Network Load Balancing driver uses port rules that describe which traffic to load-balance and which traffic to ignore. By default, the Network Load Balancing driver configures all ports for load balancing. You can modify the configuration of the Network Load Balancing driver that determines how incoming network traffic is load-balanced on a per-port basis by creating port rules for each group of ports or individual ports as required. Each port rule configures load balancing for client requests that use the port or ports covered by the port range parameter. How you load-balance your applications is mostly defined by how you add or modify port rules, which you create on each host for any particular port range.

**Affinity**
Affinity is the method used to associate client requests to cluster hosts. Network Load Balancing assists in preserving session state through client affinity settings for each port rule that Network Load Balancing creates. These settings direct all TCP connections from a given client address or class of client addresses to the same cluster host. Directing the connections to the same cluster host allows the server applications in the designated host memory to correctly maintain the session state.

**Running Network Load Balancing in an Optimal Environment**
The sections in this document provide in-depth information about how Network Load Balancing works in an optimal environment. An optimal environment for Network Load Balancing is defined as follows:

- Two or more network adapters in each cluster host are used.
- The Transmission Control Protocol/Internet Protocol (TCP/IP) network protocol is the only protocol used on the cluster adapter. Other protocols, such as Internetwork Packet Exchange (IPX), should not be added to this adapter.
- Within a given cluster, all cluster hosts must operate in either unicast or multicast mode, but not both.
- Network Load Balancing should not be enabled on a computer that is part of a server cluster.
- All hosts in a cluster must belong to the same subnet and the cluster's clients must be able to access this subnet.
- The appropriate hardware resources should be used. The goal in tuning Network Load Balancing and the applications it load-balances is to determine which hardware resource will experience the greatest demand, and then to adjust the configuration to relieve that demand and maximize total throughput.
- Cluster parameters, port rules, and host parameters are correctly configured:
    - Cluster parameters and port rules for each unique virtual IP address are identical across all hosts. Each unique virtual IP address must be configured with the same port rules across all hosts that service that virtual IP address. However, if you have multiple virtual IP addresses configured on a host, each of those virtual IP addresses can have a different set of port rules.
    - Port rules are set for all ports used by the load-balanced application. For example, FTP uses port 20, port 21, and

ports 1024–65535.

    - The dedicated IP address is unique and the cluster IP address is added to each cluster host.

- Network performance should be optimized by limiting switch port flooding.

- Windows Internet Name Service (WINS), Dynamic Host Configuration Protocol (DHCP), and Domain Name System (DNS) services can be run on Network Load Balancing cluster hosts; however, the interface to which Network Load Balancing is bound cannot use a DHCP address.

**Network Load Balancing Driver**
The Network Load Balancing driver is installed on a computer configured with Transmission Control Protocol/Internet Protocol (TCP/IP) and is bound to a single network interface called the cluster adapter. The driver is configured with a single IP address, the cluster primary IP address, on a single subnet for all of the member servers (or hosts) on the cluster. Each host has an identical media access control (MAC) address that allows the hosts to concurrently receive incoming network traffic for the cluster's primary IP address (and for additional IP addresses on multihomed hosts).

Incoming client requests are partitioned and load-balanced among the cluster hosts by the Network Load Balancing driver, which acts as a rule-based filter between the network adapter's driver and the TCP/IP stack. Each host receives a designated portion of the incoming network traffic.

**Distributed Architecture**
Network Load Balancing is a distributed architecture, with an instance of the driver installed on each cluster host. Throughput is maximized to all cluster hosts by eliminating the need to route incoming packets to individual cluster hosts, through a process called filtering. Filtering out unwanted packets in each host improves throughput; this process is faster than routing packets, which involves receiving, examining, rewriting, and resending the packets.

Another key advantage to the fully distributed architecture of Network Load Balancing is the enhanced availability resulting from (n-1) way failover in a cluster with n hosts. In contrast, dispatcher-based solutions create an inherent single point of failure that you must eliminate by using a redundant dispatcher that provides only one-way failover. Dispatcher-based solutions offer a less robust failover solution than does a fully distributed architecture.

**Load Balancing Algorithm**
The Network Load Balancing driver uses a fully distributed filtering algorithm to statistically map incoming client requests to the cluster hosts, based upon their IP address, port, and other information.

When receiving an incoming packet, all hosts within the cluster simultaneously perform this mapping to determine which host should handle the packet. Those hosts not required to service the packet simply discard it. The mapping remains constant unless the number of cluster hosts changes or the filter processing rules change.

The filtering algorithm is much more efficient in its packet handling than centralized load balancers, which must modify and retransmit packets. Efficient packet handling allows for a much higher aggregate bandwidth to be achieved on industry standard hardware.

The distribution of client requests that the statistical mapping function effects is influenced by the following:

- Host priorities

- Multicast or unicast mode

- Port rules

- Affinity

- Load percentage distribution

- Client IP address

- Client port number

- Other internal load information

The statistical mapping function does not change the existing distribution of requests unless the membership of the cluster changes or you adjust the load percentage.

**Unicast and Multicast Modes**
Network Load Balancing requires at least one network adapter; and different hosts in a cluster can have a different number of adapters, but all must use the same network IP transmission mode, either unicast or multicast.

Unicast mode is the default mode, but you can configure the Network Load Balancing driver to operate in either mode.

When you enable unicast support, the unicast mode changes the cluster adapter's MAC address to the cluster MAC address. This cluster address is the same MAC address that is used on all cluster hosts. When this change is made, clients can no longer address the cluster adapters by their original MAC addresses.

When you enable multicast support, Network Load Balancing adds a multicast MAC access to the cluster adapters on all of the cluster hosts. At the same time, the cluster adapters retain their original MAC addresses.

### Note

- The Network Load Balancing driver does not support a mixed unicast and multicast environment. All cluster hosts must be either multicast or unicast; otherwise, the cluster will not function properly.

If clients are accessing a Network Load Balancing cluster through a router when the cluster has been configured to operate in multicast mode, be sure that the router meets the following requirements:

- Accepts an Address Resolution Protocol (ARP) reply that has one MAC address in the payload of the ARP structure but appears to arrive from a station with another MAC address, as judged by the Ethernet header.

- Accepts an ARP reply that has a multicast MAC address in the payload of the ARP structure.

If your router does not meet these requirements, you can create a static ARP entry in the router. For example, some routers require a static ARP entry because they do not support the resolution of unicast IP addresses to multicast MAC addresses.

**Subnet and Network Considerations**
The Network Load Balancing architecture with a single MAC address for all cluster hosts maximizes use of the subnet's hub and/or switch architecture to simultaneously deliver incoming network traffic to all cluster hosts.

Your network configuration will typically include routers, but may also include layer 2 switches (collapsed backbone) rather than the simpler hubs or repeaters that are available. Cluster configuration, when using hubs, is predictable because the hubs distribute IP traffic to all ports.

### Note

- If client-side network connections at the switch are significantly faster than server-side connections, incoming traffic can occupy a prohibitively large portion of server-side port bandwidth.

**Network Adapters**
Network Load Balancing requires only a single network adapter, but for optimum cluster performance, you should install a second network adapter on each Network Load Balancing host. In this configuration, one network adapter handles the network traffic that is addressed to the server as part of the cluster. The other network adapter carries all of the network traffic that is destined to the server as an individual computer on the network, including cluster communication between hosts.

### Note

- Network Load Balancing with a single network adapter can provide full functionality if you enable multicast support for this adapter.

**Selecting an IP Transmission Mode**
When you are implementing a Network Load Balancing solution, the Internet Protocol transmission mode that is selected and the number of network adapters that are required are dependent upon the following network requirements:

- Layer 2 switches or hubs

- Peer-to-peer communication between hosts
- Maximized communication performance

For example, a cluster supporting a static Hypertext Markup Language (HTML) Web application can have a requirement to synchronize the Web site copies of a large number of cluster hosts. This scenario requires interhost peer-to-peer communications. You select the number of network adapters and the IP communications mode to meet this requirement.

There is no restriction on the number of network adapters, and different hosts can have a different number of adapters. You can configure Network Load Balancing to use one of four different models.

**Single Network Adapter in Unicast Mode**
The single network adapter in unicast mode is suitable for a cluster in which you do not require ordinary network communication among cluster hosts, and in which there is limited dedicated traffic from outside the cluster subnet to specific cluster hosts. In this model, the computer can also handle traffic from inside the subnet if the IP datagrams do not carry the same MAC address as the cluster adapter.

**Single Network Adapter in Multicast Mode**
This model is suitable for a cluster in which ordinary network communication among cluster hosts is necessary or desirable, but in which there is limited dedicated traffic from outside the cluster subnet to specific cluster hosts.

**Multiple Network Adapter in Unicast Mode**
This model is suitable for a cluster in which ordinary network communication among cluster hosts is necessary or desirable, and in which there is comparatively heavy dedicated traffic from outside the cluster subnet to specific cluster hosts.

This mode is the preferred configuration used by most sites because a second network adapter may enhance overall network performance.

**Multiple Network Adapter in Multicast Mode**
This model is suitable for a cluster in which ordinary network communication among cluster hosts is necessary, and in which there is heavy dedicated traffic from outside the cluster subnet to specific cluster hosts.

**Comparison of Modes**
The advantages and disadvantages of each model are listed in the following table.

### Components of the Network Load Balancing Architecture

| Adapter | Mode | Advantages | Disadvantages |
|---|---|---|---|
| Single | Unicast | Simple configuration | Poor overall performance |
| Single | Multicast | Medium performance | Complex configuration |
| Multiple | Unicast | Best balance | None |
| Multiple | Multicast | Best balance | Complex configuration |

**Network Load Balancing Addressing**
The Network Load Balancing cluster is assigned a primary Internet Protocol (IP) address. This IP address represents a virtual IP address to which all of the cluster hosts respond, and the remote control program that is provided with Network Load Balancing uses this IP address to identify a target cluster.

**Primary IP address**
The primary IP address is the virtual IP address of the cluster and must be set identically for all hosts in the cluster. You can use the virtual IP address to address the cluster as a whole. The virtual IP address is also associated with the Internet name that you specify for the cluster.

**Dedicated IP address**
You can also assign each cluster host a dedicated IP address for network traffic that is designated for that particular host only. Network Load Balancing never load-balances the traffic for the dedicated IP addresses, it only load-balances incoming traffic from all IP addresses other than the dedicated IP address.

The following figure shows how IP addresses are used to respond to client requests.

**Network Load Balancing Cluster**

**Distribution of Cluster Traffic**

When the virtual IP address is resolved to the station address (MAC address), this MAC address is common for all hosts in the cluster. You can enable client connections to only the required cluster host when more packets are sent. The responding host then substitutes a different MAC address for the inbound MAC address in the reply traffic. The substitute MAC address is referred to as the Source MAC address. The following table shows the MAC addresses that will be generated for a cluster adapter.

| IP Mode | MAC Address | Explanation |
|---|---|---|
| Unicast inbound | 02-BF-W-X-Y-Z | W-X-Y-Z = IP address<br><br>Onboard MAC disabled |
| Multicast inbound | 03-BF-W-X-Y-Z | W-X-Y-Z = IP address<br><br>Onboard MAC enabled |
| Source outbound | 02-P-W-X-Y-A | W-X-Y-Z = IP address<br><br>P = Host priority |

In the unicast mode of operation, the Network Load Balancing driver disables the onboard MAC address for the cluster adapter. You cannot use the dedicated IP address for interhost communications because all of the hosts have the same MAC address.

In multicast mode of operation, the Network Load Balancing driver supports both the onboard and the multicast address. If your cluster configuration will require connections from one cluster host to another, for example, when making a NetBIOS connection to copy files, use multicast mode or install a second network adapter.

If the cluster hosts were attached to a switch instead of a hub, the use of a common MAC address would create a conflict because Layer 2 switches expect to see unique source MAC addresses on all switch ports. To avoid this problem, Network Load Balancing uniquely modifies the source MAC address for outgoing packets, for example, a cluster MAC address of 02-BF-1-2-3-4 is set to 02-p-1-2-3-4, where p is the host's priority within the cluster.

This technique prevents the switch from learning the cluster's inbound MAC address, and as a result, incoming packets for the cluster are delivered to all of the switch ports. If the cluster hosts are connected to a hub instead of to a switch, you can disable masking of the source MAC address in unicast mode to avoid flooding upstream switches. You disable Network Load Balancing by setting the Network Load Balancing registry parameter MaskSourceMAC to 0. The use of an upstream level three switch will also limit switch flooding.

The unicast mode of Network Load Balancing induces switch flooding to simultaneously deliver incoming network traffic to all of the cluster hosts. Also, when Network Load Balancing uses multicast mode, switches often flood all of the ports by default to deliver multicast traffic. However, the multicast mode of Network Load Balancing gives the system administrator the opportunity to limit switch flooding by configuring a virtual LAN within the switch for the ports corresponding to the cluster hosts.

**Port Rules**

Port rules are created for individual ports and for groups of ports that Network Load Balancing requires for particular applications and services. The filter setting then defines whether the Network Load Balancing driver will pass or block the traffic.

The Network Load Balancing driver controls the distribution and partitioning of Transmission Control Protocol (TCP) and User

Datagram Protocol (UDP) traffic from connecting clients to selected hosts within a cluster by passing or blocking the incoming data stream for each host. Network Load Balancing does not control any incoming IP traffic other than TCP and UDP for ports that a port rule specifies.

You can add port rules or update parameters by taking each host out of the cluster in turn, updating its parameters, and then returning it to the cluster. The host joining the cluster handles no traffic until convergence is complete. The cluster does not converge to a consistent state until all of the hosts have the same number of rules. For example, if a rule is added, it does not take effect until you have updated all of the hosts have been updated and they have rejoined the cluster.

### Note

- Internet Group Membership Protocol (IGMP), ARP, or other IP protocols are passed unchanged to the TCP/IP protocol software on all of the hosts within the cluster.

Port rules define individual ports or groups of ports for which the driver has a defined action. You need to consider certain parameters when creating the port rules, such as the:

- TCP or UDP port range for which you should apply this rule.
- Protocols for which this rule should apply (TCP, UDP, or both).
- Filtering mode chosen: multiple hosts, single host, or disabled.

When defining the port rules, it is important that the rules be exactly the same for each host in the cluster because if a host attempts to join the cluster with a different number of rules from the other hosts, the cluster will not converge. The rules that you enter for each host in the cluster must have matching port ranges, protocol types, and filtering modes.

**Filtering Modes**
The filter defines for each port rule whether the incoming traffic is discarded, handled by only one host, or distributed across multiple hosts. The three possible filtering modes that you can apply to a port rule are:

**Multiple hosts**
With this filtering mode, clusters can equally distribute the load among the hosts or each host can handle a specified load weight.

**Single host**
This filtering mode provides fault tolerance for the handling of network traffic with the target host defined by its priority.

**Disabled**
This filtering mode lets you build a firewall against unwanted network access to a specific range of ports; the driver discards the unwanted packets.

**Load Weighting**
When the filter mode for a port rule is set to multiple hosts, the Load Weight parameter specifies the percentage of load-balanced network traffic that this host should handle for the associated rule. Allowed value ranges are from 0 to 100.

### Note

- To prevent a host from handling any network traffic for a port rule, set the load weight to 0.

Because hosts can dynamically enter or leave the cluster, the sum of the load weights for all cluster hosts does not have to equal 100. The percentage of host traffic is computed as the local load percentage value divided by the load weight sum across the cluster.

If you balance the load evenly across all of the hosts with this port rule, you can specify an equal load distribution parameter instead of specifying a load weight parameter.

**Priority**
When the filter mode for a port rule is set to single, the priority parameter specifies the local host's network traffic for the associated port rule. The host with the highest handling priority for this rule among the current cluster members will handle all of the traffic.

The allowed values range from 1, the highest priority, to the maximum number of hosts allowed, 32. This value must be unique

for all hosts in the cluster.

**Supporting Multiple Client Connections**
In a load-balanced multiserver environment, managing and resolving client, application, and session state for individual clients can be complex. By default, in a Network Load Balancing solution, different hosts in the cluster can service multiple client connections.

When a client creates an initial connection to a host in the cluster, the application running on this host holds the client state. If the same host does not service subsequent connections from the client, errors can occur if the application instances do not share the client state between hosts.

For example, application development for an ASP-based Web site can be more difficult if the application must share the client state among the multiple hosts in the cluster. If all of the client connections can be guaranteed to go to the same server, you can solve the difficulties with the application that is not sharing the client state among host instances.

By using a Network Load Balancing feature called affinity, you can ensure that the same cluster host handles all of the TCP connections from one client IP address. Affinity allows you to scale applications that manage session state spanning multiple client connections. In a Network Load Balancing cluster, with affinity enabled, initial client connection requests are distributed according to the cluster configuration, but after you have established the initial client request the same host will service all of the subsequent requests from that client.

**Affinity**
Clients can have many TCP connections to a Network Load Balancing cluster; the load-balancing algorithm will potentially distribute these connections across multiple hosts in the cluster.

If server applications have client or connection state information, this state information must be made available on all of the cluster hosts to prevent errors. If you cannot make state information available on all of the cluster hosts, you cannot use client affinity to direct all of the TCP connections from one client IP address to the same cluster host. Directing TCP connections from the IP address to the same host allows an application to maintain state information in the host memory.

For example, if a server application (such as a Web server) maintains state information about a client's site navigation status that spans multiple TCP connections, it is critical that all of the TCP connections for this client state information be directed to the same cluster host to prevent errors.

Affinity defines a relationship between client requests from a single client address or from a Class C network of clients (where IP addresses range from 192.0.0.1 to 223.255.255.254) and one of the cluster hosts. Affinity ensures that requests from the specified clients are always handled by the same host. The relationship lasts until convergence occurs (namely, until the membership of the cluster changes) or until you change the affinity setting. There is no time-out — the relationship is based only on the client IP address.

You can distribute incoming client connections based on the algorithm as determined by the following client affinity settings:

**No Affinity**
This setting distributes client requests more evenly, when maintaining session state is not an issue, you can use this setting to speed up response time to requests. For example, because multiple requests from a particular client can go to more than one cluster host, clients that access Web pages can get different parts of a page or different pages from different hosts. This setting is used for most applications.

With this setting, the Network Load Balancing statistical mapping algorithm uses both the port number and entire IP address of the client to influence the distribution of client requests.

**Single Affinity**
When single affinity is used, the entire source IP address (but not the port number) is used to determine the distribution of client requests.

You typically set single affinity for intranet sites that need to maintain session state. This setting always returns each client's traffic to the same server, thus assisting the application in maintaining client sessions and their associated session state.

Note that client sessions that span multiple TCP connections (such as ASP sessions) are maintained as long as the Network Load Balancing cluster membership does not change. If the membership changes by adding a new host, the distribution of client requests is recomputed, and you cannot depend on new TCP connections from existing client sessions ending up at the same server. If a host leaves the cluster, its clients are partitioned among the remaining cluster hosts when convergence completes, and other clients are unaffected.

**Class C Affinity**
When Class C affinity is used, only the upper 24 bits of the client's IP address are used by the statistical-mapping algorithm. A Class C unicast IP address ranges from 192.0.0.1 to 223.255.255.254. The first three octets indicate the network, and the last

octet indicates the host on the network. Network Load Balancing provides optional session support for Class C IP addresses (in addition to support for single IP addresses) to accommodate clients that make use of multiple proxy servers at the client site. Class-based IP addressing has been superceded by Classless Interdomain Routing (CIDR). This option is appropriate for server farms that serve the Internet. Client requests coming over the Internet might come from clients sitting behind proxy farms. In this case, during a single client session, client requests can come into the Network Load Balancing cluster from several source IP addresses during a session.

Class C affinity addresses this issue by directing all the client requests from a particular Class C network to a single Network Load Balancing host.

There is no guarantee, however, that all of the servers in a proxy farm are on the same Class C network. If the client's proxy servers are on different Class C networks, then the affinity relationship between a client and the server ends when the client sends successive requests from different Class C network addresses.

**Heartbeats and Convergence**

Network Load Balancing cluster hosts exchange heartbeat messages to maintain consistent data about the cluster's membership. By default, when a host fails to send out heartbeat messages within five seconds, it is deemed to have failed. Once a host has failed, the remaining hosts in the cluster perform convergence and do the following:

- Establish which hosts are still active members of the cluster.
- Elect the host with the highest priority as the new default host.
- Ensure that all new client requests are handled by the surviving hosts.

In convergence, surviving hosts look for consistent heartbeats. If the host that failed to send heartbeats once again provides heartbeats consistently, it rejoins the cluster in the course of convergence. When a new host attempts to join the cluster, it sends heartbeat messages that also trigger convergence. After all cluster hosts agree on the current cluster membership, the client load is redistributed to the remaining hosts, and convergence completes.

The following figure shows how the client load is evenly distributed among four cluster hosts before convergence takes place:

**Network Load Balancing Cluster Before Convergence**

The following figure shows a failed host and how the client load is redistributed among the three remaining hosts after convergence.

**Network Load Balancing Cluster After Convergence**

Convergence generally only takes a few seconds, so interruption in client service by the cluster is minimal. During

convergence, hosts that are still active continue handling client requests without affecting existing connections. Convergence ends when all hosts report a consistent view of the cluster membership and distribution map for several heartbeat periods.

By editing the registry, you can change both the number of missed messages required to start convergence and the period between heartbeats. However, be aware that making the period between heartbeats too short increases network overhead on the system. Also be aware that reducing the number of missed messages increases the risk of erroneous host evictions from the cluster.

**Note**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**Network Load Balancing Protocols**

Network Load Balancing can load-balance any application or service that uses TCP/IP as its network protocol and is associated with a specific Transmission Control Protocol (TCP) or User Datagram Protocol (UDP) port. For applications to work with Network Load Balancing, they must use TCP connections or UDP data streams.

You can also enable Internet Group Management Protocol (IGMP) support on the cluster hosts to control switch flooding when operating in multicast mode. IGMP is a protocol used by Internet Protocol version 4 (IPv4) hosts to report their multicast group memberships to any immediately neighboring multicast routers.

**Application Compatibility with Network Load Balancing**

In general, Network Load Balancing can load-balance any application or service that uses TCP/IP as its network protocol and is associated with a specific TCP or UDP port.

**Compatible Applications**

Compatible applications must have the following requirements in order to work with Network Load Balancing:

- TCP connections or UDP data streams.

- Synchronization of data. If client data that resides on one of the hosts changes as a result of a client transaction, applications must provide a means of synchronizing data updates if that data is shared on multiple instances across the cluster.

- Single or Class C affinity. If session state is an issue, applications must use single or Class C affinity or provide a means (such as a client cookie or reference to a back-end database) of maintaining session state in order to be uniformly accessible across the cluster.

As highlighted in the previous two bullets, before using Network Load Balancing, you must consider an application's requirements regarding client state. Network Load balancing can accommodate both stateless and stateful connections. However, certain factors must be considered for a stateful connection.

Application servers maintain two kinds of stateful connections:

- Interclient state. A state whose data updates must be synchronized with transactions that are performed for other clients, such as merchandise inventory at an e-commerce site. Because any host within the cluster can service client traffic, information that must be persistent across multiple requests or that must be shared among clients needs to be shared in a location that is accessible from all cluster hosts. Updates to information that is shared among the hosts needs to be synchronized, for example by using a back-end database server.

- Intraclient state. A state that must be maintained for a given client throughout a session (that can span multiple connections), such as a shopping cart process at an e-commerce site.

Network Load Balancing can be used with applications that maintain either type of state, although applications requiring interclient state are typically best accommodated with server clusters rather than Network Load Balancing. While intraclient state can be accommodated through the Network Load Balancing affinity settings, interclient state, on the other hand, requires additional components outside of Network Load Balancing.

**Interclient State**

Some applications require interclient state, that is, the applications make changes to data that must be synchronized across all

instances of the application. For example, any type of application that uses Microsoft SQL Server for data storage, such as a user registration database, requires interclient state. When applications do share and change data (require interclient state), the changes need to be properly synchronized. Each host can use local, independent copies of databases that are merged offline as necessary. Alternatively, the clustered hosts can share access to a separate, networked database server.

A combination of these approaches can also be used. For example, static Web pages can be replicated among all clustered servers to ensure fast access and complete fault tolerance. However, database requests would be forwarded to a common database server that handles updates for the multiple cluster hosts.

Network Load Balancing is a viable solution for applications that require interclient state.

**Intraclient State**
A second kind of state intraclient state (also known as session state), refers to client data that is visible to a particular client for the duration of a session. Session state can span multiple TCP connections, which can be either simultaneous or sequential. Network Load Balancing assists in preserving session state through client affinity settings. These settings direct all TCP connections from a given client address or group of client addresses to the same cluster host. This allows session state to be maintained by the server application in the host memory.

**Incompatible Applications**
Applications that are not compatible with Network Load Balancing have one or more of the following characteristics:

- They bind to actual computer names (examples of such applications are Exchange Server and Distributed File System).
- They have files that must be continuously open for writing (for example, Exchange Server). In a Network Load Balancing cluster, multiple instances of an application (on different cluster hosts) should not have a file simultaneously opened for writing unless the application was designed to synchronize file updates. This is generally not the case.

**Network Load Balancing for Scalability**
Network Load Balancing scales the performance of a server-based program, such as a Web server, by distributing its client requests across multiple identical servers within the cluster; you can add more servers to the cluster as traffic increases. Up to 32 servers are possible in any one cluster. The following figure represents how additional servers can support more users.

**How Servers Scale Out Across a Cluster**

You can improve the performance of each individual host in a cluster by adding more or faster CPUs, network adapters and disks, and in some cases by adding more memory. These additions to the Network Load Balancing cluster is called scaling up, and requires more intervention and careful planning than scaling out. Limitations of applications or the operating system configuration could mean that scaling up by adding more memory may not be as appropriate as scaling out.

You can handle additional IP traffic by simply adding computers to the Network Load Balancing cluster as necessary. Load balancing, in conjunction with the use of server clusters, is part of a scaling approach referred to as scaling out. The greater the number of computers involved in the load-balancing scenario, the higher the throughput of the overall server cluster.

**Scaling Network Load Balancing Clusters**
Network Load Balancing clusters have a maximum of 32 hosts, and all of the hosts must be on the same subnet. If a cluster

cannot meet the performance requirements of a clustered application, such as a Web site, because of a host count or subnet throughput limitation, then you can use multiple clusters to scale out further.

Combining round robin DNS and Network Load Balancing results in a very scalable and highly available configuration. Configuring multiple Network Load Balancing clusters on different subnets and configuring DNS to sequentially distribute requests across multiple Network Load Balancing clusters can evenly distribute the client load that is distributed across several clusters. When multiple Network Load Balancing Web server clusters are configured with round robin DNS, the Web servers are made resilient to networking infrastructure failures.

When you use round robin DNS in conjunction with Network Load Balancing clusters, each cluster is identified in DNS by the cluster virtual IP. Because each cluster is automatically capable of both load balancing and fault tolerance, each DNS-issued IP address will function until all hosts in that particular cluster fail. Round robin DNS enables only a limited form of TCP/IP load balancing for IP-based servers when used without Network Load Balancing. When used with multiple individual hosts, such as Web servers, round robin DNS does not function effectively as a solution. If a host fails, round robin DNS continues to route requests to the failed server until the server is removed from DNS.

**Performance Impact of Network Load Balancing**
The performance impact of Network Load Balancing can be measured in four key areas:

- CPU overhead on the cluster hosts, which is the CPU percentage required to analyze and filter network packets (lower is better).
- Response time to clients, which increases with the non-overlapped portion of CPU overhead, called latency (lower is better).
- Throughput to clients, which increases with additional client traffic that the cluster can handle prior to saturating the cluster hosts (higher is better).
- Switch occupancy, which increases with additional client traffic (lower is better) and must not adversely impact port bandwidth.

In addition, scalability determines how its performance improves as hosts are added to the cluster. Scalable performance requires that CPU overhead and latency not grow faster than the number of hosts.

**CPU Overhead**
All load-balancing solutions require system resources to examine incoming packets and make load-balancing decisions, and thus impose an overhead on network performance. As previously noted, dispatcher-based solutions examine, modify, and retransmit packets to particular cluster hosts. (They usually modify IP addresses to retarget packets from a virtual IP address to a particular host's IP address.) In contrast, Network Load Balancing independently delivers incoming packets to all cluster hosts and applies a filtering algorithm that discards packets on all but the desired host. Filtering imposes less overhead on packet delivery than re-routing, which results in lower response time and higher overall throughput.

**Throughput and Response Time**
Network Load Balancing scales performance by increasing throughput and minimizing response time to clients. When the capacity of a cluster host is reached, it cannot deliver additional throughput, and response time grows non-linearly as clients awaiting service encounter queuing delays. Adding another cluster host enables throughput to continue to climb and reduces queuing delays, which minimizes response time. As customer demand for throughput continues to increase, more hosts are added until the network's subnet becomes saturated. At that point, throughput can be further scaled by using multiple Network Load Balancing clusters and distributing traffic to them using Round Robin DNS.

**Switch Occupancy**
The filtering architecture for Network Load Balancing relies on the broadcast subnet of the LAN to deliver client requests to all cluster hosts simultaneously. In small clusters, this can be achieved using a hub to interconnect cluster hosts. Each incoming client packet is automatically presented to all cluster hosts. Larger clusters use a switch to interconnect cluster hosts, and, by default, Network Load Balancing induces switch-flooding to deliver client requests to all hosts independently. It is important to ensure that switch-flooding does not use an excessive amount of switch capacity, especially when the switch is shared with computers outside the cluster. The percentage of switch bandwidth consumed by flooding of client requests is called its switch occupancy.

# Network Load Balancing Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Network Load Balancing Tools
- Network Load Balancing Registry Entries
- Network Load Balancing WMI Classes
- Network Port Used by Network Load Balancing

This section provides summary information about the tools, registry entries, WMI classes, and network ports associated with Network Load Balancing. This information is helpful when evaluating Network Load Balancing to determine what tools are available to assist in deployment and operations tasks.

**Network Load Balancing Tools**
The following tools are associated with Network Load Balancing.

**NLB.exe command: Network Load Balancing control program**
**Category**
Tool included in the Windows Server 2003 family, Windows 2000 Standard Server SP 3 and later, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

**Version compatibility**
Available on computers running the Windows Server 2003 family of products, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

The Nlb.exe command replaces Wlbs.exe. Windows NT Load Balancing Service (WLBS) is the former name of Network Load Balancing in Windows NT Server 4.0. For reasons of backward compatibility, WLBS continues to be used in certain instances.

You can perform most cluster operations by using the nlb.exe command. Nlb.exe performs the following functions:

- Suspend and resume all cluster operations. The reason you would suspend operations is to override any remote control commands that might be issued. Resuming cluster operations would not restart the operations, but would enable use of cluster-control commands, including remote control commands.
- Start and stop cluster operations on the specified hosts.
- Disable all new traffic handling on the specified hosts.
- Enable and disable traffic handling for the rule whose port range contains the specified port.
- Display the current cluster state and the list of host priorities for the current members of the cluster.
- Display information about a given port rule.
- Reload the Network Load Balancing driver's current parameters from the registry.
- Display extensive information about the current Network Load Balancing parameters, cluster state, and past cluster activity. The last several event log records produced by Network Load Balancing are shown, including the binary data attached to those records. This assists in technical support and debugging.
- Display information about the current Network Load Balancing configuration.

- Display the media access control (MAC) address corresponding to the specified cluster name or IP address.

**Nlbmgr.exe: Network Load Balancing Manager**
**Category**
Tool included in the Windows Server 2003 family.

**Version compatibility**
Available on computers running the Windows Server 2003 family of products, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server. This tool is also part of the Windows Server 2003 Administration Tools Pack, which you can install on computers running Windows XP Professional. You can use Network Load Balancing Manager on Windows XP Professional only to manage Network Load Balancing clusters on remote computers running the Windows Server 2003 family of products. You cannot install the Network Load Balancing service itself on Windows XP Professional.

Network Load Balancing Manager is used to create and manage Network Load Balancing clusters and all cluster hosts from a single computer, and you can also replicate the cluster configuration to other hosts. By centralizing administration tasks, Network Load Balancing Manager helps eliminate many common configuration errors.

**Network Load Balancing Registry Entries**
The following registry entries are associated with Network Load Balancing.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

For more information about the following registry entries, see the Registry Reference in Tools and Settings Collection.

**network adapter ID subkey**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey.

**AliveMsgPeriod**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

Modifying this registry entry allows you to control both the message exchange period and the number of missed messages required to initiate convergence. Modifying the **AliveMsgTolerance** registry entry will also allow you to do this. The **AliveMsgPeriod** value holds the message exchange period in milliseconds, and the **AliveMsgTolerance** value specifies how many exchanged messages from a host can be missed before the cluster initiates convergence.

The values you enter should reflect your installation's requirements. A longer message exchange period reduces the heartbeat traffic needed to maintain fault tolerance, but it increases the time that it takes for Network Load Balancing to stop sending network messages to an offline host. Likewise, increasing the number of message exchanges prior to convergence reduces the number of unnecessary convergence initiations due to network congestion, but it too increases the time for an offline host to stop receiving network traffic.

Using the default values, 5 seconds are needed to discover a missing host, and another 5 seconds are needed for the cluster to redistribute the load. A total of 10 seconds to stop sending network traffic to an offline host should be acceptable for most TCP/IP applications. This configuration incurs very low networking overhead.

Default value: 1000 (1 second)

Possible range: 100–10000

**AliveMsgTolerance**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

Modifying this registry entry allows you to control both the message exchange period and the number of missed messages required to initiate convergence. Modifying the **AliveMsgPeriod** registry entry will also allow you to do this. For more information, see the previous description for **AliveMsgPeriod**.

Default value: 5

Possible range: 5–100

**DescriptorsPerAlloc**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

Determines the number of connection descriptors allocated at a time. Connection descriptors are used to track TCP connections.

Default value: 512

Possible range: 16–1024

**MaskSourceMAC**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

Enables masking of the media access control (MAC) address. The MAC address is used for communication between network adapters on the same subnet. Each network adapter has an associated MAC address.

If the host is connected to a switch when Network Load Balancing is running in unicast mode, set the value of **MaskSourceMAC** to 1 (the default). If the Network Load Balancing host is running in unicast mode and is attached to a hub that is then connected to a switch, set the value of this entry to 0. If Network Load Balancing is running in multicast mode, this setting has no effect.

Default value: 1

Possible range: 0–1

**MaxDescriptorAllocs**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

Determines the maximum number of times the connection descriptors can be allocated. This value limits the maximum memory footprint of Network Load Balancing.

Default value: 512

Possible range: 1–1024

**NetmonAliveMsgs**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

Determines whether Network Monitor (NetMon) captures Network Load Balancing heartbeat messages on the local host.

To allow NetMon to capture Network Load Balancing heartbeat messages on the local host, set the value of this entry to 1. To get the best performance, leave the value of this entry at its default value of 0.

**NumActions**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

This key is an internal Network Load Balancing entry. Increase the value of this entry only if you encounter an event log message that advises you to do so.

Default value: 100

Possible range: 5–500

**NumAliveMsgs**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

This is an internal Network Load Balancing entry. Increase the value of this entry only if you encounter an event log message that advises you to do so.

Default value: 66

Possible range: 5–500

**NumPackets**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

This is an internal Network Load Balancing entry. Increase the value of this entry only if you encounter an event log message that advises you to do so.

Default value: 200

Possible range: 5–500

**RemoteControlUDPPort**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\Interface*network adapter ID* subkey

**Version**
Available in the Windows Server 2003 family, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server.

Determines the UDP port that is used by Network Load Balancing to receive remote control messages. Note that for backwards compatibility, Network Load Balancing automatically listens to port 1717. If you decide to firewall the remote control port to block remote control messages, you also always need to firewall port 1717.

Do not use ports that are commonly used for other purposes (such as those used for FTP or DNS).

Default value: 2504

### Note

- DecriptorsPerAlloc, MaxDescriptorAllocs, NumActions, NumPackets, and NumAliveMsgs only take effect when the Network Load Balancing driver is binding to the network adapter (upon restarting the hosts, or through disabling and then re-enabling the network adapter). The remaining settings will take effect when the Network Load Balancing driver binds to the network adapter, or when Network Load Balancing is reloaded (using Nlb.exe reload command).

**Network Load Balancing WMI Classes**
The following table lists and describes the WMI classes that are associated with Network Load Balancing.

### WMI Classes Associated with Network Load Balancing

| Class Name | Namespace | Version Compatibility |
|---|---|---|

| | | |
|---|---|---|
| MicrosoftNLB_Cluster | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_ClusterClusterSetting | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_ClusterSetting | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_ExtendedStatus | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_Node | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_NodeNodeSetting | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_NodeSetting | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_NodeSettingPortRule | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_ParticipatingNode | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_PortRule | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_PortRuleDisabled | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_PortRuleFailover | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |
| MicrosoftNLB_PortRuleLoadBalanced | root\cimv2 | Included in Windows Server 2003, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Port Used by Network Load Balancing**

Network Load Balancing uses the following network port.

### Network Ports Used by Network Load Balancing

| Service Name | UDP |
|---|---|
| NLBS | 2504 |

Port numbers in a range of 0 to 65,535 are currently supported by Network Load Balancing for TCP/UDP. The default port range is 0 to 65,535. To load-balance all client requests with a single port rule, use the default port range. By using the default port range, you do not have to worry about which port or ports are associated with the application whose client requests you are load-balancing.

# Resource and Memory Management Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resource and Memory Management Components**

4GT and PAE X86 are available only in the 32-bit editions of Microsoft Windows Server 2003, Enterprise Edition, or Microsoft Windows Server 2003, Datacenter Edition, of the Windows Server 2003 family. Both technologies can provide user applications with access to additional RAM. The default virtual address space and flat addressing used on the 64-bit versions of these products negates the need to use these technologies on the 64-bit platforms.

4GT makes more of the computer's virtual memory available to applications by making less virtual memory available to the operating system. 4GT allows applications to address 3 gigabytes (GB) of virtual memory instead of the 2 GB normally allocated for user mode processes. This is a 50 percent increase in virtual memory for the applications, allowing more data to be cached by the application, which can significantly increase performance.

PAE X86 provides the operating system access to memory beyond the default memory address limit of 4 GB. PAE X86 allows software that uses the Address Windowing Extensions (AWE) API set and runs on computers with more than 4 GB of physical memory to map additional physical memory into the application's virtual address space. Applications not using the AWE API set can also benefit from PAE X86 because the operating system uses the larger physical memory to reduce paging and thus increase performance.
