- **Start of authority (SOA) properties** These include properties supported by the SOA resource record, which is used to initialize the zone and indicate zone authority for a DNS domain name (and any of its subdomains not delegated away to other servers) to others in the DNS namespace. This record affects how often the zone must be renewed and transferred by other servers that load the zone and how long clients can cache resource records (RRs) when returned in answered queries for names in the zone. For more information on this record and configuring it, see Managing authority records.

- **Name server (NS) properties** These include all fields supported by the NS resource record (RR) for the zone. The NS RR is used for designating the names of DNS servers authoritative for the zone to others. For more information on this record and configuring it, see Managing authority records.

- **Zone Transfer properties** With this feature, you can configure how the zone permits transfers to be performed.

  You can choose to deny all requests to the server for transfer of this zone, to allow them only for other DNS servers configured on the **Name Servers** tab, or to transfer the zone only to DNS servers that you specify by IP address in a configured list.

  Using **Notify** located here, you can also enable and configure DNS notification for secondary servers of the zone. When notification is used, other servers (either those configured on the **Name Servers** tab or on a list that you specify) are notified of zone changes. These servers can then pull changes by initiating a zone transfer to update the zone.

  For more information, see Configuring notify lists.

  **Note**

  - By default, the DNS server will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.

- **WINS lookup properties** The Windows Internet Name Service (WINS) lookup feature can be used to provide an expanded DNS name resolution path for zones when a queried name is not found in the zone. If WINS lookup is enabled for the zone, a WINS server (or list of WINS servers) can be contacted to assist in resolving a host name in the WINS-managed NetBIOS namespace. This feature is supported only by Microsoft DNS servers. For more information, see Using WINS lookup.

# Managing authority records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing authority records**

Zones are based on a concept of server authority. When a DNS server is configured to load a zone, it uses two types of resource records to determine the authoritative properties of the zone:

- First, the start of authority (SOA) resource record indicates the name of origin for the zone and contains the name of the server that is the primary source for information about the zone. It also indicates other basic properties of the zone.

- Next, the name server (NS) resource record is used to notate which DNS servers are designated as authoritative for the zone. By listing a server in the NS RR, it becomes known to others as an authoritative server for the zone. This means that any server specified in the NS RR is to be considered an authoritative source by others, and is able to answer with certainty any queries made for names included in the zone.

The SOA and NS resource records occupy a special role in zone configuration. They are required records for any zone and are typically the first resource records listed in files. By default, the New Zone Wizard automatically creates these records when a new primary zone is added using the DNS console.

**The SOA resource record**

The start of authority (SOA) resource record is always first in any standard zone. It indicates the DNS server that either originally created it or is now the primary server for the zone. It is also used to store other properties such as version information and timings that affect zone renewal or expiration. These properties affect how often transfers of the zone are done between servers authoritative for the zone.

The SOA resource record contains the following information:

| Field | Description |
|---|---|
| Primary server (owner) | The host name for the primary DNS server for the zone. |
| Responsible person | The e-mail address of the person responsible for administering the zone. A period (**.**) is used instead of an at sign (**@**) in this e-mail name. |
| Serial number | The revision number of the zone file. This number increases each time a resource record in the zone changes. It is important that this value increase each time the zone is changed, so that either partial zone changes or the fully revised zone can be replicated to other secondary servers during subsequent transfers. |
| Refresh interval | The time, in seconds, that a secondary DNS server waits before querying its source for the zone to attempt renewal of the zone. When the refresh interval expires, the secondary DNS server requests a copy of the current SOA record for the zone from its source, which answers this request. The secondary DNS server then compares the serial number of the source server's current SOA record (as indicated in the response) with the serial number in its own local SOA record. If they are different, the secondary DNS server requests a zone transfer from the primary DNS server. The default for this field is 900 seconds (15 minutes). |
| Retry interval | The time, in seconds, a secondary server waits before retrying a failed zone transfer. Normally, this time is less than the refresh interval. The default value is 600 seconds (10 minutes). |
| Expire interval | The time, in seconds, before a secondary server stops responding to queries after a lapsed refresh interval where the zone was not refreshed or updated. Expiration occurs because at this point in time, the secondary server must consider its local data unreliable. The default value is 86,400 seconds (24 hours). |
| Minimum (default) TTL | The default Time-To-Live (TTL) of the zone and the maximum interval for caching negative answers to name queries. The default value is 3,600 seconds (1 hour). |

The following is an example of a default SOA resource record:

```
@   IN  SOA     nameserver.example.microsoft.com.  postmaster.example.microsoft.com. (
                                1            ; serial number
                                3600         ; refresh   [1h]
                                600          ; retry     [10m]
                                86400        ; expire    [1d]
                                3600 )       ; min TTL   [1h]
```

In the example SOA record shown above, the primary or originating server for the zone is shown as nameserver.example.microsoft.com. The e-mail address for the person to contact regarding questions about this zone is postmaster.example.microsoft.com.

**Notes**

- Periods are used to represent e-mail addresses when writing and storing DNS domain names in a zone. In an e-mail application, the previous example address would instead likely appear as postmaster@example.microsoft.com.
- The parentheses used in the SOA resource record as it appears in a zone file are used to enable wrapping of the record over multiple lines of text.
- If an individual TTL value is assigned and applied to a specified resource record used in the zone, it overrides the minimum (default) TTL set in the SOA record.

**The NS resource record**

Name server (NS) resource records can be used to assign authority to specified servers for a DNS domain name in two ways:

- By establishing a list of authoritative servers for the domain so that those servers can be made known to others that request information about this domain (zone).
- By indicating authoritative DNS servers for any subdomains that are delegated away from the zone.

In the case of assigning servers with host names in the same zone, corresponding address (A) resource records are normally used in the zone to resolve the names of specified servers to their IP addresses. For servers that are specified using this RR as part of a zone delegation to a subdomain, the NS resource record usually contains out-of-zone names. For the out-of-zone names to be resolved, A resource records for the specified out-of-zone servers might be needed. When these out-of-zone NS and A records are needed to provide delegation, they are known as *glue records*.

| |
|---|
| **Description:** Used to map a DNS domain name as specified in **owner** to the name of hosts operating DNS servers specified in the *name_server_domain_name* field. |
| **Syntax:** *owner ttl* **IN NS** *name_server_domain_name* |
| **Example:**<br>`example.microsoft.com.  IN NS  nameserver1.example.microsoft.com` |

# Managing resource records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing resource records**

After you create a zone, additional resource records need to be added to it. The most common resource records (RRs) to be added are:

- **Host (A)** For mapping a DNS domain name to an IP address used by a computer.
- **Alias (CNAME)** For mapping an alias DNS domain name to another primary or canonical name.
- **Mail Exchanger (MX)** For mapping a DNS domain name to the name of a computer that exchanges or forwards mail.
- **Pointer (PTR)** For mapping a reverse DNS domain name based on the IP address of a computer that points to the forward DNS domain name of that computer.
- **Service location (SRV)** For mapping a DNS domain name to a specified list of DNS host computers that offer a specific type of service, such as Active Directory domain controllers.
- Other resource records as needed.

**Host (A) resource records**

Host (A) resource records are used in a zone to associate DNS domain names of computers (or hosts) to their IP addresses, and can be added to a zone in several ways:

- You can manually create an A resource record for a static TCP/IP client computer using the DNS console.
- Windows clients and servers use the DHCP Client service to dynamically register and update their own A resource records in DNS when an IP configuration change occurs.
- DHCP-enabled client computers running earlier versions of Microsoft operating systems can have their A resource records registered and updated by proxy if they obtain their IP lease from a qualified DHCP server (only the Windows 2000 and Windows Server 2003 DHCP Server service currently supports this feature).

The host (A) resource record is not required for all computers, but is needed by computers that share resources on a network. Any computer that shares resources and needs to be identified by its DNS domain name, needs to use A resource records to provide DNS name resolution to the IP address for the computer.

Most A RRs that are required in a zone can include other workstations or servers that share resources, other DNS servers, mail servers, and Web servers. These resource records comprise the majority of resource records in a zone database.

For more information, see Resource records reference.

**Alias (CNAME) resource records**

Alias (CNAME) resource records are also sometimes called *canonical names*. These records allow you to use more than one name to point to a single host, making it easy to do such things as host both an FTP server and a Web server on the same computer. For example, the well-known server names (ftp, www) are registered using CNAME RRs that map to the DNS host name, such as "server-1", for the server computer that hosts these services.

CNAME RRs are recommended for use in the following scenarios:

- When a host specified in an A RR in the same zone needs to be renamed.
- When a generic name for a well-known server such as www needs to resolve to a group of individual computers (each with individual A RRs) that provide the same service. For example, a group of redundant Web servers.

When renaming a computer with an existing A RR in the zone, you can use a CNAME RR temporarily, to allow a grace period for users and programs to switch from specifying the old computer name to using the new one. To do this, you need the following:

- For the new DNS domain name of the computer, a new A RR is added to the zone.
- For the old DNS domain name, a CNAME RR is added that points to the new A RR.
- The original A RR for the old DNS domain name (and its associated PTR RR if applicable) is removed from the zone.

When using a CNAME RR for aliasing or renaming a computer, set a temporary limit on how long the record is used in the zone before removing it from DNS. If you forget to delete the CNAME RR and later its associated A RR is deleted, the CNAME RR can waste server resources by trying to resolve queries for a name no longer used on the network.

The most common or popular use of a CNAME RR is to provide a permanent DNS aliased domain name for generic name resolution of a service-based name, such as www.example.microsoft.com to more than one computer or one IP address used in a Web server. For example, the following shows the basic syntax of how a CNAME RR is used.

*alias_name* **IN CNAME** *primary_canonical_name*

In this example, a computer named host-a.example.microsoft.com needs to function as both a Web server named "www.example.microsoft.com." and an FTP server named "ftp.example.microsoft.com." To achieve the intended use for naming this computer, you can add and use the following CNAME entries in the example.microsoft.com zone:

```
host-a     IN  A      10.0.0.20
ftp        IN  CNAME  host-a
www        IN  CNAME  host-a
```

If you later decide to move the FTP server to another computer, separate from the Web server on "host-a", simply change the CNAME RR in the zone for ftp.example.microsoft.com and add an additional A RR to the zone for the new computer hosting the FTP server.

Based on the earlier example, if the new computer were named "host-b.example.microsoft.com", the new and revised A and CNAME RRs would be as follows:

```
host-a     IN  A      10.0.0.20
host-b     IN  A      10.0.0.21
ftp        IN  CNAME  host-b
www        IN  CNAME  host-a
```

For more information, see Resource records reference.

**Mail exchanger (MX) resource records**

The mail exchanger (MX) RR is used by e-mail applications to locate a mail server based on a DNS domain name used in the destination address for the e-mail recipient of a message. For example, a DNS query for the name "example.microsoft.com" could be used to find an MX RR, enabling an e-mail application to forward or exchange mail to a user with the e-mail address "user@microsoft.com."

The MX RR shows the DNS domain name for the computer or computers that process mail for a domain. If multiple MX RRs exist, the DNS Client service attempts to contact mail servers in the order of preference from lowest value (highest priority) to highest value (lowest priority). The following shows the basic syntax for use of an MX RR.

*mail_domain_name* **IN MX** *preference mailserver_host*

By using the MX RRs shown below in the example.microsoft.com zone, mail addressed to user@example.microsoft.com is delivered to user@mailserver0.example.microsoft.com first if possible. If this server is unavailable, the resolver client can then use user@mailserver1.example.microsoft.com instead.

```
@          IN  MX   1    mailserver0
@          IN  MX   2    mailserver1
```

Note that the use of the at sign (**@**) in the records indicates that the mailer DNS domain name is the same as the name of origin (example.microsoft.com) for the zone.

For more information, see Resource records reference.

**Pointer (PTR) resource records**
Pointer (PTR) RRs are used to support the reverse lookup process, based on zones created and rooted in the in-addr.arpa domain. These records are used to locate a computer by its IP address and resolve this information to the DNS domain name for that computer.

PTR RRs can be added to a zone in several ways:

- You can manually create a PTR RR for a static TCP/IP client computer using the DNS , either as a separate procedure or as part of the procedure for creating an A RR.

- Computers use the DHCP Client service to dynamically register and update their PTR RR in DNS when an IP configuration change occurs.

- All other DHCP-enabled client computers can have their PTR RRs registered and updated by the DHCP server if they obtain their IP lease from a qualified server. The Windows 2000 and Windows Server 2003 DHCP Server service provides this capability.

The pointer (PTR) resource record is used only in reverse lookup zones to support reverse lookup. For more information, see Resource records reference.

**Service location (SRV) resource records**
To locate Active Directory domain controllers, service location (SRV) RRs are required. Typically, you can avoid manual administration of the SRV RR when installing Active Directory.

By default, the Active Directory installation wizard attempts to locate a DNS server based on the list of preferred or alternate DNS servers, configured in any of its TCP/IP client properties, for any of its active network connections. If a DNS server that can accept dynamic update of the SRV RR (and other RRs related to registering Active Directory as a service in DNS) is contacted, the configuration process is complete.

If, during the installation, a DNS server that can accept updates for the DNS domain name used to name your Active Directory is not found, the wizard can install a DNS server locally and automatically configure it with a zone to support the Active Directory domain.

For example, if the Active Directory domain that you chose for your first domain in the forest was example.microsoft.com, a zone rooted at the DNS domain name of example.microsoft.com would be added and configured to use with the DNS server running on the new domain controller.

Whether or not you install the DNS Server service locally, a file (Netlogon.dns) is written and created during the Active Directory installation process that contains the SRV RRs and other RRs needed to support the use of Active Directory. This file is created in the systemroot\System32\Config folder.

If you are using a DNS server that fits one of the following descriptions, you should use the records in Netlogon.dns to manually configure the primary zone on that server to support Active Directory.

1. The computer operating your DNS server is running on another platform, such as UNIX, and cannot accept or recognize dynamic updates.

2. A DNS server at this computer that is not the DNS Server service provided with the Windows Server 2003 family is authoritative for the primary zone corresponding to the DNS domain name for your Active Directory domain.

3. The DNS server supports the SRV RR, as defined in the Internet draft, "A DNS RR specifying the location of services (DNS SRV)", but does not support dynamic updates.

   For example, the DNS Server service provided with Windows NT Server 4.0, when updated to Service Pack 4 or later, fits this description.

In the future, the SRV RR might also be used to register and lookup other well-known TCP/IP services on your network if

applications implement and support DNS name queries that specify this record type. For more information, see Resource records reference.

**Other resource records**

Other additional resource records are supported by Windows Server 2003 DNS and are used less frequently in most zones. These additional types of resource records can be added as needed using the DNS console. For more information about supported resource records, see Resource records reference.

# Delegating zones

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Delegating zones**

DNS provides the option of dividing up the namespace into one or more zones, which can then be stored, distributed, and replicated to other DNS servers. When deciding whether to divide your DNS namespace to make additional zones, consider the following reasons to use additional zones:

- A need to delegate management of part of your DNS namespace to another location or department within your organization.
- A need to divide one large zone into smaller zones for distributing traffic loads among multiple servers, improve DNS name resolution performance, or create a more fault-tolerant DNS environment.
- A need to extend the namespace by adding numerous subdomains at once, such as to accommodate the opening of a new branch or site.

If, for any of these reasons, you could benefit from delegating zones, it might make sense to restructure your namespace by adding additional zones. When choosing how to structure zones, you should use a plan that reflects the structure of your organization.

When delegating zones within your namespace, be aware that for each new zone you create, you will need delegation records in other zones that point to the authoritative DNS servers for the new zone. This is necessary both to transfer authority and to provide correct referral to other DNS servers and clients of the new servers being made authoritative for the new zone.

When a standard primary zone is first created, it is stored as a text file containing all resource record information on a single DNS server. This server acts as the primary master for the zone. Zone information can be replicated to other DNS servers to improve fault tolerance and server performance.

When structuring your zones, there are several good reasons to use additional DNS servers for zone replication:

1. Added DNS servers provide zone redundancy, enabling DNS names in the zone to be resolved for clients if a primary server for the zone stops responding.
2. Added DNS servers can be placed so as to reduce DNS network traffic. For example, adding a DNS server to the opposing side of a low-speed WAN link can be useful in managing and reducing network traffic.
3. Additional secondary servers can be used to reduce loads on a primary server for a zone.

**Example: Delegating a subdomain to a new zone**

As shown in the following figure, when a new zone for a subdomain (example.microsoft.com) is created, delegation from the parent zone (microsoft.com) is needed.

In this example, an authoritative DNS server computer for the newly delegated example.microsoft.com subdomain is named based on a derivative subdomain included in the new zone (ns1.us.example.microsoft.com). To make this server known to others outside of the new delegated zone, two RRs are needed in the microsoft.com zone to complete delegation to the new zone.

These RRs include:

- An NS RR to effect the delegation. This RR is used to advertise that the server named ns1.us.example.microsoft.com is an authoritative server for the delegated subdomain.

- An A RR (also known as a glue record) is needed to resolve the name of the server specified in the NS RR to its IP address. The process of resolving the host name in this RR to the delegated DNS server in the NS RR is sometimes referred to as glue chasing.

**Note**

- When zone delegations are correctly configured, normal zone referral behavior can sometimes be circumvented if you are using forwarders in your DNS server configuration. For more information, see Directing queries through forwarders.

# Configuring notify lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring notify lists**
Notify lists can be created and managed to provide a method for a master server for a zone (such as the primary server or another secondary server) to notify a list of secondary servers when the zone changes.

To create or manage a notify list, you can use the DNS console to add and remove servers by their IP addresses in the notify list for a zone. By default, the notify list is based on the authoritative servers for the zone as listed on the **Name Servers** tab.

**Notes**

- For more information on how DNS notification works, see Understanding zones and zone transfer.
- For more information on configuring and managing notify lists, see Create and manage a notify list for a zone.
- You cannot configure a notify list for a stub zone.
- By default, a DNS server running a Windows Server 2003 operating system will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.

# Securing DNS zones

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Securing DNS zones**

The following DNS zone configuration options have security implications for both standard and Active Directory-integrated DNS zones:

- **Configure secure dynamic updates.** By default, the **Dynamic updates** setting is not configured to allow dynamic updates. This is the most secure setting as it prevents an attacker from updating DNS zones, but this setting prevents you from taking advantage of the benefits to administration that dynamic update provides. To have computers securely update DNS data, store DNS zones in Active Directory and use the secure dynamic update feature. Secure dynamic update restricts DNS zone updates to only those computers that are authenticated and joined to the Active Directory domain where the DNS sever is located, and to the specific security settings defined in the ACLs for the DNS zone.

  For more information, see Allow only secure dynamic updates.

- **Manage the discretionary access control list (DACL) on the DNS zones stored in Active Directory.** The DACL allows you to control the permissions for the Active Directory users and groups that may control the DNS zones.

  The following table lists the default group or user names and permissions for DNS zones stored in Active Directory.

| Group or user names | Permissions |
|---|---|
| Administrators | Allow: Read, Write, Create All Child objects, Special Permissions |
| Authenticated Users | Allow: Create All Child objects |
| Creator Owner | Special Permissions |
| DnsAdmins | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects, Special Permissions |
| Domain Admins | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects |
| Enterprise Admins | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects |
| Enterprise Domain Controllers | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects, Special Permissions |
| Everyone | Allow: Read, Special Permissions |
| Pre-Windows 2000 Compatible Access | Allow: Special Permissions |
| System | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects |

  For more information, see Modify security for a directory-integrated zone.

  The DNS Server service running on a domain controller that has zones stored in Active Directory stores its zone data in Active Directory using Active Directory objects and attributes. Configuring the DACL on the DNS Active Directory objects has the same effect as configuring the DACL on DNS zones in the DNS console. Consequently, the security administrators of Active Directory objects and DNS data should be in direct contact to ensure that the administrators do not reverse each other's security settings.

  The Active Directory objects and attributes used by DNS zone data stored in Active Directory are described in the following table.

| Object | Description |
| --- | --- |
| DnsZone | Container created when a zone is stored in Active Directory. |
| DnsNode | Leaf object used to map and associate a name in the zone to resource data. |
| DnsRecord | Multivalued attribute of a dnsNode object used to store the resource records associated with the named node object. |
| DnsProperty | Multivalued attribute of a dnsZone object used to store zone configuration information. |

For more information, see Assign, change, or remove permissions on Active Directory objects or attributes.

- **Restrict zone transfers.** By default, the DNS Server service only allows zone information to be transferred to servers listed in the name server (NS) resource records of a zone. This is a secure configuration, but for increased security, this setting should be changed to the option to allow zone transfers to specified IP addresses. Changing this setting to allow zone transfers to any server may expose your DNS data to an attacker attempting to footprint your network.

  For more information, see Modify zone transfer settings.

- **Understand the compromise involved in zone delegation.** When deciding whether to delegate DNS domain names to zones hosted on DNS servers that are administered separately, it is important to consider the security implications of giving multiple individuals the ability to administer the DNS data for your network. DNS zone delegation involves a compromise between the security benefits of having a single authoritative DNS server for all DNS data and the administrative benefits of distributing responsibility for your DNS namespace to separate administrators. This issue is very important when delegating the top-level domains of a private DNS namespace, as those domains contain very sensitive DNS data.

  For more information, see Delegating zones.

**DNS zone data recovery**

If your DNS data has been corrupted you can restore your DNS zone file from the backup folder located in the systemroot/DNS/Backup folder. When a zone is first created, a copy of the zone is added to the backup folder. To recover the zone, copy the original zone file from the backup folder into the systemroot/DNS folder. When you use the New Zone Wizard to create the zone, specify the zone file in the systemroot/DNS folder as the zone file for the new zone. For more information, see Add a forward lookup zone.

**Note**

- This operation only applies to standard zones that are not stored in Active Directory.

In the case of both standard and Active Directory-integrated zones, you should use the system backup feature to establish a standard data recovery procedure for your DNS infrastructure. For more information, see Create an Automated System Recovery set using Backup.

For more information, see Security information for DNS.

# Securing DNS resource records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Securing DNS resource records**

The following DNS resource record configuration options have security implications for resource records stored in both standard and Active Directory-integrated DNS zones:

- **Manage the discretionary access control list (DACL) on DNS resource records stored in Active Directory.** The DACL allows you to control the permissions for the Active Directory users and groups that may control the DNS resource records. For more information, see Modify security for a resource record.

  The following table lists the default group or user names and permissions for DNS resource records stored in Active Directory.

| Group or user names | Permissions |
|---|---|
| Administrators | Allow: Read, Write, Create All Child objects, Special Permissions |
| Authenticated Users | Allow: Create All Child objects |
| Creator Owner | Special Permissions |
| DnsAdmins | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects, Special Permissions |
| Domain Admins | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects |
| Enterprise Admins | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects |
| Enterprise Domain Controllers | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects, Special Permissions |
| Everyone | Allow: Read, Special Permissions |
| Pre-Windows 2000 Compatible Access | Allow: Special Permissions |
| System | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects |

For more information, see Security information for DNS.

# Using stub zones

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using stub zones**

Use stub zones to:

- **Keep delegated zone information current.** By updating a stub zone for one of its child zones regularly, the DNS server hosting both the parent zone and the stub zone will maintain a current list of authoritative DNS servers for the child zone.
- **Improve name resolution.** Stub zones enable a DNS server to perform recursion using the stub zone's list of name servers without needing to query the Internet or internal root server for the DNS namespace.
- **Simplify DNS administration.** By using stub zones throughout your DNS infrastructure, you can distribute a list of the authoritative DNS servers for a zone without using secondary zones. However, stub zones do not serve the same purpose as secondary zones and are not an alternative when considering redundancy and load sharing.

There are two lists of DNS servers involved in the loading and maintenance of a stub zone:

- The list of master servers from which the DNS server loads and updates a stub zone. A master server may be a primary or secondary DNS server for the zone. In both cases, it will have a complete list of the DNS servers for the zone.
- The list of the authoritative DNS servers for a zone. This list is contained in the stub zone using name server (NS) resource records.

When a DNS server loads a stub zone, such as widgets.example.com, it queries the master servers, which can be in different locations, for the necessary resource records of the authoritative servers for the zone widgets.example.com. The list of master servers may contain a single server or multiple servers and can be changed anytime. For more information, see Configure a stub zone for local master servers.

**Stub zone updates**

Stub zone updates involve the following conditions:

- When a DNS server loads a stub zone, it queries the zone's master server for the SOA resource record, NS resource records at the zone's root, and glue A resource records.
- During updates to the stub zone, the master server is queried by the DNS server hosting the stub zone for the same resource record types requested during the loading of the stub zone.
- The Refresh interval of the SOA resource record determines when the DNS server hosting the stub zone will attempt a zone transfer (update).
- If an update fails, the Retry interval of the SOA resource record determines when the update is retried.
- Once the Retry interval has expired without a successful update, the expiration time as specified in the Expires field of the SOA resource record determines when the DNS server stops using the stub zone data.

Use the DNS console in Microsoft Management Console (MMC) to perform the following stub zone update operations:

- **Reload.** Reload the stub zone from the local storage of the DNS server hosting the stub zone.
- **Transfer from master.** Have the DNS server hosting the stub zone determine if the serial number in the stub zone's SOA resource record has expired, and then perform a zone transfer from the stub zone's master server.

- **Reload from master.** Perform a zone transfer from the stub zone's master server regardless of the serial number in the stub zone's SOA resource record.

For more information, see Reload or transfer a stub zone, Add a stub zone, and Understanding stub zones.

# Active Directory-integrated stub zones

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Active Directory-integrated stub zones**
A stub zone can be stored in Active Directory on a DNS server configured as a domain controller. The following parameters are stored in the Active Directory-integrated stub zone:

- Name of the stub zone, such as widgets.example.com.
- Type of zone (stub zone).
- List of master servers.

For more information, see Understanding stub zones and Active Directory integration.

**Updating stub zones**
When Active Directory-integrated stub zones are hosted in separate sites, you can update them using a local list of master servers in each site. For example, an Active Directory-integrated stub zone, widgets.example.com, was loaded in a site in Seattle and propagated to a site in Santiago, and master servers for the stub zone also exist in each of these sites. When the stub zone in Santiago is updated, the domain controller may contact both master servers for resource records for widgets.example.com, but for network traffic reasons, you might want the domain controller in Santiago to use only the master server in Santiago and not the master server in Seattle. To force the domain controller in Santiago to use only the master server in Santiago, you can specify that the stub zone in Santiago be updated using a local list of master servers.

For information about how to use a local list of master servers to update stub zones, see Configure a stub zone for local master servers.

# Contrasting stub zones and conditional forwarders

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Contrasting stub zones and conditional forwarders**

There can be some confusion about when to use conditional forwarders instead of stub zones because both DNS features allow a DNS server to respond to a query with a referral for, or by forwarding to, a different DNS server; however, these settings are used for very different purposes. These features have the following objectives:

- A conditional forwarder setting configures the DNS server to forward a query it receives to a DNS server depending on the DNS name contained in the query.
- A stub zone keeps the DNS server hosting a parent zone aware of all the DNS servers authoritative for a child zone.

**Conditional forwarders**

In situations where you want DNS clients in separate networks to resolve each others' names without having to query DNS servers on the Internet, such as in the case of a company merger, you should configure the DNS servers in each network to forward queries for names in the other network. DNS servers in one network will forward names for clients in the other network to a specific DNS server that will build up a large cache of information about the other network. When forwarding in this way, you create a direct point of contact between two networks' DNS servers, reducing the need for recursion.

Stub zones do not provide the same server-to-server benefit because a DNS server hosting a stub zone in one network will reply to queries for names in the other network with a list of *all* authoritative DNS servers for the zone with that name, instead of the specific DNS servers you have designated to handle this traffic. This configuration complicates any type of security settings that you want to establish between specific DNS servers running in each of the networks. For more information, see Understanding forwarders.

**Stub zones**

Stub zones are used when you want a DNS server hosting a parent zone to remain aware of the authoritative DNS servers for one of its child zones. If the stub zone for a child zone is hosted on the same DNS server as the parent zone, the DNS server hosting the stub zone will receive a list of all new authoritative DNS servers for the child zone when it requests an update from the stub zone's master server . This method of updating the DNS server hosting the parent zone maintains a current list of the authoritative DNS servers for the child zone as they are added and removed.

A conditional forwarder is not an efficient method of keeping a DNS server hosting a parent zone aware of the authoritative DNS servers for a child zone. If you used this method, whenever the authoritative DNS servers for the child zone changed, the conditional forwarder setting on the DNS server hosting the parent zone would have to be manually configured with the IP address for each new authoritative DNS server for the child zone. For more information, see Understanding stub zones.

# Checking names and zone data

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checking names and zone data**

The following name-checking methods can be used with the DNS Server service and managed using the DNS console.

| Method | Description |
|---|---|
| Strict RFC (ANSI) | Uses strict checking of names according to RFC 1123 Internet host naming specifications. |
| Non RFC (ANSI) | Permits names that are nonstandard and that do not follow RFC 1123 Internet host naming specifications. |
| Multibyte (UTF8) | Permits recognition of characters other than ASCII, including Unicode, which is normally encoded as more than one octet (8 bits) in length.<br><br>With this option, multibyte characters can be transformed and represented using Unicode Transformation Format (UTF-8) support. |
| All names | Permits any naming conventions. |

**Notes**

- For more information on when to use nondefault settings for name checking with the DNS Server service, see Unicode character support.
- For more information about RFCs, see DNS RFCs.

**Checking for bad zone data**

You can configure the DNS Server service to check for bad or unrecognized zone data when the service is started. To enable this option, see Prevent loading of a zone when bad data is found.

**DNS wildcarding**

The DNS Server service can use wildcards to associate multiple possible DNS name destinations with a single computer acting as a gateway for all names based on a wildcarded name. The most common use of wildcards in DNS records is with the mail exchanger (MX) resource record; for example, to configure DNS for an Internet mail gateway host routing mail between your private network and the Internet.

**Basics of using DNS wildcards**

When you are trying to determine where to use a wildcard in DNS, such as an MX resource record used to route and forward mail, note these guidelines:

- The asterisk (*) is the character reserved to indicate the wildcarded name.
- The asterisk is only used once as the leading (leftmost) character in a DNS name. For example, *.example.microsoft.com.
- If used, an asterisk must always match at least one or more whole labels of a name that precede any non-wildcarded (exact) characters in the remaining part of the name. For example, the wildcard name *.example.microsoft.com may apply to one or more descendents of a domain, such as haifa.example.microsoft.com or seattle.us.example.microsoft.com, but it will not apply to the domain name itself, which is example.microsoft.com.
- Wildcards are not used when a query for an exact name produces an exact match.
- The contents of wildcarded resource records conform to normal DNS formats and rules for resource records.

Typically, wildcards are only used when the DNS name queried is an indeterminate name subordinate to a known name. In this

case, the closest match to the wildcarded name is used. For example, if the following MX resource record is used in the example.microsoft.com zone:

*.example.microsoft.com.  IN  MX  10  mailserver1.example.microsoft.com.

This record would allow mail destined for the following possible DNS domain names to be routed to the mail routing host (mailserver1.example.microsoft.com.) specified in the MX resource record:

haifa.example.microsoft.com.

seattle.us.example.microsoft.com.

santiago.sa.example.microsoft.com.

When wildcarding is used, the asterisk (*****) wildcard symbol must match at least one whole label beyond the specified part of the DNS name in which the wildcard is used.

For example, an e-mail message destined to user@example.microsoft.com could not use the previous example MX resource record to be forwarded to its destination. For the e-mail to be forwarded correctly, an additional explicit MX resource record needs to be added in the same zone, such as:

example.microsoft.com.  IN  MX  10  mailserver1.example.microsoft.com.

**Loose RFC wildcarding**
For Windows NT Server 4.0 (prior to Service Pack 4), the DNS Server service was not strictly compliant with the method for using wildcards in a DNS name lookup described in RFC 1034. It only stopped a wildcard lookup when it reached a node in the DNS domain namespace tree that had resource records of the type specified in a query.

For example, if in the example.microsoft.com. zone the following records were used:

```
      *.example.microsoft.com.             IN  MX  10
mailserver1.example.microsoft.com.
      example.microsoft.com.               IN  MX  10
mailserver2.example.microsoft.com.
      host-a.example.microsoft.com.        IN  A       10.0.0.1
      mailserver1.example.microsoft.com.   IN  A       10.0.0.2
      mailserver2.example.microsoft.com.   IN  A       10.0.0.3
```

and a DNS query was made by a computer, Host B, as follows:

**Queried name:** host-a.example.microsoft.com.

**Queried type:** MX

with loose wildcarding in effect, the following sequence occurs between the DNS Server service and Host B:

1. Host B sends the example query to a DNS server configured to use loose RFC wildcarding, such as a DNS server running under Windows NT Server 4.0 prior to Service Pack 4.

2. No MX resource records match the specified name (host-a.example.microsoft.com.).

3. An MX resource record -- the type specified in the query -- is included in the zone and uses a wildcarded name that is the parent of the queried name (*.example.microsoft.com.).

4. The DNS Server service checks the wildcarded MX resource record name (*.example.microsoft.com.) for its mapped host names, finds a matching A resource record for the specified name (mailserver1.example.microsoft.com.) and uses this information to answer Host B.

5. The mail program on Host B can then send mail to mailserver1.example.microsoft.com. by using its IP address.

The loose RFC approach allows you to set up only two MX records and cover queries to the entire zone. However, the two MX resource records need to be added for both the zone root (the explicit name of the zone) and a wildcard node (*****) directly below the zone root. However, if you have individual mail hosts that should receive their own mail directly, then add MX resource records for each of those hosts that refer directly to their own host name, as stated in their registered A resource record.

**Strict RFC wildcarding**

With the strict wildcarding approach as described in RFC 1034, a revised sequence of events occurs when reviewing the previous example. Based on the same specified zone and query information provided, the revised sequence of steps would be used between the DNS Server service and Host B:

1. Host B sends the example query to a DNS server configured to use strict RFC wildcarding.

2. No MX resource records match the specified name (host-a.example.microsoft.com.), but an A resource record of that name is found in the zone.

   Because the queried name was found, no wildcarding is done.

3. The DNS Server service responds to the query with an authoritative negative response that includes no errors or resource records in the answer section of the response.

4. The mail program on Host B then sends a new query for the same name, specifying that A resource records be used for the query type.

5. The DNS Server service answers the A query with an authoritative positive response, which includes the A resource record in the answer section of the response.

6. The mail program on Host B can then send mail to mailserver1.example.microsoft.com. by using its IP address.

The strict RFC approach to wildcarding is easier if your mail hosts are capable of receiving mail directly. The disadvantage to this approach is that you typically need to add more MX resource records to the zone. This can happen if you have mail hosts not capable of receiving mail directly, or if you need to advertise any mail hosts that are not mail servers.

# Using WINS lookup

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using WINS lookup**

The DNS Server service provides the ability to use Windows Internet Name Service (WINS) servers to look up names not found in the DNS domain namespace by checking the NetBIOS namespace managed by WINS.

To use WINS lookup integration, two special resource record (RR) types--the WINS and WINS-R resource records--are enabled and added to a zone. When the WINS RR is used, DNS queries that fail to find a matched host (A) RR in the zone are forwarded to WINS servers configured in the WINS RR. For reverse lookup zones, the WINS-R RR can be enabled and used to provide a similar benefit for further resolving a reverse query not answerable in the reverse in-addr.arpa domain.

A good example of when to use WINS lookup is when you are using a mixed-mode client environment consisting of UNIX clients that use only DNS name resolution and earlier-version Microsoft clients that require NetBIOS naming. In these environments, WINS lookup provides a method for permitting UNIX DNS clients to locate your WINS clients by extending DNS host name resolution into the WINS-managed NetBIOS namespace.

The WINS lookup integration feature is only supported by Windows DNS servers. If you use a mixture of Windows and other DNS servers to host a zone, you should enable the **Do not replicate this record** check box option for any primary zones when using the WINS lookup record. This prevents the WINS lookup record from being included in zone transfers to other DNS servers that do not support or recognize this record. If you do not enable the WINS lookup record to be used only on the local server, it can cause data errors or failed zone transfers at servers running other DNS server implementations that replicate the zone.

The following sections discuss WINS lookup interoperability considerations and explain the following:

- How the caching Time-To-Live (TTL) and lookup time-out values are configured for use with the WINS and WINS-R records.
- The format of the WINS and WINS-R resource records as they are used in zone files created by the DNS Server service.

**WINS lookup interoperability**

Typically, WINS lookup provides the best and most predictable results if only Windows DNS servers are used, and is only available directly for use at Windows DNS servers. There are ways, however, that you use and benefit from WINS lookup as an interoperable solution when other DNS servers are deployed.

For example, consider adding a Windows DNS server that hosts a new WINS lookup-enabled zone. When creating and naming the zone, use a subdomain added to your existing DNS namespace that is used just for WINS-specific referrals added to your DNS domain namespace.

For instance, in example.microsoft.com, call the zone wins.example.microsoft.com when you create it. You can then use this new WINS referral zone as the root zone for any of your WINS-aware computers with names that are not found in your other traditional DNS zones.

In order to use the WINS referral zone, you need to specify its domain name (wins.example.microsoft.com) in a DNS suffix search list for your clients. The suffix list is configurable as part of the TCP/IP properties for a client connection and can be updated either manually, using DHCP, or using Group Policy. As long as the name of the WINS referral zone is included in the domain suffix list, any DNS names not resolved in traditional zones can be resolved using the WINS referral subdomain.

Under normal conditions, this should result in recursion from your other DNS servers to the Windows DNS servers that host the WINS-enabled zone. If the queried host names match NetBIOS computer names found in the WINS database, the names are resolved to the IP addresses mapped in WINS data there.

In our example the WINS-enabled zone is only used for WINS lookup, therefore no additional resource records need to be added to it. In general, WINS records could be added to any forward lookup zone.

By using a specific subdomain just for WINS lookup and specifying a static DNS suffix list to be used in resolving and searching for names, you can prevent unusual situations in which DNS queries for different FQDNs resolve to the same WINS client name and IP address. This might easily occur if you add and configure many zones at each level of your namespace and enable each of them to use WINS lookup integration.

For example, suppose you have two zones both configured to use WINS lookup. The zones are rooted and originate at the following DNS domain names:

example1.microsoft.com.

example2.microsoft.com.

With this configuration, a WINS client named HOST-A could be unintentionally resolved using either of the following FQDNs:

host-a.example1.microsoft.com.

host-a.example2.microsoft.com.

#### WINS resource record

**Description:** WINS forward lookup resource record. Used in a zone to provide further resolution of DNS queries for names not found in the zone by using a name query to WINS servers configured and listed with this record. If used, the WINS record only applies for the topmost level within a zone and not for subdomains used in the zone. The various fields that are used with the WINS RR include the following:

- ***owner*** Indicates the owner domain for this record, should always be set to "@" to indicate that the current domain is the same as the zone origin.
- ***class*** Indicates the class for this record, should always be set to "IN" as the Internet class is the only supported class for DNS servers running Windows Server 2003.
- **LOCAL** When used, indicates that the WINS RR is to used only locally at the DNS server and is not to be included during zone replication with other DNS servers. This field corresponds to whether the **Do not replicate this record** check box was selected when configuring WINS lookup at the DNS console. If this check box was cleared, this field will not be included when the record is written to the zone.
- ***lookup_timeout*** The lookup time-out value to be applied for this record.
- ***cache_timeout*** The cache time-out value to be applied for this record.
- ***wins_ip_addresses*** Used to specify one or more IP addresses of WINS servers. At least one IP address of a valid WINS server is required.

**Syntax:** *owner class* **WINS** [LOCAL] [**L***lookup_timeout*] [**C**cache_timeout] wins_ip_addresses

**Example:**

```
@ IN        WINS  10.0.0.1
@ IN        WINS LOCAL L1 C10 10.10.10.1 10.10.10.2 10.10.10.3
```

**Note**

- In the provided example WINS records, the zone root is assumed to be the current origin.

#### WINS-R resource record

**Description:** WINS reverse lookup resource record. Used in a reverse lookup zone to provide further resolution for reverse queries not found in the zone by using a NetBIOS adapter node status query sent to the queried IP addresses. When this record is used, you need to specify the parent domain to be appended to a NetBIOS computer name when a successful reverse lookup occurs. Other fields used in the WINS-R record have similar description and purpose as described previously for their use in the WINS forward lookup record.

**Syntax:** *owner class* **WINS** [LOCAL] [**L***lookup_timeout*] [**C**cache_timeout] *Domain_to_append_to_returned_NetBIOS_names*

**Example:**

```
@ IN       WINS-R LOCAL L1 C10 example.microsoft.com.
@ IN       WINS-R wins.example.microsoft.com.
```

**Note**

- In the provided example WINS-R records, the zone root is assumed to be the current origin.

**Advanced parameters for WINS lookups**

Two following advanced timing parameters are used with the WINS and WINS-R records:

- The Cache timeout value, which indicates to a DNS server how long it should cache any of the information returned in a WINS lookup. By default, this value is set to 15 minutes.

- The Lookup timeout value, which specifies how long to wait before timing out and expiring a WINS lookup performed by the DNS Server service. By default, this value is set to 2 seconds.

These parameters are configured using the **Advanced** button in the zone properties dialog box when you configure the zone. This button appears on either the WINS or WINS-R tab, depending on whether the zone you are configuring is being used for forward lookup or reverse lookup.

If you are using either the WINS or WINS-R resource record, be aware that the minimum Time-To-Live (TTL) set in the SOA record for the zone is not the default TTL used with these records. Instead, when either an IP address or a host name gets resolved with WINS lookup, the information is cached on the DNS server for the amount of time configured for the WINS cache time-out value. If this address is then ever forwarded to another DNS server, the WINS cache time-out value TTL is what is sent. If your WINS data rarely changes, you can increase the default TTL of 15 minutes.

**Notes**

- If you have a zone configured for WINS lookup, then all DNS servers that are authoritative for that zone need to be capable of WINS lookup or you will have intermittent behavior.

- Because you can select that the WINS and WINS-R RRs not be replicated to other DNS servers, you can selectively enable and configure WINS lookup at each of your secondary servers for zones where this feature is used. This is not a standard practice for other types of resource records which are only to be configured at the primary server for the zone.

For more information, see Enable DNS to use WINS resolution.

# Managing reverse lookup zones

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing reverse lookup zones**

When adding reverse lookup zones, you can simplify the process of adding pointer (PTR) resource records to these zones by:

- Using the **Update associated pointer (PTR) record** option when manually adding host (A) resource records to forward lookup zones.
- Deploying DHCP servers and enabling DHCP-DNS integration features to help manage and update reverse lookup zones for legacy clients.
- Installing Windows XP as the standard operating system in your organization for deploying new client hardware.

  With Windows XP on your client computers, either the client or its Windows Server 2003 DHCP server can be enabled to perform pointer (PTR) resource record registration for the client when its IP address is obtained and configured.

**Subnetted reverse lookup zones**

Default subnet masks (which have either a value of 0 or 255 used in each of the four octets of the masked value) are assumed by the DNS when configuring a new reverse lookup zone. If necessary, you can use custom subnetting to adjust the subnet mask value to a nondefault length.

Subnetted reverse lookup zones are supported when using the Advanced view setting available through Microsoft Management Console (MMC) and the DNS. This allows you to add and configure a reverse lookup for an IP network address that uses nondefault subnet mask lengths, such as 255.255.248.0, which has a nondefault subnet value of 248 in the third octet.

For more information, see Using the Windows Deployment and Resource Kits.

**Notes**

- Subnetted reverse lookup zones are further described in RFC 2317, "Classless IN-ADDR.ARPA delegation." For more information on RFCs or how to obtain them, see TCP/IP RFCs.

  PTR resource records created automatically when adding an A resource record to a zone will be deleted automatically if the corresponding A resource record is deleted.

# Monitoring and Optimizing Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitoring and optimizing servers**
This section covers:

- Monitoring DNS server performance
- Using server debug logging options
- Verifying server configuration
- Configuring round robin
- Prioritizing local subnets
- Tuning advanced server parameters
- Using DNS Security Extensions (DNSSEC)
- Using Extension Mechanisms for DNS (EDNS0)

# Monitoring DNS server performance

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitoring DNS server performance**

Because DNS servers are of critical importance in most environments, monitoring their performance can help in the following ways:

- By providing a useful benchmark for predicting, estimating, and optimizing DNS server performance.
- In troubleshooting DNS servers where server performance has degraded either over time or during periods of peak activity.

As you begin your DNS server monitoring, you can review sample test results for DNS servers that were collected during product development and testing. You can use this information as a starting reference as you begin to monitor your DNS servers to measure and benchmark performance.

A set of DNS server performance counters are provided with System Monitor to measure and monitor various aspects of server activity.

**Sample DNS server performance test results**

The DNS development and testing team compiled some statistics as a profile of DNS server performance during preliminary testing. In testing, two different DNS server hardware configurations were used and overall DNS query and dynamic update activity was measured, along with processor utilization.

The results of each of these tests are listed in the table below.

| Server configuration | Queries/sec | Dynamic updates/sec | Processor utilization |
|---|---|---|---|
| Intel P-III 733 MHz single-processor | 9500 | 1300 | 75% |

During the collection of these measurements (over 4 days), the monitored DNS server was processing both queries and dynamic updates simultaneously. The numbers above reflect this.

For dynamic updates, standard primary type zones were used, not Active Directory-integrated zones. Where directory integration is used for zones, the rate at which dynamic updates can be processed decreases, since the DNS server must additionally write to and rely upon the Active Directory database.

In addition, if a zone is configured to accept only secure dynamic updates, the update rate can also decrease. Network performance might also be a factor in these cases since the directory database may require network activity to process updates.

For additional background information about the two server hardware configurations used during these tests, see the following section.

**Important**

- These measurements are not intended to indicate maximum performance or server limitations for DNS servers running Windows Server 2003. The objective of the tests was to sample typical DNS server performance and obtain a working benchmark based on standard available hardware as a basis to begin server capacity planning.
- Note that these numbers are approximate and can be influenced by the type of resource records entered in zones, the number of resource records with the same owner name, and the number of zones in use at a specific DNS server.

**Background information on sample DNS server tests**

The list of specific hardware that the Windows Server 2003 DNS development and test team used during the described testing included the following:

| Hardware components | Sizing |
|---|---|

| | |
|---|---|
| Number of processors | One |
| Processor | Intel Pentium III 733 MHz |
| Amount of RAM | 256 MB (megabytes) |
| Hard disk drive space | 4 GB (gigabytes) |

These measurements were based on the server computer running a DNS server, with no additional services in use. Where other hardware specifications or software configurations are made when deploying DNS servers, your performance results are likely to vary from those documented here.

For more information on determining how to perform DNS server capacity planning, see Server planning for DNS.

**DNS server performance counters**

DNS server performance counters can be used to measure and monitor various aspects of server activity, such as the following:

- Overall DNS server performance statistics, such as the number of overall queries and responses processed by a DNS server.
- User Datagram Protocol (UDP) or Transmission Control Protocol (TCP) counters, for measuring DNS queries and responses that are processed respectively using either of these transport protocols.
- Dynamic update and secure dynamic update counters, for measuring registration and update activity generated by dynamic clients.
- Memory usage counters, for measuring system memory usage and memory allocation patterns created by operating the server computer as a DNS server running Windows Server 2003.
- Recursive lookup counters, for measuring queries and responses when the DNS Server service uses recursion to look up and fully resolve DNS names on behalf of requesting clients.
- WINS lookup counters, for measuring queries and responses made to WINS servers when the WINS lookup integration features of the DNS Server service are used.
- Zone transfer counters, including specific counters for measuring: all zone transfer (AXFR), incremental zone transfer (IXFR), and DNS zone update notification activity.

Each of these DNS server performance counters is described in more detail in the following sections.

**All zone transfer (AXFR) counters**

| Field | Description |
|---|---|
| AXFR Request Received | The total number of full zone transfer requests received by the DNS Server service when operating as a master server for a zone. |
| AXFR Request Sent | The total number of full zone transfer requests sent by the DNS Server service when operating as a secondary server for a zone. |
| AXFR Response Received | The total number of full zone transfer requests received by the DNS Server service when operating as a secondary server for a zone. |
| AXFR Success Received | The total number of full zone transfers received by the DNS Server service when operating as a secondary server for a zone. |
| AXFR Success Sent | The total number of full zone transfers successfully sent by the DNS Server service when operating as a master server for a zone. |

**DNS server memory counters**

| Field | Description |
| --- | --- |
| Caching Memory | The total amount of system memory in use by the DNS Server service for caching. |
| Database Node Memory | The total amount of system memory in use by the DNS Server service for database nodes. |
| Nbtstat Memory | The total amount of system memory in use by the DNS Server service for Nbtstat. |
| Record Flow Memory | The total amount of system memory in use by the DNS Server service for record flow. |

**Dynamic update counters**

| Field | Description |
| --- | --- |
| Dynamic Update NoOperation | The total number of No-operation/Empty dynamic update requests received by the DNS server. |
| Dynamic Update NoOperation/sec | The average number of No-operation/Empty dynamic update requests received by the DNS server in each second. |
| Dynamic Update Queued | The total number of dynamic updates queued by the DNS server. |
| Dynamic Update Received | The total number of dynamic update requests received by the DNS server. |
| Dynamic Update Received/sec | The average number of dynamic update requests received by the DNS server in each second. |
| Dynamic Update Rejected | The total number of dynamic updates rejected by the DNS server. |
| Dynamic Update TimeOuts | The total number of dynamic update time-outs of the DNS server. |
| Dynamic Update Written to Database | The total number of dynamic updates written to the database by the DNS server. |
| Dynamic Update Written to Database/sec | The average number of dynamic updates written to the database by the DNS server in each second. |

**Incremental zone transfer (IXFR) counters**

| Field | Description |
| --- | --- |
| IXFR Request Received | The total number of incremental zone transfer requests received by the master DNS server. |
| IXFR Request Sent | The total number of incremental zone transfer requests sent by the secondary DNS server. |
| IXFR Response Received | The total number of incremental zone transfer responses received by the secondary DNS server. |
| IXFR Success Received | The total number of successful incremental zone transfers received by the secondary DNS server. |
| IXFR Success Sent | The total number of successful incremental zone transfers of the master DNS server. |
| IXFR TCP Success Received | The total number of successful TCP incremental zone transfers received by the secondary DNS server. |
| IXFR UDP Success Received | The total number of successful UDP incremental zone transfers received by the secondary DNS server. |

**Notification counters**

| Field | Description |
| --- | --- |
| Notify Received | The total number of notifies received by the secondary DNS server. |
| Notify Sent | The total number of notifies sent by the master DNS server. |

**Recursion counters**

| Field | Description |
|---|---|
| Recursive Queries | The total number of recursive queries received by the DNS server. |
| Recursive Queries/sec | The average number of recursive queries received by the DNS server in each second. |
| Recursive Query Failure | The total number of recursive query failures. |
| Recursive Query Failure/sec | The average number of recursive query failures in each second. |
| Recursive TimeOuts | The total number of recursive query sending time-outs. |
| Recursive TimeOuts/sec | The average number of recursive query sending time-outs in each second. |

**Secure dynamic update counters**

| Field | Description |
|---|---|
| Secure Update Failure | The total number of secure updates failed on the DNS server. |
| Secure Update Received | The total number of secure update requests received by the DNS server. |
| Secure Update Received/sec | The average number of secure update requests received by the DNS server in each second. |

**TCP counters**

| Field | Description |
|---|---|
| TCP Message Memory | The total TCP message memory used by the DNS server. |
| TCP Query Received | The total number of TCP queries received by the DNS server. |
| TCP Query Received/sec | The average number of TCP queries received by the DNS server in each second. |
| TCP Response Sent | The total number of TCP responses sent by the DNS server. |
| TCP Response Sent/sec | The average number of TCP responses sent by the DNS server in each second. |

**Total (overall performance) counters**

| Field | Description |
|---|---|
| Total Query Received | The total number of queries received by the DNS server. |
| Total Query Received/sec | The average number of queries received by the DNS server in each second. |
| Total Response Sent | The total number of responses sent by the DNS server. |
| Total Response Sent/sec | The average number of responses sent by the DNS server in each second. |

**UDP counters**

| Field | Description |
|---|---|
| UDP Message Memory | The total UDP message memory used by the DNS server. |
| UDP Query Received | The total number of UDP queries received by the DNS server. |
| UDP Query Received/sec | The average number of UDP queries received by the DNS server in each second. |
| UDP Response Sent | The total number of UDP responses sent by the DNS server. |
| UDP Response Sent/sec | The average number of UDP responses sent by the DNS server in each second. |

**WINS lookup counters**

| Field | Description |
|---|---|
| WINS Lookup Received | The total number of WINS lookup requests received by the server. |
| WINS Lookup Received/sec | The average number of WINS lookup requests received by the server in each second. |
| WINS Response Sent | The total number of WINS lookup responses sent by the server. |
| WINS Response Sent/sec | The average number of WINS lookup responses sent by the server in each second. |
| WINS Reverse Lookup Received | The total number of WINS reverse lookup requests received by the server. |
| WINS Reverse Lookup Received/sec | The average number of WINS reverse lookup requests received by the server in each second. |
| WINS Reverse Response Sent | The total number of WINS Reverse lookup responses sent by the server. |
| WINS Reverse Response Sent/sec | The average number of WINS Reverse lookup responses sent by the server in each second. |

**Zone transfer counters**

| Field | Description |
|---|---|
| Zone Transfer Failure | The total number of failed zone transfers of the master DNS server. |
| Zone Transfer Request Received | The total number of zone transfer requests received by the master DNS server. |
| Zone Transfer SOA Request Sent | The total number of zone transfer SOA requests sent by the secondary DNS server. |
| Zone Transfer Success | The total number of successful zone transfers of the master DNS server. |

# Using server debug logging options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using server debug logging options**

The following DNS debug logging options are available:

- **Direction of packets**

  **Send** Packets sent by the DNS server are logged in the DNS server log file.

  **Receive** Packets received by the DNS server are logged in the log file.

- **Content of packets**

  **Standard queries** Specifies that packets containing standard queries (per RFC 1034) are logged in the DNS server log file.

  **Updates** Specifies that packets containing dynamic updates (per RFC 2136) are logged in the DNS server log file.

  **Notifies** Specifies that packets containing notifications (per RFC 1996) are logged in the DNS server log file.

- **Transport protocol**

  **UDP** Specifies that packets sent and received over UDP are logged in the DNS server log file.

  **TCP** Specifies that packets sent and received over TCP are logged in the DNS server log file.

- **Type of packet**

  **Request** Specifies that request packets are logged in the DNS server log file (a request packet is characterized by a QR bit set to 0 in the DNS message header).

  **Response** Specifies that response packets are logged in the DNS server log file (a response packet is characterized by a QR bit set to 1 in the DNS message header).

- **Enable filtering based on IP address** Provides additional filtering of packets logged in the DNS server log file. This option allows logging of packets sent from specific IP addresses to a DNS server, or from a DNS server to specific IP addresses.

- **File name** Lets you specify the name and location of the DNS server log file.

  For example:

  - *dns.log* specifies that the DNS server log file should be saved as *dns.log* in the systemroot\System32\Dns directory.

  - *temp\dns.log* specifies that the DNS server log file should be saved as *dns.log* in the systemroot\Temp directory

- **Log file maximum size limit** Lets you set the maximum file size for the DNS server log file. When the specified maximum size of the DNS server log file is reached, the DNS server overwrites the oldest packet information with new information. Note: If left unspecified, the DNS server log file's size can take up a large amount of hard disk space.

By default, all debug logging options are disabled. When selectively enabled, the DNS Server service can perform additional trace-level logging of selected types of events or messages for general troubleshooting and debugging of the server.

Debug logging can be resource intensive, affecting overall server performance and consuming disk space. Therefore, it should only be used temporarily when more detailed information about server performance is needed.

**Notes**

- Dns.log contains debug logging activity. By default, it is located in the *windir*\System32\Dns folder.
- To enable and use file-based logging, see Select and enable debug logging options on the DNS server.
- For more information about RFCs, see DNS RFCs.

# Verifying server configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Verifying server configuration**

When using the DNS console, you can perform either manual or automated verification testing of your DNS servers to monitor their ability to process and resolve queries. This feature is accessed through the **Monitoring** tab in DNS server properties.

When using this feature, two types of test are available:

- **A simple query against this DNS server**.

  This type of test specifies that the DNS server perform a simple or iterative query. This test is a localized query using the DNS resolver (client) on the server computer to query the local DNS server (also located on the same computer).

  For more information, see How DNS query works.

- **A recursive query to other DNS servers.**

  This type of test specifies that the DNS server perform a recursive query. This test is similar in its initial query processing to the previous test in that it uses the local DNS resolver (client) to query the local DNS server, also located on the same computer.

  In this test, however, the client asks the server to use recursion to resolve an NS-type query for the root of the DNS domain namespace, stated as a single dot ("."). This type of query should typically require additional recursive processing and can be helpful in verifying that server root hints or zone delegations have been properly set.

  For more information, see How DNS query works.

Once you have selected the tests to be used, you can either click the **Test Now** button to manually perform the tests immediately, or you can perform automatic testing at a specified time interval.

Automated tests are performed when the **Perform automatic testing at the following interval** check box is selected and a test interval is specified in **Test interval**.

Results of all selected tests, whether manually or automatically performed, are displayed in the **Test results** list box. Typically, this information includes:

- The date and time when each query was made.

- Additional status results of the specific test used, such as whether the simple or recursive query failed or succeeded.

# Configuring round robin

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring round robin**
Round robin is a local balancing mechanism used by DNS servers to share and distribute network resource loads. You can use it to rotate all resource record (RR) types contained in a query answer if multiple RRs are found.

By default, DNS uses round robin to rotate the order of RR data returned in query answers where multiple RRs of the same type exist for a queried DNS domain name. This feature provides a simple method for load balancing client use of Web servers and other frequently queried multihomed computers.

If round robin is disabled for a DNS server, the order of the response for these queries is based on a static ordering of RRs in the answer list as they are stored in the zone (either its zone file or Active Directory).

**Example: Round-robin rotation**
A forward lookup-type query (for all A RRs that match a DNS domain name) is made for a multihomed computer (multihomed.example.microsoft.com) that has three IP addresses. Separate A RRs are used to map the host's name to each of these IP addresses in the zone. In the stored example.microsoft.com zone, the RRs appear in this fixed order:

multihomed IN A 10.0.0.1

multihomed IN A 10.0.0.2

multihomed IN A 10.0.0.3

The first DNS client that queries the server to resolve this host's name receives the list in default order. When a second client sends a subsequent query to resolve this name, the list is rotated as follows:

multihomed IN A 10.0.0.2

multihomed IN A 10.0.0.3

multihomed IN A 10.0.0.1

**Restricting round-robin rotation for selected RR types**
By default, DNS will perform round-robin rotation for all RR types. You can specify that certain RR types are not to be round-robin rotated in the registry. There is a registry entry called **DoNotRoundRobinTypes** (REG_SZ) with a string value containing a list of RR types. By modifying this entry, you turn off round-robin rotation for specific RR types. For example, to prevent round-robin rotation for A, PTR, SRV, and NS record types, you would enter the following value for the registry entry:

**a ptr srv ns**

**Restricting round-robin rotation for all RR types**
The default setting for round-robin rotation is contained in the registry entry **RoundRobin** (REG_DWORD). By default, this entry's value is 1, rotating all RR types except those listed in the **DoNotRoundRobinTypes** registry entry. If the value of **RoundRobin** is set to 0, then no RR types will be round-robin rotated.

### Caution

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. You can also use the Last Known Good Configuration startup option if you encounter problems after manual changes have been applied.

### Notes

- The string value for the DoNotRoundRobinTypes registry entry may contain types in numeric (as shown above) of mnemonic formats.

- Both of the round robin registry entries must be created and stored in the following registry subkey:

  HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

- Local subnet priority supersedes the use of round-robin rotation for multihomed names. When enabled, round-robin continues to be a secondary method used to sort multiple RRs returned in a listed answer. For more information on local subnet priority, see Prioritizing local subnets.

# Prioritizing local subnets

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Prioritizing local subnets**

By default, the DNS Server service uses local subnet prioritizing as the method for giving preference to IP addresses on the same network when a client query resolves to a host name that is mapped to more than one IP address. This feature requires that the client application attempt to connect to the host using its closest (and typically fastest) IP address available for connection.

The DNS Server service uses local subnet priority as follows:

1. The DNS Server service determines if local subnet prioritization is needed to order the query response.

   If more than one A resource record (RR) matches the queried host name, the DNS Server service can reorder the records by their subnet location. If the queried host name only matches a single A resource record, or if the IP network address of the client does not match an IP network address for any of the mapped addresses in an answer list of multiple RRs, no prioritizing is necessary.

2. For each RR in the matched answer list, the DNS Server service determines which records (if any) match the subnet location of the requesting client.

3. The DNS Server service reorders the answer list so that A RRs which match the local subnet of the requesting client are placed first in the answer list.

4. Prioritized by subnet order, the answer list is returned to the requesting client.

**Simple example: Local network prioritizing**

A multihomed computer, multihomed.example.microsoft.com, has three A RRs for its three separate host IP addresses in the example.microsoft.com zone. A separate A RR is used for each of the host's addresses, which appear in this order in the zone:

multihomed IN A 192.168.1.27

multihomed IN A 10.0.0.14

multihomed IN A 172.16.20.4

If a DNS client resolver at IP address 10.4.3.2 queries the server for the IP addresses of host multihomed.example.microsoft.com, the DNS Server service notes that the originating IP network address (10.0.0.0) of the client matches the network (class A) portion of the 10.0.0.4 address in the answer list of RRs. The DNS Server service then reorders the addresses in the response as follows:

multihomed IN A 10.0.0.14

multihomed IN A 192.168.1.27

multihomed IN A 172.16.20.4

If the IP address of the requesting client has no local network match with any of the RRs in the answer list, then the list is not prioritized.

**Complex example: Local subnet prioritizing**

If you are working in a network that uses IP subnetting (nondefault subnet masks), there are only a few minor differences. If more than one address matches in the network portion, then the matching addresses are further ordered and the RR having the closest matching subnet address is placed first.

For example, a multihomed computer, multihomed.example.microsoft.com, has four A RRs for four separate host IP addresses in the example.microsoft.com zone. Two of these IP addresses are for nonlocal networks. The other two IP addresses share a common IP network address but, because IP subnetting is used, represent different physical subnetted network connections based on their custom (nondefault) subnet mask value of 255.255.248.0. These example RRs appear in the following order in

the zone:

```
multihomed   IN  A  192.168.1.27

multihomed   IN  A  172.16.22.4

multihomed   IN  A  10.0.0.14

multihomed   IN  A  172.16.31.5
```

If the IP address of the requesting client is 172.16.22.8, both of the IP addresses that match the same IP network as the client, the 172.16.0.0 network, are returned at the top of the answer list to the client. However, in this example, the 172.16.22.4 address is placed ahead of the 172.16.31.5 address because it matches the client IP address down through the 172.16.20.0 subnet address.

The reordered answer list returned by the DNS Server service would be:

```
multihomed   IN  A  172.16.22.4

multihomed   IN  A  172.16.31.5

multihomed   IN  A  192.168.1.27

multihomed   IN  A  10.0.0.14
```

**Notes**

- IP subnetting is imposed by using a custom or nondefault subnet mask value with all IP addresses on your network. For more information, see Subnet masks.

- Local subnet priority supersedes the use of round-robin rotation for multihomed names. When round robin is enabled, however, RRs continue to be rotated using round robin as the secondary method of sorting the response list. For more information on round robin, see Configuring round robin.

# Tuning advanced server parameters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tuning advanced server parameters**

When initialized for service, DNS servers use server configuration settings taken from the parameters stated in a boot information file, the registry, and possibly zone information provided through Active Directory integration.

In most situations, the installation defaults are acceptable and should not require modification. However, when needed, you can use the DNS console to tune the following advanced parameters, accommodating special deployment needs and situations.

For making these adjustments, use the **Advanced** tab in DNS server **Properties**.

| Value | Description |
|---|---|
| Disable recursion | Determines whether or not the DNS server uses recursion. By default, the DNS Server service is enabled to use recursion. For more information, see Modifying server defaults. |
| BIND secondaries | Determines whether to use fast transfer format when transferring a zone to DNS servers running legacy Berkeley Internet Name Domain (BIND) implementations.<br><br>By default, all Windows-based DNS servers use a fast zone transfer format, which uses compression and can include multiple records per TCP message during a connected transfer. This format is also compatible with more recent BIND-based DNS servers that run versions 4.9.4 and later.<br><br>For more information, see Interoperability issues. |
| Fail on load if bad zone data | Sets the DNS server to parse files strictly.<br><br>By default, the DNS Server service logs data errors, ignore any erred data in zone files, and continue to load a zone. This option can be reconfigured using the DNS console so that the DNS Server service logs errors and fails to load a zone file containing records data that is determined to have errors.<br><br>For more information, see Checking names and zone data. |
| Enable round robin | Determines whether the DNS server uses round robin to rotate and reorder a list of resource records (RRs) if multiple RRs exist of the same type exisit for a query answer.<br><br>By default, the DNS Server service uses round robin. For more information, see Configuring round robin. |
| Enable netmask ordering | Determines whether the DNS server reorders A resource records within the same resource record set in its response to a query based on the IP address of the source of the query.<br><br>By default, the DNS Server service uses local subnet priority. For more information, see Prioritizing local subnets. |
| Secure cache against pollution | Determines whether the server attempts to clean up responses to avoid cache pollution. This setting is enabled by default.<br><br>By default, DNS servers use a secure response option that eliminates adding unrelated resource records included in a referral answer to their cache. In most cases, any names added in referral answers are typically cached and help expedite the speed of resolving subsequent DNS queries.<br><br>With this feature, however, the server can determine that referred names are potentially polluting or insecure and discard them. The server determines whether to cache the name offered in a referral on the basis of whether or not it is part of the exact related DNS domain name tree for which the original queried name was made.<br><br>For example, if a query was originally made for "example.microsoft.com" and a referral answer provided a record for a name outside of the "microsoft.com" domain name tree, such as msn.com, then that name would not be cached where this feature is enabled for use. |

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**Notes**

- It is recommended that you use the DNS console to configure these and other server parameter values.

- Additional advanced parameters can be configured by registry-based configuration. For more information, see Using the Windows Deployment and Resource Kits.

- DNS server parameter key values are stored in the following location in the registry:

  HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

- DNS zone parameter key values are stored in the following location in the registry:

  HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\DNS Server

- When using registry-based configuration, changes are applied to DNS servers only when the service is re-initialized. In these cases, if a value is manually changed directly in the registry, the DNS server must always be restarted for the new value to be used.

  For more information, see Start or stop a DNS server.

# Using DNS Security Extensions (DNSSEC)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using DNS Security Extensions (DNSSEC)**
Windows Server 2003 DNS provides basic support of the DNS Security Extensions (DNSSEC) protocol as defined in RFC 2535. The current feature support allows DNS servers to perform as secondary DNS servers for existing DNSSEC-compliant, secure zones. DNS supports the storing and loading of the DNSSEC-specific resource records (RRs). Currently, a DNS server is not capable of signing zones and resource records (creating cryptographic digital signatures) or validating the SIG RRs. The DNSSEC resource records are KEY, SIG, and NXT. For more information about resource records, see Resource records reference. For more information about RFCs, see DNS RFCs.

**Server support for DNSSEC**
When loading a zone containing DNSSEC resource records, the DNS server loads these records along with all other types of resource records contained in the zone. When receiving a zone transfer containing DNSSEC resource records (SIG, KEY, NXT), the DNS server writes these records to the zone storage (zone data file or Active Directory) along with all other resource records.

When a DNS server receives a request or response containing DNSSEC resource records, it does not verify the digital signatures but caches the response and uses it for ensuing queries. When a DNS server receives a request for a resource record in a zone also containing DNSSEC resource records, it attaches the appropriate DNSSEC records to the response.

When a signed zone contains resource records for an owner name including a CNAME resource record for that name, the DNS server will return the DNSSEC resource records associated with the owner name and the CNAME resource record's alias name. The DNS server will not suppress the retrieval of the CNAME resource record, and it will not return a SIG resource record for the canonical name. Rather, it will return the SIG resource record for the alias name.

**Client support for DNSSEC**
The DNS client does not read and store a key for the trusted zone and, consequently, it does not perform any cryptography, authentication, or verification. When a resolver initiates a DNS query and the response contains DNSSEC resource records, programs running on the DNS client will return these records and cache them in the same manner as any other resource records. This is the extent to which Windows XP DNS clients support DNSSEC. When the DNS client receives the SIG RR relating to the RRset, it will not perform an additional query to obtain the associated KEY record or any other DNSSEC records.

Resolvers do not authenticate resource records by verifying the signature information contained in the SIG resource record. The DNS client does not contain any information to indicate which resource records have been authenticated or to what extent they have been authenticated.

When a resolver receives a response or performs a query operation, it does not recognize the checking disabled (CD) query header bit, which in DNSSEC indicates that the data is authenticated by the server according to its policies, or set the authentic data (AD) query header bit, which in DNSSEC indicates that nonauthenticated data is acceptable to the resolver.

For more information, see Modify DNSSEC configuration and DNSSEC overview.

### Note

- If there is a signing agent running on the DNS server running Windows Server 2003 that signs the zone resource records, this DNS server may also be used as a primary server for DNSSEC-compliant secure zones.

# Using Extension Mechanisms for DNS (EDNS0)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Extension Mechanisms for DNS (EDNS0)**
Extension Mechanisms for DNS (EDNS0 as defined in RFC 2671) allow DNS requestors to advertise the size of their UDP packets and facilitate the transfer of packets larger than 512 octets, the original DNS restriction for UDP packet size (RFC 1035). When a DNS server receives a request over the UDP Transport Layer, it identifies the requestor's UDP packet size from the OPT resource record (RR) and scales its response to contain as many resource records as are allowed in the maximum UDP packet size specified by the requestor. For more information about resource records, see Resource records reference. For more information about RFCs, see DNS RFCs.

**EDNS0 UDP responses**
Before a DNS server assumes that the requestor supports EDNS0, the DNS server must receive a query containing an OPT resource record. An OPT record contains no actual DNS data and its contents relate to the UDP Transport Layer message only. The OPT record stores the sender's UDP payload size in its CLASS field and lists the number of octets in the largest UDP payload that the requestor can deliver in the requestor's network.

When the DNS server receives a query containing an OPT record advertising the maximum UDP packet size, it will truncate any UDP response's size larger than the limit specified in the OPT record.

By default, the DNS server includes OPT resource records indicating its UDP maximum in responses to queries containing OPT resource records. For information about modifying the OPT response setting, see Modify EDNS0 configuration.

If the DNS server receives a query that does not contain an OPT resource record, it assumes the requestor's server does not support EDNS0 and will respond to the requestor assuming that the sender does not accept UDP packets larger than 512 octets. In this case, the DNS server will truncate its UDP response size to a maximum of 512 octets.

**EDNS0 UDP queries**
Before the requesting DNS server sends a query, it checks its cache to identify if the responding DNS server supports EDNS0. If the responding DNS server supports EDNS0, the requesting DNS server attaches an OPT resource record to the additional section of the query it sends. (All queries have five sections: header, question, answer, authority, and additional.) If, according to the requesting DNS server's cache, the responding DNS server does not support EDNS0, the requesting DNS server will not attach an OPT resource record to the query before it is sent. For more information, see Modify UDP message size.

**Identifying and caching EDNS0 support**
When the DNS server receives a request or response from a host containing an OPT record, the DNS server caches the EDNS version supported by the host (such as EDNS0). If there is no OPT record in a request or response from a host, the DNS server's cache will indicate that the host does not support EDNS0. If the cache already indicates that the host does support ENDS0, then cache will not be changed.

The default value for how long a host's EDNS0 support information is cached is 86400 (one day, specified in seconds). This value can be modified in the **EDNSCacheTimeout** registry entry, in the following registry subkey:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dns\Parameters**

The range of values allowed is from 3600 (1 hour) to 15724800 (182 days). For information about modifying the EDNS0 cache setting, see Modify EDNS0 configuration.

The DNS server decides that a host does not support EDNS0 when it requests an OPT resource record and receives a response containing one of the following RCODE values in the header:

| Name | Value | Description |
|---|---|---|
| FORMERR | 1 | Format Error. The name server did not interpret the OPT resource record. |
| SERVFAIL | 2 | Server Failure. The name server did not process the query because of a problem with the name server. |
| NOTIMPL | 4 | Not Implemented. The name server does not support the kind of query requested. |

(The RCODE field, or response code field, is a 4-bit field set in the header section as part of responses.) In this situation (as a requester), the DNS server identifies that the server does not support EDNS0 and caches this information.

**Caution**

- When considering packet sizes, you should take account of the network transmission path's discovered Maximum Transmission Unit (MTU), if this information is available. When configuring the UDP packet size to be larger than 512 octets, remember that the UDP packets must travel through devices other than UDP hosts and these devices, such as routers, may not support UDP packets larger than 512 octets. The maximum UDP packet size should always be compared with the MTU, which in some cases may be smaller. It is recommended that you establish the maximum UDP packet length support for all devices, and configure your UDP hosts for this maximum.

**Note**

- EDNS0 refers to the first RFC for EDNS (RFC 2671). Future RFCs for EDNS will be identified by greater numbers, such as EDNS1.

# DNS Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resources**

This section covers:

- Resource records reference
- DNS server log reference
- DNS-related files
- DNS updated technical information
- DNS RFCs
- Top-level domains
- DNS bibliography

# Resource records reference

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resource records reference**

A DNS database consists of one or more zone files used by the DNS server. Each zone holds a collection of structured resource records, the following of which are supported by the DNS Server service.

**Format of DNS resource records**

All resource records have a defined format that uses the same top-level fields, as described in the following table.

| Field | Description |
|---|---|
| Owner | Indicates the DNS domain name that owns a resource record. This name is the same as that of the console tree node where a resource record is located. |
| Time to Live (TTL) | For most resource records, this field is optional. It indicates a length of time used by other DNS servers to determine how long to cache information for a record before expiring and discarding it. For example, most resource records created by the DNS Server service inherit the minimum (default) TTL of 1 hour from the start of authority (SOA) resource record which prevents overlong caching by other DNS servers. For an individual resource record, you can specify a record-specific TTL that overrides the minimum (default) TTL inherited from the SOA RR. TTL values of zero (0) can also be used for resource records that contain volatile data not to be cached for later use after the current DNS query in progress is completed.<br>**Note**<br>• In the resource record examples below, the TTL field is omitted wherever it is optional. The TTL field is included in the syntax for each record to indicate where it may be added. |
| Class | Contains standard mnemonic text indicating the class of the resource record. For example, a setting of "IN" indicates that the resource record belongs to the Internet class, which is the only class supported by Windows Server 2003 DNS. This field is required. |
| Type | Contains standard mnemonic text indicating the type of resource record. For example, a mnemonic of "A" indicates that the resource record stores host address information. This field is required. |
| Record-specific data | A required, variable-length field that contains information describing the resource. The format of this information varies according to the type and class of the resource record. |

**A**

**Description:** Host address (A) resource record. Maps a DNS domain name to an Internet Protocol (IP) version 4 32-bit address. For more information, see RFC 1035.

**Syntax:**

*owner class ttl* **A***IP_v4_address*

**Example:**

```
host1.example.microsoft.com.     IN  A  127.0.0.1
```

**AAAA**

**Description:** IPv6 host address (AAAA) resource record. Maps a DNS domain name to an Internet Protocol (IP) version 6 128-bit address. For more information, see RFC 1886.

**Syntax:**

*owner class ttl* **AAAA***IP_v6_address*

**Example:**

```
ipv6_host1.example.microsoft.com.     IN  AAAA  4321:0:1:2:3:4:567:89ab
```

**AFSDB**

**Description:** Andrew File System Database (AFSDB) resource record. Maps a DNS domain name in the *server_host_name* field to the host name for a server computer of a server subtype. The *subtype* field can have either of the following recognized and supported values:

- A value of **1** to indicate that the server is an AFS version 3.0 volume location server for the named AFS cell.
- A value of **2** to indicate that the server is an authenticated name server holding the cell-root directory node for the server that uses either Open Software Foundation's (OSF) DCE authenticated cell-naming system or HP/Apollo's Network Computing Architecture (NCA).

For more information, see RFC 1183.

**Syntax:**

*owner ttl class* **AFSDB***subtype server_host_name*

**Example:**

```
example.microsoft.com.   AFSDB   1 afs-server1.example.microsoft.com
```

**ATMA**

**Description:** Asynchronous Transfer Mode address (ATMA) resource record. Maps a DNS domain name in the *owner* field to an ATM address referenced in the *atm_address* field.

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

For more information, see "ATM Names Service" at the MFA Forum site. At the MFA Forum site, download **af-saa-0069.000**.

**Syntax:**

*owner ttl class* **ATMA***atm_address*

**Example:**

```
atm-host   ATMA   47.0079.00010200000000000000.00a03e000002.00
```

**CNAME**

**Description:** Canonical name (CNAME) resource record. Maps an aliased or alternate DNS domain name in the *owner* field to a canonical or primary DNS domain name specified in the *canonical_name* field. The canonical or primary DNS domain name used in the data is required and must resolve to a valid DNS domain name in the namespace.

**Syntax:**

*owner ttl class* **CNAME** *canonical_name*

**Example:**

```
aliasname.example.microsoft.com.   CNAME   truename.example.microsoft.com
```

**HINFO**

**Description:** Host information (HINFO) resource record. Specifies the type of CPU and operating system in the *cpu_type* and *os_type* fields, respectively, for the host DNS domain name in the *owner* field. Well-known CPU and operating system types that are most often used are noted in RFC 1700. This information can be used by application protocols such as FTP, which use special procedures when communicating with computers of a known CPU and operating system type.

**Syntax:**

*owner ttl class* **HINFO** *cpu_type os_type*

**Example:**

```
my-computer-name.example.microsoft.com.    HINFO   INTEL-386  WIN32
```

**ISDN**

**Description:** Integrated Services Digital Network (ISDN) resource record. Maps a DNS domain name to an ISDN telephone number. Telephone numbers used with this record should follow ITU-T E.163/E.164 international telephone numbering standards, which are compatible with current international phone numbering plans already in use. For more information, see RFC 1183.

**Syntax:**

*owner ttl class* **ISDN** *isdn_address sub_address*

**Example:**

```
my-isdn-host.example.microsoft.com.    ISDN   141555555539699 002
```

**KEY**

**Description:** Public key resource record. Contains a public key that is associated with a zone. In full DNSSEC implementation, resolvers and servers use KEY resource records to authenticate SIG resource records received from a signed zones. KEY resource records are signed by the parent zone, allowing a server that knows a parent zone's public key to discover and verify the child zone's key. Name servers or resolvers receiving resource records from a signed zone obtain the corresponding SIG record then retrieve the zone's KEY record. For more information, see RFC 2535.

**Syntax:**

*owner class* **KEY** *protocol digital_signature_algorithm (DSA) public_key*

**Example:**

```
widgets.microsoft.com IN KEY 0x0000 3 0
```

**MB**

**Description:** Mailbox (MB) resource record. Maps a specified domain mailbox name in the *owner* field to a mailbox host name in *mailbox_hostname*. The mailbox host name must be the same as a valid host address (A) resource record already used by a host in the same zone. Additionally, the specified host must have a domain mailbox that accepts mail for the specified owner. For more information, see RFC 1035.

**Syntax:**

*owner ttl class* **MB** *mailbox_hostname*

**Example:**

```
mailbox.example.microsoft.com.    MB   mailhost1.example.microsoft.com
```

**MG**

**Description:** Mail group (MG) resource record. Used to add domain mailboxes, each specified by a mailbox (MB) resource record in the current zone, to the domain mailing group identified by *owner* in this resource record. Names used in the *mailbox_name* field must be identical to valid mailbox (MB) resource records already present in the current zone. For more information, see RFC 1035.

**Syntax:**

*owner ttl class* **MG** *mailbox_name*

**Example:**

```
administrator.example.microsoft.com.    MG   mailbox1.example.microsoft.com
                                         mailbox2.example.microsoft.com
```

**MINFO**

**Description:** Mailbox mail list information (MINFO) resource record. Specifies (in *responsible_mailbox*) a domain mailbox name for a responsible person who maintains a mailing list or mailbox specified in the *owner* field. The *error_mailbox* field can also be used to specify a domain mailbox that receives error messages related to this mailing list or mailbox. Mailboxes specified for responsible contacts and error forwarding must be the same as valid mailbox (MB) records that already exist in the current zone. For more information, see RFC 1035.

**Syntax:**

*owner ttl class* **MINFO** *responsible_mailbox error_mailbox*

**Example:**

```
administrator.example.microsoft.com.    MINFO  resp-mbox.example.microsoft.com err-
mbox.example.microsoft.com
```

**MR**

**Description:** Mailbox renamed (MR) resource record. Specifies a domain mailbox name in *new_renamed_mailbox*, the proper rename of an existing mailbox specified in the *owner* field. An MR resource record is often used as a forwarding entry for a user who has moved to a different mailbox. MR records do not cause additional section processing. For more information, see RFC 1035.

**Syntax:**

*owner ttl class* **MR** *new_renamed_mailbox*

**Example:**

```
old-mbox.example.microsoft.com.    MR  new-renamed-mbox.example.microsoft.com
```

**MX**

**Description:** Mail exchanger (MX) resource record. Provides message routing to a mail exchanger host, as specified in *mail_exchanger_host*, for mail sent to the domain name specified in the **owner** field. A 2-digit preference value indicates preferred ordering if multiple exchanger hosts are specified. Each exchanger host must have a corresponding host (A) address resource record in a valid zone. For more information, see RFC 1035.

**Syntax:**

*owner ttl class* **MX** *preference mail_exchanger_host*

**Example:**

```
example.microsoft.com.    MX  10 mailserver1.example.microsoft.com
```

**NS**

**Description:** Used to map a DNS domain name as specified in **owner** to the name of hosts operating DNS servers specified in the *name_server_domain_name* field.

**Syntax:**

*owner ttl IN* **NS** *name_server_domain_name*

**Example:**

```
example.microsoft.com.    IN NS  nameserver1.example.microsoft.com
```

**NXT**

**Description:** Next resource record. NXT resource records indicate the nonexistence of a name in a zone by creating a chain of all of the literal owner names in that zone. They also indicate what resource record types are present for an existing name. For more information, see RFC 2535.

**Syntax:**

*owner class* **NXT** *next_domain_name last_record_type* **NXT**

**Example:**

```
east.widgets.microsoft.com. IN NXT ftp.widgets.microsoft.com. A NXT
```

**OPT**

**Description:** Option resource record. One OPT resource record can be added to the additional data section of either a DNS request or response. An OPT resource record belongs to a particular transport level message, such as UDP, and not to actual DNS data. Only one OPT resource record is allowed, but not required, per message. For more information, see RFC 2671.

**Syntax:**

*name***OPT** *class ttl rdlen rdata*

**Example:**

```
null  OPT  IN  1280  0  0
```

**PTR**

**Description:**Pointer (PTR) resource record. Points from the name in **owner** to another location in the DNS namespace as specified by *targeted_domain_name*. Often used in special domains such as the in-addr.arpa domain tree to provide reverse lookups of address-to-name mappings. In most cases, each record provides information that points to another DNS domain name location, such as a corresponding host (A) address resource record in a forward lookup zone. For more information, see RFC 1035.

**Syntax:**

*owner ttl class* **PTR** *targeted_domain_name*

**Example:**

```
1.0.0.10.in-addr.arpa.    PTR  host.example.microsoft.com
```

**RP**

**Description:** Responsible Person (RP) resource record. Specifies the domain mailbox name for a responsible person in *mailbox_name*. This name is then mapped to a domain name in *text_record_name* for which (TXT) resource records exist in the same zone. When RP records are used in DNS queries, subsequent queries are used to retrieve associated text (TXT) resource record information. For more information, see RFC 1183.

**Syntax:**

*owner ttl class* **RP** *mailbox_name text_record_name*

**Example:**

```
example.microsoft.com.                RP    admin.example.microsoft.com.  admin-info.example.microsoft.com.
admin-info.example.microsoft.com.     TXT  "Joe Administrator, (555) 555-0110"
```

**RT**

**Description:** Route through (RT) resource record. Provides an intermediate host binding for internal hosts that do not have a direct wide area network (WAN) or external network connection. The RT record is similar to the MX record in that any communication from an internal host is routed through the *intermediate_host* for the destination DNS domain name specified in the *owner* field. A 2-digit preference value is used to set priority if multiple intermediate routing hosts are specified. For each intermediate host specified, a corresponding host (A) address resource record is needed in the current zone. For more information, see RFC 1183.

**Syntax:**

*owner ttl class* **RT** *preference intermediate_host*

**Example:**

```
example.microsoft.com.    RT    2 lan-router.example.microsoft.com
                          RT   10 wan-router.example.microsoft.com
```

**SIG**

**Description:** Signature resource record. Encrypts a RRset to a signer's (RRset's zone owner) domain name and a validity interval. For more information, see RFC 2535.

**Syntax:**

*owner class* **SIG** *ttl signature_expiration signature_inception key_identifier signer_name***{***digital_signature***}**

**Example:**

```
widgets.microsoft.com IN SIG 86400 19700101000000 19700101000000 49292
widgets.microsoft.com.{
AIYADP8d3zYNyQwW2EM4wXVFdslEJcUx/fxkfBeH1El4ixPFhpfHFElxbvKoWmvjDTCmfiYy2X+8XpFjwICHc398kzWsTMKlxovpz2FnCTM=
}
```

**SOA**

**Description:** Start of authority (SOA) resource record. Indicates the name of origin for the zone and contains the name of the server that is the primary source for information about the zone. It also indicates other basic properties of the zone. The SOA resource record is always first in any standard zone. It indicates the DNS server that either originally created it or is now the primary server for the zone. It is also used to store other properties such as version information and timings that affect zone renewal or expiration. These properties affect how often transfers of the zone are done between servers authoritative for the zone. For more information, see Managing authority records.

**Note**

- In the example below, the owner (primary DNS server) is specified as "@" because the domain name is the same as the origin of all data in the zone (example.microsoft.com.). This is a standard notation convention for resource records and is most often seen in the SOA record.

**Syntax:**

*owner class* **SOA** *name_server responsible_person (serial_number refresh_interval retry_interval expiration minimum_time_to_live)*

**Example:**

```
@   IN  SOA     nameserver.example.microsoft.com.  postmaster.example.microsoft.com. (
                                1            ; serial number
                                3600         ; refresh   [1h]
                                600          ; retry     [10m]
                                86400        ; expire    [1d]
                                3600 )       ; min TTL   [1h]
```

**SRV**

**Description:** Service locator (SRV) resource record. Allows multiple servers providing a similar TCP/IP-based service to be located using a single DNS query operation. This record enables you to maintain a list of servers for a well-known server port and transport protocol type ordered by preference for a DNS domain name. For example, in Windows Server 2003 DNS, it provides the means to locate domain controllers that use Lightweight Directory Access Protocol (LDAP) service over TCP port 389.

The purposes of each of the specialized fields used in an SRV resource record are as follows:

- **service** A symbolic name for the desired service. For well-known services, a reserved universal symbolic name such as "_telnet" or "_smtp" is defined in RFC 1700. If a well-known service name is not defined in RFC 1700, a local or user-preferred name can be used instead. Some widely used TCP/IP services, notably the Post Office Protocol (POP), do not have a single universal symbolic name. If RFC 1700 assigns a name for a service indicated in this field, the RFC-defined name is the only name that is legal to use. Only locally defined services can be named locally.

- **protocol** Indicates the transport protocol type. Typically, this is either TCP or UDP, although any transport protocol named in RFC 1700 can be used.

- **name** The DNS domain name referred to by this resource record. The SRV resource record is unique among other DNS record types in that it is not used to perform the search or query.

- **priority** Sets the preference for a host specified in the *target* field. DNS clients that query for SRV resource records attempt to contact the first reachable host of the lowest numbered preference listed here. Although *target* hosts have the same stated preference value, they can be tried in random order. The range of preference values is 0 to 65535.

- **weight** Can be used in addition to preference to provide a load-balancing mechanism where multiple servers are specified in the **target** field and are all set to the same level of preference. When selecting a target server host among those of equal preference, this value can be used to set an added level of preference that can be used to determine the exact order or balancing of selection for the target hosts used in an answered SRV query. When a non-zero value is used, servers of equal preference are tried in proportion to the weight of this value. The range of values is 1 to 65535. If load balancing is not needed, use a value of **0** in this field to make the record easier to read.

- **port** The server port on the **target** host that provides the service indicated in the *service* field. The range of port numbers is 0 to 65535, although the number is often a well-known assigned service port number, as specified in RFC 1700. Unassigned ports can be used as needed.

- **target** Specifies the DNS domain name of the host that provides the type of service being requested. For each host name used, a corresponding host address (A) resource record in the DNS namespace is required. A single period (.) can be used in this field to indicate authoritatively that the requested service specified in this SRV resource record is not available at this DNS domain name.

For more information, see the Internet draft "A DNS RR for specifying the location of services (DNS SRV)."

**Syntax:**

*service.protocol.name ttl class* **SRV** *preference weight port target*

**Example:**

```
_ldap._tcp._msdcs    SRV  0 0   389 dc1.example.microsoft.com
                   SRV 10 0   389 dc2.example.microsoft.com
```

**TXT**

**Description:** Text (TXT) resource record. Maps a DNS domain name specified in the *owner* field to a string of characters in *text_string* serving as descriptive text. For more information, see RFC 1035.

**Syntax:**

*owner ttl class* **TXT** *text_string*

**Example:**

```
example.microsoft.com.    TXT  "This is an example of additional domain name information."
```

**WKS**

**Description:** Well-known service (WKS) resource record. Describes the well-known TCP/IP services supported by a particular protocol on a specific IP address. WKS records provide TCP and UDP availability information for TCP/IP servers. If a server either supports both TCP and UDP for a well-known service or has multiple IP addresses that support a service, then multiple WKS records are used. For more information, see RFC 1035.

**Syntax:**

*owner ttl class* **WKS** *address protocol service_list*

**Example:**

```
example.microsoft.com.    WKS  10.0.0.1 TCP ( telnet smtp ftp )
```

**X25**

**Description:** X.25 (X25) resource record. Maps a DNS domain name in the **owner** field to a Public Switched Data Network (PSDN) address number specified in *psdn_number*. PSDN numbers used with this record should follow the X.121 international numbering plan. For more information, see RFC 1183.

**Syntax:**

*owner ttl class* **X25** *psdn_number*

**Example:**

```
example.microsoft.com.    X25  52204455506
```

# DNS server log reference

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS server log reference**

The following is a partial list of events recorded in the DNS server log. You can view this log by using the DNS console after the DNS Server service is installed on the server computer. For more information, see View the DNS server system event log.

| Event ID | Description |
|---|---|
| 2 | The DNS server has started.<br><br>This message generally appears at startup when either the server computer is started or the DNS Server service is manually started. For more information, see Start or stop a DNS server. |
| 3 | The DNS server has shut down.<br><br>This message generally appears when either the server computer is shut down or the DNS Server service is stopped manually. |
| 408 | The DNS server could not open socket for address *[IPaddress]*. Verify that this is a valid IP address for the server computer.<br><br>To correct the problem, you can do the following:<br><br>• If the specified IP address is not valid, remove it from the list of restricted interfaces for the server and restart the server. For more information, see Restrict a DNS server to listen only on selected addresses.<br><br>• If the specified IP address is no longer valid and was the only address enabled for the DNS server to use, the server might not have started as a result of this configuration error. To correct this problem, delete the following value from the registry and restart the DNS server:<br><br>HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters\ListenAddress<br><br>• If this is a valid IP address for the server computer, verify that no other application that would attempt to use the same DNS server port (such as another DNS server application) is running. By default, DNS uses TCP port 53. |
| 413 | The DNS server will send requests to other DNS servers on a port other than its default port (TCP port 53).<br><br>This DNS server is multihomed and has been configured to restrict DNS Server service to only some of its configured IP addresses. For this reason, there is no assurance that DNS queries made by this server to other remote DNS servers will be sent using one of the IP addresses enabled for the DNS server.<br><br>This might prevent query answer responses returned by these servers from being received on the DNS port that the server is currently configured to use. To avoid this problem, The DNS server sends queries to other DNS servers using an arbitrary non-DNS port, and the response is received regardless of the IP address used.<br><br>If you want to limit the DNS server to using only its configured DNS port for sending queries to other DNS servers, use the DNS console to perform one of the following changes in server properties configuration on the **Interfaces** tab:<br><br>1. Either select **All IP addresses** to enable the DNS server to listen on all configured server IP addresses<br><br>2. Or, if you continue to select and use **Only the following IP addresses**, limit the **IP address** list to a single server IP address.<br><br>For more information, see Restrict a DNS server to listen only on selected addresses. |

| | |
|---|---|
| 414 | The server computer currently has no primary DNS suffix configured. Its DNS name is currently a single label host name. For example, its currently configured name is "host" rather than "host.example.microsoft.com" or another fully qualified name.<br><br>While the DNS server has only a single label name, default resource records created for its configured zones use only this single label name when mapping the host name for this DNS server. This can lead to incorrect and failed referrals when clients and other DNS servers use these records to locate this server by name.<br><br>In general, the DNS server should be reconfigured with a full DNS computer name appropriate for its domain or workgroup use on your network. |
| 708 | The DNS server did not detect any zones of either primary or secondary type. It will run as a caching-only server but will not be authoritative for any zones.<br><br>For more information, see Using caching-only servers. |
| 3150 | The DNS server wrote a new version of zone *[zonename]* to file *[filename]*. You can view the new version number by clicking the **Record Data** tab.<br><br>This event should only appear if the DNS server is configured to operate as a root server. For more information, see DNS-related files. |
| 6527 | Zone *[zonename]* expired before it could obtain a successful zone transfer or update from a master server acting as its source for the zone. The zone has been shut down.<br><br>This event ID might appear when the DNS server is configured to host a secondary copy of the zone from another DNS server acting as its source or master server. Verify that this server has network connectivity to its configured master server.<br><br>If the problem continues, consider one or more of the following options:<br><br>1. Delete the zone and recreate it, specifying either a different master server, or an updated and corrected IP address for the same master server.<br><br>For more information, see Add and Remove Zones.<br><br>2. If zone expiration continues, consider adjusting the expire interval.<br><br>For more information, see Adjust the expire interval for a zone.<br><br>For more information, see Understanding zones and zone transfer. |

For more information about all other messages not described in this topic, refer directly to the message text itself as it appears in the DNS server event log.

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**Notes**

- Event messages logged by the DNS Client service are logged in System log, and can also be viewed using Event Viewer at the applicable client computer. For more information, see Windows interface administrative tool reference A-Z: Event Viewer.

- If needed to troubleshoot persistent problems, you can also enable for use advanced debugging options at the DNS server for obtaining a more detailed log of server activity. For more information, see Using server debug logging options or View a DNS server debug log file.

# DNS-related files

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS-related files**

The following files relate to using and configuring DNS servers and clients.

| File | Description |
|---|---|
| Boot | BIND boot configuration file. This file is not created by the DNS console. However, as an optional configuration for the DNS Server service, it can be copied from another DNS server running the Berkeley Internet Name Domain (BIND) server implementation of DNS. To use this file with the DNS Server service, you need to click **From file** in Server properties. On BIND servers, this file is often called the "named.boot" file. |
| Cache.dns | Used to preload resource records into the DNS server names cache. DNS servers use this file to help locate root servers on either your network or the Internet.<br><br>By default, this file contains DNS resource records that prime the local cache of the server with the addresses of authoritative root servers for the Internet. If you are setting up a DNS server to resolve Internet DNS names, the information in this file is required unless you enable the use of another DNS server as a forwarder to resolve these names.<br><br>Traffic to the Internet root servers is heavy, but because host names are not usually resolved at this level, the load can be reasonably handled. Instead, the root hints file provides referral information that can be useful during DNS name resolution to redirect a query to other servers that are authoritative for names located beneath the root.<br><br>For DNS servers operating privately on your internal network, the DNS console can learn and replace the contents of this file with internal root servers on your network, provided they are reachable through the network when you are setting up and configuring new DNS servers. It can be updated using the DNS console from the **Root Hints** tab located under the applicable server properties.<br><br>This file preloads the server names cache when it is started. |
| Root.dns | Root zone file. This file can appear at a DNS server if it is configured as a root server for your network. |
| *zone_name*.dns | Used when a standard zone (either primary or secondary) is added and configured for the server. Files of this type are not created or used for primary type zones that are directory-integrated, which are stored in the Active Directory database. |

These files can be found in the systemroot\System32\Dns folder on the server computer.

**Notes**

- For more information about operating a DNS server as a root server, see Updating root hints.
- For more information on hosting your own DNS presence on the Internet, see Interoperability issues.
- For more information about configuring DNS servers on your network to use forwarders, see Using forwarders.
- If you are migrating server files from a BIND server to use with a Windows DNS server, you need to rename these files and copy them to the folder used by the DNS Server service. For more information, see Migrating servers.

# DNS updated technical information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS updated technical information**

Updated technical information for DNS can be obtained by searching technical articles available from Product Support Services at the Microsoft Web site. For more information, see Updated technical information.

# DNS RFCs

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS RFCs**

Request for Comments (RFCs) are an evolving series of reports, proposals for protocols, and protocol standards used by the Internet community. Domain Name System (DNS) specifications are based on approved RFCs published by the Internet Engineering Task Force (IETF) and other working groups.

**RFCs for the DNS Server service**

The following RFCs contain specifications used to design and implement the DNS Server and Client services:

| RFC | Title |
|---|---|
| 1034 | Domain Names -- Concepts and Facilities |
| 1035 | Domain Names -- Implementation and Specification |
| 1123 | Requirements for Internet Hosts -- Application and Support |
| 1886 | DNS Extensions to Support IP Version 6 |
| 1995 | Incremental Zone Transfer in DNS |
| 1996 | A Mechanism for Prompt Notification of Zone Changes (DNS NOTIFY) |
| 2136 | Dynamic Updates in the Domain Name System (DNS UPDATE) |
| 2181 | Clarifications to the DNS Specification |
| 2308 | Negative Caching of DNS Queries (DNS NCACHE) |
| 2535 | Domain Name System Security Extensions (DNSSEC) |
| 2671 | Extension Mechanisms for DNS (EDNS0) |
| 2782 | A DNS RR for specifying the location of services (DNS SRV) |
| 2930 | Secret Key Establishment for DNS (TKEY RR) |
| 3645 | Generic Security Service Algorithm for Secret Key Transaction Authentication for DNS (GSS-TSIG) |
| 3646 | DNS Configuration options for Dynamic Host Configuration Protocol for IPv6 (DHCPv6) |

**Other specifications for DNS**

The following additional specifications are used to design and implement the DNS Server and Client services:

| File name | Title |
|---|---|
| af-saa-0069.000.pdf | ATM Names Service<br><br>This specification is published by the MFA Forum. For more information, you can obtain this specification by downloading it from the MFA Forum site. |

**Obtaining DNS RFCs**

You can obtain RFCs from the RFC Editor Web site. RFCs are classified as one of the following: approved Internet standards, proposed Internet standards (circulated in draft form for review), Internet best practices, or For Your Information (FYI) documents.

## Notes

- RFCs 1034 and 1035 define the original DNS standard protocol to support domain name services in a TCP/IP environment. These RFCs describe the protocols in a detailed manner, emphasizing the underlying ideas and techniques used in all DNS implementations.

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# Top-level domains

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Top-level domains**

The following is a list of the eight top-level domains most often used on the Internet to classify organizations by type when they register a second-level domain name for use. For example, microsoft.com (the second-level domain name registered to Microsoft) is registered in the "com" domain, because this is the top-level domain provided for organizations that do business (commerce) on the Internet.

| Top-level name | Description | Used by |
|---|---|---|
| arpa | Owned by Advanced Research Project Agency (ARPA). Used to register reverse mapping of Internet Protocol (IP) version 4 (IPv4) and IP version 6 (IPv6) addresses assigned by the Internet Assigned Number Authority (IANA) to Domain Name System (DNS) domain names for computers that use those addresses on the Internet. | The in-addr.arpa domain, the ip6.arpa domain |
| com | For business and commercial use. | Businesses and corporations |
| edu | For educational use. | Public and private schools, colleges, and universities |
| gov | For use by governmental institutions. | Local, state, and federal government agencies |
| int | Reserved for international use. Originally planned for use in RFC 1886 to register reverse mapping of IPv6 addresses. For more information about RFCs, see DNS RFCs. | |
| mil | For use by military agencies. | Department of Defense (DoD), U.S. Navy, U.S. Army, U.S. Air Force, and other military agencies |
| net | For use by organizations that provide large-scale Internet or telephony-based service. | InterNIC, AT&T, and other large-scale Internet and telephone service providers |
| org | For use by noncommercial, nonprofit organizations. | Churches and charitable institutions |

**Note**

- In addition to these top-level domains which are all three letters in length, the use of two-letter country/region codes (such as "uk" for United Kingdom) are reserved for use. These country/region codes can also be used in conjunction with the three-letter codes listed above to further specify the country or region of origin for organizations that register names in the Internet DNS namespace.

# DNS bibliography

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

# Troubleshooting DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting**

This section covers:

- Troubleshooting DNS clients
- Troubleshooting DNS servers
- Troubleshooting dynamic updates
- Troubleshooting zone problems

# Troubleshooting DNS clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting DNS clients**
What problem are you having?

- The DNS client received a "Name not found" error message.
- The DNS client appears to have received a response with stale or incorrect information in it.
- The DNS client appears to be affected by another problem not described above.

**The DNS client received a "Name not found" error message.**
**Cause:** The DNS client computer does not have a valid IP configuration for the network.

**Solution:** Verify that TCP/IP configuration settings for the client computer are correct, particularly those used for DNS name resolution.

To verify a client IP configuration, use the **ipconfig** command. In the command output, verify that the client has a valid IP address, subnet mask, and default gateway for the network where it is attached and being used.

If the client does not have a valid TCP/IP configuration, you can either:

1. For dynamically configured clients, use the **ipconfig /renew** command to manually force the client to renew its IP address configuration with the DHCP server.
2. For statically configured clients, modify the client TCP/IP properties to use valid configuration settings or complete its DNS configuration for the network.

**See also:** Ipconfig; Configure TCP/IP for dynamic addressing; Configure TCP/IP for static addressing; Configure TCP/IP to use DNS; Configuring DNS client settings.

**Cause:** The client was not able to contact a DNS server because of a network or hardware related failure.

**Solution:** Verify that the client computer has a valid and functioning network connection. First, check that related client hardware (cables and network adapters) are working properly at the client using basic network and hardware troubleshooting steps.

If the client hardware appears to be prepared and functioning properly, verify that it can ping other computers on the same network.

**See also:** Test a TCP/IP configuration by using the ping command.

**Cause:** The DNS client cannot contact its configured DNS servers.

**Solution:** If the DNS client has basic connectivity to the network, verify that it can contact a preferred (or alternate) DNS server.

To verify whether a client has basic TCP/IP access to the DNS server, first try pinging the preferred DNS server by its IP address.

For example, if the client uses a preferred DNS server of 10.0.0.1, type **ping 10.0.0.1** at the command prompt on the client computer. If you are not sure what the IP address is for the preferred DNS server, you can observe it by using the **ipconfig** command.

For example, at the client computer, type **ipconfig /all|more** if necessary to pause the display so you can read and note any IP addresses listed in **DNS servers** for the command output.

If no configured DNS servers respond to a direct pinging of their IP address, it indicates that the source of the problem is more likely a network connectivity problem between the client and the DNS servers. If that is the case, follow basic TCP/IP network

troubleshooting steps to fix the problem.

**See also:** Test a TCP/IP configuration by using the ping command.

**Cause:** The DNS server is not running or responding to queries.

**Solution:** If the DNS client can ping the DNS server computer, verify that the DNS server is started and able to listen for and respond to client requests. Try using the **nslookup** command to test whether the server can respond to DNS clients.

**See also:** Verify DNS server responsiveness using the nslookup command; Start or stop a DNS server.

**Cause:** The DNS server the client is using does not have authority for the failed name and cannot locate the authoritative server for this name.

**Solution:** Confirm whether the DNS domain name the client is trying to resolve is one for which its configured DNS servers are authoritative.

For example, if the client is attempting to resolve the name host.example.microsoft.com, verify that the preferred (or an alternate, if one is being used) DNS server queried by the client loads the authoritative zone where a host (A) resource record (RR) for the failed name should exist.

If the preferred server is authoritative for the failed name and loads the applicable zone, determine whether the zone is missing the appropriate RRs. If needed, add the RRs to the zone.

If the preferred server is not authoritative for the failed name, it indicates that configuration errors at the DNS server are the likely cause. As needed, further troubleshoot the problem at the DNS server.

**See also:** Manage Resource Records; Troubleshooting DNS servers.

**The DNS client appears to have received a response with stale or incorrect information in it.**

**Cause:** The DNS server the client is using does not have authority for the failed name and is using stale information from its local DNS database.

**Solution:** Determine whether the DNS server is authoritative for the name and proceed accordingly.

For example, if the client is attempting to resolve the name host.example.microsoft.com, verify that the preferred (or an alternate, if one is being used) DNS server queried by the client loads the authoritative zone where a host (A) resource record (RR) for the failed name should exist.

If the preferred server is authoritative for the name and answered using incorrect data, it indicates that the applicable zone might have outdated or stale information in the applicable RR data. If that is the case, you can add and remove the appropriate RRs in the zone.

Another option where dynamic updates are enabled is to force registration and update at the computer targeted by the query. You can force it to update the registration of its resource records by typing the **ipconfig /registerdns** command at a command prompt.

If the preferred server is not a direct authority for the queried name, it likely answered the query based on information obtained and cached during an earlier recursive lookup. In this case, you might consider clearing the server names cache. This compels the server to use new recursive queries for this RR data and rebuild its cache contents based on current information.

**See also:** Manage Resource Records; Troubleshooting DNS servers; Renew DNS client registration using the ipconfig command; Clear the server names cache.

**Cause:** The preferred DNS server is a secondary server for the zone containing the targeted name and has outdated information.

**Solution:** If the server that answered the client is a secondary server for the zone, the version of the zone in use at that server might be stale and need to be updated more often.

As an immediate solution, you can initiate a zone transfer at the secondary server to its master server to update the zone. You might also consider using any of the following to improve the freshness of secondary zone data in the future:

1. Specify additional master servers for the secondary server to use when refreshing the zone.

2. Adjust the refresh interval on the zone slightly to decrease the length of time that all authoritative servers for the zone can use the zone before they are required to refresh it.

3. Configure a notify list at a master server that acts as the zone source for the secondary server and enable it to notify this server when the zone changes.

**See also:** Initiate a zone transfer at a secondary server; Adjust the refresh interval for a zone; Create and manage a notify list for a zone; Using secondary servers; Understanding zones and zone transfer.

**Cause:** The name queried was specified in error, either through user input or in a stored client configuration.

**Solution:** Verify that the name was correctly specified in the application where the name query originated.

In most cases, incorrect data in a positive query response indicates one of three possibilities:

- An incorrect DNS name was entered at the client by a user.
- A short unqualified name was used at the client and completed by the local resolver using an unintended DNS suffix.
- Resource records specified in the query were not updated correctly at the DNS server.

Confirm that the name was not entered in error by the user. Verify the exact set of characters entered by the user when the original DNS query was made or check in application settings, such as for any Internet mail or Web browser configurations that were made.

If the name used in the initial query was unqualified, and not the fully qualified domain name (FQDN), try using the FQDN instead in the client application and repeating the query. If you do, be sure to include the trailing dot (.) at the end of the name to indicate that the name entered is an exact FQDN.

If the FQDN query succeeds and returns correct data in the response, the most likely cause of the problem is a misconfigured DNS domain suffix search list used in the client resolver settings.

If you are using DNS in an environment that does not support dynamic updates, or generally administer zone data manually, you might also want to verify that the RRs involved in answering the query were not entered incorrectly. View them to ensure the record data stored in the zone is correct or modify it accordingly.

**See also:** Configure TCP/IP to use DNS; Modify an existing resource record in a zone.

**Cause:** The primary zone might have missing or errored data

**Solution:** Verify that the primary server for the zone has complete and accurate data.

The most likely cause for a primary DNS server for a zone to have missing or incomplete data is because of a failed update request. It is possible that support for dynamic update has not been fully implemented or configured. To resolve the problem, review the DNS dynamic update protocol (RFC 2136) and any requirements it has for DNS servers and clients that use it.

For directory-integrated zones, it is also possible that the affected records for the errored query have been updated in Active Directory but not replicated to all DNS servers loading the zone. By default, all DNS servers that load zones from Active Directory poll it at a set interval (typically every 15 minutes), and update the zone for any incremental changes to it. In most cases, a DNS update takes no more than 20 minutes to replicate to all DNS servers used in an Active Directory domain environment using default replication settings and reliable high-speed links.

If you have specifically configured your zones to disable dynamic update, keep in mind that you need to manually add and update most types of resource records used in a zone. If this is the case, use the DNS console to view and update the affected records.

Another possibility for the errored data is in whether WINS lookup integration is enabled and used with the zone. If you are using WINS lookup with your zones, verify that WINS is not the source of the errored data.

**See also:** Troubleshooting dynamic updates; Manage Resource Records; Managing resource records; Verify WINS as the source for answering a DNS query.

**The DNS client appears to be affected by another problem not described above.**
**Cause:** My problem is not described above.

**Solution:** Search TechNet at the Microsoft Web site for the latest technical information that could relate to the problem. If necessary, you can obtain information and instructions that pertain to your problem or issue.

If you are connected to the Internet, the latest operating system updates are available at the Microsoft Web site.

To obtain the latest service pack updates for Windows NT Server, see the Microsoft Web site.

**See also:** DNS updated technical information; DNS; Using the Windows Deployment and Resource Kits.

# Troubleshooting DNS servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting DNS servers**
What problem are you having?

- The DNS server is not responding to clients.
- The DNS server does not resolve names correctly.
- The DNS server appears to be affected by a problem for reasons not described above.

**The DNS server is not responding to clients.**
**Cause:** The DNS server is affected by a network failure.

**Solution:** Verify that the server computer has a valid functioning network connection. First, check that related client hardware (cables and network adapters) are working properly at the client using basic network and hardware troubleshooting steps.

If the server hardware appears to be prepared and functioning properly, check that it has network connectivity by pinging other computers or routers (such as its default gateway) that are used and available on the same network as the affected DNS servers.

**See also:** Test a TCP/IP configuration by using the ping command.

**Cause:** The DNS server is reachable through basic network testing but is not responding to DNS queries from clients.

**Solution:** If the DNS client can ping the DNS server computer, verify that the DNS server is started and able to listen to and respond to client requests. Try using the **nslookup** command to test whether the server can respond to DNS clients.

**See also:** Verify DNS server responsiveness using the nslookup command; Start or stop a DNS server.

**Cause:** The DNS server has been configured to limit service to a specific list of its configured IP addresses. The IP address originally used in testing its responsiveness is not included in this list.

**Solution:** If the server was previously configured to restrict the IP addresses for which it responds to queries, it is possible that the IP address being used by clients to contact it is not in the list of restricted IP addresses permitted to provide service to clients.

Try testing the server for a response again, but specify a different IP address known to be in the restricted interfaces list for the server. If the DNS server responds for that address, add the missing server IP address to the list.

**See also:** Verify DNS server responsiveness using the nslookup command; Restrict a DNS server to listen only on selected addresses.

**Cause:** The DNS server has been configured to disable the use of its automatically created default reverse lookup zones.

**Solution:** Verify that automatically created reverse lookup zones have been created for the server or that advanced configuration changes have not been previously made to the server.

By default, DNS servers automatically create the following three standard reverse lookup zones based on Request for Comments (RFC) recommendations:

These zones are created with common IP addresses covered by these zones that are not useful in a reverse lookup search (0.0.0.0, 127.0.0.1, and 255.255.255.255). By being authoritative for the zones corresponding to these addresses, the DNS service avoids unnecessary recursion to root servers in order to perform reverse lookups on these types of IP addresses.

It is possible, although unlikely, that these automatic zones are not created. This is because disabling the creation of these zones involves advanced manual configuration of the server registry by a user.

To verify that these zones have been created, do the following:

1. Open the DNS console.

2. From the **View** menu, click **Advanced**.

3. In the console tree, click **Reverse Lookup Zones**.

   **Where?**

   - **DNS**/*applicable DNS server*/**Reverse Lookup Zones**

4. In the details pane, verify that the following reverse lookup zones are present:

   - 0.in-addr.arpa
   - 127.in-addr.arpa
   - 255.in-addr.arpa

**See also:** Open the DNS console; DNS RFCs.

**Cause:** The DNS server is configured to use a non-default service port, such as in an advanced security or firewall configuration.

**Solution:** Verify that the DNS server is not using a non-standard configuration.

This is a rare but possible cause. By default, the **nslookup** command sends queries to targeted DNS servers using User Datagram Protocol (UDP) port 53. If the DNS server is located on another network only reachable through an intermediate host (such as a packet-filtering router or proxy server), the DNS server might use a non-standard port to listen for and receive client requests.

If this situation applies, determine whether any intermediate firewall or proxy server configuration is intentionally used to block traffic on well-known service ports used for DNS. If not, you might be able to add such a packet filter onto these configurations to permit traffic to standard DNS ports.

Also, check the DNS server event log to see if Event ID 414 or other critical service-related events have occurred which might indicate why the DNS server is not responding.

**See also:** DNS server log reference; View the DNS server system event log; Microsoft Windows Deployment and Resource Kits.

**The DNS server does not resolve names correctly.**
**Cause:** The DNS server provides incorrect data for queries it successfully answers.

**Solution:** Determine the cause of the incorrect data for the DNS server.

Some of the most likely causes include the following:

- Resource records (RRs) were not dynamically updated in a zone.
- An error was made when manually adding or modifying static resource records in the zone.
- Stale resource records in the DNS server database, left from cached lookups or zone records not updated with current information or removed when they are no longer needed.

To help prevent the most common types of problems, be sure to first review best practices for tips and suggestions on deploying and managing your DNS servers. Also, follow and use the checklists appropriate for installing and configuring DNS servers and clients based on your deployment needs.

If you are deploying DNS for Active Directory, note new directory integration features. These features can cause some differences for DNS server defaults when the DNS database is directory-integrated, that differ from those used with traditional

file-based storage.

Many DNS server problems start with failed queries at a client, so it is often good to start there and troubleshoot the DNS client first.

**See also:** DNS best practices; DNS Checklists; Troubleshooting DNS clients; Modify an existing resource record in a zone; Clear the server names cache; Modifying server defaults.

**Cause:** The DNS server does not resolve names for computers or services outside of your immediate network, such as those located on external networks or the Internet.

**Solution:** The server has a problem based on its ability to correctly perform recursion. Recursion is used in most DNS configurations to resolve names that are not located within the configured DNS domain name used by the DNS servers and clients.

If a DNS server fails to resolve a name for which it is not authoritative, the cause is usually a failed recursive query. Recursive queries are used frequently by DNS servers to resolve remote names delegated to other DNS zones and servers.

For recursion to work successfully, all DNS servers used in the path of a recursive query must be able to respond to and forward correct data. If not, a recursive query can fail for any of the following reasons:

- The recursive query times out before it can be completed.
- A remote DNS server fails to respond.
- A remote DNS server provides incorrect data.

If a server fails a recursive query for a remote name, review the following possible causes to troubleshoot the problem. If you do not understand recursion or the DNS query process, review conceptual topics in Help to better understand the issues involved.

**See also:** How DNS query works.

**Cause:** The DNS server is not configured to use other DNS servers to assist it in resolving queries.

**Solution:** Check whether the DNS server can use both forwarders and recursion.

By default, all DNS servers are enabled to use recursion, although the option to disable its use is configurable using the DNS console to modify advanced server options. The other possibility where recursion might be disabled is if the server is configured to use forwarders and recursion has been specifically disabled for that configuration.

**Note**

- If you disable recursion on the DNS server, you will not be able to use forwarders on the same server.

**See also:** Disable recursion on the DNS server; Configure a DNS server to use forwarders.

**Cause:** Current root hints for the DNS server are not valid.

**Solution:** Check whether server root hints are valid.

If configured and used correctly, root hints always should point to DNS servers authoritative for the zone containing the domain root and top-level domains.

By default, DNS servers are configured to use root hints appropriate to your deployment, based on the following available choices when using the DNS console to configure a server:

1. If the DNS server is installed as the first DNS server for your network, it is configured as a root server.

   For this configuration, root hints are disabled at the server because the server is authoritative for the root zone.

2. If the installed server is an additional DNS server for your network, you can direct the Configure DNS Server Wizard to update its root hints from an existing DNS server on the network.

3. If you do not have other DNS servers on your network but still need to resolve Internet DNS names, you can use the default root hints file which includes a list of Internet root servers authoritative for the Internet DNS namespace.

**See also:** Update root hints on the DNS server; Updating root hints.

**Cause:** The DNS server does not have network connectivity to the root servers.

**Solution:** Test for connectivity to the root servers.

If root hints appear to be configured correctly, verify that the DNS server used in a failed query can ping its root servers by IP address.

If a ping attempt to one root server fails, it might indicate that an IP address for that root server has changed. Reconfiguration of root servers, however, is uncommon.

A more likely cause is a full loss of network connectivity or in some cases, poor network performance on the intermediate network links between the DNS server and its configured root servers. Follow basic TCP/IP network troubleshooting steps to diagnose connections and determine whether this is the problem.

By default, the DNS service uses a recursive time-out of 15 seconds before failing a recursive query. Under normal network conditions, this time-out does not need to be changed. If performance warrants it, however, you can increase this value.

To review additional performance related information on DNS queries, you can enable and use the DNS server debug log file, Dns.log, which can provide extensive information about some types of service-related events.

**See also:** Test a TCP/IP configuration by using the ping command; Using server debug logging options; View a DNS server debug log file; Tuning advanced server parameters.

**Cause:** Other problems exist with updating DNS server data, such as an issue related to zones or dynamic updates.

**Solution:** Determine whether the problem is related to zones. As needed, Troubleshoot any issues in this area, such as possible failure of zone transfer.

**See also:** Troubleshooting dynamic updates; Troubleshooting zone problems.

**The DNS server appears to be affected by a problem for reasons not described above.**
**Cause:** My problem is not described above.

**Solution:** Search TechNet at the Microsoft Web site for the latest technical information that could relate to the problem. If necessary, you can obtain information and instructions that pertain to your problem or issue.

If you are connected to the Internet, the latest operating system updates are available at the Microsoft Web site.

To obtain the latest service pack updates for Windows NT Server, see the Microsoft Web site.

**See also:** DNS updated technical information; DNS; Using the Windows Deployment and Resource Kits.

# Troubleshooting dynamic updates

Published: January 21, 2005

Updated: August 25, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting dynamic updates**
What problem are you having?

- The DNS client is not performing dynamic updates.
- The DNS server is not performing dynamic updates.
- I am having a different problem related to dynamic updates than those described above.

**The DNS client is not performing dynamic updates.**
**Cause:** The client (or its DHCP server) do not support the use of the DNS dynamic update protocol.

**Solution:** Verify that your clients or servers support the DNS dynamic update protocol.

In order for client computers to be registered and updated dynamically with a DNS server, either:

1. Install or upgrade client computers to Windows XP or Windows Server 2003 .
2. Install and use the DHCP Server service on your network to lease client computers.

By default, computers attempt to register and perform dynamic update of their DNS names and IP addresses with a DNS server.

For other types of computers, you can deploy Windows Server 2003 DHCP servers, which can perform proxied registrations and updates as needed for non-dynamic clients.

**Notes**

- By default, the DNS client on Windows XP does not attempt dynamic update over a Remote Access Service (RAS) or virtual private network connection. To modify this configuration, you can modify the advanced TCP/IP settings of the particular network connection or modify the registry. For more information, see Configure TCP/IP to use DNS and the Microsoft Windows Resource Kits Web site.
- By default, the DNS client does not attempt dynamic update of top-level domain (TLD) zones. Any zone named with a single-label name is considered a TLD zone, for example, com, edu, blank, my-company. To configure the DNS client to allow the dynamic update of TLD zones, you can use the **Update Top Level Domain Zones** policy setting or modify the registry.

**Cause:** The client was not able to register with the DNS server because of intermittent problems with either the DNS server or the network.

**Solution:** At the client computer, use the **ipconfig** command as appropriate to retry registration or renewal and update client information with the DNS server.

You can use the **ipconfig /registerdns** command option to manually force a retry of its dynamic registration.

For computers running earlier versions of Windows, you can use the options of the **ipconfig** command to verify, view, or renew the client TCP/IP configuration details as appropriate.

For example, if the client computer obtains its IP address lease from a DHCP server, you might use the **ipconfig /renew** command to force it to renew its lease with the DHCP server. This action would then cause the DHCP server to proxy an update request to its configured DNS server on behalf of the client.

If the DHCP server succeeds in performing the proxied update with the DNS server, the result would be updated DNS host name and IP address information for the client computer in the DNS database.

**See also:** Renew DNS client registration using the ipconfig command.

**Cause:** The client was not able to register and update with the DNS server because of missing or incomplete DNS configuration.

**Solution:** Verify that the client is fully and correctly configured for DNS, and update its configuration as needed.

One common cause of the client failing to update with the DNS server is that it does not have a DNS suffix (either a primary suffix or connection-specific suffix) configured. This might result in the client attempting to register an incorrect or unintended DNS domain name.

For example, the client could be attempting to register its short or unqualified computer or host name as a top-level domain name in the root zone. This happens because without a DNS suffix configured for the client computer, it determines the configured short name of a computer (such as host-a) is its fully qualified domain name (FQDN). This only occurs because the computer name does not have a DNS suffix to append to it and qualify the computer name when registering it for the client in DNS.

To update the DNS configuration for a client, either:

1. Configure a primary DNS suffix at the client computer for static TCP/IP clients.

2. Configure a connection-specific DNS suffix for use at one of the installed network connections at the client computer.

**See also:** Configure the primary DNS suffix for a client computer; Configure TCP/IP to use DNS; Install and Configure Clients; Managing Clients.

**Cause:** The DNS client attempted to update its information with the DNS server but failed because of a problem related to the server.

**Solution:** If a client can reach its preferred and alternate DNS servers as configured, it is likely that the cause of its failed updates can be found elsewhere.

At Windows-based client computers, you can use Event Viewer to check the System log for any event messages that explain why attempts by the client to dynamically update its host (A) or pointer (PTR) resource records failed.

When reviewing messages in the System log, filter or order the display of all messages to view those that specify **DnsApi** as the source for the message. Typically, these messages are related to the performance of DNS activities, such as DNS queries or dynamic updates.

A common reason updates might fail for a mobile client is that the DNS server required to accept and perform the update does not respond when the client starts at a remote location on the network. This could be due to network performance issues or might indicate a problem in the underlying design of your network. Where these issues persist or seem likely, you should review your DNS deployment and modify it accordingly.

**See also:** Deploying DNS; Dynamic update.

**The DNS server is not performing dynamic updates.**
**Cause:** The DNS server does not support dynamic updates.

**Solution:** Verify that the DNS server used by the client can support the DNS dynamic update protocol, as described in RFC 2136.

Only the Windows 2000 and Windows Server 2003 DNS Server service supports dynamic updates. The DNS Server service provided with Windows NT Server 4.0 does not.

If you are using other DNS servers on your network, verify that they are running a DNS server implementation that supports dynamic updates.

**See also:** Dynamic update; DNS RFCs.

**Cause:** The DNS server supports dynamic updates but is not configured to accept them.

**Solution:** Verify that the primary zone where clients require updates is configured to allow dynamic updates.

The default for a new primary zone is to not accept dynamic updates. At the DNS server that loads the applicable primary zone, modify zone properties to allow updates.

**See also:** Allow dynamic updates.

**Cause:** The zone database is not available.

**Solution:** Verify that the zone is available for update.

First, if necessary, verify that the zone exists. For a standard primary zone, verify that the zone file exists at the server and that the zone is not paused. If you are using Active Directory-integrated zones, verify that the DNS server is running as a domain controller and has access to the Active Directory database where zone data is stored.

Secondary zones do not support dynamic updates. If you are trying to determine which server is the primary server for a standard zone, review zone authority records to determine which server is referenced in both the start of authority (SOA) and name server (NS) resource records for the zone. This is the primary server for the zone which can accept dynamic updates to it.

If you need to, you can use the DNS console to change a secondary zone to become a primary zone so that it can accommodate dynamic updates. However, because standard primary zones use a single-master update model, you can only configure one server to accept dynamic updates for the zone.

If you change the zone type at a secondary server so that it becomes the primary server for that zone, you need to either remove the zone or convert it to another zone type (such as a secondary zone) at the original primary server. Otherwise, zone data would become inconsistent and cause additional problems.

If you want to have more than one DNS server be able to update a zone, it is recommended that you change the zone type so that it becomes Active Directory-integrated. To be able to use this zone type, Active Directory must be installed and the server computer must be promoted to a domain controller.

Once the zone is stored in the directory, other domain controllers can load the zone automatically and be allowed to update it when they are running the DNS Server service. This is because Active Directory supports a multiple (or floating) master update model where more than one computer can process updates to the directory database.

**See also:** Change the zone type; Add and Remove Zones; Managing authority records; Active Directory integration.

**Cause:** The DNS server is configured to allow only secure dynamic updates and has a security-related problem.

**Solution:** Verify that zone or resource record security does not block or prevent dynamic updates at the server.

Secure update can be enabled for directory-integrated zones and their resource records. If secure dynamic update is in effect for a directory-integrated zone, then only users, groups, or computers that have write permissions may add new resource records to the zone. If secure dynamic update is in effect for resource records, then only users, groups, or computers that have write permissions can update these resource records. Consequently, security might block or prevent a DNS client (or its DHCP server) from performing an update of its host (A) and pointer (PTR) resource records.

In most cases, secure dynamic update does not prevent new records from being created or added to a zone, but it does restrict who is given default permissions to update or modify records. Where necessary, you can use the access control list (ACL) editing features available for directory-integrated zones to modify security permissions on a zone or its resource records and enable update by another user, group, or computer.

Typically, this is only needed if the computer requesting the update is different from the one that owns the client records and originally created them.

**See also:** Dynamic update; Modify security for a directory-integrated zone; Modify security for a resource record.

**Cause:** The DNS server required to perform the updates is not available on the network.

**Solution:** Verify that the DNS server is available on the network or troubleshoot any further issues as necessary.

**See also:** Troubleshooting DNS servers.

**I am having a different problem related to dynamic updates than those described above.**
**Cause:** My problem is not described above.

**Solution:** Search TechNet at the Microsoft Web site for the latest technical information that could relate to the problem. If necessary, you can obtain information and instructions that pertain to your problem or issue.

If you are connected to the Internet, the latest operating system updates are available at the Microsoft Web site.

To obtain the latest service pack updates for Windows NT Server, see the Microsoft Web site.

# Troubleshooting zone problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting zone problems**
What problem are you having?

- I am having a problem related to zone transfers.
- I am trying to use a zone delegation but it appears to be broken.
- I am having a different zone problem than the ones described above.

**I am having a problem related to zone transfers.**
**Cause:** The DNS Server service is stopped or the zone is paused.

**Solution:** Verify that the master (source) and secondary (destination) DNS servers involved in completing transfer of the zone are both started and that the zone is not paused at either server.

**See also:** Start or stop a DNS server; Start a zone; Understanding zones and zone transfer.

**Cause:** The DNS servers used during a transfer do not have network connectivity with each other.

**Solution:** Eliminate the possibility of a basic network connectivity problem between the two servers.

Using the **ping** command, ping each DNS server by its IP address from its remote counterpart.

For example, at the source server, use the **ping** command to test IP connectivity with the destination server. At the destination server, repeat the ping test, substituting the IP address for the source server.

Both ping tests should succeed. If not, investigate and resolve intermediate network connectivity issues.

**See also:** Command-line utilities.

**Cause:** The serial number is the same at both the source and destination servers. Because the value is the same at both servers, no zone transfer occurs between the servers.

**Solution:** Using the DNS console, perform the following tasks:

1. Increase the value of the serial number for the zone at the master server (source) to a number greater than the value at the applicable secondary server (destination).
2. Once you have increased the serial number at the master server to a higher value than is used currently at the secondary server, initiate zone transfer at the secondary server.

When working within the DNS console, the zone serial number can be viewed from the **Start of Authority (SOA)** tab in the applicable zone properties. To increase this number in the zone, click **Increment**.

**See also:** Modify the start of authority (SOA) record for a zone; Initiate a zone transfer at a secondary server.

**Cause:** The master server (source) and its targeted secondary server (destination) are having interoperability-related problems.

**Solution:** Investigate possible causes for any problems related to interoperability between DNS servers running Windows Server 2003 and other DNS server implementations, such as an older version of the Berkeley Internet Name Domain (BIND) distribution.

Older BIND servers use an uncompressed zone transfer format. By default, servers running Windows Server 2003 (and later version BIND servers) use a faster compressed format during zone transfers. To accommodate zone transfer with older BIND servers, you need to change advanced server options at your DNS servers running Windows Server 2003.

Another possible interoperability issue is the use and inclusion of WINS forward lookup (WINS) resource records in a zone or their counterpart, the WINS reverse lookup (WINS-R) resource record used for reverse lookup zones. BIND servers do not recognize these records when they are included in zone data being transferred and can flag these records as bad data, possibly failing the zone transfer.

To prevent these records from being used or included in zone transfers to BIND-based servers and other servers that do not recognize them, select **Do not replicate this record** when configuring WINS properties at the applicable zone.

**See also:** Interoperability issues; Enable or disable fast transfer format during zone transfers; Interoperability issues; Using WINS lookup; Enable DNS to use WINS resolution.

**Cause:** The zone has resource records or other data that cannot be interpreted by the DNS server.

**Solution:** Verify that the zone does not contain incompatible data, such as unsupported resource records types or data errors.

In most cases, the DNS Server service supports all resource record (RR) types that are approved and required for Internet standard DNS usage.

Also, verify that the server has not been configured in advance to prevent loading a zone when bad data is found and investigate its method for checking names. These settings can be configured using DNS console.

**See also:** Resource records reference; Prevent loading of a zone when bad data is found; Change the name-checking method used by the DNS server; Checking names and zone data.

**Cause:** Authoritative zone data is incorrect.

**Solution:** If a zone transfer continues to fail, ensure that the zone does not contain nonstandard data.

If you manually edit zone files, be aware that records need to be formatted and used according to standard record usage and formatting guidelines as specified in the Request for Comments (RFCs) for DNS. In most cases, user input and data errors can be avoided if records are added and managed using the DNS console.

To determine if errored zone data is a likely source for a failed zone transfer, look in the DNS server event log for messages. You can also use the **nslookup** command with the **-ls** option to simulate and test a zone transfer, while observing the data returned in a terminates before full transfer of the zone is complete.

**See also:** Nslookup; DNS RFCs.

**I am trying to use a zone delegation but it appears to be broken.**
**Cause:** Zone delegations are not configured correctly.

**Solution:** Review how zone delegations are used and revise your zone configurations as needed.

Zones contain information about DNS domains and subdomains. For each new zone you create, the zone originally begins as a single-node database for one DNS domain. As needed, new subdomain nodes can be added directly below the original (parent) domain and stored as a single zone. Sometimes when new subdomains remain part of the same zone, they are called *sub-zones*.

If used as sub-zones, new subdomains are retained as part of the zone and replicated and updated along with it as a single entity. You can, however, delegate subdomains away and manage them in their own zones. For each subdomain delegated to its own zone, the parent zone needs to have delegation records added to it.

You can use the New Delegation wizard provided in the DNS console to simplify adding these records.

**See also:** Delegating zones; Create a zone delegation; Verify a zone delegation using the nslookup command.

**I am having a different zone problem than the ones described above.**
**Cause:** My problem is not described above.

**Solution:** Search TechNet at the Microsoft Web site for the latest technical information that could relate to the problem. If necessary, you can obtain information and instructions that pertain to your problem or issue.

If you are connected to the Internet, the latest operating system updates are available at the Microsoft Web site.

To obtain the latest service pack updates for Windows NT Server, see the Microsoft Web site.

# DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP**

Dynamic Host Configuration Protocol (DHCP) is an IP standard designed to reduce the complexity of administering address configurations by using a server computer to centrally manage IP addresses and other related configuration details used on your network. The Microsoft® Windows Server 2003 family provides the DHCP service, which enables the server computer to perform as a DHCP server and configure DHCP-enabled client computers on your network as described in the current DHCP draft standard, RFC 2131.

DHCP includes Multicast Address Dynamic Client Assignment Protocol (MADCAP) which is used to perform multicast address allocation. When registered clients are dynamically assigned IP addresses through MADCAP, they can participate efficiently in the data stream process, such as for real-time video or audio network transmissions.

- Before installing a DHCP or MADCAP server, see DHCP Checklists.
- To find features that have been moved in the Windows Server 2003 family, see New ways to do DHCP tasks.
- For tips about using DHCP, see DHCP Best Practices.
- For help with specific tasks, see DHCP How To....
- For general background information, see DHCP Concepts.
- For problem-solving instructions, see DHCP Troubleshooting.

# DHCP Checklists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklists**

- Checklist: Installing a DHCP server
- Checklist: Administering a DHCP server
- Checklist: Installing a MADCAP server

# Checklist: Installing a DHCP server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a DHCP server**

| Step | Reference |
|---|---|
| Review DHCP concepts such as scopes, leases, and options.<br>**Important**<br>• If you are operating in a domain environment under an earlier version of Windows NT Server, it is recommended that you first upgrade your domain controllers to Windows Server 2003 family before installing DHCP on your network. | DHCP terminology |
| Determine the IP address range or ranges for which DHCP will be needed to provide configuration service on your network. | Configuring scopes |
| Manually configure TCP/IP properties for the DHCP server computer. | Configure TCP/IP for static addressing |
| Install the DHCP server. | Install a DHCP server |
| Open the DHCP console. | Open the DHCP console |
| Authorize the DHCP server in Active Directory. | Authorize a DHCP server in Active Directory; Authorizing DHCP servers |
| If the DHCP server is multihomed, disable service bindings for any connection not to be used to listen and provide service to clients. | Selectively set DHCP server bindings for network connections; Multihomed DHCP servers |
| Set DNS dynamic update policy for the DHCP server. | Enable DNS dynamic updates for clients; Using DNS servers with DHCP |
| (Optional) If you are using multiple scopes, configure any default option types for the server that should be inherited by all scopes. Server options are assigned to all DHCP clients that lease an IP address from any scope configured on the server. | Assign a server-based option; Assigning options |
| Create a new scope and assign commonly used options, such as WINS and DNS servers (unless these are already configured as server options). Scope options are assigned only to DHCP clients that lease an IP address from the scope where the option is configured. | Create a new scope; Configuring scopes; Assigning options |
| (Optional) Configure additional scope option types if you have subnets that need option configurations in addition to server options that are already configured. | Assign a scope-based option; Assigning options |
| (Optional) Add reservations for clients that require a reserved IP address assigned by DHCP. Reservations assure that DHCP clients keep the same IP address and have DHCP options refreshed each time the client renews the IP address lease. | Add a client reservation; Using client reservations |

| | |
|---|---|
| (Optional) Create exclusion ranges to prevent some IP addresses from being leased by the DHCP server. If you have network devices (such as printers, servers, or wireless access points) that must be configured with static IP addresses, create an exclusion range within the scope's address range; you can then assign static addresses to devices from the range of addresses excluded from distribution by the DHCP server. | Exclude an address from a scope |
| Activate the scope. | Activate a scope |
| (Optional) For additional fault tolerance, you can implement DHCP clustering support using a server cluster.<br><br>**Note**<br><br>• DHCP clustering servers are implemented using the Clustering service, which is provided only with Windows Server 2003, Enterprise Edition. | Cluster support for DHCP servers |

# Checklist: Administering a DHCP server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Administering a DHCP server**
The following table lists optional actions you can take to administer your DHCP server, depending on your network configuration.

| Step | Reference |
|---|---|
| If clients share a commonly defined vendor type or a common need for a unique DHCP options configuration, configure and assign option classes. | Using option classes; Manage Options and Classes |
| If predefined options do not meet your needs, define additional option types. | Define a new option; Assigning options |
| If the default lease time of eight days is too long or too short, adjust the length of lease durations.<br><br>For example, you can shorten leases for wireless clients on wireless subnets, or lengthen leases for subnets whose DHCP clients all have reservations. | Change or view scope properties; Managing leases |
| If you need to implement support for more than one logical network for each physical network, create and use superscopes. | Create a superscope; Using superscopes |
| If you have a routed network, determine if you need to implement relay agents or update routers, and if so, review relay agent configurations and related design issues. | DHCP/BOOTP Relay Agents; Configure the DHCP Relay Agent |
| If you want to deploy your DHCP server as a multicast server, create multicast scopes. | Create a multicast scope; Using multicast scopes |
| If you want to support BOOTP clients on your network, configure the BOOTP table. | Add an entry to the BOOTP table; View the BOOTP table |
| If DHCP clients have problems accessing network resources, verify DHCP service to clients. | Verify, release, or renew a client address lease; Ipconfig; Command-line utilities |
| If you want to manually configure IP addresses for clients running Windows 2000, Windows XP, or Windows Server 2003 family, disable automatic address configuration. | Disable automatic address configuration |
| If you want to track DHCP server performance, use System Monitor. | Monitoring DHCP server performance; System Monitor overview |
| If you want to allow users to have read-only or administrative access to the DHCP server, add users to DHCP groups. | DHCP groups; Default groups |
| If you are having DHCP-related problems, troubleshoot and resolve common DHCP-related problems, or review DHCP server audit log files. | DHCP Troubleshooting; Analyzing server log files |

# Checklist: Installing a MADCAP server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a MADCAP server**

| Step | Reference |
|---|---|
| Review Multicast Address Dynamic Client Allocation Protocol (MADCAP) concepts such as IP multicasting and multicast address allocation. | Multicast address allocation; Understanding Multicasting |
| Determine the multicast IP address range or ranges for use in your MADCAP server configuration. The ranges you select depend on whether you need to use administrative local scoping or global scoping practices to provide multicast address allocation service on your network. | Using multicast scopes |
| Manually configure TCP/IP properties for the DHCP (MADCAP) server computer. | Configure TCP/IP for static addressing |
| To install a MADCAP server, install the DHCP service.<br><br>**Important**<br><br>• The DHCP service can be used to deploy MADCAP servers independently of how DHCP servers are used on your network. For example, to install Windows Server 2003 DHCP for MADCAP service only:<br><br>1. Create multicast scopes.<br><br>2. Do not create other scopes or superscopes.<br><br>Only where other scopes or superscopes are configured, does the server computer also function as a DHCP server. | Install a DHCP server |
| Open the DHCP console. | Open the DHCP console |
| Authorize the DHCP (MADCAP) server in Active Directory. | Authorize a DHCP server in Active Directory |
| (Optional) If the DHCP (MADCAP) server is multihomed, you can disable service bindings for any connection not to be used to listen and provide service to DHCP (MADCAP) clients. | Selectively set DHCP server bindings for network connections; Multihomed DHCP servers |
| Create a multicast scope. | Create a multicast scope |
| If necessary, you can additionally manage multicast IP address allocation by creating and removing scopes, or by modifying multicast scope properties, such as scope TTL and lifetime settings as needed. | Manage Multicast Scopes |
| (Optional) For additional fault tolerance, you can implement DHCP clustering support using a server cluster.<br><br>**Note**<br><br>• DHCP clustering servers are implemented using the Clustering service, which is provided only with Windows Server 2003, Enterprise Edition. | Cluster support for DHCP servers |

# New ways to do DHCP tasks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New ways to do familiar tasks**

The following table lists common tasks for managing DHCP servers using the DHCP console. The user interface for performing these tasks is different in this version of Windows from the way it was in Windows NT 4.0.

**Note**

- There are no significant user interface differences between Windows 2000, Windows XP, and the Windows Server 2003 family for this component.

| If you want to | In Windows NT 4.0 use | In this version of Windows use |
|---|---|---|
| Install a DHCP server on this computer | **Network** in Control Panel | Add or Remove Programs<br><br>For more information, see Install a DHCP server. |
| Start the DHCP console | Click **Start**, point to **Administrative Tools**, and then click **DHCP Manager**. | The DHCP console.<br><br>For more information, see Open the DHCP console. |
| Authorize a DHCP server in Active Directory prior to use | Not available in Windows NT Server 4.0 | Log on first as a user who is a member of the Enterprise Admins group for the enterprise where you need to authorize the server.<br><br>For more information, see Authorize a DHCP server in Active Directory. |
| Start or stop a DHCP server | **Services** in Control Panel | The DHCP console.<br><br>For more information, see Start or stop a DHCP server. |
| Add a server to the DHCP console to manage | **Server** menu in **DHCP Manager** | The DHCP console.<br><br>For more information, see Connect to a DHCP server. |
| Add and configure a scope for a DHCP server | **Create** option on **Scope** menu in **DHCP Manager** | The DHCP console.<br><br>For more information, see Create a new scope. |

# DHCP Best Practices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Best practices**

- **Use the 80/20 design rule for balancing scope distribution of addresses where multiple DHCP servers are deployed to service the same scope.**

  Using more than one DHCP server on the same subnet provides increased fault tolerance for servicing DHCP clients located on it. With two DHCP servers, if one server is unavailable, the other server can take its place and continue to lease new addresses or renew existing clients.

  A common practice when balancing a single network and scope range of addresses between two DHCP servers is to have 80 percent of the addresses distributed by one DHCP server and the remaining 20 percent provided by a second. For more information and an example of this concept, see Configuring scopes.

- **Use superscopes for multiple DHCP servers on each subnet in a LAN environment.**

  When started, each DHCP client broadcasts a DHCP discover message (DHCPDISCOVER) to its local subnet to attempt to find a DHCP server. Because DHCP clients use broadcasts during their initial startup, you cannot predict which server will respond to the DHCP discover request of a client if more than one DHCP server is active on the same subnet.

  For example, if two DHCP servers service the same subnet and its clients, clients can be leased at either server. Actual leases distributed to clients can depend on which server responds first to any given client. Later, the server first selected by the client to obtain its lease might be unavailable when the client attempts to renew.

  If renewal fails, the client then delays trying to renew its lease until it enters the rebinding state. In this state, the client broadcasts to the subnet to locate a valid IP configuration and continue without interruption on the network. At this point, a different DHCP server might respond to the client request. If this occurs, the responding server might send a DHCP negative acknowledgement message (DHCPNAK) in reply. This can occur even if the original server that first leased the client is available on the network.

  To avoid these problems when using more than one DHCP server on the same subnet, use a new superscope configured similarly at all servers. The superscope should include all valid scopes for the subnet as member scopes. For configuring member scopes at each server, addresses must only be made available at one of the DHCP servers used on the subnet. For all other servers in the subnet, use exclusion ranges for the same scope ranges of addresses when configuring the corresponding scopes.

  For more information, see Using superscopes.

- **Deactivate scopes only when removing a scope permanently from service.**

  Once you activate a scope, it should not be deactivated until you are ready to retire the scope and its included range of addresses from use on your network.

  Once a scope is deactivated, the DHCP server no longer accepts those scope addresses as valid addresses. This is only useful when the intention is to permanently retire a scope from use. Otherwise, deactivating a scope causes undesired DHCP negative acknowledgement messages (DHCPNAKs) to be sent to clients.

  If the intent is only to affect temporary deactivation of scope addresses, editing or modifying exclusion ranges in an active scope achieves the intended result without undesired results.

  For more information, see Manage Scopes.

- **Use server-side conflict detection on DHCP servers only when it is needed.**

Conflict detection can be used by either DHCP servers or clients to determine whether an IP address is already in use on the network before leasing or using the address.

DHCP client computers running Windows 2000 or Windows XP that obtain an IP address use a gratuitous ARP request to perform client-based conflict detection before completing configuration and use of a server offered IP address. If the DHCP client detects a conflict, it will send a DHCP decline message (DHCPDECLINE) to the server.

If your network includes legacy DHCP clients (clients running a version of Windows earlier than Windows 2000), you can use server-side conflict detection provided by the DHCP Server service under specific circumstances. For example, this feature might be useful during failure recovery when scopes are deleted and recreated. For more information, see DHCP Troubleshooting.

By default, the DHCP service does not perform any conflict detection. To enable conflict detection, increase the number of ping attempts that the DHCP service performs for each address before leasing that address to a client. Note that for each additional conflict detection attempt that the DHCP service performs, additional seconds are added to the time needed to negotiate leases for DHCP clients.

Typically, if DHCP server-side conflict detection is used, you should set the number of conflict detection attempts made by the server to use one or two pings at most. This provides the intended benefits of this feature without decreasing DHCP server performance.

For more information, see Enable address conflict detection.

- **Reservations should be created on all DHCP servers that can potentially service the reserved client.**

  You can use a client reservation to ensure that a DHCP client computer always receives the same IP address lease at startup. If you have more than one DHCP server reachable by a reserved client, add the reservation at each of your other DHCP servers.

  This allows the other DHCP servers to honor the client IP address reservation made for the reserved client. Although the client reservation is only acted upon by the DHCP server where the reserved address is part of the available address pool, you can create the same reservation on other DHCP servers that exclude this address.

  For more information, see Add a client reservation.

- **For server performance, note that DHCP is disk-intensive and purchase hardware with optimal disk performance characteristics.**

  DHCP causes frequent and intensive activity on server hard disks. To provide the best performance, consider RAID solutions when purchasing hardware for your server computer that improves disk access time.

  When evaluating performance of your DHCP servers, you should evaluate DHCP as part of making a full performance evaluation of the entire server. By monitoring system hardware performance in the most demanding areas of utilization (CPU, memory, disk input/output), you obtain the best assessment of when a DHCP server is overloaded or in need of an upgrade.

  Note that the DHCP service includes several System Monitor counters that can be used to monitor service. For more information, see Monitoring DHCP server performance.

- **Keep audit logging enabled for use in troubleshooting.**

  By default, the DHCP service enables audit logging of service-related events. Audit logging provides a long-term service monitoring tool that makes limited and safe use of server disk resources. For more information, see Audit logging.

  For more information on interpreting server audit log files, see Analyzing server log files.

- **Reduce lease times for DHCP clients that use Routing and Remote Access service for remote access.**

If Routing and Remote Access service is used on your network to support dial-up clients, you can adjust the lease time on scopes that service these clients to less than the default of eight days. One recommended way to support remote access clients in your scopes is to add and configure the built-in Microsoft vendor class provided for the purpose of client identification.

- **Increase the duration of scope leases for large, stable, fixed networks if available address space is plentiful.**

  For small networks (for example, one physical LAN not using routers), the default lease duration of eight days is a typical period. For larger routed networks, consider increasing the length of scope leases to a longer period of time, such as 16-24 days. This can reduce DHCP-related network broadcast traffic, particularly if client computers generally remain in fixed locations and scope addresses are plentiful (at least 20 percent or more of the addresses are still available).

- **Integrate DHCP with other services, such as WINS and DNS.**

  WINS and DNS can both be used for registering dynamic name-to-address mappings on your network. To provide name resolution services, you must plan for interoperability of DHCP with these services. Most network administrators implementing DHCP also plan a strategy for implementing DNS and WINS servers.

- **For routed networks, either use relay agents or set appropriate timers to prevent undesired forwarding and relay of BOOTP and DHCP message traffic.**

  If you have multiple physical networks connected through routers, and you do not have a DHCP server on each network segment, the routers must be capable of relaying BOOTP and DHCP traffic. If you do not have such routers, you can set up the DHCP Relay Agent component on at least one server running Windows Server 2003 in each routed subnet. The relay agent relays DHCP and BOOTP message traffic between the DHCP-enabled clients on a local physical network and a remote DHCP server located on another physical network.

  When using relay agents, be sure to set the initial time delay in seconds that relay agents wait before relaying messages on to remote servers. For more information on DHCP relay agents, see DHCP/BOOTP Relay Agents.

- **Use the appropriate number of DHCP servers for the number of DHCP-enabled clients on your network.**

  In a small LAN (for example, one physical subnet not using routers), a single DHCP server can serve all DHCP-enabled clients. For routed networks, the number of servers needed increases, depending on several factors, including the number of DHCP-enabled clients, the transmission speed between network segments, the speed of network links, whether DHCP service is used throughout your enterprise network or only on selected physical networks, and the IP address class of the network. For more information on determining how many DHCP servers to set up, see Planning DHCP networks.

- **For DNS dynamic updates performed by the DHCP service, use the default client preference settings.**

  The Windows Server 2003 DHCP service can be configured to perform DNS dynamic updates for DHCP clients based on how clients request these updates to be done. This setting provides the best use of the DHCP service to perform dynamic updates on behalf of its clients as follows:

  - DHCP client computers running Windows 2000, Windows XP, or a Windows Server 2003 operating system explicitly request that the DHCP server only update pointer (PTR) resource records used in DNS for the reverse lookup and resolution of the client's IP address to its name. These clients update their address (A) resource records for themselves.

  - Clients running earlier versions of Windows cannot make an explicit request for DNS dynamic update protocol preference. For these clients, the DHCP service updates both the PTR and the A resource records when the service is configured to do so.

  For more information, see Using DNS servers with DHCP, Enable DNS dynamic updates for clients, and Configure DNS dynamic update credentials.

- **Use the manual backup and restore methods in the DHCP server console.**

  Use the **Backup** command on the **Action** menu of the DHCP console to perform full backup of the DHCP service at an interval that protects you from significant data loss. When you use the manual backup method, all DHCP server data is included in the backup, including all scope information, log files, registry keys, and DHCP server configuration information (except DNS dynamic update credentials). Do not store these backups on the same hard drive upon which the DHCP service is installed, and make sure that the access control list (ACL) for the backup folder only contains the Administrators group and DHCP Administrator groups as members. In addition to performing manual backups, backup to other locations, such as a tape drive, and make sure unauthorized persons do not have access to your backup copies. You can use Windows Backup for this purpose. For more information, see Best practices for Backup.

  When restoring the DHCP service, use a backup created with the manual **Backup** command or a copy of the database created with synchronous backup by the DHCP service. In addition, use the **Restore** command on the **Action** menu in the DHCP console to restore a DHCP server.

  For more information, see Backing up the DHCP database and Restoring server data.

- **Follow the recommended process for moving a DHCP server database from old server computer hardware to new hardware.**

  Moving a DHCP server database can be problematic. To manage moving the server database more easily, choose and follow a process tried and used by Microsoft Product Support Services such as the following:

  - For restoring server data at the same server computer, see Restoring server data.

  - For moving DHCP server data to another server computer, such as in the case of hardware failure or data recovery, see Move a DHCP database to another server.

- **Before you install a DHCP server, identify the following:**

  - The hardware and storage requirements for the DHCP server.

    For more information, see Planning DHCP networks.

  - Which computers you can immediately configure as DHCP clients for dynamic TCP/IP configuration and which computers you should manually configure with static TCP/IP configuration parameters, including static IP addresses.

    For more information, see Checklist: Configuring TCP/IP.

  - The DHCP option types and their values to be predefined for DHCP clients.

    For more information, see Assigning options.

# DHCP How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

- Use DHCP client alternate configuration
- Install and Administer Servers
- Manage Server Access
- Monitor and Configure Servers
- Manage Scopes
- Manage Superscopes
- Manage Multicast Scopes
- Manage Options and Classes
- Manage Clients and Leases
- Manage Reservations and Reserved Clients
- Manage Databases
- Manage BOOTP and Remote Access Clients
- Use DHCP Command-line Tools

# Use DHCP client alternate configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To use DHCP client alternate configuration**

1. Open Network Connections.
2. Right-click the network connection that you want to configure, and then click **Properties**. The **Local Area Connection Properties** dialog box appears.
3. On the **General** tab, click **Internet Protocol (TCP/IP)**, and then click **Properties**. The **Internet Protocol (TCP/IP) Properties** dialog box appears.
4. On the **General** tab, click **Obtain an IP address automatically**.
5. Click the **Alternate Configuration** tab, and then click **User configured**.
6. In **IP address** and **Subnet mask**, type an IP address and subnet mask.
7. You can perform any of the following optional tasks:
   - In **Default gateway**, type the default gateway address.
   - In **Preferred DNS server**, type the primary Domain Name Service (DNS) server address.
   - In **Alternate DNS server**, type the secondary DNS server address.
   - In **Preferred WINS server**, type the primary Windows Internet Name Service (WINS) server address.
   - In **Alternate WINS server**, type the secondary WINS server address.

**Note**

- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Install and Administer Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Install and administer servers**

- Install a DHCP server
- Open the DHCP console
- Connect to a DHCP server
- Disconnect from a DHCP server
- Start or stop a DHCP server
- Reconcile the DHCP database
- Remove or uninstall DHCP

# Install a DHCP server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install a DHCP server**

1. Open Windows Components Wizard.
2. Under **Components**, scroll to and click **Networking Services**.
3. Click **Details**.
4. Under **Subcomponents of Networking Services**, click **Dynamic Host Configuration Protocol (DHCP)**, and then click **OK**.
5. Click **Next**. If prompted, type the full path to the Windows Server 2003 distribution files, and then click **Next**.

   Required files are copied to your hard disk.

## Notes

- To open the Windows Components Wizard, click **Start**, click **Control Panel**, double-click **Add or Remove programs**, and then click **Add/Remove Windows Components**.
- DHCP servers must be configured with a static IP address.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Open the DHCP console
Authorize a DHCP server in Active Directory

# Open the DHCP console

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To open the DHCP console**

- Open DHCP.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- The DHCP console is an administrative tool for managing DHCP servers. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to a DHCP server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to a DHCP server**

1. Open DHCP.
2. In the console tree, click **DHCP**.
3. On the **Action** menu, click **Add Server**.
4. In the **Add Server** dialog box, do one of the following:
   - Click **This server**, enter the name of the DHCP server that you want to connect to, and then click **OK**.
   - Click **This authorized DHCP server**, click the DHCP server that you want to connect to, and then click **OK**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- If you are operating DHCP in an Active Directory environment and are connecting to a server for the first time, you need to first authorize the new DHCP server in the directory service. For more information, see Related Topics.
- If DHCP is installed and running on this computer, you do not need to make a manual connection using the wizard. In most cases, the local DHCP server automatically appears in the list of servers when the DHCP console starts, and you connect to the server by clicking it in the console tree.
- Only users belonging to the following groups can connect to a DHCP server:
  - DHCP Users
  - DHCP Administrators
  - Domain Admins
  - Enterprise Admins

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Disconnect from a DHCP server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disconnect from a DHCP server**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Delete**.
4. When prompted to confirm removing the server, click **Yes**.

**Note**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Start or stop a DHCP server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start or stop a DHCP server**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, point to **All Tasks** and then click one of the following:

   - To start the service, click **Start**.
   - To stop the service, click **Stop**.
   - To interrupt the service, click **Pause**.
   - To stop and then automatically restart the service, click **Restart**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- After you pause or stop the server, the **Resume** option appears and can be clicked to immediately resume service.
- You can also perform these tasks at a command prompt by using the following commands:
  - **net start dhcpserver**
  - **net stop dhcpserver**
  - **net pause dhcpserver**
  - **net continue dhcpserver**
- You can also perform these tasks at the **netsh>** command prompt or in a script using the Netsh commands for DHCP. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Reconcile the DHCP database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To reconcile the DHCP database**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Reconcile All Scopes**.
4. In the **Reconcile All Scopes** dialog box, click **Verify**.

   Inconsistencies found are reported in the status window.

5. If the database is found to be consistent, click **OK**.

   If the database is not consistent, click the displayed addresses that need to be reconciled, and click **Reconcile** to repair inconsistencies.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove or uninstall DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove or uninstall DHCP**

1. If necessary, stop the DHCP server on this computer.

   For more information, see Related Topics.

2. Open Windows Components Wizard.

3. Under **Components**, scroll to and click **Networking Services**.

4. Click **Details**.

5. In **Subcomponents of Networking Services**, scroll to **Dynamic Host Configuration Protocol (DHCP)** and clear the check box.

## Notes

- To open the Windows Components Wizard, click **Start**, click **Control Panel**, double-click **Add or Remove programs**, and then click **Add/Remove Windows Components**.

- When you remove DHCP, all DHCP files are deleted from the server except program files that are in use. When the system is restarted, these files are removed as well.

- If you do not stop the DHCP Server service in step 1, this procedure only deletes the DHCP server registry entries.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Server Access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage server access**

- Authorize a DHCP server in Active Directory
- Unauthorize a DHCP server in Active Directory
- Delegate ability to authorize DHCP servers to a non-enterprise administrator
- Selectively set DHCP server bindings for network connections
- Add a user or group as a DHCP user at a member server
- Add a user or group as a DHCP user at a domain controller
- Add a user or group as a DHCP administrator at a member server
- Add a user or group as a DHCP administrator at a domain controller

# Authorize a DHCP server in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To authorize a DHCP server in Active Directory**

1. Open DHCP.
2. In the console tree, click **DHCP**.
3. On the **Action** menu, click **Manage authorized servers**.

   The **Manage Authorized Servers** dialog box appears.
4. Click **Authorize**.
5. When prompted, type the name or IP address of the DHCP server to be authorized, and then click **OK**.

## Notes

- For a DHCP server to be authorized in an Active Directory domain environment, you must first be logged on as a member of the Enterprise Admins group for the enterprise where the server is being added.
- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- This procedure is usually only needed if you are running a DHCP server on a member server. In most cases, if you are installing a DHCP server on a computer also running as a domain controller, the server is automatically authorized the first time you add the server to the DHCP console.
- The fully qualified domain name (FQDN) of the DHCP server cannot exceed 64 characters. If the FQDN of the DHCP server exceeds 64 characters, the attempt to authorize the server fails with the error message, "A constraint violation has occurred." If your DHCP server FQDN exceeds 64 characters, authorize the server using the IP address of the server instead of its FQDN.
- DHCP servers running Windows 2000 cannot be authorized using the Windows Server 2003 administrative tools (the DHCP console and the Netsh commands for DHCP) unless Windows 2000 Server Service Pack 2 is installed.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Unauthorize a DHCP server in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To unauthorize a DHCP server in Active Directory**

1. Open DHCP.
2. In the console tree, click **DHCP**.
3. On the **Action** menu, click **Manage authorized servers**.

   The **Manage Authorized Servers** dialog box appears.
4. In **Authorized DHCP servers**, select the server you want to unauthorize.
5. Click **Unauthorize**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Removing authorization for a DHCP server from the directory causes that server to stop responding to client requests.
- If the server you unauthorize is the only DHCP server, clients will be unable to obtain IP address leases through DHCP.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delegate ability to authorize DHCP servers to a non-enterprise administrator

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delegate ability to authorize DHCP servers to anon-enterpriseadministrator**

1. Open Active Directory Sites and Services while logged on as an enterprise administrator.

   For more information, see Notes.

2. On the **View** menu, click **Show Services Node**.

3. In the console tree, click **NetServices**.

   **Where?**

   - Active Directory Sites and Services/Services/NetServices

4. On the **Action** menu, click **Delegate Control**.

5. In the Delegation of Control Wizard, click **Next**.

6. On the **Users or Groups** page, click **Add**.

7. In the **Select Users, Computers, or Groups** dialog box, under **Enter the object names to select**, type the name of the user you want to add to the DHCP Administrators group, and then click **OK**. To add multiple users in one operation, type user names separated by semicolons, and then click **OK**. When you finish adding users, click **Next**.

8. On the **Tasks to Delegate** page, click **Create a custom task to delegate**, and then click **Next**.

9. On the **Active Directory Object Type** page, under **Delegate control of**, click **This folder, existing objects in this folder, and creation of new objects in this folder**, and then click **Next**.

10. On the **Permissions** page, under **Permissions**, select the **Full Control** check box, and then click **Next**.

    This enables access control rights to the user or group account that you delegated in this procedure so that the user or group can add, modify, or delete new objects of DHCP class type in the NetServices folder.

## Notes

- To be logged on as an enterprise administrator, you must log on using a member account in the Enterprise Admins group. By default, this can typically be done by logging on as local administrator at the first domain controller created in your enterprise.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- For more information on setting permissions, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Selectively set DHCP server bindings for network connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To selectively set DHCP server bindings for network connections**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. Click **Bindings**.
6. In the **Bindings** dialog box, for the list of **Connections and server bindings**, select or clear check boxes for any statically configured network connections that should be enabled or disabled for use at the applicable DHCP server. Click **OK**.
7. On the **Advanced** tab, click **Apply**.

**Notes**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- If a network connection has more than one IP address configured, only the first configured IP address is used or affected by the DHCP server bindings. Any additional configured IP addresses are not used or configurable for bindings and are never used to service clients.
- The DHCP Server service never binds to any wide area network (WAN) or DHCP-enabled network connections on a server computer. For this reason, these connections do not appear in the **Bindings** dialog box.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a user or group as a DHCP user at a member server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a user or group as a DHCP user at a member server**

1. Open Computer Management if the DHCP server is installed as a domain member server (or a stand-alone workgroup server).

2. In the console tree, click **Local Users and Groups**.

   **Where?**

   - Computer Management (Local)/System Tools/Local Users and Groups

3. In the details pane, double-click **Groups**, and then click **DHCP Users**.

4. On the **Action** menu, click **Properties**.

5. On the **General** tab, click **Add**.

   The **Select Users** dialog box opens.

6. In **Enter the object names to select**, type the name of the user you want to add as a DHCP User, and then click **OK**. To add multiple users in one operation, type user names separated by semicolons, and then click **OK**.

## Notes

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.

- The DHCP Users group provides a way to grant read-only console access to the DHCP server. Members of DHCP Users group are granted the right to view, but not to modify, data for the applicable server in the DHCP console. For more information about DHCP groups, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a user or group as a DHCP user at a domain controller

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a user or group as a DHCP user at a domain controller**

1. Open Active Directory Users and Computers if the DHCP server is installed at a domain controller.
2. In the console tree, click **Users**.

   **Where?**

   - Active Directory Users and Computers/*applicable domain*/Users

3. In the details pane, click **DHCP Users**.
4. On the **Action** menu, click **Properties**.
5. Click the **Members** tab, and then click **Add**.

   The **Select Users** dialog box opens.

6. In **Enter the object names to select**, type the name of the user you want to add as a DHCP User, and then click **OK**. To add multiple users in one operation, type user names separated by semicolons, and then click **OK**.

## Notes

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- The DHCP Users group provides a way to grant read-only console access to the DHCP server. Members of DHCP Users group are granted the right to view, but not to modify, data for the applicable server in the DHCP console. For more information about DHCP groups, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a user or group as a DHCP administrator at a member server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a user or group as a DHCP administrator at a member server**

1. Open Computer Management if the DHCP server is installed as a domain member server (or a stand-alone workgroup server).

2. In the console tree, click **Local Users and Groups**.

   **Where?**

   - Computer Management (Local)/System Tools/Local Users and Groups

3. In the details pane, double-click **Groups**, and then click **DHCP Administrators**.

4. On the **Action** menu, click **Properties**, and then click **Add**.

5. In **Enter the object names to select**, type the name of the user you want to add as a DHCP Administrator, and then click **OK**. To add multiple users in one operation, type user names separated by semicolons, and then click **OK**.

## Notes

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.

- The DHCP Administrators group provides a way to grant limited administrative access to the DHCP server. Members of the DHCP Administrators group are granted the right to fully administer the applicable server using DHCP tools (the DHCP console and Netsh commands for DHCP); they do not have access to other services running on the server and are not able to perform other administrative actions on the server computer. For more information about DHCP groups, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a user or group as a DHCP administrator at a domain controller

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a user or group as a DHCP administrator at a domain controller**

1. Open Active Directory Users and Computers if the DHCP server is installed at a domain controller.
2. In the console tree, click **Users**.

   **Where?**

   - Active Directory Users and Computers/*applicable domain*/Users

3. In the details pane, click **DHCP Administrators**.
4. On the **Action** menu, click **Properties**.
5. Click the **Members** tab, and then click **Add**.

   The **Select Users** dialog box opens.

6. In **Enter the object names to select**, type the name of the user you want to add as a DHCP Administrator, and then click **OK**. To add multiple users in one operation, type user names separated by semicolons, and then click **OK**.

## Notes

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- The DHCP Administrators group provides a way to grant limited administrative access to the DHCP server. Members of the DHCP Administrators group are granted the right to fully administer the applicable server using DHCP tools (the DHCP console and Netsh commands for DHCP); they do not have access to other services running on the server and are not able to perform other administrative actions on the server computer. For more information about DHCP groups, see Related Topics.

# Monitor and Configure Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitor and configure servers**

- Configure DNS dynamic update credentials
- Enable server statistics to automatically refresh
- Enable DHCP server logging
- Enable address conflict detection
- Enable DNS dynamic updates for clients
- Manually refresh server statistics
- View DHCP server statistics
- View DHCP server properties

# Configure DNS dynamic update credentials

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure DNS dynamic update credentials**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Properties**.
4. In ***Server* Properties**, click the **Advanced** tab, and then click **Credentials**.

   The **DNS dynamic update credentials** dialog box appears.

5. In **DNS dynamic update credentials**, type the information required to provide credentials that will determine DNS record ownership, and then click **OK**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- If the supplied credentials belong to an object (such as a computer) that is a member of the **DnsUpdateProxy** security group, the next object to register the same name record in DNS will become the record owner.
- If you specified the credentials (user name, domain, and password) that the DHCP server uses when registering DHCP client computers in DNS, these credentials are not backed up with either synchronous or asynchronous backup. After a DHCP database is restored, new credentials must be configured.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable server statistics to automatically refresh

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable server statistics to automatically refresh**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Properties**.
4. On the **General** tab, for **Automatically update statistics every**, specify the number of hours and minutes to use as a refresh interval, and then click **OK**.

**Note**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable DHCP server logging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable DHCP server logging**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Properties**.
4. On the **General** tab, select **Enable DHCP audit logging**, and then click **OK**.

**Note**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable address conflict detection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable address conflict detection**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. For **Conflict detection attempts**, type a number greater than 0 (zero) and less than six, and then click **OK**.

   The number you type determines how many times the DHCP server tests an IP address before leasing it to a client.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- When conflict detection attempts are set, the DHCP server uses the Packet Internet Groper (ping) process to test available scope IP addresses before including these addresses in DHCP lease offers to clients.
- A successful ping means the IP address is in use on the network. Therefore, the DHCP server does not offer to lease the address to a client. If the ping request fails and times out, the IP address is not in use on the network. In this case, the DHCP server offers to lease the address to a client.
- Each additional conflict detection attempt delays the DHCP server response by a second while waiting for the ping request to time out. This increases the load on the server. A value of no greater than two (2) for ping attempts is recommended.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable DNS dynamic updates for clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable DNS dynamic updates for clients**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Properties**.
4. Click the **DNS** tab.
5. Select the **Enable DNS dynamic updates according to the settings below** check box.
6. If needed, modify other DNS update settings.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- DHCP clients running Windows 2000, Windows XP, or a Windows Server 2003 operating system explicitly request that the DHCP server update only the pointer (PTR) resource records that are used in DNS for the reverse lookup and resolution of the IP address of the client to the name of the client. These clients update their address (A) resource records for themselves.
- Clients running earlier versions of Windows cannot make an explicit request for DNS dynamic update protocol preference. For these clients, the DHCP service updates both the PTR and the A resource records.
- For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manually refresh server statistics

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manually refresh server statistics**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Display Statistics**.
4. In the ***Server* Statistics** dialog box, click **Refresh**.

**Note**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Scopes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage scopes**

- Create a new scope
- Remove a scope
- Exclude an address from a scope
- Activate a scope
- Deactivate a scope
- Change or view scope properties
- Reconcile a scope

# Create a new scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a new scope**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **New Scope**.
4. Follow the instructions in the New Scope Wizard.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Before you create the scope, determine starting and ending IP addresses to be used within it.
- Depending on the starting and ending IP addresses for your scope, the DHCP console suggests a default subnet mask useful for most networks. If you know a different subnet mask is required for your network, you can modify the value as needed.
- When you finish creating a new scope, you might need to complete additional tasks, such as activating the scope for use or assigning scope options.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove a scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove a scope**

1. Open DHCP.
2. In the console tree, click the applicable scope.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*

3. On the **Action** menu, click **Delete**.
4. When prompted, click **Yes** to delete the scope.

### Important

- Before removing a scope, be sure to have deactivated the scope long enough to migrate clients to a different scope. To migrate clients, either wait for 50% of the configured scope lease time to elapse or manually renew clients in another active scope. Once all clients have been moved or forced to seek leases in another scope, you can safely remove the inactive scope.

### Note

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Exclude an address from a scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To exclude an address from a scope**

1. Open DHCP.
2. In the console tree, click **Address Pool**.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Address Pool

3. On the **Action** menu, click **New Exclusion Range**.
4. In the **Add Exclusion** dialog box, type the **Start IP address** that you want to exclude from this scope.

   To exclude a range of more than one IP address, type an **End IP address**.

5. Click **Add**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Addresses that are excluded from the scope are not offered by the DHCP server to clients obtaining leases from this scope.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Activate a scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To activate a scope**

1. Open DHCP.
2. In the console tree, click the applicable scope.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*

3. On the **Action** menu, click **Activate**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Activating a scope is needed only for new scopes to start lease distribution. You must activate a scope to make it available for DHCP clients.
- Do not activate a scope until you specify the options you want.
- The **Action** menu command changes to **Deactivate** when the selected scope is currently activated. Do not deactivate a scope unless you are retiring it permanently from use on your network.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Deactivate a scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To deactivate a scope**

1. Open DHCP.
2. In the console tree, click the applicable scope.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*

3. On the **Action** menu, click **Deactivate**.

**Important**

- Do not use **Deactivate** to pause a scope. Instead, adjust the available scope address range by setting exclusions for scope addresses.
- The **Action** menu command name changes to **Activate** when the selected scope is currently deactivated.

**Note**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Reconcile a scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To reconcile a scope**

1. Open DHCP.
2. In the console tree, click the applicable scope.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*

3. On the **Action** menu, click **Reconcile**.
4. In the **Reconcile** dialog box, click **Verify**.

   Inconsistencies found are reported in the status window.

5. If the scope is found to be consistent, click **OK**.

   If the scope is not consistent, select the displayed addresses that need to be reconciled, and click **Reconcile** to repair inconsistencies.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Superscopes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage superscopes**

- Create a superscope
- Remove a superscope
- Add a scope to a superscope
- Activate a superscope
- Deactivate a superscope

# Create a superscope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a superscope**

1. Open DHCP.

2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **New Superscope**.

   This menu option only appears if at least one scope, that is not currently part of a superscope, has been created at the server.

4. Follow the instructions in the New Superscope Wizard.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

- A superscope can have scopes added to it, either during or after its creation.

- Scopes that are contained within superscopes are sometimes called *child scopes* or *member scopes*.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a scope to a superscope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a scope to a superscope**

1. Open DHCP.
2. In the console tree, click the applicable scope.

   **Where?**

   - DHCP/*applicable DHCP server/applicable scope*

3. On the **Action** menu, click **Add To Superscope**.
4. In the **Available superscopes** list, click the superscope to which you want to add this scope.

**Notes**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- In order to complete this procedure, at least one superscope must already exist at the applicable DHCP server.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**

# Activate a superscope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To activate a superscope**

1. Open DHCP.
2. In the console tree, locate the applicable superscope.

   **Where?**

   - DHCP/*applicable DHCP server/applicable superscope*

3. On the **Action** menu, click **Activate**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Activating a superscope is needed only for new superscopes. When you activate a superscope, it activates all member scopes in the superscope, allowing the DHCP server to lease IP addresses from the superscope to clients on your network. You must activate a superscope to make IP addresses for all of its member scopes available for use by DHCP clients.
- Do not activate a superscope until you specify the options you want for each of its member scopes.
- The **Action** menu command changes to **Deactivate** when the selected scope is currently activated. Do not deactivate a superscope unless you intend to permanently retire all of its member scopes from use on your network.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove a multicast scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove a multicast scope**

1. Open DHCP.
2. In the console tree, click the applicable multicast scope.

   **Where?**

   - DHCP/*applicable DHCP server/applicable multicast scope*

3. On the **Action** menu, click **Delete**.
4. When prompted, click **Yes** to remove the multicast scope.

**Notes**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Removing a multicast scope does not necessarily stop the use of multicast groups associated with scope addresses on your network.
- If computers on your network are configured by means other than DHCP to use these same addresses, the multicast group might still be used even after this procedure is complete.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**

# Set the multicast scope Time-To-Live (TTL) value

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the multicast scope Time-To-Live (TTL) value**

1. Open DHCP.
2. In the console tree, click the applicable multicast scope.

   **Where?**

   - DHCP/*applicable DHCP server/applicable multicast scope*

3. On the **Action** menu, click **Properties**.
4. In **Time to live**, specify a new value.

**Notes**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- The multicast Time-To-Live (TTL) value specifies the number of routers (hops) that multicast traffic is permitted to pass through before expiring on the network. For each router (hop), the original specified TTL is decremented by one (1). When its TTL reaches a value of zero (0), each multicast datagram expires and is no longer forwarded through the network to other subnets.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Specify a finite lifetime for a multicast scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify a finite lifetime for a multicast scope**

1. Open DHCP.
2. In the console tree, click the applicable multicast scope.

   **Where?**

   - DHCP/*applicable DHCP server/applicable multicast scope*

3. On the **Action** menu, click **Properties**.
4. Click the **Lifetime** tab.
5. For **Multicast scope lifetime**, click **Multicast scope expires on**.
6. Using the controls, specify a date and time when the multicast scope is to be expired and removed from the applicable DHCP server.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- By default, multicast scopes do not expire. When created, they exist until they are manually removed. This procedure, however, can be used to provide a means of having the DHCP server automatically remove the multicast scope at an appointed future date and time.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Options and Classes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage options and classes**

- Assign a server-based option
- Assign a scope-based option
- Assign an advanced (class-based) option
- Create a new user or vendor class
- Define a new option
- Modify an option
- Remove an option

# Assign a server-based option

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To assign a server-based option**

1. Open DHCP.
2. In the console tree, click **Server Options**.

   **Where?**

   - DHCP/*applicable DHCP server*/Server Options

3. On the **Action** menu, click **Configure Options**.
4. In list of **Available Options**, select the check box for the first option you want to configure.
5. Under **Data entry**, type the information required for this option.
6. Repeat the two previous steps for any other server options you want to specify, and then click **OK**.
7. In addition, you can click the **Advanced** tab and specify additional server options to be applied only for members of select user or vendor classes.

   Options assigned at this level are only provided to clients identified as members of the classes specified at this tab.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Server options are inherited as default values for all scopes created at the applicable DHCP server. Option values you configure here are overridden by any scope-based or client-based values assigned for the same options.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Assign a scope-based option

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To assign a scope-based option**

1. Open DHCP.
2. In the console tree, click **Scope Options**.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Scope Options

3. On the **Action** menu, click **Configure Options**.
4. In list of **Available Options**, select the check box for the first option you want to configure.
5. Under **Data entry**, type the information required for this option.
6. Repeat the two previous steps for any other server options you want to specify, and then click **OK**.
7. In addition, you can click the **Advanced** tab and specify additional scope options to be applied only for members of select user or vendor classes.

   Options assigned at this level are only provided to clients identified as members of the classes specified at this tab.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Scope options are inherited as default values for all clients of the applicable scope. Option values you configure here are overridden by any reserved client-based values assigned for the same options.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Assign an advanced (class-based) option

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To assign an advanced (class-based) option**

1. Open DHCP.
2. In the console tree, choose one:
   - Click **Server Options**, if you want to assign advanced options for use by all new scopes at the DHCP server.

     **Where?**

     - DHCP/*applicable DHCP server*/Server Options
   - Click **Scope Options**, if you want to assign advanced options for use by a specific scope at the DHCP server.

     **Where?**

     - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Scope Options
3. Right-click the folder, and click **Configure Options**.
4. Click the **Advanced** tab.
5. Select from the following:
   - For **Vendor class**, scroll to select the defined vendor class at the DHCP server (or use the default, **DHCP Standard Options**) for assigning options for the server or scope.
   - For **User class**, scroll to select the defined user class at the DHCP server (or use the default, **Default User Class**) for assigning options for the server or scope.
6. In the list of **Available Options**, select the check box for the first option you want to configure.
7. Under **Data entry**, type the information required for this option.
8. Repeat the two previous steps for any other options you want to specify, and then click **OK**.

**Notes**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- If a class-based option is assigned, it only applies to DHCP clients that are identified as members of the specified user or vendor class.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create a new user or vendor class

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a new user or vendor class**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, choose one of the following:

   - To create a new user class, click **Define User Classes**.
   - To create a new vendor class, click **Define Vendor Classes**.

4. Click **Add**.
5. In **New Class**, type the required information.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- In the **DHCP User Classes** and **DHCP Vendor Classes** dialog boxes, you can also click either **Edit** or **Remove** to modify or delete option classes.
- In the **New Class** dialog box, for **ID**, set the same binary or ASCII string that matches the DHCP class ID string which is either implemented or set at member clients.
- You can use the **ipconfig /showclassid** command to display all the DHCP class IDs allowed for any network adapter installed on your computer.
- For DHCP client computers running Windows 2000 or Windows XP, the **ipconfig /setclassid** command can be used to set the specified DHCP class ID string. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Define a new option

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To define a new option**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Set Predefined Options**.
4. In **Predefined Options and Values**, click **Add**.
5. In **Option Type**, type the required information to define the new option, and then click **OK**.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- By default, standard DHCP options and BOOTP extensions as described in RFC 2132 are predefined for use at DHCP servers running Windows Server 2003 . For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify an option

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify an option**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Set Predefined Options**.
4. In **Predefined Options and Values**, select the following:

   - For **Option class**, select the class where the option to be modified is used.
   - For **Option name**, scroll to select the option you want to modify.

5. Click **Edit**.
6. Modify the **Name** and **Description** fields for the option as needed.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- For options already defined, only the **Name** and **Description** fields can be modified using this procedure. To change other fields (such as **Data type**, **Code**, or the applicable class where the option is used), the existing option must be removed and a new option defined.
- By default, standard DHCP options and BOOTP extensions as described in RFC 2132 are predefined for use at DHCP servers running Windows Server 2003 . For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove an option

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove an option**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP
   - *applicable DHCP server*

3. On the **Action** menu, click **Set Predefined Options**.
4. In **Predefined Options and Values**, select the following:

   - For **Option class**, select the class where the option to be removed is used.
   - For **Option name**, scroll to select the user-defined option you want to remove.

5. Click **Delete**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- By default, standard DHCP options and BOOTP extensions as described in RFC 2132 are predefined at DHCP servers running Windows Server 2003 for use and cannot be removed using this procedure. For more information, see Related Topics.

# Manage Clients and Leases

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage clients and leases**

- View client lease information
- Delete a client lease
- Verify, release, or renew a client address lease
- Set DHCP class ID information at a client computer
- Show DHCP class ID information at a client computer

# View client lease information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view client lease information**

1. Open DHCP.
2. In the console tree, click **Address Leases**.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Address Leases

3. In the details pane, locate the client lease for which you want to view information.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- For most clients displayed in the DHCP console, you cannot edit the displayed lease information. Only reserved scope clients permit some of this information to be edited.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Add a client reservation
Delete a client lease

# Delete a client lease

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete a client lease**

1. Open DHCP.
2. In the console tree, click **Address Leases**.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Address Leases

3. In the details pane, click the IP address of the client you want to delete.
4. On the **Action** menu, click **Delete**.
5. Make a reservation with the IP address, or exclude it from the range.
6. Force the client with the existing lease to give it up. At the command prompt on the client computer, type **ipconfig /release**.
7. If needed, give the client a new IP address. At the command prompt on the client computer, type **ipconfig /renew**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- If you want, you can cancel leases for all clients in the scope. To cancel all current leases, select all of the clients in **Address Leases**, right-click, and then click **Delete**.
- Deleting a client lease does not prevent the server from offering that IP address again in a future client lease. It also does not prevent the client from requesting the address again, unless steps 5 to 7 are followed.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Verify, release, or renew a client address lease

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To verify, release, or renew a client address lease**

1. At a DHCP-enabled client computer running Windows XP or a member of Windows Server 2003 family, open a Command Prompt.

2. Use the Ipconfig command-line utility to verify, release, or renew the lease of the client with a DHCP server, as follows:

   - To verify a DHCP client lease, type **ipconfig** to view lease-status information.

     Or, type **ipconfig /all**.

   - To release a DHCP client lease, type **ipconfig /release**.

   - To renew a DHCP client lease, type **ipconfig /renew**.

**Note**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set DHCP class ID information at a client computer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set DHCP class ID information at a client computer**

1. At a DHCP-enabled client computer running Windows XP, open a Command Prompt.

2. Use the Ipconfig command-line utility to set the DHCP class ID the client uses when obtaining its lease from the DHCP server.

   You can type the **ipconfig /setclassid** command as demonstrated in the following example command, which sets an ASCII string ("MyNewClassId") as the DHCP class ID string for the local area network connection in use at the client computer:

```
C:\>ipconfig /setclassid "Local Area Connection" MyNewClassId

Windows XP IP Configuration

        DHCP ClassId successfully modified for adapter"Local Area Connection"
```

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command Prompt**.

- You can use the **ipconfig /showclassid** command to display all the DHCP class IDs allowed for any network adapter installed on your computer.

- For a DHCP options class to be in effect between the DHCP server and its clients, both must be configured with a matching DHCP class ID string that identifies the client as a member of a specific user or vendor options class when it obtains its address lease from the server.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Show DHCP class ID information at a client computer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To show DHCP class ID information at a client computer**

1. At a DHCP-enabled client computer running Windows XP or Windows 2000, open a Command Prompt.

2. Use the Ipconfig command-line utility to show the DHCP class ID that the client uses when obtaining its lease from the DHCP server.

   You can type the **ipconfig /showclassid** command as demonstrated in the following example command. This example shows an ASCII string ("MyNewClassId") that is currently set as the DHCP class ID for the local area network connection at the client computer:

```
C:\>ipconfig /showclassid "Local Area Connection"

Windows XP IP Configuration

DHCP Class ID for Adapter "Local Area Connection":
        DHCP ClassID Name . . . . . . . . . : Default BOOTP Class
        DHCP ClassID Description  . . . . . : User class for BOOTP clients
        DHCP ClassID Name . . . . . . . . . : Default Remote Access Class
        DHCP ClassID Description  . . . . . : User class for remote access clients

        Host Name . . . . . . . . . . . . . : HOSTA
        Primary DNS Suffix  . . . . . . . . : example.microsoft.com
        Node Type . . . . . . . . . . . . . : Hybrid
        IP Routing Enabled. . . . . . . . . : No
        WINS Proxy Enabled. . . . . . . . . : No

Ethernet adapter Local Area Connection:

        Connection-specific DNS Suffix  . :
        Description . . . . . . . . . . . . : Combo PCMCIA EthernetCard
        Physical Address. . . . . . . . . . : 00-00-00-00-7C-DC
        DHCP Enabled. . . . . . . . . . . . : Yes
        Autoconfiguration Enabled . . . . . : Yes
        IP Address. . . . . . . . . . . . . : 10.0.0.51
        Subnet Mask . . . . . . . . . . . . : 255.255.255.0
        Default Gateway . . . . . . . . . . : 10.0.0.1
        DHCP Class ID . . . . . . . . . . . : MyNewClassId
        DNS servers . . . . . . . . . . . . : 10.0.0.3
        Primary WINS server . . . . . . . . : 10.0.0.5
```

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command Prompt**.

- For a DHCP options class to be in effect between the DHCP server and its clients, both must be configured with a matching DHCP class ID string that identifies the client as a member of a specific user or vendor options class when it obtains its address lease from the server.

# Manage Reservations and Reserved Clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage reservations and reserved clients**

- Add a client reservation
- Change information for a reserved client
- Assign an option to a reserved client
- Configure advanced (class-based) options for a reserved client
- Change the reserved IP address for a client

# Add a client reservation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a client reservation**

1. Open DHCP.
2. In the console tree, click **Reservations**.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Reservations

3. On the **Action** menu, click **New Reservation**.
4. In **New Reservation**, type the information required to complete the client reservation.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**.

5. To add the client reservation to the scope, click **Add**.
6. Repeat the two previous steps for any other client reservations you want to add, and then click **Close**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- When adding a reservation, the DHCP server checks for the address you enter in the database to make sure it is not currently in use by another client.
- Reservations are applied on the basis of the DHCP client media access control (MAC) address for the applicable network connection. To locate this address, at the client computer, type **ipconfig /all** at a command prompt, and view the Physical Address for the connection. Alternately, you can right-click the connection in the Network Connections folder, and select **Properties** to view this information.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**

# Change information for a reserved client

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change information for a reserved client**

1. Open DHCP.
2. In the console tree, click **Reservations**.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Reservations

3. In the details pane, click the reserved client for which you want to change information.
4. On the **Action** menu, click **Properties**.
5. Modify the reservation properties you want to change, and then click **OK**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Reservation IP addresses cannot be modified. If you want to change the IP address of a reservation, delete the reservation, and then recreate it with the new IP address.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Assign an option to a reserved client

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To assign an option to a reserved client**

1. Open DHCP.
2. In the console tree, click **Reservations**.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Reservations

3. In the details pane, click the reserved client for which you want to assign options.
4. On the **Action** menu, click **Configure Options**.
5. In the list of **Available Options**, select the check box for the first option you want to configure.
6. Under **Data entry**, type the information required for this option.
7. Repeat the two previous steps for any other reservation options you want to specify, and then click **OK**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Reservation options configured here override option values assigned at either the server or scope levels of configuration.
- Locally defined options configured manually at the client override reservation options.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure advanced (class-based) options for a reserved client

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure advanced (class-based) options for a reserved client**

1. Open DHCP.
2. In the console tree, click **Reservations**.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Reservations

3. In the details pane, click the reserved client for which you want to assign options.
4. On the **Action** menu, click **Configure Options**.
5. Click the **Advanced** tab.
6. Select from the following:

   - For **Vendor class**, scroll to select the defined vendor class at the DHCP server (or use the default, **DHCP Standard Options**) for assigning options to the reserved client.
   - For **User class**, scroll to select the defined user class at the DHCP server (or use the default, **Default User Class**) for assigning options to the reserved client.

7. In the list of **Available Options**, select the check box for the first option you want to configure.
8. Under **Data entry**, type the information required for this option.
9. Repeat the two previous steps for any other options you want to specify, and then click **OK**.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- If a class-based option is assigned, it only applies if the reserved client is identified as a member of the specified user or vendor classes.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the reserved IP address for a client

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the reserved IP address for a client**

1. Open DHCP.
2. In the console tree, click **Reservations**.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*/Reservations

3. In the details pane, select the reserved client for which you want to change the IP address.
4. To delete the current reservation, on the **Action** menu, click **Delete**.
5. Add a new reservation in DHCP that uses the new IP address for the client.

   For more information, see Related Topics.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- The IP address in an existing client reservation cannot be modified directly. To achieve similar results, the existing reservation must be deleted and a new reservation added.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Databases

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage databases**

- Back up the DHCP database
- Move a DHCP database to another server
- Restore the DHCP database
- Set the DHCP database backup path
- Set the DHCP database path

# Back up the DHCP database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To back up the DHCP database**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server/*

3. On the **Action** menu, click **Backup**.
4. In the **Browse For Folder** dialog box, select the folder where you want to store the backup DHCP database, and then click **OK**.

## Notes

- To perform this procedure you must be a member of the Administrators group or the DHCP Administrators group on the DHCP server.
- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- You must choose a local drive for the DHCP database backup folder.
- The DHCP service creates an automatic backup of the DHCP database during normal operation. The default storage location for this copy of the database backup is *systemroot*\System32\Dhcp\Backup.
- It is recommended that you back up your DHCP database to a location other than the local drive using Windows Backup (ntbackup.exe) or non-Microsoft backup software. For more information, see Related Topics.
- When you store a manually created backup of the DHCP database in the same location as the synchronous backup that the DHCP server creates every 60 minutes, the manual backup is overwritten when automatic backup occurs.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Move a DHCP database to another server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To move a DHCP database to another server**
This topic provides details on how to move a DHCP database from one server computer (the source server) to another server computer (the destination server).

**To back up the DHCP database (at the source server)**

1. Open DHCP.

2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Backup**.

4. In the **Browse For Folder** dialog box, select the folder that will contain the backup DHCP database, and then click **OK**.

5. Stop the DHCP server.

   This prevents the server from assigning new address leases to clients after the database has been backed up.

   For more information, see Start or stop a DHCP server.

6. Disable the DHCP Server service in the list of services.

   This prevents the DHCP server from starting after the database has been transferred. For more information, see Enable or disable a service for a hardware profile.

7. Copy the folder that contains the backup DHCP database to the destination DHCP server computer.

### Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

- You must choose a local drive for the DHCP database backup folder.

- When you stop the DHCP service, DHCP clients cannot obtain address leases or renewals from the server.

- The DHCP service creates an automatic backup of the DHCP database during normal operation. The default storage location for this copy of the database backup is *systemroot*\System32\Dhcp\Backup.

**To restore the DHCP database (at the destination server)**

1. If you have not already installed the DHCP server software, install it.

   For more information, see Install a DHCP server.

2. Open DHCP.

3. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

4. On the **Action** menu, click **Restore**.

5. In the **Browse For Folder** dialog box, select the folder that contains the backup DHCP database, and then click **OK**.

## Notes

- To perform this procedure you must be a member of the Administrators group or the DHCP Administrators group on the source and destination DHCP servers.

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

- Only DHCP databases from the same language version can be restored. For example, a DHCP database from DHCP server running an English language version of the operating system cannot be restored to a DHCP server running a Japanese language version of the operating system.

- To restore the DHCP database, the DHCP service is temporarily stopped. When it is stopped, DHCP clients are unable to contact the DHCP server and obtain IP addresses.

### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Restore the DHCP database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restore the DHCP database**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP*applicable DHCP server*

3. On the **Action** menu, click **Restore**.
4. In the **Browse For Folder** dialog box, select the folder that contains the backup DHCP database, and then click **OK**.

## Notes

- To perform this procedure you must be a member of the Administrators group or the DHCP Administrators group on the DHCP server.
- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Only a DHCP database backed up from the same Windows Server version can be restored. Restoring a DHCP database from a different Windows server version is not supported. To migrate a DHCP database from one Windows Server version to another, use the netsh export/import command.
- Only DHCP databases from the same language version can be restored. For example, a DHCP database from DHCP server running an English language version of the operating system cannot be restored to a DHCP server running a Japanese language version of the operating system.
- To restore the DHCP database, the DHCP service is temporarily stopped. When it is stopped, DHCP clients are unable to contact the DHCP server and obtain IP addresses.
- For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set the DHCP database backup path

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the DHCP database backup path**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Properties**.
4. In the ***Server* Properties** dialog box, click the **Advanced** tab, click **Backup path**, and delete the default backup path (C:\WINDOWS\System32\dhcp\backup).
5. Type the backup path you prefer, or click **Browse** to select a folder location.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- This procedure describes how to specify the path DHCP uses when backing up the database. It does not set the path used by DHCP to store the primary database on the applicable server.
- By default, the DHCP database is automatically backed up every hour. However, when you change the backup folder location, an automatic backup of the database does not occur. You can back up the database immediately after changing the backup folder location by using **Backup** on the DHCP console **Action** menu. Automatic backups will then occur every hour.
- For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set the DHCP database path

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the DHCP database path**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Properties**.
4. In ***Server* Properties**, click the **Advanced** tab, select **Database path**, and then delete the default database path (C:\WINDOWS\System32\Dhcp).
5. Type the path you prefer, or click **Browse** to select a folder location.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- This procedure describes how to specify the path DHCP uses when storing the database on the applicable DHCP server. It does not set the path used by DHCP when you back up a database with the **Backup** command.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage BOOTP and Remote Access Clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage BOOTP and remote access clients**

- View the BOOTP table
- Add an entry to the BOOTP table
- Add dynamic BOOTP client support to a scope
- Change the lease time for remote access clients

# View the BOOTP table

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view the BOOTP table**

1. Open DHCP.
2. In the console tree, click the applicable DHCP server.

   **Where?**

   - DHCP/*applicable DHCP server*

3. On the **Action** menu, click **Properties**.
4. Verify that the **Show the BOOTP table folder** check box is selected.

   If the check box is cleared, select it and then click **OK**.

5. In the console tree, click **BOOTP Table**.

   **Where?**

   - DHCP/*applicable DHCP server*/BOOTP Table

   BOOTP entries, if any have been added to the BOOTP table, appear in the details pane.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- By default, the BOOTP table is empty. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add an entry to the BOOTP table

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add an entry to the BOOTP table**

1. Open DHCP.
2. In the console tree, click **BOOTP Table**.

   **Where?**

   - DHCP/*applicable DHCP server*/BOOTP Table

   If the BOOTP table does not appear, see Related Topics.
3. On the **Action** menu, click **New Boot Image**.
4. In the **Add BOOTP Entry** dialog box, enter the required information.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**.
5. Click **Add**.
6. Repeat the previous two steps for each additional BOOTP entry you want to add, and then click **Close**.

**Note**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add dynamic BOOTP client support to a scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add dynamic BOOTP client support to a scope**

1. Open DHCP.
2. In the console tree, click the applicable scope.

   **Where?**

   - DHCP/*applicable DHCP server*/*applicable superscope* (if used)/*applicable scope*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. For **Assign IP addresses dynamically to clients of**, click either **Both** or **BOOTP only**.
6. If needed, in **Lease duration for BOOTP clients** adjust the default lease length.

   The lease length is used by the DHCP server to determine how long to preserve leases made dynamically for BOOTP clients of the applicable scope.

## Notes

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.
- Unlike DHCP, where clients can initiate a protocol message to release or renew their address lease, BOOTP clients can only obtain or negotiate their IP address lease at boot time. For this reason, it is recommended that you select a lease length for BOOTP clients that exceeds the time between when BOOTP clients are restarted on the network.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the lease time for remote access clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the lease time for remote access clients**

1. Open DHCP.
2. In the console tree, click **Scope Options**.

   **Where?**

   - DHCP/*applicable DHCP server/applicable scope*

3. Right-click **Scope Options** and click **Configure Options**.
4. Click **Advanced**.
5. In **User class**, select **Default Routing and Remote Access Class**.
6. In **Available Options**, click the check box for **051 Lease**.
7. In **Long**, type the lease value in seconds.

   For example, if you want the lease time to be one hour, type: 3600

**Note**

- To open DHCP, click **Start**, click **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DHCP**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Use DHCP Command-line Tools

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Use DHCP command-line tools**

- Use DHCP commands interactively at the command prompt
- Use DHCP commands non-interactively or in scripts

# Use DHCP commands interactively at the command prompt

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To use DHCP commands interactively at the command prompt**

1. Open Command Prompt.
2. Type **netsh**.
3. At the **netsh>** command prompt, type **dhcp**.
4. At the **dhcp>** command prompt, type:

   **server***ServerName*

   Or, type:

   **server***IPAddress*

   Where *ServerName* and *IPAddress* are the server that you want to manage.
5. Once connected, you can use any supported Netsh DHCP context command. Type **/?** or **help** to display the immediate context command menu, or type **list** to list all of the Netsh DHCP context commands available for use.

## Notes

- You must be a member of the Administrators group or the DHCP Administrators group to administer DHCP servers using the DHCP console or the Netsh commands for DHCP. You should restrict the membership of these groups to the minimum number of users necessary to administer the server. In addition, only members of the Domain Admins group can authorize or unauthorize a DHCP server in Active Directory. If there are users who need read-only access to the DHCP console, add them to the DHCP Users group instead of the DHCP Administrators group. For more information about using Netsh commands for DHCP, see Related Topics.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- The *****ServerName* parameter is optional and can be left unspecified if you are performing commands locally at the DHCP server. If the server being managed is remote, this parameter is required, and the name of the server must be specified.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Use DHCP commands non-interactively or in scripts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To use DHCP commands non-interactively or in scripts**

1. Open Command Prompt.

2. At the command prompt or in scripted usage, you can use Netsh commands for DHCP non-interactively by using the following fully qualified command syntax:

   **netsh dhcp server** [****_ServerName_] _SubCommand_

## Notes

- You must be a member of the Administrators group or the DHCP Administrators group to administer DHCP servers using the DHCP console or the Netsh commands for DHCP. You should restrict the membership of these groups to the minimum number of users necessary to administer the server. In addition, only members of the Domain Admins group can authorize or unauthorize a DHCP server in Active Directory. If there are users who need read-only access to the DHCP console, add them to the DHCP Users group instead of the DHCP Administrators group. For more information about using Netsh commands for DHCP, see Related Topics.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- The ****_ServerName_ parameter is optional and can be left unspecified if you are performing commands locally at the DHCP server. If the server being managed is remote, this parameter is required, and the name of the server must be specified.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Security information for DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security information for DHCP**
It is important to follow best practices for security when using DHCP servers on your network. For more information, see Best practices for security.

The following are known security issues for DHCP and related protocols:

- **DHCP is an unauthenticated protocol.**

  When a user connects to the network, the user is not required to provide credentials in order to obtain a lease. An unauthenticated user can, therefore, obtain a lease for any DHCP client whenever a DHCP server is available to provide a lease. Any option values that the DHCP server provides with the lease, such as WINS server or DNS server IP addresses, are available to the unauthenticated user. If the DHCP client is identified as a member of a user class or vendor class, the options that are associated with the class are also available.

  Malicious users with physical access to the DHCP-enabled network can instigate a denial-of-service attack on DHCP servers by requesting many leases from the server, thereby depleting the number of leases that are available to other DHCP clients.

  **Recommendations:**

  - Ensure that unauthorized persons do not have physical or wireless access to your network.

  - Enable audit logging for every DHCP server on your network. Regularly check audit log files, and monitor them when the DHCP server receives an unusually high number of lease requests from clients. Audit log files provide the information that you need to track the source of any attacks made against the DHCP server. The default location of audit log files is %windir%\System32\Dhcp. For more information, see Enable DHCP server logging, Audit logging, and Analyzing server log files. You can also check the system event log for explanatory information about the DHCP Server service.

    **Note**

When clients running Microsoft® Windows® XP use 802.1X-enabled local area network (LAN) switches or wireless access points to access the network , authentication occurs before the DHCP server assigns a lease, thereby providing greater security for DHCP.

- **Denial-of-service attacks against the DNS server can be made through the DHCP server.**

  When the DHCP server is configured to act as a DNS proxy server for DHCP clients and to perform DNS dynamic updates, it is possible for a malicious user to perform a denial-of-service attack against both the DHCP server and the DNS server by flooding the DHCP server with requests for leases.

  **Recommendations:**

  - Ensure that unauthorized persons do not have physical or wireless access to your network.

  - Use the DHCP audit logs, located by default at %windir%\System32\Dhcp, to monitor DNS dynamic updates by the DHCP server. The following event IDs are used for DNS dynamic update events:

| Event ID | DHCP Event |
|---|---|
| 30 | DNS dynamic update request to the DNS server |

| | |
|---|---|
| 31 | DNS dynamic update failed |
| 32 | DNS dynamic update successful |

The IP address of the DHCP client is included in the DHCP audit log, providing the ability to track the source of the denial-of-service attack. For more information, see Analyzing server log files and Audit logging.

- **Unauthorized, non-Microsoft DHCP servers can lease IP addresses to DHCP clients.**

  Only DHCP servers running Windows 2000 or Windows Server 2003 can be authorized in Active Directory®. If a DHCP server running Windows 2000 or Windows Server 2003 discovers it is not authorized in Active Directory, the DHCP server stops servicing DHCP clients. Because of this authorization feature, if a malicious or incompetent user installs an unauthorized DHCP server running Windows 2000 or Windows Server 2003 on the organization network, the server cannot assign incorrect or conflicting leases, configure DHCP clients with inaccurate options, or disrupt network services.

  Non-Microsoft DHCP server software does not include the authorization feature that is included in Windows 2000 and Windows Server 2003 DHCP. Because DHCP clients broadcast DHCP discover messages to the nearest DHCP server, if a malicious user installs a non-Microsoft DHCP server on the organization network, nearby DHCP clients will receive incorrect leases that might conflict with the IP addresses assigned to other DHCP clients on the network. In addition, DHCP clients that obtain a lease from the non-Microsoft DHCP server can be configured by the server with option information that is inaccurate. This might reroute network traffic, causing the network to function improperly.

  **Recommendation:**

  - Ensure that unauthorized persons do not have physical or wireless access to your network.

**Additional recommendations**

Before you install and configure DHCP for your network, consider:

- **Restricting who can administer the DHCP service.**

  You must be a member of the Administrators group or the DHCP Administrators group to administer DHCP servers using the DHCP console or the Netsh commands for DHCP. In addition, only members of the Domain Admins group can authorize or unauthorize a DHCP server in Active Directory. Restrict the membership of these groups to the minimum number of users necessary to administer the server.

  If there are users who need read-only access to the DHCP console, add them to the DHCP Users group instead of to the DHCP Administrators group. For more information, see DHCP groups.

# DHCP defined

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP defined**

Dynamic Host Configuration Protocol (DHCP) is an IP standard for simplifying management of host IP configuration. The DHCP standard provides for the use of DHCP servers as a way to manage dynamic allocation of IP addresses and other related configuration details for DHCP-enabled clients on your network.

Every computer on a TCP/IP network must have a unique IP address. The IP address (together with its related subnet mask) identifies both the host computer and the subnet to which it is attached. When you move a computer to a different subnet, the IP address must be changed. DHCP allows you to dynamically assign an IP address to a client from a DHCP server IP address database on your local network:

For TCP/IP-based networks, DHCP reduces the complexity and amount of administrative work involved in reconfiguring computers.

The Microsoft® Windows Server 2003 family provides an RFC-compliant DHCP service you can use to manage IP client configuration and automate IP address assignment on your network.

# Benefits of using DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Benefits of using DHCP**

DHCP provides the following benefits for administering your TCP/IP-based network:

- **Safe and reliable configuration**

  DHCP avoids configuration errors caused by the need to manually type in values at each computer. Also, DHCP helps prevent address conflicts caused by a previously assigned IP address being reused to configure a new computer on the network.

- **Reduces configuration management**

  Using DHCP servers can greatly decrease time spent configuring and reconfiguring computers on your network. Servers can be configured to supply a full range of additional configuration values when assigning address leases. These values are assigned using DHCP options.

  Also, the DHCP lease renewal process helps assure that where client configurations need to be updated often (such as users with mobile or portable computers who change locations frequently), these changes can be made efficiently and automatically by clients communicating directly with DHCP servers.

# How DHCP works

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How DHCP works**

DHCP uses a client-server model. The network administrator establishes one or more DHCP servers that maintain TCP/IP configuration information and provide it to clients. The server database includes the following:

- Valid configuration parameters for all clients on the network.
- Valid IP addresses maintained in a pool for assignment to clients, plus reserved addresses for manual assignment.
- Duration of a lease offered by the server. The lease defines the length of time for which the assigned IP address can be used.

With a DHCP server installed and configured on your network, DHCP-enabled clients can obtain their IP address and related configuration parameters dynamically each time they start and join your network. DHCP servers provide this configuration in the form of an address-lease offer to requesting clients.

# DHCP terminology

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP terminology**

| Term | Description |
|---|---|
| scope | A *scope* is the full consecutive range of possible IP addresses for a network. Scopes typically define a single physical subnet on your network to which DHCP services are offered. Scopes also provide the primary way for the server to manage distribution and assignment of IP addresses and any related configuration parameters to clients on the network. |
| superscope | A *superscope* is an administrative grouping of scopes that can be used to support multiple logical IP subnets on the same physical subnet. Superscopes only contain a list of *member scopes* or *child scopes* that can be activated together. Superscopes are not used to configure other details about scope usage. For configuring most properties used within a superscope, you need to configure member scope properties individually. |
| exclusion range | An *exclusion range* is a limited sequence of IP addresses within a scope, excluded from DHCP service offerings. Exclusion ranges assure that any addresses in these ranges are not offered by the server to DHCP clients on your network. |
| address pool | After you define a DHCP scope and apply exclusion ranges, the remaining addresses form the available *address pool* within the scope. Pooled addresses are eligible for dynamic assignment by the server to DHCP clients on your network. |
| lease | A *lease* is a length of time that a DHCP server specifies, during which a client computer can use an assigned IP address. When a lease is made to a client, the lease is *active*. Before the lease expires, the client typically needs to renew its address lease assignment with the server. A lease becomes *inactive* when it expires or is deleted at the server. The duration for a lease determines when it will expire and how often the client needs to renew it with the server. |
| reservation | You use a *reservation* to create a permanent address lease assignment by the DHCP server. Reservations assure that a specified hardware device on the subnet can always use the same IP address. |
| option types | *Option types* are other client configuration parameters a DHCP server can assign when serving leases to DHCP clients. For example, some commonly used options include IP addresses for default gateways (routers), WINS servers, and DNS servers. Typically, these option types are enabled and configured for each scope. The DHCP console also permits you to configure default option types that are used by all scopes added and configured at the server. Most options are predefined through RFC 2132, but you can use the DHCP console to define and add custom option types if needed. |
| options class | An *options class* is a way for the server to further manage option types provided to clients. When an options class is added to the server, clients of that class can be provided class-specific option types for their configuration. For Microsoft® Windows® 2000 and Windows XP, client computers can also specify a class ID when communicating with the server. For earlier DHCP clients that do not support the class ID process, the server can be configured with default classes to use instead when placing clients in a class. Options classes can be of two types: vendor classes and user classes. |

# DHCP tools

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP tools**
The primary tools that you use to manage DHCP servers are the DHCP console and the Netsh commands for DHCP.

**The Netsh commands for DHCP**
You can type the Netsh commands for DHCP in a command prompt window at the **netsh dhcp>** command prompt, or you can execute the Netsh commands for DHCP in batch files and other scripts. All of the functionality that is available in the DHCP console is available at the **netsh dhcp>** command prompt.

For more information about Netsh commands for DHCP (including syntax, parameters, and examples), see Netsh commands for DHCP. For an example of how to use Netsh commands for DHCP in batch files and scripts, see Netsh DHCP example.

**The DHCP console**
The DHCP console is added to the Administrative Tools folder in Control Panel when you install a DHCP server running Windows Server 2003. The DHCP console appears as a Microsoft Management Console (MMC) snap-in, to further integrate DHCP administration into your total network management.

After you install a DHCP server, you can use the DHCP console or the Netsh commands for DHCP to perform these basic administrative server tasks:

1. Create scopes.
2. Add and configure superscopes and multicast scopes.
3. View and modify scope properties for scopes, such as setting additional exclusion ranges.
4. Activate scopes, multicast scopes, or superscopes.
5. Monitor scope leasing activity by reviewing the active leases for each scope.
6. Create reservations in scopes as needed for DHCP clients that require a permanent IP address for leased use.

In addition, you can also use the DHCP console or the Netsh commands for DHCP to perform the following optional or advanced setup tasks:

- Add new custom default option types.
- Add and configure any user or vendor-defined option classes.
- Further configure other server properties, such as audit logging or BOOTP tables.

The DHCP console also contains enhancements that were suggested by network managers. These include enhanced server performance monitoring, more predefined DHCP option types, dynamic update support for clients running earlier versions of Windows, and detection of unauthorized DHCP servers on your network.

**Notes**

- The Microsoft® Windows Server 2003 family includes new features beyond those provided in earlier versions. For more information, see New features for DHCP.
- The DHCP console provides new ways to perform familiar DHCP administrative tasks previously performed in Windows NT® 4.0 using DHCP Manager. For more information, see New ways to do DHCP tasks.
- For a simple list of Netsh commands for DHCP (not including syntax, parameters, and examples), see Managing DHCP

from the command line. To learn more about using the Netsh command-line tool, see Use DHCP Command-line Tools.

- DHCP servers running Windows 2000 cannot be authorized in Active Directory® using the Windows Server 2003 administrative tools (the DHCP console and the Netsh commands for DHCP) unless Windows 2000 Server Service Pack 2 is installed.

# Multicast address allocation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multicast address allocation**
DHCP servers running Microsoft® Windows Server 2003 allow the assignment of multicast addresses, in addition to the assignment of unicast addresses.

A proposed Internet Engineering Task Force (IETF) standard defines a client/server protocol, the Multicast Address Dynamic Client Allocation Protocol (MADCAP), for defining multicast address allocation between supporting servers and clients. The primary benefit of the proposed MADCAP standard is that you can use it to leverage your existing network infrastructure for assigning multicast addresses in the same way as other IP addresses are currently assigned using DHCP.

Typical applications for multicast are conferencing and audio, which usually require users to specially configure multicast addresses. Unlike IP broadcasts, which are received by all computers or other hosts on the network, a multicast address is a group of computers, using the concept of a group membership to identify the computers to which the message is to be sent.

The multicast address allocation feature has two parts:

1. A MADCAP server, which distributes multicast addresses.

   To use this feature, the administrator first configures multicast scopes and the corresponding multicast IP ranges on the server, through the DHCP console. Once these scopes are configured and activated, the DHCP Server service can provide multicast addresses in the same way it normally provides unicast IP addresses where DHCP scopes are used.

2. Client-side application programming interfaces (APIs), which MADCAP clients can use to request, renew, or release multicast addresses.

   Applications that implement MADCAP client support can call these APIs to request a multicast address from a given multicast scope at the MADCAP server. The underlying MADCAP implementation uses protocol messages similar to the DHCP messaging format to negotiate the multicast address lease between the client and server.

For more information, see Using multicast scopes.

**Notes**

- The standards for multicast address allocation are managed by the Multicast address-allocation (MALLOC) working group of the IETF.

- You can obtain RFCs from the Request for Comments Web site.

  This Web site is currently maintained by members of the Information Sciences Institute (ISI), who publish a classified listing of all RFCs. RFCs are classified as one of the following: approved Internet standard, proposed Internet standard (circulated in draft form for review), Internet best practices, or For Your Information (FYI) documents.

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# New features for DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New features for DHCP**

Microsoft® Windows Server 2003 Dynamic Host Configuration Protocol (DHCP) provides the following new features:

- **DHCP client alternate configuration**

  With DHCP client alternate configuration, you can easily move a computer between two or more networks, one configured with static IP addresses and one or more configured with DHCP, without needing to reconfigure network adapter parameters, such as IP address, subnet mask, default gateway, preferred and alternate Domain Name Service (DNS) servers, and Windows Internet Name Service (WINS) servers. For more information, see DHCP client alternate configuration and Use DHCP client alternate configuration.

- **DHCP database backup and restore**

  You can back up and restore the DHCP database using the **Backup** and **Restore** commands in the DHCP console. For more information about the **Backup** command, see Backing up the DHCP database and Back up the DHCP database. For more information about the **Restore** command, see Restoring server data and Restore the DHCP database.

The following features were new for Windows 2000 Server and are also provided with the Windows Server 2003 family:

- **Local groups for providing limited server and console access to DHCP administrators and users**

  Two local administrative groups are created when a DHCP server is installed on a server computer: the DHCP Users and DHCP Administrators groups. The DHCP Users group can be used to provide read-only console access to the server. Where used, this group grants members the ability to view, but not modify, server data.

  The DHCP Administrators group provides a higher level of administrative access. Members added to this group can fully manage and modify any data at the DHCP server, but are not provided full unlimited administrative access, such as if the local Administrators group were used instead to provide administrative access to the applicable DHCP server. For more information, see DHCP groups.

- **Automatic assignment of IP addresses**

  For Windows 98, Windows 2000, Windows XP, and the Windows Server 2003 family, DHCP-enabled clients are automatically assigned a temporary IP configuration if a DHCP server is unavailable to provide a lease when the client starts on a network. For DHCP clients running these versions of Windows, the client tries to contact a DHCP server in the background every five minutes to eventually obtain its valid IP address lease.

  Automatic assignment is always transparent to users, who are not prompted if the client fails to obtain a lease from a DHCP server. Addresses are self-assigned from a network address range that is reserved for private TCP/IP usage and not used on the Internet.

- **Enhanced performance monitoring and server reporting capabilities**

  DHCP is critical to the success of your network infrastructure. Without working DHCP servers, IP clients can lose some or all of their ability to access or use your network. Because many experienced network administrators realize the importance of closely monitoring DHCP servers, several changes have been made to assist in this area.

  Performance monitoring counters are available on computers running Windows 2000 or Windows Server 2003 operating systems to help you monitor DHCP server performance on your network. For more information, see Monitoring DHCP server performance.

- **Expanded scope support for multicast scopes and superscopes**

Microsoft DHCP server supports additional scopes that you can use to streamline your ongoing administration of IP address configurations.

New multicast scopes make it possible for DHCP-enabled clients to lease Class D-type IP addresses (224.0.0.0 to 239.255.255.255) for participation in multicast groups. For more information, see Using multicast scopes.

Superscopes (a late addition to Windows NT® Server 4.0) are useful for creating an administrative grouping of member scopes. Superscopes can be helpful when you want to renumber or expand the IP address space on your network without disturbing currently active scopes. For more information, see Using superscopes.

- **Support for user-specified and vendor-specified option classes**

  You can use this feature to separate and distribute appropriate options for clients with similar or special configuration needs.

  For example, you might assign all DHCP-enabled clients on the same floor of your building to the same option class. You could use this class (configured with the same DHCP Class ID value) to distribute other options data during the lease process, overriding any scope or global default options. In this way, options appropriate to a set of class-member clients in the same network location (such as a specific default gateway or parent domain name) are applied as class-specific options. For more information, see Using option classes.

- **Integration of DHCP with DNS**

  A DHCP server running Windows 2000 or Windows Server 2003 can enable dynamic updates in the DNS namespace for any of its clients that support these updates. Scope clients can then use DNS dynamic update protocol to update their host name-to-address mapping information (which is stored in *zones* on the DNS server) whenever changes occur to their DHCP-assigned address. For more information, see Using DNS servers with DHCP.

- **Detection of unauthorized DHCP servers through the use of Active Directory® integration**

  When a DHCP server is unintentionally started on a network, it can cause a variety of network problems. To prevent this scenario from occurring, Windows 2000 Server and the Windows Server 2003 family provide a method for authorizing a DHCP server as well as a means to detect and shut down unauthorized servers.

  When a domain member DHCP server running Windows 2000 or Windows Server 2003 attempts to start on the network, Active Directory is queried, and the IP address of the server is compared to the list of authorized DHCP servers. If a match is found, the server computer is authorized as a DHCP server. If a match is not found, the following occurs:

  - The server is not authorized in Active Directory.
  - The server is identified as an unauthorized server.
  - The server stops leasing IP addresses to DHCP clients.

  In order to use DHCP server authorization, you must deploy Active Directory and the DHCP service on a server running Windows 2000 or Windows Server 2003 . Other DHCP servers do not support this feature.

  For more information, see Authorizing DHCP servers.

- **Dynamic support for BOOTP clients.**

  The DHCP service provides additional support for BOOTP clients in large enterprise networks through the addition of *dynamic BOOTP*.

  Dynamic BOOTP is an extension of the BOOTP protocol that permits the DHCP server to configure BOOTP clients without having to use explicit fixed address configuration. This feature provides easier administration of large BOOTP networks by allowing automatic distribution of IP addresses (much the same way that DHCP does) without having to change client

side behavior.

# Planning DHCP networks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning DHCP networks**

This topic covers the following DHCP network planning issues.

- How to determine the number of DHCP servers to use
- How to support DHCP clients on additional subnets
- Planning for routed DHCP networks
- Other planning considerations for enterprise networks

**How to determine the number of DHCP servers to use**

Because there is no fixed limit to the maximum number of clients a DHCP server can service or to the number of scopes you can create on a DHCP server, the primary factors to consider when you determine the number of DHCP servers to use are network architecture and server hardware. For example, in a single subnet environment, only one DHCP server is necessary, although you may want to use two servers or deploy a DHCP server cluster for increased fault tolerance. In multiple subnet environments, routers must forward DHCP messages between subnets, so router performance can affect your DHCP service. In both cases, DHCP server hardware affects service to clients.

For more information on deploying a DHCP server cluster, see Cluster support for DHCP servers.

When you determine the number of DHCP servers to use, consider the following:

- The location of routers on the network and whether you want a DHCP server on each subnet.

  When you extend the use of a DHCP server across more than one network, you often need to configure additional DHCP relay agents and, in some cases, use superscopes as well.

- The transmission speed between the segments for which DHCP service is provided.

  If you have slower WAN links or dial-up links, you may need a DHCP server on both sides of these links to service clients locally.

- The speed of the server disk drives and the amount of random access memory (RAM) installed in the DHCP server computer.

  In order to maximize DHCP server performance, use the fastest disk drives and the most RAM possible. Carefully evaluate disk access time and average times for disk read and write operations when you plan for your DHCP server hardware needs.

- Practical constraints based on the IP address class selected for use and other server configuration details.

You can test your DHCP servers before deployment on the organization network in order to determine the limitations and abilities of your hardware and to see whether network architecture, traffic, and other factors affect DHCP server performance. Hardware and configuration tests also allow you to determine the number of scopes to configure at each server.

To provide a general idea of DHCP server performance, a DHCP server running Microsoft® Windows Server 2003 was run in a test lab environment, and a custom stress application was used against the server. The details of this lab test can help you configure your tests and determine how many DHCP servers to use on your network:

**Server and network configuration**

- Processors: Two x86 Family 6 Model 7 Stepping 3 GenuineIntel ~498 megahertz (MHz)

- Total physical memory: 256.00 megabytes (MBs)
- Network adapters: Three Ethernet 802.3 100 megabits per second (mbps)
- Subnets serviced: Six, four of which are separated from the test server by routers running the DHCP Relay Agent service.
- Operating system: Windows Server 2003, Enterprise Edition
- Number of scopes: 5,155
- DHCP database size at maximum load: 2 gigabytes (GBs)
- Additional factors: Several thousand exclusion ranges, option values, and reservations are configured in the scopes on the server.

**Test details**
The DHCP server was hit with both valid and invalid DHCP client lease and renewal requests from a client/attack simulation stress application on six subnets for 1,152 hours (48 days).

**Test results**
The DHCP server provided clients with the following service during the test:

| DHCP server function | Message and lease volume handled (1,152 hours) |
|---|---|
| Lease assignments | 68,412,059 |
| DHCP discover messages | 20,039,592 |
| DHCP offer messages | 20,039,253 |
| DHCP request messages | 57,559,426 |
| DHCP acknowledgement messages | 57,470,934 |
| DHCP negative acknowledgement messages sent by the server | 484,012 |
| DHCP decline messages | 190,901 |
| Lease releases | 0 |

**Notes**

- These test results are intended to provide a general idea of DHCP server performance capacity. Tests were performed on average hardware and do not imply any limitation of the DHCP service. In addition, the large size of the test DHCP server database (2 GBs) is extremely unusual and was produced due to the high volume of DHCP traffic that the test application generated. In real world environments, typical database sizes are in the tens of MBs or less.
- When you add a large number of scopes to the server, be aware that each scope creates a corresponding need for additional, incremental increases to the amount of disk space used for the DHCP server registry and for the server paging file. For more information, see Change the size of the virtual memory paging file.
- DHCP servers running Windows Server 2003 provide performance monitoring tools that you can use to test and monitor your servers. For more information, see Monitoring DHCP server performance.

**A DHCP planning alternative: configuring standby servers**
Most networks need one primary online DHCP server and one other DHCP server acting as a secondary or backup server. If you choose not to implement two DHCP servers using the 80/20 rule for balancing scopes but want to continue to provide a measure of potential fault tolerance, you might consider implementing a backup or hot standby DHCP server as an alternative.

For more information, see the section "Using the 80/20 rule for scopes" in Configuring scopes.

In the hot standby configuration, the standby DHCP server is another server computer that is installed and configured identically to your primary DHCP server. In the case of the standby, the only difference is that the standby server and its scopes are not activated for use under normal conditions. Duplicate scopes are configured but not activated except when critically needed, such as to substitute for the primary DHCP server because it has stopped or been taken offline for an extended period of time.

Because the hot standby solution requires special attention to its configuration and also manual administration for ensuring fall-over transition for DHCP clients to use it, it is less recommended as a planning alternative than the use of two to three DHCP servers that balance active scope use.

**Supporting additional subnets**
For DHCP service to support additional subnets on your network, you must first determine whether the routers used to connect adjoining subnets can support relaying of BOOTP and DHCP messages. If routers cannot be used for DHCP and BOOTP relay, you can set up either of the following for each subnet:

- A computer running Windows NT® Server 4.0, Windows 2000 Server, or a Windows Server 2003 operating system configured to use the DHCP Relay Agent component.

  This computer simply forwards messages back and forth between clients on the local subnet and a remote DHCP server, using the IP address of the remote server. The DHCP Relay Agent service is available only on computers running Windows NT Server 4.0, Windows 2000 Server, or Windows Server 2003 operating systems.

- A computer running a Windows Server 2003 operating system configured as a DHCP server for the local subnet.

  This server computer must contain and manage scope and other address-configurable information for the local subnet it serves.

For more information, see Relay agent configurations.

**Planning for routed DHCP networks**
In routed networks that use subnets to divide network segments, planning options for DHCP services must observe some specific requirements for a full implementation of DHCP services to function. These requirements include:

- One DHCP server must be located on at least one subnet in the routed network.

- For a DHCP server to support clients on other remote subnets separated by routers, a router or remote computer must be used as a DHCP and BOOTP relay agent to support forwarding of DHCP traffic between subnets.

The following illustration shows a simple routed network with DHCP implemented.

**Enterprise planning considerations**
For an enterprise DHCP network, you should:

- Plan the physical subnets of the network and relative placement of DHCP servers.

- Specify the DHCP option types and their values to be predefined per scope for the DHCP clients.

  This can include planning for scopes based on the needs of particular groups of users. For example, a unit that frequently moves computers to different locations, like a marketing group that uses portable computers docked at different stations, shorter lease durations can be defined for the related scopes. This approach collects IP addresses that are changed

frequently and disposed of and returns them to the pool of available addresses that can be used for new lease offerings.

- Recognize the impact that slower links have on your WAN environment.

  Place DHCP, WINS, and DNS servers to maximize response time and minimize low-speed traffic.

As one example of planning for a large enterprise network, the segmenting of the WAN into logical subnets can match the physical structure of the internetwork. Then one IP subnet can serve as the backbone and, this backbone in relation to each physical subnet maintains a separate IP subnet address.

# Understanding DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding DHCP**
This section covers:

- DHCP servers
- DHCP options
- DHCP groups
- Understanding user and vendor classes
- BOOTP and DHCP
- The DHCP database
- Audit logging
- DHCP client alternate configuration
- DHCP/BOOTP Relay Agents

# DHCP servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP servers**

Configuring DHCP servers for a network provides the following benefits:

- The administrator can assign and specify global and subnet-specific TCP/IP parameters centrally for use throughout the entire network.
- Client computers do not require manual TCP/IP configuration.
- When a client computer moves between subnets, its old IP address is freed for reuse. The client reconfigures its TCP/IP settings automatically when the computer is restarted in its new location.
- Most routers can forward DHCP and BOOTP configuration requests, so DHCP servers are not required on every subnet in the network.

**How clients use servers**

A computer running Windows XP becomes a DHCP client if **Obtain an IP address automatically** is selected in its TCP/IP properties. When a client computer is set to use DHCP, it accepts a lease offer and can receive from the server the following:

- Temporary use of an IP address known to be valid for the network it is joining.
- Additional TCP/IP configuration parameters for the client to use in the form of *options* data.

Also, if conflict detection is configured, the DHCP server attempts to ping each available address it intends to offer prior to presenting the address in a lease offer to a client. This ensures that each IP address offered to clients is not already in use by another non-DHCP computer that uses manual TCP/IP configuration.

**How servers provide optional data**

In addition to an IP address, DHCP servers can be configured to provide optional data to fully configure TCP/IP for clients. Some of the most common DHCP option types configured and distributed by the DHCP server during leases include:

- Default gateways (routers), which are used to connect a network segment to other network segments.
- Other optional configuration parameters to assign to DHCP clients, such as IP addresses for the DNS servers or WINS servers that the client can use in resolving network host names.

For more information, see DHCP options.

# DHCP options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP options**

DHCP provides an internal framework for passing configuration information on to clients on your network. Configuration parameters and other control information are carried in tagged data items stored within protocol messages exchanged between the DHCP server and its clients. These data items are called *options*.

Most standard DHCP options are currently defined in Request for Comments (RFCs) published by the Internet Engineering Task Force (IETF). The full set of standard DHCP options are described specifically in RFC 2132, "DHCP Options and BOOTP Vendor Extensions."

All DHCP options mentioned in RFC 2132 are predefined for you to configure and use at any DHCP server running Windows Server 2003 . If needed, you can also use the DHCP console to define new DHCP options at each server.

Even though most DHCP servers can assign many options, most DHCP clients are typically designed to request or support only a subset of the full RFC-specified standard options set.

- For more information about DHCP options, see "DHCP Options" at the Microsoft Windows Resource Kits Web site.

**How options are applied**

Options can be managed using different levels assigned for each managed DHCP server, including:

- **Server options** These options are applied for all scopes defined at a DHCP server.
- **Scope options** These options are applied specifically to all clients that obtain a lease within a particular scope.
- **Class options** These options are applied only to clients that are identified as members of a specified user or vendor class when obtaining a lease.
- **Reservation options** These options apply only for a single reserved client computer and require a reservation to be used in an active scope.

For more information, see Setting Up Options.

# DHCP groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP groups**
When you install the DHCP Server service, two domain local groups are created: DHCP Users and DHCP Administrators.

**DHCP Users**
Members of the DHCP Users group have read-only DHCP console access to the server, which allows DHCP Users to view, but not to modify, server data, including DHCP server configuration, registry keys, DHCP log files, and the DHCP database. DHCP Users cannot create scopes, modify option values, create reservations or exclusion ranges, or modify the DHCP server configuration in any other way.

**DHCP Administrators**
Members of the DHCP Administrators group can view and modify any data at the DHCP server. DHCP Administrators can create and delete scopes, add reservations, change option values, create superscopes, or perform any other activity needed to administer the DHCP server, including export or import of the DHCP server configuration and database. DHCP Administrators perform these tasks using the Netsh commands for DHCP or the DHCP console. For more information, see DHCP tools.

Members of the DHCP Administrators group do not have unlimited administrative rights. For example, if a DHCP server is also configured as a DNS server, a member of the DHCP Administrators group can view and modify the DHCP configuration but cannot modify DNS server configuration on the same computer.

Because members of the DHCP Administrators group have rights on the local computer only, DHCP Administrators cannot authorize or unauthorize DHCP servers in Active Directory. Only members of the Domain Admins group can perform this task. If you want to authorize or unauthorize a DHCP server in a child domain, you must have enterprise administrator credentials for the parent domain. For more information about authorizing DHCP servers in Active Directory, see Authorizing DHCP servers and Authorize a DHCP server in Active Directory.

**Note**

- To be logged on as an enterprise administrator, you must log on using a member account in the Enterprise Admins group. By default, this is done by logging on as local administrator at the first domain controller created in your enterprise.

**Using groups to administer DHCP servers in a domain**
When you add a user or group to a DHCP Users or DHCP Administrators group on a DHCP server, the rights of the DHCP group member do not apply to all of the DHCP servers in the domain. The rights apply only to the DHCP service on the local computer. In order to assign rights to a user or group that apply to all of the DHCP servers in the domain, you can add the user or group to the DHCP Administrators group on each DHCP server in the domain. This approach is practical only on a small network with one or two DHCP servers.

An alternative approach is to add the user or group to the global group called Domain Admins. Members of the Domain Admins group can administer all of the DHCP servers in the domain, however the administrative rights of Domain Admins are not limited to the DHCP service on each DHCP server. Domain Admins have complete administrative rights on all of the computers in the domain. For this reason, it is recommended that you do not add users or groups to the Domain Admins group solely because you want to assign administrative rights for the DHCP service on all of the DHCP servers in the domain.

If you have more than two DHCP servers on your network, you can use the following steps to most effectively add members to a DHCP group:

1. In the Active Directory Users and Computers console, create a group with universal or global scope. For more information, see Create a new group.

2. Add users or groups to the new group you created. For more information, see Add a member to a group.

3. At each DHCP server in the domain, add the new group (that you created in the first step) to either the DHCP Users group or the DHCP Administrators group, depending on the rights and permissions that you want group members to have.

For more information about how to add members to groups and other related tasks, see Manage Server Access.

For more information about groups, see Group scope and Default groups.

For more information about delegating administrative credentials, see Delegate ability to authorize DHCP servers to a non-enterprise administrator.

# Understanding user and vendor classes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding user and vendor classes**

There are significant differences in the way in which vendor and user classes are available for use by DHCP clients and servers. The following table compares and contrasts the features of these classes.

| User classes | Vendor classes |
|---|---|
| Part of proposed DHCP standard drafts.<br><br>For updated information, obtain the latest draft from the Request for Comments Web site. | Part of accepted DHCP standard drafts (RFC 2131, 2132). |
| Clients identify user class membership with User class information. | Clients identify vendor class membership by using the Vendor class identifier option. |
| User class IDs can be set and viewed at DHCP clients running Windows 2000, Windows XP, or Windows Server 2003 operating systems using the **ipconfig** command.<br><br>For more information, see:<br><br>• Set DHCP class ID information at a client computer<br><br>• Show DHCP class ID information at a client computer | Vendor class IDs are configured internally by DHCP client system vendors, such as Microsoft and other vendors.<br><br>When adding a vendor class at the server, you need to specify class data at the server that matches identically the class ID used by same-vendor clients. For more information, contact the applicable vendor. |
| With user classes, you can take advantage of predefined classes that can be used to support specialized groups of clients, such as BOOTP or Routing and Remote Access clients. | With vendor classes, Microsoft has implemented vendor classes to the provided classification of its DHCP clients by Windows 98, Windows 2000, or Microsoft DHCP clients which share the use of the Microsoft-reserved vendor prefix ("MSFT") in any class-related data used. |
| User classes are typically created for administrative reasons, such as to identify all DHCP clients in a specific site or location.<br><br>For example, all computers and printers located on the same floor in an office building might be assigned or configured as part of the same user class. | Vendor classes are typically created for the enhancement of vendor-specific DHCP functionality.<br><br>For example, Microsoft provides several additional vendor-specific options, such as the ability to disable NetBIOS over TCP/IP at DHCP clients running Windows 2000 or Windows XP. |
| User classes are most helpful to users for managing DHCP option assignments based on their needs.<br><br>If your DHCP network is large enough to benefit from user classes, you can freely customize your DHCP environments with them. In most cases, the user class provides a way to assign and override standard DHCP option values set at either the server, scope, or reserved client level. | Vendor classes are most helpful to vendors for managing DHCP option assignments based on vendor-specific needs without disturbing other non-vendor DHCP clients.<br><br>With a vendor class, options are passed to clients using the Vendor specific information option, which encapsulates the options it sends. This helps non-vendor clients to recognize the information as vendor-specific and ignore and discard it as needed. |

**Notes**

- For more information about DHCP options, see "DHCP Options" at the Microsoft Windows Resource Kits Web site.
- For more information, see Using option classes or Create a new user or vendor class.
- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# BOOTP and DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BOOTP and DHCP**

The bootstrap protocol (BOOTP) is a host configuration protocol developed before DHCP. DHCP improves on BOOTP and resolves specific limitations BOOTP had as a host configuration service. RFC 951 defines BOOTP.

**BOOTP/DHCP similarities**

Because of the relationship between BOOTP and DHCP, both protocols share some defining characteristics. The common elements include:

- **The format structure each uses to exchange messages between the server and clients**

  BOOTP and DHCP use nearly identical request messages (sent by clients) and reply messages (sent by servers). Messages in either of these protocols use a single User Datagram Protocol (UDP) datagram of 576 bytes to enclose each protocol message. Message headers are the same for both BOOTP and DHCP with one exception: the final message header field used to carry optional data. For BOOTP, this optional field is called the *vendor-specific area* and is limited to 64 octets. For DHCP, this area is called the *options* field and can carry up to 312 octets of DHCP options information.

- **Use of well-known UDP ports for client/server communication**

  Both BOOTP and DHCP use the same reserved protocol ports for sending and receiving messages between servers and clients. Both BOOTP and DHCP servers use UDP port 67 to listen for and receive client request messages. BOOTP and DHCP clients typically reserve UDP port 68 for accepting message replies from either a BOOTP server or DHCP server.

  Because DHCP and BOOTP messages use nearly identical format types and packet structures, and typically use the same well-known service ports, BOOTP or DHCP relay agent programs usually treat BOOTP and DHCP messages as essentially the same message type, without differentiating between them.

- **IP address distribution as an integral part of configuration service**

  Although both BOOTP and DHCP allocate IP addresses to clients during startup, they use different methods of allocation. BOOTP typically provides fixed allocation of a single IP address for each client, permanently reserving this address in the BOOTP server database. DHCP typically provides dynamic, leased allocation of available IP addresses, reserving each DHCP client address temporarily in the DHCP server database.

**BOOTP/DHCP differences**

There are significant differences in the way in which BOOTP and DHCP perform host configuration. The following table compares and contrasts the features of the two protocols that vary.

| BOOTP | DHCP |
|---|---|
| Designed prior to DHCP. | Designed after BOOTP. |
| Intended to configure diskless workstations with limited boot capabilities. | Intended to configure frequently relocated networked computers (such as portables) that have local hard drives and full boot capabilities. |
| Dynamic BOOTP has a default 30-day expiration on IP address leases. | DHCP has a default eight-day expiration on IP address leases. |
| Supports a limited number of client configuration parameters called *vendor extensions*. | Supports a larger and extensible set of client configuration parameters called *options*. |

| | |
|---|---|
| Describes a two-phase bootstrap configuration process, as follows:<br>● Clients contact BOOTP servers to perform address determination and boot file name selection.<br>● Clients contact Trivial File Transfer Protocol (TFTP) servers to perform file transfer of their boot image. | Describes a single-phase boot configuration process whereby a DHCP client negotiates with a DHCP server to determine its IP address and obtain any other initial configuration details it needs for network operation. |
| BOOTP clients do not rebind or renew configuration with the BOOTP server except when the system restarts. | DHCP clients do not require a system restart to rebind or renew configuration with the DHCP server. Instead, clients automatically enter a rebinding state at set timed intervals to renew their leased address allocation with the DHCP server. This process occurs in the background and is transparent to the user. |

# The DHCP database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The DHCP database**

There is no set limit to the number of records that a DHCP server can store. The size of the database is dependent upon the number of DHCP clients on the network. The DHCP database grows over time as a result of clients starting and stopping on the network.

The size of the DHCP database is not directly proportional to the number of active client lease entries. Over time, as some DHCP client entries become obsolete and are deleted, there remains some unused space.

To recover the unused space, the DHCP database is compacted. Starting with Windows NT Server 4.0, dynamic database compaction occurs on DHCP servers as an automatic background process during idle time or after a database update.

**Note**

- When using or upgrading DHCP databases used with earlier versions of Windows NT Server, the DHCP database requires conversion. In the Windows Server 2003 family, if a previous copy of the DHCP server database is detected during an upgrade, it is automatically converted to the current database version and format. For larger databases, this process can increase the time needed to complete the installation.

**DHCP database files**

The DHCP server database in Windows Server 2003 family uses the Exchange Server JET storage engine. When you install the DHCP service, the files shown in the following table are automatically created in the *Systemroot*\System32\Dhcp directory.

**DHCP service database files**

| File | Description |
|---|---|
| Dhcp.mdb | The DHCP server database file. |
| Dhcp.tmp | A temporary file used by the DHCP database as a swap file during database index maintenance operations. This file sometimes remains in the *Systemroot*\System32\Dhcp directory after a system failure. |
| J50.log and J50#####.log | A log of all database transactions. This file is used by the DHCP database to recover data when necessary. |
| J50.chk | A checkpoint file. |

**Important**

- The J50.log file, J50#####.log file, Dhcp.mdb file, and Dhcp.tmp file should not be removed or altered.

The DHCP server database is a dynamic database that is updated as DHCP clients are assigned or as they release their TCP/IP configuration parameters. Because the DHCP database is not a distributed database like the WINS server database, maintaining the DHCP server database is less complex.

The DHCP database and related registry entries are automatically backed up at a specific interval (60 minutes by installation default). You can change this installation default by changing the value of **BackupInterval** in the following registry key:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DHCPServer\Parameters**

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

# Audit logging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Audit logging**
DHCP servers running Windows Server 2003 include several logging features and server parameters that provide enhanced auditing capabilities. You can specify the following features:

- The directory path in which the DHCP server stores audit log files. DHCP audit logs are located by default at %windir%\System32\Dhcp.
- A maximum size restriction (in megabytes) for the total amount of disk space available for all audit log files created and stored by the DHCP service.
- An interval for disk checking that is used to determine how many times the DHCP server writes audit log events to the log file before checking for available disk space on the server.
- A minimum size requirement (in megabytes) for server disk space that is used during disk checking to determine if sufficient space exists for the server to continue audit logging.

### Notes

- You can selectively enable or disable the audit logging feature at each DHCP server. For more information, see Enable DHCP server logging.
- Only the directory path in which the DHCP server stores audit log files can be modified using the DHCP console. To do so, first select the applicable DHCP server in the console tree. On the **Action** menu, click **Properties**. Next, click the **Advanced** tab and edit **Audit log file path** as necessary.
- Other audit logging parameters described above are adjusted through registry-based configuration changes. For more information about the Windows Server 2003 DHCP server registry, see "Dynamic Host Configuration Protocol" at the Microsoft Windows Resource Kits Web site.

**How audit logging works**
The audit logging behavior discussed in this section applies only to Windows 2000 DHCP and Windows Server 2003 DHCP. It replaces the previous DHCP logging behavior used in earlier versions of Windows NT Server, which do not perform audit checks and use only a single log file named *Dhcpsrv.log* for logging service events.

The formatted structure of DHCP server logs and the level of reporting maintained for audited logging are the same as in earlier DHCP server versions provided with Windows NT Server. For more information, see Analyzing server log files.

**Naming audit log files**
The DHCP Server service bases the name of the audit log file on the current day of the week, as determined by checking the current date and time at the server.

For example, when the DHCP server starts, if the current date and time are:

Monday, April 7, 2003, 04:56:42 P.M.

then the server audit log file is named:

DhcpSrvLog-Mon

**Starting a daily audit log**
When a DHCP server starts or a new day begins (when the local time on the computer is 12:00 A.M.), the server writes a header message in the audit log file, indicating that logging has started. Then, depending on whether the audit log file is a new or existing file, the following actions occur:

- If the file already existed without modification for more than a day, it is overwritten.
- If the file already existed but was modified within the previous 24 hours, the file is not overwritten. Instead, new logging activity is appended to the end of the existing file.

**Disk checks**

After audit logging starts, the DHCP server performs disk checks at regular intervals, to ensure both the ongoing availability of server disk space and that the current audit log file does not become too large or that log-file growth is not occurring too rapidly.

The DHCP server performs a full disk check whenever either of the following conditions occurs:

- A set number of server events are logged.
- When the date changes on the server computer.

By default, the DHCP server performs a periodic disk space check for every 50 events it writes to the audit log. A date change can also be detected by the DHCP server when the server computer reaches 12:00 A.M. on its locally set clock.

Each time a disk check is completed, the server determines whether disk space is filled. The disk is considered full if either of the following conditions is true:

- **Disk space on the server computer is lower than the required minimum amount for DHCP audit logging.**

  By default, if the amount of disk space remaining on the server disk reaches less than 20 megabytes, audit logging is halted.

- **The current audit log file is larger than one-seventh (1/7) of the maximum allotted space or size for the combined total of all audit logs currently stored on the server.**

  At the time of the disk check, the DHCP server compares the exact size (in megabytes) of the current audit log file with a value obtained by dividing the current value for the maximum number of log files the server permits to be stored simultaneously before overwriting and discarding of older log files. By default, seven is the maximum number of log files the server permits to be stored, one for each day of the week. Assuming the default is set, the largest size that the current audit log file can reach is one megabyte.

In either case, if the disk is full, the DHCP server closes the current file and ignores further requests to log audit events until either 12:00 A.M. or until disk status is improved and the disk is no longer full.

Even if audit logged events are ignored because of a disk full condition, the DHCP server continues disk checking every 50 events (or the currently set interval) to determine whether disk conditions have improved. If subsequent disk checks determine that the required amount of server disk space is available, the DHCP server reopens the current log file and resumes logging.

**Ending a daily audit log**

At 12:00 A.M. local time on the server computer, the DHCP server closes the existing log and moves to the log file for the next day of the week. For example, if the day of the week changes at 12:00 A.M. from Wednesday to Thursday, the log file named DhcpSrvLog-Wed is closed, and the file named DhcpSrvLog-Thu is opened and used for logging events.

# DHCP client alternate configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP client alternate configuration**

With DHCP client alternate configuration, you can easily move a computer between two or more networks, one configured with static IP addresses and one or more configured with DHCP. Alternate configuration provides simplified computer migration (for example, a laptop) between networks without requiring that you reconfigure network adapter parameters such as IP address, subnet mask, default gateway, preferred and alternate Domain Name Service (DNS) servers, and Windows Internet Name Service (WINS) servers.

**Configuration options**

When you configure TCP/IP properties for a local area network connection, you have the following options:

- **Static IP address configuration**

  When you click**Use the following IP address**, you can provide values for static IP address settings, such as IP address, subnet mask, default gateway, preferred and alternate DNS servers, and WINS servers. However, if you click **Obtain an IP address automatically** to change the configuration of your network adapter to a DHCP client configuration, all static IP address settings are lost. Additionally, if you move the computer and configure it for another network, when you return to the original network you will need to reconfigure the computer with the original static IP address settings.

- **Dynamic IP address configuration without alternate configuration**

  When you click **Obtain an IP address automatically**, your computer acts as a DHCP client and obtains IP address, subnet mask, and other configuration parameters from your network DHCP server. If the DHCP server is unavailable, the network adapter is configured using IP autoconfiguration.

- **Dynamic IP address configuration with alternate configuration**

  When you click **Obtain an IP address automatically**, click the **Alternate Configuration** tab, and type an alternate configuration, you can move your computer between one statically configured network (such as a home network) and one or more dynamically configured networks (such as a corporate network) without changing any settings. If the DHCP server is unavailable (for example, when your computer is connected to your home network), the network adapter is automatically configured with your alternate configuration, and the computer functions correctly on the network. When you move the computer back to the dynamically configured network and the DHCP server is available, the network adapter is automatically configured with the dynamic configuration assigned by the DHCP server. The alternate configuration is used only when the DHCP client cannot locate a DHCP server.

**DHCP server discover attempts**

If you use DHCP without an alternate configuration and the DHCP client cannot locate a DHCP server, IP autoconfiguration is used to configure the network adapter. The DHCP client continues to attempt to discover a DHCP server on the network every five minutes. If a DHCP server is found, the network adapter is assigned a valid DHCP IP address lease.

If you use DHCP with an alternate configuration, and the DHCP client cannot locate a DHCP server, the alternate configuration is used to configure the network adapter. Normally, there are no additional discovery attempts. However, a DHCP server discovery attempt will occur if:

- The network adapter is disabled and then enabled again.
- Media (such as network cabling) is disconnected and then reconnected.
- The TCP/IP settings for the adapter are changed, and DHCP remains enabled after these changes.

If a DHCP server is found, the network adapter is assigned a valid DHCP IP address lease.

**Notes**

- It is possible that a static alternate configuration could conflict with the configuration of another computer on a network. For example, a client using alternate configuration might have the same IP address as another computer on the network. If this occurs, Address Resolution Protocol (ARP) detects the conflict, and the network adapter of the computer configured with the alternate configuration is automatically set to 0.0.0.0. No additional attempts are made to discover a DHCP server, obtain a lease, or use the static alternate configuration.

- When switching from an alternate configuration to a configuration using IP autoconfiguration, the network adapter is configured with IP autoconfiguration settings (169.254.*x.x*), and a DHCP server discovery attempt is initiated at the same time. If the discovery is successful, the adapter is assigned a valid DHCP lease.

- For more information, see Use DHCP client alternate configuration.

# DHCP/BOOTP Relay Agents

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP/BOOTP relay agents**
This section covers:

- Understanding relay agents
- Relay agent configurations
- Relay agent design issues

# Understanding relay agents

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding relay agents**
A relay agent is a small program that relays DHCP/BOOTP messages between clients and servers on different subnets. DHCP/BOOTP relay agents are part of the DHCP and BOOTP standards and function according to the Request for Comments (RFCs), standard documents that describe protocol design and related behavior.

**DHCP/BOOTP router support**
In TCP/IP networking, routers are used to interconnect hardware and software used on different physical network segments called *subnets* and forward IP packets between each of the subnets. To support and use DHCP service across multiple subnets, routers connecting each subnet should comply with DHCP/BOOTP relay agent capabilities described in RFC 1542.

To be compliant with RFC 1542 and provide relay agent support, each router must be able to recognize BOOTP and DHCP protocol messages and process (relay) them appropriately. Because routers interpret DHCP messages as BOOTP messages (such as a UDP message sent through the same UDP port number and containing shared message structure), a router with BOOTP-relay agent capability typically relays DHCP packets and any BOOTP packets sent on the network.

If a router cannot function as a DHCP/BOOTP relay agent, each subnet must have either its own DHCP server or another computer that can function as a relay agent on that subnet. In cases where it is impractical or impossible to configure routers to support DHCP/BOOTP relay, you can configure a computer running Windows NT Server 4.0 or later to act as a relay agent by installing the DHCP Relay Agent service.

In most cases, routers support DHCP/BOOTP relay. If your routers do not, contact your router manufacturer or supplier to find out if a software or firmware upgrade is available to support this feature.

**How relay agents work**
A relay agent relays DHCP/BOOTP messages that are broadcast on one of its connected physical interfaces, such as a network adapter, to other remote subnets to which it is connected by other physical interfaces. The following illustration shows how client C on Subnet 2 obtains a DHCP address lease from DHCP server 1 on Subnet 1.

1. DHCP client C broadcasts a DHCP/BOOTP discover message (DHCPDISCOVER) on Subnet 2, as a User Datagram Protocol (UDP) datagram using the well-known UDP server port of 67 (the port number reserved and shared for BOOTP and DHCP server communication).

2. The relay agent, in this case a DHCP/BOOTP relay-enabled router, examines the gateway IP address field in the DHCP/BOOTP message header. If the field has an IP address of 0.0.0.0, the agent fills it with the relay agent or router's IP address and forwards the message to the remote Subnet 1 where the DHCP server is located.

3. When DHCP server 1 on remote Subnet 1 receives the message, it examines the gateway IP address field for a DHCP scope that can be used by the DHCP server to supply an IP address lease.

4. If DHCP server 1 has multiple DHCP scopes, the address in the gateway IP address field (GIADDR) identifies the DHCP scope from which to offer an IP address lease.

   For example, if the gateway IP address (GIADDR) field has an IP address of 10.0.0.2, the DHCP server checks its available set of address scopes for a scope range of addresses that matches the class A IP network that includes the gateway

address as a host. In this case, the DHCP server would make a check for a scope of addresses between 10.0.0.1 and 10.0.0.254. If a matching scope exists, the DHCP server selects an available address from the matched scope to use in an IP address lease offer response to the client.

5. When DHCP server 1 receives the DHCPDISCOVER message, it processes and sends an IP address lease offer (DHCPOFFER) directly to the relay agent identified in the gateway IP address (GIADDR) field.

6. The router then relays the address lease offer (DHCPOFFER) to the DHCP client.

   The client IP address is still unknown, so it has to be broadcast on the local subnet. Similarly, a DHCPREQUEST message is relayed from client to server, and a DHCPACK message is relayed from server to client, according to RFC 1542.

**Note**

- For more information, see Relay agent design issues.

# Relay agent configurations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Relay agent configurations**

There are several relay agent configuration options available if you plan to incorporate a relay agent into your DHCP/BOOTP-enabled network. These options include using non-Microsoft routers, Windows Server 2003 Routing and Remote Access service, and the DHCP Relay Agent component provided in Windows NT Server 4.0.

**Non-Microsoft router**

This example shows a non-Microsoft router configuration. The router is running a relay agent forwarding DHCP requests between Subnet A and Subnet B. Typically, the relay agent on the router must be configured with the IP address of the DHCP server.

**The Routing and Remote Access service**

This example shows the Windows Server 2003 Routing and Remote Access configuration. The DHCP Relay Agent in the Windows Server 2003 family must be configured with the IP address of the DHCP server in order to relay DHCP requests between Subnet A and Subnet B. For more information about setting up the DHCP Relay Agent, see Configure the DHCP Relay Agent.

**The Windows Server 2003 family**

This example shows how a standard IP router can be used with a Windows Server 2003 operating system to relay DHCP requests between Subnet A and Subnet B.

# Relay agent design issues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Relay agent design issues**

There are important design issues to consider before you set up relay agents on your network.

When you have multiple DHCP servers, Microsoft recommends that you place your DHCP servers on different subnets, to achieve a degree of fault tolerance, rather than having all of them on one subnet. The servers should not have common IP addresses in their scopes (each server should have a unique pool of addresses).

If the DHCP server on the local subnet shuts down, requests are relayed to a remote subnet. The DHCP server at that location can respond to DHCP requests if it maintains a scope of IP addresses for the requesting subnet. If the remote server has no scope defined for the requesting subnet, it cannot provide IP addresses even if it has available addresses for other scopes. If each DHCP server has a pool of addresses for each subnet, then it can provide IP addresses for remote clients whose own DHCP server is offline.

**Recommended**

The following relay agent implementation is recommended for best routed DHCP network performance. It uses two DHCP servers that are attached to two different subnets. The relay agents operating on each of the routers used to connect the subnets have varied delay intervals (one is set to 4 seconds, the other uses no delay). This eliminates the risk of undesirable floods of DHCP packets through randomly selected network paths.

**Not recommended**

The following relay agent implementation is not recommended. It has the same number of DHCP servers and subnets as in the previous example, but less caution has been used. There is a higher risk of DHCP discovery messages (DHCPDISCOVERs), which are broadcast by the DHCP clients at startup, being randomly forwarded or duplicated when destined for the other subnets. Moreover, the relay agents do not use any delay interval. This increases the likelihood that both relay agents (routers) duplicate any client broadcasted messages, which could potentially flood the remote subnets.

# Administering DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering DHCP**

This section provides information about administering DHCP:

- Managing DHCP from the command line
- DHCP performance monitoring reference
- Managing DHCP Servers
- Setting Up Scopes
- Setting Up Options
- DHCP Interoperability Issues

# Managing DHCP from the command line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing DHCP from the command line**

The Netsh commands for DHCP offer a command-line tool that helps with the administration of DHCP servers and provides an equivalent alternative to console-based management. This can be useful in the following situations:

- When managing DHCP servers in wide area networks (WANs), commands can be used in interactive mode at the **netsh>** command prompt to better manage across slow-speed network links.
- When managing a large number of DHCP servers, commands can be used in batch mode to help script and automate recurring administrative tasks that need to be performed for all DHCP servers.

For a comprehensive **netsh dhcp** command reference (including syntax, parameters, and examples), see Netsh commands for DHCP.

**Notes**

- For information about how to use the Netsh commands provided for DHCP, see Use DHCP Command-line Tools.
- For an example of how to use Netsh commands for DHCP in batch files and scripts, see Netsh DHCP example.
- For more information about Netsh, see The Netsh Command-Line Utility.

# DHCP performance monitoring reference

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP performance monitoring reference**

The Windows Server 2003 DHCP service includes a set of performance counters that can be used to monitor various types of server activity. To access these counters, you must use System Monitor. For more information, see System Monitor overview.

By default, performance monitoring of DHCP servers is available for use after the DHCP service component is installed. DHCP performance is measured using the following metrics and counters:

| Name | Description |
|---|---|
| Packets Received/sec | The number of message packets received per second by the DHCP server. A large number indicates heavy DHCP-related message traffic to the server. |
| Duplicates Dropped/sec | The number of duplicated packets per second dropped by the DHCP server. This number can be affected by multiple DHCP relay agents or network interfaces forwarding the same packet to the server. A large number here indicates that either clients are probably timing out too fast or the server is not responding fast enough. |
| Packets Expired/sec | The number of packets per second that expire and are dropped by the DHCP server. When a DHCP-related message packet is internally queued for 30 seconds or more, it is determined to be stale and expired by the server. A large number here indicates that the server is either taking too long to process some packets while other packets are queued and becoming stale, or traffic on the network is too high for the server to manage. |
| Milliseconds per packet (Avg.) | The average time in milliseconds used by the DHCP server to process each packet it receives. This number can vary depending on the server hardware and its I/O subsystem. A sudden or unusual increase might indicate a problem, either with the I/O subsystem becoming slower or because of an intrinsic processing overhead on the server computer. |
| Active Queue Length | The current length of the internal message queue of the DHCP server. This number equals the number of unprocessed messages received by the server. A large number might indicate heavy server traffic. |
| Conflict Check Queue Length | The current length of the conflict check queue for the DHCP server. This queue holds messages without responses while the DHCP server performs address conflict detection. A large value here might indicate that **Conflict Detection Attempts** has been set too high or that there is unusually heavy lease traffic at the server. |
| Discovers/sec | The number of DHCP discover messages (DHCPDISCOVERs) received per second by the server. These messages are sent by clients when they start on the network and obtain a new address lease. A sudden or unusual increase indicates a large number of clients are attempting to initialize and obtain an IP address lease from the server, such as when a number of client computers are started at any given time. |
| Offers/sec | The number of DHCP offer messages (DHCPOFFERs) sent per second by the DHCP server to clients. A sudden or unusual increase in this number indicates heavy traffic on the server. |
| Requests/sec | The number of DHCP request messages (DHCPREQUESTs) received per second by the DHCP server from clients. A sudden or unusual increase in this number indicates a large number of clients trying to renew their leases with the DHCP server. This might indicate that scope lease durations are too short. |
| Informs/sec | The number of DHCP information messages (DHCPINFORMs) received per second by the DHCP server. DHCP inform messages are used when the DHCP server queries for the directory service for the enterprise root and when dynamic updates are being done on behalf of clients by the server. |
| Acks/sec | The number of DHCP acknowledgment messages (DHCPACKs) sent per second by the DHCP server to clients. A sudden or unusual increase in this number indicates that a large number of clients are being renewed by the DHCP server. This might indicate that scope lease durations are too short. |

| | |
|---|---|
| Nacks/sec | The number of DHCP negative acknowledgment messages (DHCPNAKs) sent per second by the DHCP server to clients. A very high value might indicate potential network trouble in the form of misconfiguration of either the server or clients. When servers are misconfigured, one possible cause is a deactivated scope. For clients, a very high value could be caused by computers moving between subnets, such as laptop portables or other mobile devices. |
| Declines/sec | The number of DHCP decline messages (DHCPDECLINEs) received per second by the DHCP server from clients. A high value indicates that several clients have found their address to be in conflict, possibly indicating network trouble. In this situation, it can help to enable conflict detection on the DHCP server. This should only be used temporarily. Once the situation returns to normal, it should be turned off. |
| Releases/sec | The number of DHCP release messages (DHCPRELEASEs) received per second by the DHCP server from clients. This number only exists if a DHCP client sends a release to the server. This can occur manually, such as when the **ipconfig** command is used at the client computer. Release messages can also be sent by the client if it is configured with the "Release DHCP lease on shutdown" option. Because clients rarely release their address, the value of this counter remains low for many DHCP network configurations. For more information about DHCP options, see "DHCP Options" at the Microsoft Windows Resource Kits Web site. |

**Note**

- Values for the following registry key can be used by a member of the local Administrators group:

  **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DHCPServer\Performance**

  **Caution**

  - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

  By changing values stored at this registry path location, you can deny or modify permissions that determine who can view System Monitor counters used for the DHCP server on the server computer. Values under this key are used by the System Monitor DLL (Perfctrs.dll) to identify each of the counters described. For more information, see System Monitor overview.

# Managing DHCP Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing DHCP servers**

This section covers:

- Authorizing DHCP servers
- Monitoring DHCP server performance
- Restoring server data
- Backing up the DHCP database
- Analyzing server log files
- Cluster support for DHCP servers

# Authorizing DHCP servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Authorizing DHCP servers**

The Windows Server 2003 family provides integrated security support for networks that use Active Directory. This support adds and uses a class of objects that is part of the base directory schema, providing the following enhancements:

- A list of IP addresses available for the computers that you authorize to operate as DHCP servers on your network.
- Detection of unauthorized DHCP servers and prevention of their starting or running on your network.

The following sections discuss:

- Background information about the detection of unauthorized DHCP servers.
- How computers are authorized in Active Directory to provide DHCP service.
- How an unauthorized server is detected and prevented from providing DHCP service.
- Notes and limitations for implementing DHCP service, depending on whether the Active Directory directory service is available.

**Background on unauthorized DHCP servers**

When configured correctly and authorized for use on a network, DHCP servers provide a useful and intended administrative service. However, when a misconfigured or unauthorized DHCP server is introduced into a network, it can cause problems. For example, if an unauthorized DHCP server starts, it might begin either leasing incorrect IP addresses to clients or negatively acknowledging DHCP clients attempting to renew current address leases.

Either of these configurations can produce further problems for DHCP-enabled clients. For example, clients that obtain a configuration lease from the unauthorized server can fail to locate valid domain controllers, preventing clients from successfully logging on to the network.

To resolve these issues, DHCP servers running Windows Server 2003 are verified as authorized in Active Directory before they can service clients. This avoids most of the accidental damage caused by running DHCP servers with incorrect configurations or correct configurations on the wrong network.

**How DHCP servers are authorized**

The authorization process for DHCP server computers depends on the installed role of the server on your network. In the Windows Server 2003 family there are three roles or server types for which each server computer can be installed:

- **Domain controller.** The computer keeps and maintains a copy of the Active Directory database and provides secure account management for domain member users and computers.
- **Member server.** The computer is not operating as a domain controller but has joined a domain in which it has a membership account in the Active Directory database.
- **Stand-alone server.** The computer is not operating as a domain controller or a member server in a domain. Instead, the server computer is made known to the network through a specified workgroup name, which can be shared by other computers, but is used only for browsing purposes and not to provide secured logon access to shared domain resources.

If you deploy Active Directory, all computers operating as DHCP servers must be either domain controllers or domain member servers before they can be authorized and provide DHCP service to clients.

Although it is not recommended, you can use a stand-alone server as a DHCP server as long as it is not on a subnet with any authorized DHCP servers. When a stand-alone DHCP server detects an authorized server on the same subnet, it automatically stops leasing IP addresses to DHCP clients.

For more information about DHCP server installation, see Install a DHCP server and Open the DHCP console.

For more information about authorizing a DHCP server in Active Directory, see Authorize a DHCP server in Active Directory.

For more information about delegating administrative credentials, see Delegate ability to authorize DHCP servers to a non-enterprise administrator.

**How unauthorized servers are detected**
DHCP servers running Windows Server 2003 provide detection of both authorized and unauthorized servers using the following specific enhancements for the DHCP standard:

- The use of information messaging between DHCP servers using the DHCP information message (DHCPINFORM).
- The addition of several new vendor-specific option types, for communicating information about the root domain.

A DHCP server running Windows Server 2003 uses the following process to determine whether Active Directory is available. If found, the server ensures that it is authorized by adhering to the following procedure, depending on whether it is a member server or a stand-alone server:

- For **member servers** (a server joined to a domain that is part of the enterprise), the DHCP server queries Active Directory for the list of authorized DHCP server IP addresses.

  If the server finds its IP address in the authorized list, it initializes and starts providing DHCP service to clients. If it does not find itself in the authorized list, it does not initialize and stops providing DHCP services.

  When installed in a multiple forest environment, DHCP servers seek authorization from within their forest only. Once authorized, DHCP servers in a multiple forest environment lease IP addresses to all reachable clients. Therefore, if clients from another forest are reached using routers with DHCP/BOOTP forwarding enabled, the DHCP server leases IP addresses to them.

  If Active Directory is not available, the DHCP server continues to operate in its last known state.

- For **stand-alone servers** (a server not joined to any domain or part of an existing enterprise). When the DHCP service starts, it sends a DHCP information message (DHCPINFORM) request to the reachable network, using the local limited broadcast address (255.255.255.255) to locate the root domain on which other DHCP servers are installed and configured.

  This message includes several vendor-specific option types that are known and supported by other DHCP servers running Windows Server 2003 . When received by other DHCP servers, these option types enable the query and retrieval of information about the root domain. When queried, the other DHCP servers reply with DHCP acknowledgement messages (DHCPACK) to both acknowledge and answer with Active Directory root domain information.

  If the stand-alone server receives no reply, it initializes and starts providing DHCP services to clients. If the stand-alone server receives a reply from a DHCP server that is authorized in Active Directory, the stand-alone server does not initialize and does not provide DHCP services to clients.

Authorized servers repeat the detection process at a default interval of 60 minutes. Unauthorized servers repeat the detection process at a default interval of 10 minutes.

Efforts to detect unauthorized servers are noted as "Restarting rogue detection" entries in the audit log.

**Notes**

- The process of authorizing DHCP servers is useful only for DHCP servers running Windows 2000 or Windows Server 2003 .
- When a DHCP server running Windows Server 2003 is installed in a Windows NT 4.0 domain, the server initializes and begins serving DHCP clients in the absence of directory services. However, if there is a Windows Server 2003 domain on the same subnet or on a connected network with routers configured for DHCP or BOOTP forwarding, the DHCP server in the Windows NT 4.0 domain detects its own unauthorized status and ceases to provide IP address leases to clients. If you

authorize the DHCP server in Active Directory, it can provide DHCP service to the clients in the Windows NT 4.0 domain.

- For the directory authorization process to work properly, it is necessary that the first DHCP server introduced on your network participate in Active Directory. This requires that the server be installed as either a domain controller or a member server. When planning or deploying Active Directory with Windows Server 2003 DHCP, it is important that you do not install your first DHCP server as a stand-alone server.

- Most commonly, there is one enterprise root and, therefore, only a single point for directory authorization of the DHCP servers. However, there is no restriction on authorizing DHCP servers for more than one enterprise root.

- The fully qualified domain name (FQDN) of the DHCP server cannot exceed 64 characters. If the FQDN of the DHCP server exceeds 64 characters, the attempt to authorize the server fails with the error message, "A constraint violation has occurred." If your DHCP server FQDN exceeds 64 characters, authorize the server using the server's IP address instead of its FQDN.

- DHCP servers running Windows 2000 cannot be authorized using the Windows Server 2003 administrative tools (the DHCP console and the Netsh commands for DHCP) unless Windows 2000 Server Service Pack 2 is installed.

# Monitoring DHCP server performance

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitoring DHCP server performance**
Because DHCP servers are of critical importance in most environments, monitoring their performance can help in troubleshooting cases where server performance has been degraded.

The Windows Server 2003 family provides a set of DHCP server performance counters that can be used to measure and monitor various aspects of server activity, such as the following:

- All types of DHCP messages sent and received by the DHCP service.
- The average amount of processing time spent by the DHCP server per message packet sent and received.
- The number of message packets dropped because of internal delays at a DHCP server computer.

For more information, see DHCP performance monitoring reference.

# Restoring server data

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Restoring server data**

Restoring the DHCP server database is useful in situations where the database has either become corrupted or lost. In order to successfully restore the database, you need to back up the database on a regular basis. By default, DHCP performs synchronous backups that occur automatically at a 60 minute interval to the folder location *systemroot*\System32\Dhcp\Backup, but you can also perform manual backups, or use backup software to copy the database to other locations. For more information, see Backing up the DHCP database and Backup.

You can restore the DHCP database from a backup copy of the database file, Dhcp.mdb, using the **Restore** command on the **Action** menu in the DHCP console. When you restore the DHCP database from a backup copy of Dhcp.mdb, the following information is configured on the server:

- All scopes, including superscopes and multicast scopes
- Reservations
- Leases
- All options, including server options, scope options, reservation options, and class options
- All registry keys and other configuration settings (for example, audit log settings and folder location settings) set in DHCP server properties.

**Note**

- The DNS dynamic update credentials (user name, domain, and password) that the DHCP server uses when registering DHCP client computers in DNS are not backed up with any backup method, therefore they are not restored during the restore procedure. After restoring your DHCP database, configure credentials for your server. For more information, see Configure DNS dynamic update credentials.

For more information, see Restore the DHCP database and Move a DHCP database to another server.

# Backing up the DHCP database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Backing up the DHCP database**

Maintaining a backup of the DHCP database protects you from data loss if the DHCP database is lost (for example, due to hard disk failure) or becomes corrupted. There are three backup methods supported by the DHCP Server service:

- Synchronous backups that occur automatically. The default backup interval is 60 minutes.
- Asynchronous (manual) backups, performed by using the **Backup** command on the DHCP console. For more information about asynchronous backups, see Back up the DHCP database.
- Backups using Windows Backup (ntbackup.exe) or non-Microsoft backup software. For more information about Windows Backup, see Backup.

When a synchronous or asynchronous backup occurs, the entire DHCP database is saved, including the following:

- All scopes, including superscopes and multicast scopes
- Reservations
- Leases
- All options, including server options, scope options, reservation options, and class options
- All registry keys and other configuration settings (for example, audit log settings and folder location settings) set in DHCP server properties. These settings are stored in the following registry subkey:

  **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DHCPServer\Parameters**

  To back up this subkey, open Registry Editor, and save the specified key to a text file. For more information, see Open Registry Editor and Import or Export Registry Keys.

### Note

- The DNS dynamic update credentials (user name, domain, and password) that the DHCP server uses when registering DHCP client computers in DNS are not backed up with any backup method.

**Backup locations**

The default DHCP database backup path is *systemroot*\System32\Dhcp\Backup. You can change the database backup folder by selecting a different local folder during a manual backup or by changing the backup folder location in DHCP server properties. For more information, see Set the DHCP database backup path.

When planning your backup strategy, consider the following:

- Synchronous backups are performed while the DHCP service is running. Similarly, when you perform asynchronous (manual) backups, you do not need to stop the DHCP service unless you are moving your database to a new server. For more information, see Move a DHCP database to another server.
- The backup folder location must be a local path.

### Notes

- This topic assumes that the DHCP database and its backup directories are located on the default drive and path locations.

- The default automatic database backup interval is 60 minutes. You can change the automatic backup interval through the following registry key:

  **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DHCPServer\Parameters\BackupInterval**

  **Caution**

  - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

- Do not store DHCP server backups on the same hard drive on which the DHCP service is installed, and make sure that the access control list (ACL) for the backup folder contains only the Administrators group and the DHCP Administrator group as members. In addition to performing manual backups, back up to other locations, such as a tape drive, and make sure that unauthorized persons do not have access to your backup copies. You can use Windows Backup for this purpose. For more information, see Best practices for Backup.

# Analyzing server log files

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Analyzing server log files**

In Windows Server 2003 family, DHCP server log files are designed to use Audit logging to permit log files to remain enabled for use without requiring added monitoring or administering to manage log file growth or conserve disk resources. DHCP audit logs are located by default at %windir%\System32\Dhcp.

The following section outlines the format of these log files and how they can be used to gather more information about DHCP Server service operations on the network.

**DHCP server log file format**

DHCP server logs are comma-delimited text files with each log entry representing a single line of text. Following are the fields (and the order in which they appear) in a log file entry:

*ID, Date, Time, Description, IP Address, Host Name, MAC Address*

Each of these fields is described in detail in the following table:

| Field | Description |
|---|---|
| ID | A DHCP server event ID code. |
| Date | The date on which this entry was logged on the DHCP server. |
| Time | The time at which this entry was logged on the DHCP server. |
| Description | A description of this DHCP server event. |
| IP Address | The IP address of the DHCP client. |
| Host Name | The host name of the DHCP client. |
| MAC Address | The media access control address used by the network adapter hardware of the client. |

**DHCP server log: Common event codes**

DHCP server audit log files use reserved event ID codes to provide information about the type of server event or activity logged. The following table describes these event ID codes in more detail.

| Event ID | Description |
|---|---|
| 00 | The log was started. |
| 01 | The log was stopped. |
| 02 | The log was temporarily paused due to low disk space. |
| 10 | A new IP address was leased to a client. |
| 11 | A lease was renewed by a client. |
| 12 | A lease was released by a client. |
| 13 | An IP address was found in use on the network. |
| 14 | A lease request could not be satisfied because the address pool of the scope was exhausted. |
| 15 | A lease was denied. |
| 20 | A BOOTP address was leased to a client. |

**DNS dynamic update events**

When the DHCP server is configured to perform DNS dynamic updates on behalf of DHCP clients, you can use the DHCP audit logs to monitor update requests by the DHCP server to the DNS server, DNS record update successes, and DNS record update failures. The following event ID's are used for DNS dynamic update events:

| ID number | DHCP Event |
|---|---|
| 30 | DNS dynamic update request |
| 31 | DNS dynamic update failed |
| 32 | DNS dynamic update successful |

The IP address of the DHCP client computer is included in the DHCP audit log, providing the ability to track the source in the event of a denial of service attack.

**DHCP server logs: Server authorization events**

The following are additional server log event ID codes and descriptions. These events can appear in logs made by DHCP servers running Windows Server 2003 . They pertain to the applicable DHCP server and its authorization status when deployed in Active Directory environments.

| Event ID | Description |
|---|---|
| 50 | **Unreachable domain**<br><br>The DHCP server could not locate the applicable domain for its configured Active Directory installation. |
| 51 | **Authorization succeeded**<br><br>The DHCP server was authorized to start on the network. |
| 52 | **Upgraded to a** Windows Server 2003 **operating system**<br><br>The DHCP server was recently upgraded to a Windows Server 2003 operating system, and, therefore, the unauthorized DHCP server detection feature (used to determine whether the server has been authorized in Active Directory) was disabled. |
| 53 | **Cached Authorization**<br><br>The DHCP server was authorized to start using previously cached information. Active Directory was not currently visible at the time the server was started on the network. |
| 54 | **Authorization failed**<br><br>The DHCP server was not authorized to start on the network. When this event occurs, it is likely followed by the server being stopped. |
| 55 | **Authorization (servicing)**<br><br>The DHCP server was successfully authorized to start on the network. |
| 56 | **Authorization failure, stopped servicing**<br><br>The DHCP server was not authorized to start on the network and was shut down by the operating system. You must first authorize the server in the directory before starting it again. For more information, see Authorize a DHCP server in Active Directory. |
| 57 | **Server found in domain**<br><br>Another DHCP server exists and is authorized for service in the same domain. |
| 58 | **Server could not find domain**<br><br>The DHCP server could not locate the specified domain. |

| | |
|---|---|
| 59 | **Network failure**<br><br>A network-related failure prevented the server from determining if it is authorized. |
| 60 | **No DC is DS Enabled**<br><br>No Windows Server 2003 domain controller (DC) was located. For detecting whether the server is authorized, a DC that is enabled for Active Directory is needed. |
| 61 | **Server found that belongs to DS domain**<br><br>Another DHCP server was found on the network that belongs to the Active Directory domain. |
| 62 | **Another server found**<br><br>Another DHCP server was found on the network. |
| 63 | **Restarting rogue detection**<br><br>The DHCP server is trying once more to determine whether it is authorized to start and provide service on the network. |
| 64 | **No DHCP enabled interfaces**<br><br>The DHCP server has its service bindings or network connections configured so that it is not enabled to provide service. This usually means one of the following:<br><br>1. The network connections of the server are either not installed or not actively connected to a network.<br><br>2. The server has not been configured with at least one static IP address for one of its installed and active network connections. For more information, see Configure TCP/IP for static addressing.<br><br>3. All of the statically configured network connections for the server are disabled. For more information, see Multihomed DHCP servers. |

**Example: Excerpt from a sample DHCP server audit log**
The following is a brief excerpt of sample log activity from an audit log generated by the DHCP Server service:

```
ID Date,Time,Description,IP Address,Host Name,MAC Address
00,04/19/99,12:43:06,Started,,,
60,04/19/99,12:43:21,No DC is DS Enabled,,MYDOMAIN,
63,04/19/99,12:43:28,Restarting rogue detection,,,
01,04/19/99,13:11:13,Stopped,,,
00,04/19/99,12:43:06,Started,,,
55,04/19/99,12:43:54,Authorized(servicing),,MYDOMAIN,
```

In this sample, the DHCP server could not be authorized when initially started and is subsequently stopped. Once authorized, the server is then able to start and service clients.

### Note

- For more information, see Audit logging.

# Cluster support for DHCP servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster support for DHCP servers**
The Windows Server 2003 DHCP Server service is a cluster-aware application. You can implement additional DHCP (or MADCAP) server reliability by deploying a DHCP server cluster using the Cluster service provided with Windows Server 2003, Enterprise Edition.

By using clustering support for DHCP, you can implement a local method of DHCP server failover, achieving greater fault tolerance. You can also enhance fault tolerance by combining DHCP server clustering with a remote failover configuration, such as by using a split scope configuration.

**Requirements for setting up a DHCP clustered resource**
The DHCP Server service, when used in a server cluster, requires the following resource types: a disk resource, an IP address resource, and a name resource.

In this type of configuration, a virtual IP address is defined for the IP address resource using the Cluster Administrator tool. This address must be a static IP address, not one obtained from another DHCP server.

The DHCP Server service then binds to this virtual IP address. This IP address must then be used to authorize the DHCP Server service in Active Directory so it can function correctly and service clients on the network.

Once the virtual IP is set using cluster configuration, each network adapter installed on each node (that is, a server in the cluster) needs an IP address configuration. Because the DHCP Server service does not bind to adapter IP addresses, you can either provide them through DHCP or configure them statically. If you use static configuration, the IP addresses for each linked pair of network adapters (linked node-to-node) should be from the same subnet.

Addresses that are statically configured using TCP/IP properties from the Network Connections folder can also be viewed through server bindings properties in the DHCP console. However, for a DHCP server cluster, the bindings information that appears in these views does not correspond to the virtual IP address used for the server cluster. Therefore, these settings do not apply.

When a scope is created for a DHCP clustered server, the virtual IP addresses used in the cluster context must be excluded so that they are not distributed to clients. Additionally. you should configure the database path, audit log file path, and the database backup path using the Cluster Administrator tool on the shared disk.

**Other options for DHCP failover**
Another way to implement DHCP remote failover is to deploy two DHCP servers in the same network that share a split scope configuration based on the 80/20 rule. For more information, see the section " Using the 80/20 rule for scopes" in Configuring scopes.

For more information about installing a DHCP resource type on a Windows Server 2003, Enterprise Edition, cluster server, see Checklist: Installing a DHCP Service resource.

### Notes

- The Jet database upon which the DHCP Server service relies is not cluster aware. If the clustered DHCP database becomes inaccessible to the DHCP Server service, the service will report thousands of ESENT application log errors, and DHCP service by the cluster will be interrupted.

- If you need only to remotely manage DHCP server clusters that are deployed on remote computers running Windows Server 2003, Enterprise Edition, you can use Cluster Administrator to do this.

- For more information about configuring DHCP clustering, see "Dynamic Host Configuration Protocol" at the Microsoft Windows Resource Kits Web site.

# Setting Up Scopes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up scopes**

This section covers:

- Configuring scopes
- Using superscopes
- Using multicast scopes
- Removing scopes
- Managing leases
- Using client reservations
- Reconciling scopes

# Configuring scopes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring scopes**

A scope is an administrative grouping of IP addresses for computers on a subnet that use the DHCP service. The administrator first creates a scope for each physical subnet and then uses the scope to define the parameters used by clients. A scope has the following properties:

- A range of IP addresses from which to include or exclude addresses used for DHCP service lease offerings.
- A subnet mask, which determines the subnet for a given IP address.
- A scope name assigned when it is created.
- Lease duration values, which are assigned to DHCP clients that receive dynamically allocated IP addresses.
- Any DHCP scope options configured for assignment to DHCP clients, such as DNS server, router IP address, and WINS server address.
- Reservations, optionally used to ensure that a DHCP client always receives the same IP address.

**Before adding scopes**

A DHCP scope consists of a pool of IP addresses on a given subnet, such as 192.168.0.1 to 192.168.0.254, that the DHCP server can lease to clients.

Each subnet can have only a single DHCP scope with a single continuous range of IP addresses. To use several address ranges within a single scope or subnet for DHCP service, you must first define the scope and then set any needed exclusion ranges.

- **Defining the scope**

  Use the entire range of consecutive IP addresses that make up the local IP subnet for which you are enabling DHCP service.

- **Setting exclusion ranges**

  You should set exclusion ranges for any IP addresses within the scope that you do not want the DHCP server to offer or use for DHCP assignment. For example, you can exclude the first 10 addresses in the previous example scope by creating an exclusion for 192.168.0.1 to 192.168.0.10.

  By setting an exclusion for these addresses, you specify that DHCP clients are never offered these addresses when they request leased configuration from the server. Excluded IP addresses can be active on your network, but only by manually configuring these addresses at hosts that do not use DHCP to obtain an address.

**Creating scopes**

When you create a DHCP scope, you use the DHCP console to enter the following required information:

- A scope name, assigned by you or the administrator who created the scope.
- A subnet mask used to identify the subnet to which an IP address belongs.
- A range of IP addresses contained within the scope.
- A time interval (known as a *lease duration*) that specifies how long a DHCP client can use an assigned IP address before it must renew its configuration with the DHCP server.

**Using the 80/20 rule for scopes**

For balancing DHCP server usage, a good practice is to use the "80/20" rule to divide the scope addresses between the two DHCP servers. If Server 1 is configured to make available most (approximately 80%) of the addresses, then Server 2 can be configured to make the other addresses (approximately 20%) available to clients. The following illustration is an example of the 80/20 rule:

## Notes

- For detailed information on applying the 80/20 rule, see DHCP Best Practices.
- When creating a new scope, the IP address used to create it should not include addresses of existing statically configured computers, such as the DHCP server. Either these static addresses should be outside the range for the scope, or they should be excluded from the scope address pool.

**After scopes are added**

After you define a scope, you can additionally configure the scope by performing the following tasks:

- **Set additional exclusion ranges.**

  You can exclude any other IP addresses that must not be leased to DHCP clients. You should use exclusions for all devices that must be statically configured. The excluded ranges should include all IP addresses that you assigned manually to other DHCP servers, non-DHCP clients, diskless workstations, or Routing and Remote Access and PPP clients.

- **Create reservations.**

  You can choose to reserve some IP addresses for permanent lease assignment to specified computers or devices on your network. You should make reservations only for devices that are DHCP-enabled and that must be reserved for specific purposes on your network (such as print servers).

- **Adjust the length of lease durations.**

  You can modify the lease duration to be used for assigning IP address leases. The default lease duration is eight days.

  For most LANs, the default value is acceptable but can be further increased if computers seldom move or change locations. Also, infinite lease times can be set but should be used with caution. For information about circumstances under which modifying this setting is most useful, see Managing leases.

- **Configure options and classes to be used with the scope.**

  To provide full configuration for clients, DHCP options need to be configured and enabled for the scope. For more information, see Setting Up Options.

  For more advanced discrete management of scope clients, you can add or enable user or vendor-defined option classes. For more information, see Using option classes.

**Notes**

- After you define and configure a scope, the scope must be *activated* before the DHCP server begins providing service to clients. However, you should not activate a new scope until you have specified the DHCP options for it. For information on how to activate a scope, see Activate a scope.

- After you activate a scope, you should not change the range of scope addresses.

# Using superscopes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using superscopes**

A superscope is an administrative feature of DHCP servers running Windows Server 2003 that you can create and manage through the DHCP console. Using a superscope, you can group multiple scopes as a single administrative entity. With this feature, a DHCP server can:

- Support DHCP clients on a single physical network segment (such as a single Ethernet LAN segment) where multiple logical IP networks are used. When more than one logical IP network is used on each physical subnet or network, such configurations are often called *multinets*.

- Support remote DHCP clients located on the far side of DHCP and BOOTP relay agents (where the network on the far side of the relay agent uses multinets).

In multinet configurations, you can use DHCP superscopes to group and activate individual scope ranges of IP addresses used on your network. In this way, the DHCP server computer can activate and provide leases from more than one scope to clients on a single physical network.

Superscopes can resolve certain types of DHCP deployment issues for multinets, including situations in which:

- The available address pool for a currently active scope is nearly depleted, and more computers need to be added to the network. The original scope includes the full addressable range for a single IP network of a specified address class. You need to use another IP network range of addresses to extend the address space for the same physical network segment.

- Clients must be migrated over time to a new scope (such as to renumber the current IP network from an address range used in an existing active scope to a new scope that contains another IP network range of addresses).

- You want to use two DHCP servers on the same physical network segment to manage separate logical IP networks.

**Superscope configurations for multinets**

The following section shows how a simple DHCP network consisting originally of one physical network segment and one DHCP server, can be extended to use superscopes for support of multinet configurations.

**Example 1: Non-routed DHCP server (before superscope)**

In this preliminary instance, a small local area network (LAN) with one DHCP server supports a single physical subnet, Subnet A. The DHCP server in this configuration is limited to leasing addresses to clients on this same physical subnet.

The following illustration shows this example network in its original state. At this point, no superscopes have been added and a single scope, Scope 1, is used to service all DHCP clients on Subnet A.

Single scope here configured as follows:
**Scope1:** 192.168.1.1 - 192.168.1.254
**Subnet mask:** 255.255.255.0
**Excluded addresses:** 192.168.1.1 - 192.168.1.10

**Example 2: Superscope for non-routed DHCP server supporting local multinets**

To include multinets implemented for client computers on Subnet A, the same network segment where the DHCP server is

located, you can configure a superscope which includes as members: the original scope (Scope 1) and additional scopes for the logical multinets for which you need to add support (Scope 2, Scope 3).

This illustration shows the scope and superscope configuration to support the multinets on the same physical network (Subnet A) as the DHCP server.

Superscope here with member scopes:
**Scope 1:** 192.168.1.1 - 192.168.1.254
**Scope 2:** 192.168.2.1 - 192.168.2.254
**Scope 3:** 192.168.3.1 - 192.168.3.254

**Subnet mask for all scopes:** 255.255.255.0
**Excluded addresses for member scopes:**
**Scope 1:** 192.168.1.1 - 192.168.1.10
**Scope 2:** 192.168.2.1 - 192.168.2.10
**Scope 3:** 192.168.3.1 - 192.168.3.10

**Example 3: Superscope for routed DHCP server with relay agent supporting remote multinets**
To include multinets implemented for client computers on Subnet B, the remote network segment located across a router from the DHCP server on Subnet A, you can configure a superscope which includes as members: the additional scopes for the logical multinets for which you need to add remote support (Scope 2, Scope 3).

Note that since the multinets are for the remote network (Subnet B), the original scope (Scope 1) does not need to be part of the added superscope.

This illustration shows the scope and superscope configuration to support the multinets on the remote physical network (Subnet B) away from the DHCP server.

Scope for local Subnet A:
**Scope 1:** 192.168.1.1 - 192.168.1.254
**Subnet mask:** 255.255.255.0
**Excluded addresses:** 192.168.1.1 - 192.168.1.10

Superscope added here with
member scopes for Subnet B:
**Scope 2:** 192.168.2.1 - 192.168.2.254
**Scope 3:** 192.168.3.1 - 192.168.3.254
**Subnet mask:** 255.255.255.0
**Excluded addresses:**
**(Scope 2)** 192.168.2.1 - 192.168.2.10
**(Scope 3)** 192.168.3.1 - 192.168.3.10

**Note**

- A DHCP relay agent is used for DHCP servers to support clients on remote subnets, as shown in Example 3. For more information, see Understanding relay agents.

# Using multicast scopes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using multicast scopes**

Multicast scopes are supported through the use of Multicast Address Dynamic Client Allocation Protocol (MADCAP), a proposed standard protocol for performing multicast address allocation. The MADCAP protocol describes how multicast address allocation (or MADCAP) servers can dynamically provide IP addresses to other computers (MADCAP clients) on your network.

Typically, a MADCAP client might also be a multicast server (MCS) used to support IP multicasting. An MCS manages the shared or group use of the allocated multicast IP address and streams data traffic to members that share the use of the specified group address.

Once an MCS is configured and allocated a group IP address to use, any multicast clients that have registered their membership with the MCS can receive streams sent to this address. By registering with the MCS, clients can participate efficiently in the stream process, such as for real-time video or audio network transmissions. The MCS also manages the multicast group list, updating its membership and status so that multicast traffic is received by all current members.

**Background on multicast addresses**

Ordinarily, you use DHCP scopes to provide client configurations by allocating ranges of IP addresses from the standard address classes, Class A, B, or C. By using DHCP scopes you can assign IP addresses from the ranges provided by these classes for your DHCP clients to be configured to use unicast (or point-to-point) directed communication between other TCP/IP networked computers.

The multicast address range uses an additional address class, Class D, that includes IP addresses that range from 224.0.0.0 to 239.255.255.255 for use in IP multicasting. Addresses in this class are used for multicasting only and not for regular DHCP scopes.

In all TCP/IP networks, each host is required to first be configured with its own IP address, taken from one of the standard address classes. You must assign this required unicast IP address before you can configure a host to support and use secondary IP addresses, such as a multicast IP address.

Another difference between unicast and multicast addresses, is that a group of TCP/IP host computers are intended to be able to share the use of a multicast IP address. This is not normally the case with unicast IP addresses, which are intended to be assigned individually to only one configured host and not shared with other hosts.

When the destination address for an IP datagram is an IP multicast address, the datagram is forwarded to all members of a *multicast group*, which is a set of zero or more hosts identified by the address. The membership of a multicast group is dynamic in that individual hosts can join or leave the group at any time.

Membership and use of multicast groups is unrestricted and can be compared to membership and use of a group e-mail address: Group membership can be any size, and hosts can be members of many multicast groups.

You can permanently reserve multicast group addresses or temporarily assign and use them as needed on your network. For a permanent group IP address to be reserved for Internet use, you must register it with the Internet Assigned Numbers Authority (IANA).

For multicast IP addresses not permanently reserved with the IANA, all Class D addresses that remain unreserved can then be used dynamically to assign and form temporary multicast groups. These temporary groups can exist as long as one or more hosts on the network are configured with the group address and actively share its use.

For more information, see Understanding Multicasting or Internet Group Management Protocol (IGMP).

**Determining the ranges to use for multicast scopes**

When deciding the IP address ranges to use for multicast scopes on your MADCAP server, there are two overall best practices recommended by the Multicast Allocation (MALLOC) working group, an IETF team of industry volunteers who help establish multicast address allocation standards. These practices include:

- **Administrative scoping** This is most useful when you are using multicast IP addresses privately in your own network. It is similar to private IP addressing, as used currently in the unicast IP address spaces (such as the use of the 10.0.0.0 network address space). It is fully discussed in RFC 2365, "Administratively Scoped IP Multicast."

With administratively scoped multicast IP, the range most recommended that you begin with is the 239.192.0.0 range. This range is known as the IPv4 Organization Local Scope and has a subnet mask of 255.252.0.0 (14-bits in length). It is intended for use by an entire organization setting multicast scopes privately for its own internal or organizational use. Starting with this address, you can create a considerable number of addresses--up to $2^{18}$, or 262,144 group addresses--for use in all subnets within your organization's network.

For more information, refer directly to the RFC, which can be obtained at the Request for Comments Web site.

- **Global scoping** This practice is most useful when you are using multicast group IP addresses in a public network address space, particularly the Internet.

  Because most organizations requiring one or more public addresses likely have already been assigned some public unicast IP addresses, a subnet allocation scheme has been proposed. For MADCAP, the 233.0.0.0 range of the Class D address space is recommended for use as a global scope range.

  When the 233.0.0.0 range is used, the allocation of global addresses works in the following way:

  1. A network registry, such as the Internet Assigned Numbers Authority (IANA), allocates and reserves the first 8 bits of the range (for example, the "233" portion of this range).

  2. The next 16 bits (the two middle octet numbers of addresses in this range) are based on a previously assigned Autonomous System (AS) number. This number is recorded with the applicable Internet Assigned Numbers Authority (IANA) registry for your region.

     If you already register your IP addresses with a regional network registry, you might know your AS number. You can also look it up easily using the Whois database system on the Internet. If you are obtaining IP addresses through an Internet service provider (ISP), you might contact them to find out what your AS number is.

     AS numbers are allocated to the regional registries by the IANA. If you or your ISP are located in the United States, you can apply directly to the American Registry for Internet Numbers (ARIN) to obtain an AS number. For more information, see the ARIN Web site.

     For other regions, AS numbers can also be obtained from appropriate regional registries. Other regional registries include the following:

ARIN or <hostmaster@arin.net> for the Americas, Caribbean, and Africa.

RIPE-NCC <ncc@ripe.net> for Europe.

AP-NIC <admin@apnic.net> for the Asia-Pacific region.

1. The last 8 bits in the address are local use bits.

   These provide the IP address range from which to configure any multicast scopes for group addresses you want to use publicly on the Internet. With this global scoping system in use, a subnet mask of 255.255.255.0 should be applied. This provides each organization with an assigned AS number of up to 255 multicast group addresses for use on the Internet.

   For more information on either the practice of global scoping for multicast address allocation or the use and allocation of AS numbers, use the IETF Web site. For global scoping, refer directly to the current available draft entitled "Static Allocation in 233/8," and for more information on AS numbering, refer to RFC 1930, "Guidelines for creation, selection, and registration of an Autonomous System (AS)."

**MADCAP and DHCP**

The Windows Server 2003 DHCP service supports both the DHCP and MADCAP protocols. These protocols function separately and are not dependent on each other. For example, a DHCP client might or might not be a MADCAP client and a MADCAP client might or might not be a DHCP client.

It is also worth mentioning that the DHCP Server service can be used to deploy MADCAP servers independent of how DHCP servers are used on your network. For example, to install Windows Server 2003 DHCP for MADCAP service only:

1. Create multicast scopes.

2. Do not create other scopes or superscopes.

Only where other scopes or superscopes are configured does the server computer also function as a DHCP server.

For more information about MADCAP, see Multicast address allocation.

**Important**

- Multicast scopes and MADCAP only provide a mechanism for dynamically allocating IP address configuration for multicast-ranged IP addresses. Other network configuration details are normally required to enable multicasting for your deployment needs. For more information, see Checklist: Installing IP multicast video conferencing.

**Notes**

- Multicast scopes do not require or support the use of DHCP options, but can be configured with a finite lifetime, enabling the multicast scope to expire and be removed by the server.

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

- For more information, see Manage Multicast Scopes.

# Removing scopes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Removing scopes**

When a subnet is no longer in use, or any other time you want to remove an existing scope, you can remove it at the DHCP console. In most cases, scopes are removed only when you need to renumber your network to use a different IP address range.

To retire a current scope and renumber your network to use a different scope, be sure to do the following first:

1. Create the new scope using a different range of addresses.
2. Configure options for the new scope.
3. Activate the new scope and deactivate the old scope.
4. When all clients are no longer using the old scope, remove the old scope.

**Scope migration strategies**

To remove old scopes without disrupting DHCP service to clients on the subnet, use the following suggestions to design your scope migration strategy:

- Activate a new replacement scope for the subnet before the old scope is deactivated. You can create a replacement scope on a different DHCP server or on the same server.
- Deactivate a scope before removing it. After a scope is deactivated, it does not acknowledge lease or renewal requests. DHCP clients will be unable to renew their leases from the deactivated scope and the original server, so the clients will seek new leases from an available DHCP server.
- Superscopes, reservations, and exclusion ranges can be used individually or together to provide a smooth migration of clients from one scope to another. For example, you can create a superscope that contains both a new scope and the original scope that has been targeted for deactivation. If you create an exclusion range on the original scope, clients with leases that fall within the exclusion range are unable to renew their leases and are assigned leases from the new scope instead. Or, if you create reservations for clients in the new scope, when a client attempts to renew its lease from the original scope, the client is instead assigned the address for which a reservation has been configured.

**Note**

- When manually reconfiguring Windows XP-based client computers, you can use the commands **ipconfig /release** and **ipconfig /renew** at the command prompt to release an old IP address and acquire a new lease from a replacement scope.

# Managing leases

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing leases**

IP addresses are leased by the DHCP server to its clients. Each lease has an expiration date, which the client must renew if it is going to continue to use that address.

Leases are retained in the DHCP server database four hours after expiration. This grace period protects a client lease in case the client and server are in different time zones, the individual computer clocks are not synchronized, or the client computer is off the network when the lease expires. Expired leases are included in the list of active leases and are distinguished by a different icon.

You can delete the lease of any DHCP client in the scope. The main reason for doing so is to remove a lease that conflicts with an IP address exclusion or a client reservation that you want to add. Deleting a lease has the same effect as if the client lease expired: the next time that client computer starts, it must enter the initialization state and obtain new TCP/IP configuration information from a DHCP server. There is nothing, however, to prevent the client from obtaining a new lease for the same IP address. You must make the address unavailable before the client requests another lease.

Delete only entries for clients that are no longer using the assigned DHCP lease or that are to be moved immediately to a new address. Deleting an active client could result in duplicate IP addresses on the network, because deleted addresses will be assigned to new active clients. After you delete the lease of the client and set a reservation or exclusion, you should always use **ipconfig /release** on the client computer to force the client to free its IP address.

**Note**

- You can view lease information for individual clients by first selecting the Active Leases folder for a scope in the DHCP console. When Active Leases for a scope is selected as the console view, the list of currently active client leases for the scope appears in the details pane.

**Modifying default lease durations for a scope**

When a scope is created, the default lease duration is set to eight days. In most cases, this value is sufficient. However, because lease renewal is an ongoing process that can affect the performance of DHCP clients and your network, it is sometimes useful to change the lease duration. Use the following guidelines to decide how to best modify lease duration settings for improving DHCP performance on your network:

- If you have a large number of IP addresses available and configurations that rarely change on your network, increase the lease duration to reduce the frequency of lease renewal queries between clients and the DHCP server. This reduces some network traffic caused by clients renewing their leases.

- If you have a limited number of IP addresses available and if client configurations change or clients move often on your network, reduce the lease duration to promote scavenging of old IP addresses by the DHCP server. This increases the rate at which addresses are returned to the available address pool for reassignment to new clients.

**Note**

- You can also set a separate lease time, different from the default scope lease time used by your DHCP clients, such as alternate lease times for supporting other types of clients such as BOOTP or Routing and Remote Access clients. For more information, see Manage BOOTP and Remote Access Clients.

# Using client reservations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using client reservations**

With client reservations, you can reserve a specific IP address for permanent use by a DHCP client. Typically, you will need to do this if the client uses an IP address that was assigned using another method for TCP/IP configuration.

If multiple DHCP servers are configured with a scope that covers the range of the reserved IP address, the client reservation must be made and duplicated at each of these DHCP servers. Otherwise, the reserved client computer can receive a different IP address, depending on the responding DHCP server.

If you want to change a reserved IP address for a current client, you have to remove the existing address reservation of the client, and then add a new reservation. You can change any other information about a reserved client while keeping the reserved IP address.

If you are reserving an IP address for a new client, or an address that is different from its current one, you should verify that the address has not already been leased by the DHCP server. Reserving an IP address in a scope does not automatically force a client currently using that address to stop using it.

If the address is already in use, the client using the address must first release is by issuing a DHCP release message (DHCPRELEASE). To make this happen, at the command prompt of a client computer running Windows 2000 or Windows XP, type **ipconfig /release**.

Reserving an IP address at the DHCP server also does not force the new client for which the reservation is made to immediately move to that address. In this case, too, the client must first issue a DHCP request message (DHCPREQUEST). To make this happen, at the command prompt of a client computer running Windows 2000 or Windows XP, type **ipconfig /renew**.

For clients using Windows 95 or Windows 98, you can use the Winipcfg.exe program to cause release or renewal of the reserved IP address in DHCP. For clients using MS-DOS, and some clients using other operating systems, a computer must be restarted for the change to take effect.

Once these changes are made, the reserved client is leased the IP address now reserved for its permanent use each time it renews its lease with the DHCP server.

**Notes**

- Reserved clients can have DHCP options configured specifically for their use. When options are configured for a reserved client, these values override any option type parameters distributed via server-based, scope-based, or class-based options assignment.

- You can also use the **ipconfig** command on computers running earlier versions of Windows NT to release and renew DHCP leases. However, not all other **ipconfig** command options are available when executed at clients running under these earlier versions.

- You can create reservations using any IP address in the scope's address range, even if the IP address is also within an exclusion range. Because of this design, when the 80/20 rule is implemented and all addresses in the scope are excluded (80% at one server, 20% at the other), reservations still function properly.

# Reconciling scopes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Reconciling scopes**

Reconciling scopes can fix inconsistencies, such as incorrect or missing information for client IP addresses that are stored in scope lease information. Scope IP address lease information is stored in two forms by the DHCP Server service:

- Detailed IP address lease information, stored in the DHCP database.
- Summary IP address lease information, stored in the DHCP database.

When reconciling scopes, the detail and summary entries are compared to find inconsistencies.

To correct and repair these inconsistencies, you need to reconcile any scope inconsistencies found when performing this operation. Once you select and reconcile scope inconsistencies, the DHCP service either restores those IP addresses to the original owner or creates a temporary reservation for those addresses. These reservations are valid for the lease time assigned to the scope. When the lease time expires, the addresses are recovered for future use.

For more information, see Reconcile the DHCP database or Reconcile a scope.

# Setting Up Options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up options**

This section covers:

- Assigning options
- Using option classes

# Assigning options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

### Assigning options

You can manage DHCP options at several distinct levels:

- **Predefined options.** At this level, you control which types of options are predefined for the DHCP server to expose as available options for assigning from any of the option configuration dialog boxes (such as **Server Options**, **Scope Options**, or **Reservation Options**) available through the DHCP console. You can add or remove options to and from the predefined list of standard options as needed. Although options are made available in this way, they are not assigned values until administratively configured at either the server, scope, or reservation.

- **Server options.** Assign values here (using the **General** tab) for options that should apply to or be inherited by all scopes and clients of the DHCP server as defaults. Options configured here can have their values overridden by different values if those values are set at either a scope, options class, or reserved client level.

- **Scope options.** Assign values here (using the **General** tab) for options that should apply only to clients of an applicable scope selected in the DHCP console tree. Options configured here can have their values overridden by different values if those values are set at either an options class or reserved client level.

- **Reservation options.** Assign values for options that should apply only to a specific reserved DHCP client. To use this level of assignment, you must first add a reservation for the applicable client to the applicable DHCP server and scope where the client is to obtain its IP address. These options are set for an individual DHCP client configured with an address reservation in a scope. Only properties manually configured at the client computer can override options assigned at this level.

- **Class options.** When using any of the option configuration dialog boxes (**Server Options**, **Scope Options** or **Reservation Options**), you can click the **Advanced** tab to configure and enable options for assignment to identifying member clients of a specified user or vendor class.

  Depending on the context, only those DHCP clients that identify themselves according to the selected class are distributed options data you have configured specifically for that class. For example, if a class-assigned option is set at a scope, only clients of that scope that indicate class membership during leasing activity are configured with class-assigned option values. Other non-member clients are configured using scope option values set from the **General** tab.

  Options configured here can override values assigned and set at the same context (either server, scope, or reservation options) or values inherited from options configured at a higher context. However, the ability of the client to indicate membership in a specific options class is typically the decisive criteria for using this level of options assignment. For more information, see Using option classes.

### Guidelines for assigning options

The following guidelines can help you determine what level to assign the options you use for clients on your network.

- Add or define new custom option types only if you have new software or applications that require a nonstandard DHCP option.

- If your DHCP server manages many scopes for a large network, be selective when assigning **Server Options**. These options apply by default to *all* clients of a DHCP server computer, unless otherwise overridden.

- Use **Scope Options** for assigning most options that clients use. In most networks, this level is typically preferred for assigning and enabling the use of DHCP options.

- Use **Class Options** if you have a mixture of DHCP clients with diverse needs that are able to identify a specific class on the DHCP server when obtaining a lease. For example, if you have a limited number of DHCP client computers running

Windows 2000, these clients can be configured to receive vendor-specific options that other clients do not use.

- Use **Reservation Options** for individual DHCP clients in your network that have special configuration requirements.

  For any hosts (that is, computers or other networked devices) that do not support DHCP or are not recommended to use it, you can also consider excluding IP addresses for those computers and devices and manually setting the IP address configuration directly at the applicable host. For example, you often need to statically configure the IP address for routers.

**Commonly used options**

After you set basic TCP/IP configuration settings (such as IP address, subnet mask, and default gateway) for clients, most clients also need the DHCP server to provide other information through DHCP options. The most common of these include the following:

- **Routers.** A preferred list of IP addresses for routers on the same subnet as DHCP clients. The client can then contact these routers as needed to forward IP packets destined for remote hosts.

- **DNS servers.** IP addresses for DNS name servers that DHCP clients can contact and use to resolve a domain host name query.

- **DNS domain.** Specifies the domain name that DHCP clients should use when resolving unqualified names during DNS domain name resolution.

- **WINS node type.** A preferred NetBIOS name resolution method for the DHCP client to use (such as b-node for broadcast only or h-node for a hybrid of point-to-point and broadcast methods).

- **WINS server.** IP addresses of primary and secondary WINS servers for the DHCP client to use.

**Note**

- When the DHCP service is installed, no DHCP option definitions are created. Option definitions are created only when the DHCP console is opened for the first time. If you want to configure the value of an option on a DHCP server on which the console has never been opened, you must first use the Netsh DHCP context command **server add optiondef** (at a **netsh dhcp>** command prompt or in a batch file or script) to create the option definition. To use Netsh to assign a value to the option definition you have created, use the Netsh DHCP context command **server set optionvalue**. For more information, see Netsh commands for DHCP.

# Using option classes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using option classes**

Option classes offer an additional method for grouping DHCP-provided configuration details for clients within a scope. For computers running Windows Server 2003 operating systems, there are two types of option classes that can be used for submanaging options:

- User classes, for assigning options to clients identified as sharing a common need for similar DHCP options configuration.
- Vendor classes, for assigning vendor-specific options to clients identified as sharing a commonly defined vendor type.

For more information, see Understanding user and vendor classes.

**How user classes work**

User classes allow DHCP clients to differentiate themselves by specifying a User Class option. When available for client use, this option includes a user-determined class ID that can help to group clients of similar configuration needs within a scope. For example, you might support users and computers with mobile computing needs by configuring a user class at the DHCP server and setting the related class ID at the client computers.

A user class is useful when you need to keep separate options that cover the special needs of identifying client computers, such as providing a shorter lease time for portable computers that move frequently or use remote access often. In this example, you could configure the DHCP server to distribute different options that are specific to the needs of clients.

For instance, shorter leases could be assigned to mobile clients. For more information, see Change the lease time for remote access clients.

The user class feature gives you greater flexibility in configuring DHCP clients on your network, but is not required for standard DHCP use. If user-defined option classes are not configured, options are provided through the applicable server, scope, or client option settings instead. For more information, see Assigning options.

DHCP servers running Windows Server 2003 , which support recognition of user class IDs, perform the following added steps to lease clients identifying themselves according to this process:

1. The server determines whether the user class identified by the client in its lease request is a recognized class, previously defined on the server.

   If a predefined user classes exists at the server and is configured, class-based assignment is enabled. For other user classes, you must first add and configure them at the server before they are available for use.

2. If the user class is recognized, the server determines whether any additional DHCP options are configured for this class in the active lease context (either the scope or a client reservation) where the server is leasing the client.

3. If the scope or reservation options are configured to provide options for the user-defined class of the client, the server returns those options to the client as part of its DHCP acknowledgment message (DHCPACK), which is sent to confirm the lease.

**Additional user class examples**

You can define specific user class identifiers to convey information about client software configuration, its physical location in a building, or about its user preferences. For example, an identifier can specify that DHCP clients are members of a user-defined class called "2nd floor, West," which has need for a special set of router, DNS, and WINS server settings.

You can also use the Microsoft predefined user classes for isolating configuration details specific for clients with special needs, such as BOOTP or Routing and Remote Access service. For more information, see Assign an advanced (class-based) option.

## Notes

- In addition to configuring or adding user classes at the DHCP server, at computers running Windows 2000, or Windows XP, you can set a DHCP class identifier with the **ipconfig /setclassid** command. For more information, see Set DHCP class ID information at a client computer.

- When you configure user classes at the DHCP server, be certain that the class identifying data you set at both the DHCP server and member client computers is identically matching binary or ASCII data. For more information, see Create a new user or vendor class.

- The user class option only permits one class ID to be used for identifying clients. Each client computer can only be identified as a member of a single user class at the DHCP server. You can use additional user classes and make new hybrids from your other user classes, as needed.

**How vendor classes work**

Vendor-defined option classes can be used by DHCP clients that are configured to optionally identify themselves by their vendor type to the DHCP server when obtaining a lease. For a client to identify its membership in a vendor class, the client provides a value in the **Vendor class identifier** option when it requests or selects a lease from the server.

The vendor class identifier information is a string of character data interpreted by a DHCP server. Microsoft supports vendor class identification for its DHCP clients running Windows 98 or Windows XP.

Most vendor types are derived from standard reserved hardware and operating system type abbreviation codes listed in Request for Comments (RFC) 1700. For more information, see TCP/IP RFCs.

Other vendors might choose to define their own specific vendor class IDs for either conveying vendor-specific information or handling special needs for their DHCP clients.

DHCP servers running Windows Server 2003 , which support recognition of vendor class IDs, perform the following additional steps to lease the clients that identify themselves according to this process:

1. The server determines whether the vendor class identified by the client in its lease request is a recognized class, previously defined on the server.

   Only Microsoft vendor classes are predefined at the server. For other vendor classes, you must manually add and configure these options at your DHCP servers running Windows Server 2003 before they are available for use.

2. If the vendor class is a recognized one, the server determines whether any additional DHCP options are configured for this class in the active lease context (either the scope or a client reservation) where the server is leasing the client.

3. If the scope or reservation options are configured to provide options for the vendor-defined class of the client, the server returns them using the **Vendor specific information** option as part of its DHCP acknowledgment message (DHCPACK), which is sent to confirm the lease.

Vendor classes permit other system vendors to support custom applications for DHCP in mixed vendor environments. Vendor-specific options, when provided, are used in addition to any of the standard DHCP options assigned or required for DHCP.

For more information about DHCP, see "Dynamic Host Configuration Protocol" at the Microsoft Windows Resource Kits Web site or refer directly to RFC 2132.

**Notes**

- For more information about DHCP options, see "DHCP Options" at the Microsoft Windows Resource Kits Web site.

- In most cases, the default (or unspecified) vendor class, DHCP standard options, can provide a useful default for grouping any DHCP clients that do not specify or recognize vendor class IDs.

- When you add new vendor classes at the DHCP server, be sure that the vendor class ID data you set at the server matches the actual vendor class ID used by clients for your vendor. For more information, contact the appropriate vendor.

# DHCP Interoperability Issues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Interoperability issues**

The following section covers issues that affect the use of the DHCP Server service with other services or network configurations.

- Using DNS servers with DHCP
- Using Routing and Remote Access servers with DHCP
- Multihomed DHCP servers

# Using DNS servers with DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using DNS servers with DHCP**
When installing the Windows Server 2003 DHCP service, you can configure the server to perform updates on behalf of its DHCP clients to any Domain Name System (DNS) servers that support dynamic updates.

**How DHCP/DNS update interaction works**
The DHCP server can be used to register and update the pointer (PTR) and host (A) resource records on behalf of its DHCP-enabled clients.

This process requires the use of an additional DHCP option, the Client FQDN option (option 81). This option permits the client to provide its fully qualified domain name (FQDN) as well as instructions to the DHCP server on how it would like the server to process DNS dynamic updates (if any) on its behalf.

When this option is issued by a qualified DHCP client, such as a DHCP-enabled computer running Windows 2000, Windows XP, or a Windows Server 2003 operating system, option 81 is processed and interpreted by a DHCP server running Windows Server 2003 to determine how the server initiates updates on behalf of the client. If the server is configured to perform DNS dynamic updates, it takes one of the following actions:

- The DHCP server updates both DNS A and PTR records if requested by clients using option 81.
- The DHCP server updates DNS A and PTR records regardless of whether the client requests this action or not.

In addition, the DHCP server can dynamically update DNS A and PTR records on behalf of legacy clients that are not capable of sending option 81 to the server. You can also configure the DHCP server to discard client A and PTR records when the client lease is deleted.

The DHCP server might be configured in one of the following ways:

- The DHCP server registers and updates client information with the authoritative DNS server of the zone in which the DHCP server is located *according to the DHCP client request*.

  This is the default configuration for DHCP servers running Windows Server 2003 and DHCP clients running Windows 2000, Windows XP, or a Windows Server 2003 operating system. In this mode, the DHCP client can request the way in which the DHCP server performs updates of its host (A) and pointer (PTR) resource records. If possible, the DHCP server accommodates the client request for handling updates to its name and IP address information in DNS.

  To modify this setting, select the **Dynamically update DNS A and PTR records only if requested by the DHCP clients** check box, which is located in **Properties** on the **DNS** tab on the applicable DHCP server or on one of its scopes.

- The DHCP server *always* registers and updates client information in DNS.

  This is a modified configuration supported for DHCP servers running Windows Server 2003 and DHCP clients running Windows 2000, Windows XP, or a Windows Server 2003 operating system. In this mode, the DHCP server always performs updates of the client's FQDN, leased IP address information, and both its host (A) and pointer (PTR) resource records, regardless of whether the client has requested to perform its own updates.

  To modify this setting, select the **Enable DNS dynamic updates according to the settings below** check box and click **Always dynamically update DNS A and PTR records**, which is located in **Properties** on the **DNS** tab on the applicable DHCP server or on one of its scopes.

- The DHCP server *never* registers and updates client information in DNS.

  To set this behavior, the DHCP server must be configured to disable performance of DHCP/DNS proxied updates. By disabling this feature, no client host (A) or pointer (PTR) resource records are updated in DNS for DHCP clients.

If necessary, this change in setting can be made at DHCP servers running Windows Server 2003 by clearing the **Enable DNS dynamic updates according to the settings below** check box, which is located in **Properties** on the **DNS** tab on the applicable DHCP server or one of its scopes. By default, updates are always performed for newly installed DHCP servers running Windows Server 2003 and any new scopes created for them.

**Advanced DHCP/DNS server configuration options**

In addition to these standard DHCP/DNS interactions, the DHCP server can be configured to perform these optional update tasks as follows:

1. The server can selectively be configured to *not* send updates for discarding a client host (A) resource record when the client lease expires.

   When the DHCP server is enabled to perform DNS updates, it always sends updates to discard the client pointer (PTR) resource records when the lease expires. Whether the server also does this with client host (A) resource records when the lease of a client expires (by default, the server discards these) is a configurable option.

   To modify this at the applicable DHCP server, clear the **Discard forward (name-to-address) lookups when leases expires** check box in **Properties** on the **DNS** tab.

2. The server can be selectively configured to *not* send updates for clients unable to use the Client FQDN option (option 81), to request the way that updates are handled.

   By default, the DHCP server does not send updates for clients that do not support option 81.

   To modify this setting, select the **Dynamically update DNS A and PTR records for DHCP clients that do not request updates (for example, clients running Windows NT 4.0)** check box, which is located in **Properties** on the **DNS** tab on the applicable DHCP server or one of its scopes.

**Windows DHCP clients and DNS dynamic update protocol**

DHCP clients running Windows 2000, Windows XP, or a Windows Server 2003 operating system interact differently than earlier versions of Windows when performing the DHCP/DNS interactions previously described. The following examples and graphics show how this process varies in different cases.

**Example 1: DHCP/DNS update interaction for DHCP clients running Windows 2000, Windows XP , or a Windows Server 2003 operating system**

DHCP clients running Windows 2000, Windows XP, or a Windows Server 2003 operating system interact with DNS dynamic update protocol as follows:

1. The client initiates a DHCP request message (DHCPREQUEST) to the server and includes DHCP option 81. By default, the client requests that the DHCP server register the DNS PTR record, while the client registers its own DNS A record.

2. The server returns a DHCP acknowledgment message (DHCPACK) to the client, granting an IP address lease and including DHCP option 81. If the DHCP server is configured with the default settings (dynamically update DNS A and PTR records only if requested by the DHCP clients), then option 81 instructs the client that the DHCP server will register the DNS PTR record and the client will register the DNS A record.

3. Asynchronously, the client registers its DNS A record, and the DHCP server registers the DNS PTR record of the client.

**Example 2: DHCP/DNS update interaction for earlier Windows DHCP clients (prior to Windows 2000)**

Earlier versions of Windows DHCP clients do not support the DNS dynamic update process directly, and therefore, cannot directly interact with the DNS server. For these DHCP clients, updates are typically handled as follows:

1. The client initiates a DHCP request message (DHCPREQUEST) to the server. The request does not include DHCP option 81.

2. The server returns a DHCP acknowledgment message (DHCPACK) to the client, granting an IP address lease, without DHCP option 81.

3. The server then sends updates to the DNS server for the forward lookup record of the client, which is a host (A) resource record. The server also sends updates for the reverse lookup record of the client, which is a pointer (PTR) resource record.

**DNS record ownership and the DnsUpdateProxy group**
As previously described, you can configure a DHCP server so that it dynamically registers host (A) and pointer (PTR) resource records on behalf of DHCP clients. In this configuration, the use of secure dynamic update with DNS servers might cause stale resource records.

For example, suppose the following sequence of events occurs:

1. A DHCP server running Windows Server 2003 (DHCP1) performs a secure dynamic update on behalf of one of its clients for a specific DNS domain name.

2. Because the DHCP server successfully created the name, it becomes the owner of the name.

3. Once the DHCP server becomes the owner of the name, only that DHCP server can update the DNS records for that name.

In some circumstances, this can cause problems. For example, if DHCP1 fails and a second backup DHCP server comes online, the second server cannot update the client name because it is not the owner of the name.

In another example, if the DHCP server performs DNS dynamic updates for legacy DHCP clients (clients running a version of Windows earlier than Windows 2000), and those clients are later upgraded to Windows 2000, Windows XP, or a Windows Server 2003 operating system, the upgraded client cannot take ownership of or update its own DNS records.

To solve this problem, the built-in security group called DnsUpdateProxy is provided. If all DHCP servers are added as members of the DnsUpdateProxy group, then the records of one server can be updated by another server if the first server fails. Also, because all of the objects that are created by the members of the DnsUpdateProxy group are not secured, the first user (that is not a member of the DnsUpdateProxy group) to modify the set of records that is associated with a DNS name becomes its owner. When legacy clients are upgraded, they can therefore take ownership of their name records at the DNS server. If every DHCP server registering resource records for legacy clients is a member of the DnsUpdateProxy group, the problems discussed earlier are eliminated.

You can configure the DnsUpdateProxy security group through Active Directory Users and Computers. For more information, see Add a member to a group.

**Securing records when using the DnsUpdateProxy group**
DNS domain names that are registered by the DHCP server are not secure when the DHCP server is a member of the DnsUpdateProxy group. The host (A) resource record for the DHCP server itself is an example of such a record. Also, because objects created by the members of the DnsUpdateProxy group are not secured, it is impossible to use this group effectively in an Active Directory integrated zone that allows only secure dynamic updates unless you take additional steps to allow records created by members of the group to be secured.

To protect against unsecured records, or to allow members of the DnsUpdateProxy group to register records in zones that allow only secured dynamic updates, you can create a dedicated user account and configure DHCP servers to perform DNS dynamic updates with the user account credentials (user name, password, and domain). The credentials of one dedicated user

account can be used by multiple DHCP servers.

A dedicated user account is a user account whose sole purpose is supplying DHCP servers with credentials for DNS dynamic update registrations. When you create a dedicated user account and configure DHCP servers with the account credentials, each DHCP server supplies these credentials when registering names on behalf of DHCP clients using DNS dynamic update. The dedicated user account should be created in the forest where the primary DNS server for the zone to be updated resides. The dedicated user account can also be located in another forest as long as the forest it resides in has a forest trust established with the forest containing the primary DNS server for the zone to be updated. For more information about establishing forest trusts, see Forest trusts.

When the DHCP Server service is installed on a domain controller, configuring the DHCP server with the credentials of the dedicated user account will prevent the server from inheriting, and possibly misusing, the power of the domain controller. When installed on a domain controller, the DHCP Server service inherits the security permissions of the domain controller and has the authority to update or delete any DNS record that is registered in a secure Active Directory-integrated zone (this includes records that were securely registered by other computers running Windows 2000 or a Windows Server 2003 operating system, including domain controllers).

It is necessary to configure a dedicated user account and configure the DHCP server with the account credentials under the following circumstances:

- A domain controller is configured to function as a DHCP server.
- The DHCP server is configured to perform DNS dynamic updates on behalf of DHCP clients.
- The DNS zones to be updated by the DHCP server are configured to allow only secure dynamic updates.

Once you have created a dedicated user account, you can configure DHCP servers with the user account credentials by using the DHCP console or by using the Netsh DHCP context command **server set dnscredentials**. For more information on configuring credentials using the DHCP console, see Configure DNS dynamic update credentials. For a comprehensive reference about Netsh commands for DHCP (including syntax, parameters, and examples for the **set dnscredentials** command at the **server** context of **netsh dhcp**), see Netsh commands for DHCP.

For more information on groups and accounts, see Create a new user account and Default groups.

**Additional resources on DHCP and DNS interaction**
Because of the close integration of DHCP and DNS described in this section, you might want to investigate or review these additional topics as resources for your deployment issues related to this feature.

For more information:

- On the DNS dynamic update protocol and considerations for securing dynamic updates when using Active Directory, see Dynamic update.
- On how to configure DNS servers to enable some or all updates for specific zones, see Allow dynamic updates and Allow only secure dynamic updates.
- On how to enable DHCP servers to initiate updates on behalf of its clients for specific scopes (or all scopes), see Enable DNS dynamic updates for clients.
- On how you can modify or set computers to initiate dynamic updates on their own behalf, see Configure TCP/IP to use DNS.
- On DNS resource records, see DNS or Resource records reference.

### Notes

- Microsoft supports the DHCP/DNS update interaction currently under final review as a proposed Internet standard Request for Comment (RFC) document by the Internet Engineering Task Force (IETF).

  This interactive process is fully described in the applicable draft, "Interaction between DHCP and DNS." To obtain the current or final version of this draft, see the Request for Comments Web site.

- If you are using legacy DNS servers that do not support dynamic updates, you can implement the following changes for dynamically updating and registering names and addresses for your DHCP clients:

    1. If you are using WINS and legacy Windows DNS servers (that is, DNS servers running Windows NT Server 4.0), you might be able to use WINS lookup integration to support resolution of client names and addresses on your network that are not updated dynamically in DNS.

    2. Upgrade or replace older DNS servers with DNS servers running Windows Server 2003 .

- For more information about DHCP, see "Dynamic Host Configuration Protocol" at the Microsoft Windows Resource Kits Web site.

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

For more information about the DNS registration changes related to DHCP Servers running Windows Server 2003, see DNS registration changes for Windows Server 2003 based DHCP Servers

# DNS registration changes for Windows Server 2003 based DHCP Servers

Updated: August 19, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This article describes the DNS registration changes for DHCP Servers that are running Windows Server® 2003.

**Overview**

When the DHCP Server role is installed on a domain controller, the DHCP Server inherits the security permissions of the domain controller. To prevent possible misuse of the domain controller's elevated permissions, DHCP Servers that are installed on Windows Server 2003 do not register DNS records on behalf of the clients that are associated with the DHCP Server unless the DHCP Server is explicitly configured with DNS credentials. This behavior prevents a potential escalation of privilege to clients of the DHCP Server.

**Configuring DNS credentials on a DHCP Server that is running Windows Server 2003**

Follow these steps to configure the DNS credentials of a DHCP Server that is installed on a domain controller running the Windows Server 2003 operating system:

1. Start the DHCP management console. Click **Start**, then click **Run** and type **dhcpmgmt.msc**.

2. In the DHCP navigation pane, expand the server node and right-click **IPv4**, and then click **Properties**.

3. In the resulting dialog box, click the **Advanced** tab, and then click **Credentials**.

4. In the **DNS dynamic update credentials** dialog box, enter the DNS credentials (User name, Domain, and Password) for the account that is used by the DHCP Server for DNS registrations.

| **Note** |
| --- |
| These credentials should belong to a member of the DnsAdmins or the DnsUpdateProxy group. |

**Related information**

For more information about creating and adding a user account as a member of a group by using the Active Directory® Users and Groups console, see Changing group memberships.

# Using Routing and Remote Access servers with DHCP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Routing and Remote Access servers with DHCP**

The DHCP Server service can be deployed along with the Routing and Remote Access service to provide remote access clients with a dynamically assigned IP address during connection. When these services are used together on the same server computer, the information provided during dynamic configuration is provided differently than in the case of typical DHCP configuration for LAN-based clients.

In LAN environments, DHCP clients negotiate and receive the following configuration information, based entirely on settings configured in the DHCP console for the DHCP server:

- A leased IP address provided from the available address pool of an active scope on the DHCP server. The DHCP server directly manages and distributes the address to the LAN-based DHCP client.
- Additional parameters and other configuration information provided through assigned DHCP options in the address lease. The values and list of options used correspond to option types configured and assigned on the DHCP server.

When a Routing and Remote Access server provides dynamic configuration for dial-up clients, it first performs the following steps:

- When the Routing and Remote Access server starts with the **Use DHCP to assign remote TCP/IP addresses** option, it instructs the DHCP client to obtain 10 IP addresses from a DHCP server.
- The remote access server utilizes the first of these 10 IP addresses obtained from the DHCP server for the remote access server interface.
- The remaining nine addresses are allocated to TCP/IP-based clients as they dial in to establish a session with the remote access server.

IP addresses that are freed when remote access clients disconnect are reused. When all 10 IP addresses are used, the remote access server obtains 10 more from a DHCP server. When the Routing and Remote Access service is stopped, all IP addresses obtained through DHCP are released.

When the Routing and Remote Access server uses this type of proactive caching of DHCP address leases for dial-up clients, it records the following information for each lease response it obtains from the DHCP server:

- The IP address of the DHCP server
- The client leased IP address (for later distribution to the Routing and Remote Access client)
- The time at which the lease was obtained
- The time at which the lease expires
- The duration of the lease

All other DHCP option information returned by the DHCP server (such as server, scope, or reservation options) is discarded. When the client dials in to the server and requests an IP address (that is, when **Server Assigned IP Address** is selected), it uses a cached DHCP lease to provide the dial-up client with dynamic IP address configuration.

When the IP address is provided to the dial-up client, the client is unaware that the IP address has been obtained through this intermediate process between the DHCP server and the Routing and Remote Access server. The Routing and Remote Access server maintains the lease on behalf of the client. Therefore, the only information that the client receives from the DHCP server is the IP address lease.

In dial-up environments, DHCP clients negotiate and receive dynamic configuration using the following modified behavior:

- A leased IP address from the Routing and Remote Access server cache of DHCP scope addresses. The Routing and Remote Access server obtains and renews its cached address pool with the DHCP server.

- If additional parameters and other configuration information provided through assigned DHCP options in the address lease is normally provided by the DHCP server, this information is returned to the Routing and Remote Access client based on TCP/IP properties configured on the Routing and Remote Access server.

**Note**

- DHCP servers running Windows Server 2003 provide a predefined user class, the **Default Routing and Remote Access Class**, for assigning options that are specific and provided only to Routing and Remote Access clients.

# Multihomed DHCP servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multihomed DHCP servers**

A multihomed DHCP server is a computer running a Windows Server 2003 operating system that uses the DHCP service for more than a single network connection. For a server computer to be multihomed, each network connection must attach the computer to more than a single physical network. This requires that additional hardware (in the form of multiple installed network adapters) be used on the computer.

A computer running a Windows Server 2003 operating system can perform as a multihomed DHCP server. For multihomed servers, the DHCP service binds to the first IP address statically configured for each network connection in use.

By default, the service bindings depend on whether the first network connection is configured dynamically or statically for TCP/IP. Based on the method of configuration it uses, reflected by its current settings in **Internet Protocol (TCP/IP)** properties, the DHCP Server service performs default service bindings as follows:

- If the first network connection uses a manually specified IP address, the connection is enabled in server bindings. For this to occur, a value for **IP address** must be configured and the **Use the following IP address** option selected in Internet Protocol (TCP/IP) properties. In this mode, the DHCP server listens for and provides service to DHCP clients.

- If the first network connection uses an IP address configured dynamically, the connection is disabled in server bindings. This occurs when the **Obtain an IP address automatically** option is selected in Internet Protocol (TCP/IP) properties. For computers running Windows Server 2003 operating systems, this is the default setting. In this mode, the DHCP server does not listen for and provide service to DHCP clients until a static IP address is configured.

- The DHCP server will bind to the first static IP address configured on each adapter.

### Notes

- By design, DHCP server bindings are enabled and disabled on a per-connection, not per-address basis. All bindings are based on the first configured IP address for each connection appearing in the Network Connections folder. If additional static IP addresses (for example, as set in Advanced TCP/IP properties) are configured for the applicable connection, these addresses are never used by DHCP servers running Windows Server 2003 and are inconsequential for server bindings.

- For more information, see About Network Connections.

- DHCP servers running Windows Server 2003 never bind to any of the NDISWAN or DHCP-enabled interfaces used on the server. These interfaces are not displayed in the DHCP console under the current server bindings list because they are never used for DHCP service. Only additional network connections that have a primary static IP address configured can appear in the server bindings list (or be selectively enabled or disabled there).

- For more information, see Selectively set DHCP server bindings for network connections.

**Example: Configuring a multihomed DHCP server**

The following illustration is an example of a multihomed DHCP server with three network adapters installed. Each adapter is configured to lease addresses on separate physical subnets.

Note that in the graphic, each network adapter is configured statically with a single IP address. In this network example, three Class C ranges of IP addresses are used:

| Subnet | IP Address Range |
|---|---|
| Subnet A | 192.168.0.1 - 192.168.0.254 |
| Subnet B | 192.168.1.1 - 192.168.1.254 |
| Subnet C | 192.168.2.1 - 192.168.2.254 |

Each of the three adapters in this example connects the server to three different physical subnets (Subnets A, B, and C). To achieve the intended result of having DHCP provide leased configuration service to all clients in each of the respective subnets, two configuration details are essential and must be verified during deployment plans:

1. The server must use a statically configured IP address on the same subnet as the IP address range it services.

2. The server must have each of its valid subnet IP addresses excluded from the scope used to offer leases to clients.

The default subnet mask value (255.255.255.0) is used for all three subnets, providing 254 IP addresses available per subnet for lease to DHCP clients.

To provide a small pool of ten IP addresses available for statically configured devices such as the DHCP server, printers, and other devices, an exclusion range is created in the scope for each subnet:

| Subnet | Exclusion Range |
|---|---|
| Subnet A | 192.168.0.1 - 192.168.0.10 |
| Subnet B | 192.168.1.1 - 192.168.1.10 |
| Subnet C | 192.168.2.1 - 192.168.2.10 |

Exclusion ranges prevent the DHCP server from assigning IP addresses to DHCP clients, so all of the IP addresses contained in the exclusion ranges will remain available for static configurations even after the DHCP server is started and begins servicing clients.

Addresses that are not excluded remain available for assignment to DHCP clients. These ranges of IP addresses form each subnet's address pool:

| Subnet | Address Pool |
|---|---|
| Subnet A | 192.168.0.11 - 192.168.0.254 |
| Subnet B | 192.168.1.11 - 192.168.1.254 |

| | |
|---|---|
| Subnet C | 192.168.2.11 - 192.168.2.254 |

**Note**

- For more information on IP subnetting, see Subnet masks or the Microsoft Windows Server 2003 *Resource Kit*.

# DHCP updated technical information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP updated technical information**

Updated technical information for DHCP can be obtained by searching technical articles available from the Personal Support Center at the Microsoft Web site. For more information, see Updated technical information.

You can also obtain additional in-depth information on DHCP in the Microsoft Windows Server 2003 *Resource Kit*.

For more information about DHCP, see "Dynamic Host Configuration Protocol" at the Microsoft Windows Resource Kits Web site.

For more information about DHCP options, see "DHCP Options" at the Microsoft Windows Resource Kits Web site.

# DHCP console icons reference

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP console icons reference**
DHCP provides context-specific icons to dynamically represent the state of console objects. Objects include the DHCP servers, clients, scopes, and option types that are used and managed for each server.

**General usage of console icons**
Some of the icons used in DHCP have specific meanings, but most are used to communicate general status information about the current state of the console. For example, when an icon is used with an hourglass superimposed, such as:

it means that the console is attempting to connect to the server.

Likewise, when an icon is used with a red circle and a superimposed 'X', such as:

it often means that DHCP has lost its connection to the server.

**Glossary of specific icons**
The following is a partial list of console icons used in DHCP.

- Server-related icons
- Scope-related icons
- Option-related icons
- Other console icons

**Server-related icons**

| Icon | Description |
|---|---|
| | DHCP server added to console. |
| | DHCP server connected and active in console. |
| | DHCP server connected but not authorized in Active Directory for use on your network. |
| | DHCP server connected but current user does not have the administrative credentials to manage the server. |
| | DHCP server warning. Available addresses for server scopes are 90 percent or more leased and in use. This means that the server is nearly depleted of available addresses to lease to clients. |
| | DHCP server alert. No addresses are available from server scopes because the maximum (100 percent) of the addresses allocated for use are currently leased. This represents a failure of the DHCP server on the network because it is not able to lease or service clients. |

**Scope-related icons**

| Icon | Description |
|---|---|
| | Scope or superscope is active. |
| | Scope or superscope is inactive. |

| | |
|---|---|
| | Scope or superscope warning. Scope warning: 90 percent or more of the scope's IP addresses are in use. Superscope warning: If any scope within the superscope has a warning, the superscope has a warning. |
| | Scope or superscope alert. Scope alert: All IP addresses have been allocated by the DHCP server and are in use. No more clients can obtain IP addresses from the DHCP server because it has no more IP addresses to allocate. Superscope alert: At least one scope contained in the superscope has all IP addresses allocated by the DHCP server. No clients can obtain an IP address from the range defined in the scope that is 100 percent allocated. If other scopes within the superscope contain available addresses, the DHCP server can allocate addresses from these scopes. |

**Option-related icons**

| Icon | Description |
|---|---|
| | Server options folder. |
| | Server option. |
| | Scope options folder. |
| | Scope option. |
| | Reservation option. |

**Other console icons**

| Icon | Description |
|---|---|
| | Root of the DHCP console. |
| | Address pool folder. |
| | Scope allocation range. Addresses in this range are allocated to the available address pool used to offer leases to clients. |
| | Scope exclusion range. Addresses in this range are excluded from the available address pool used to offer leases to clients. |
| | Active leases folder. |
| | Active lease: this address is not available for lease by the DHCP server. |
| | Expired lease: this address is available for lease by the DHCP server. |
| | Active lease, DNS dynamic update pending. This address is not available for lease by the DHCP server. |
| | Client is using dial-up network connection through a remote access server. |
| | An individual reservation and the reservations folder. |
| | Bootstrap Protocol (BOOTP) table. |
| | BOOTP entry in the table. |

# DHCP Troubleshooting

# Troubleshooting DHCP clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting DHCP clients**
What problem are you having?

- The DHCP client does not have an IP address configured or indicates that its IP address is 0.0.0.0.
- The DHCP client appears to have automatically assigned itself an IP address that is incorrect for the current network.
- The DHCP client appears to be missing some network configuration details or is unable to perform related tasks, such as resolving names.
- The DHCP client appears to have incorrect or incomplete options, such as an incorrect or missing router (default gateway) configured for the subnet on which it is located.
- Many DHCP clients are unable to get IP addresses from the DHCP server.
- The DHCP client appears to be affected by another problem not described above.

**The DHCP client does not have an IP address configured or indicates that its IP address is 0.0.0.0.**

- **Cause:** The client was not able to contact a DHCP server and obtain an IP address lease, either because of a network hardware failure or because the DHCP server is unavailable.
- **Solution:** Verify that the client computer has a valid functioning network connection. First, check that related client hardware (cables and network adapters) are working properly at the client using basic network and hardware troubleshooting steps.

  If the client hardware appears to be prepared and functioning properly, check that the DHCP server is available on the network by pinging it from another computer on the same network as the affected DHCP client.

**The DHCP client appears to have automatically assigned itself an IP address that is incorrect for the current network.**

- **Cause:** The client running Windows 98, Windows Millennium Edition, or Windows XP could not find a DHCP server and has used IP autoconfiguration to configure its IP address.

  In some larger networks, disabling IP autoconfiguration might be desirable for network administration.
- **Solution:** First, use the ping command to test connectivity from the client to the server. Your next step would be to either verify or manually attempt to renew the client lease. Depending on your network requirements, it might be necessary to disable IP autoconfiguration at the client. You can learn more about IP autoconfiguration and how it works prior to making this decision.
- **See also:** Test a TCP/IP configuration by using the ping command; Verify, release, or renew a client address lease; Configure TCP/IP for automatic addressing; Disable automatic address configuration

**The DHCP client appears to be missing some network configuration details or is unable to perform related tasks, such as resolving names.**

- **Cause:** The client might be missing DHCP options in its leased configuration, either because the DHCP server is not configured to distribute them or the client does not support the options distributed by the server.
- **Solution:** For Microsoft DHCP clients, verify that the most commonly used and supported options have been configured

at the server, scope, client, or class level of options assignment.

- **See also:** Manage Options and Classes; Assigning options

**The DHCP client appears to have incorrect or incomplete options, such as an incorrect or missing router (default gateway) configured for the subnet on which it is located.**

- **Cause:** The client has the full and correct set of DHCP options assigned but its network configuration does not appear to be working correctly.

  If the DHCP server is configured with an incorrect DHCP router option (option code 3) for the default gateway address of the client, clients running Windows NT, Windows 2000, or Windows XP use the correct address. However, DHCP clients running Windows 95 use the incorrect address.

- **Solution:** Change the IP address list for the router (default gateway) option at the applicable DHCP scope and server. If you are configuring the router option as a **Server Option** at the affected DHCP server, remove it there and set the correct value in the **Scope Options** node for the applicable DHCP scope that services the client.

  In rare instances, you might have to configure the DHCP client to use a specialized list of routers different from other scope clients. In such cases, you can add a reservation and configure the router option list specifically for the reserved client.

- **See also:** Assign a server-based option; Assign a scope-based option; Assign an option to a reserved client; Add a client reservation; Assigning options

  For more information about DHCP options, see "DHCP Options" at the Microsoft Windows Resource Kits Web site.

**Many DHCP clients are unable to get IP addresses from the DHCP server.**

- **Cause:** The IP address of the DHCP server was changed and now DHCP clients cannot get IP addresses.

- **Solution:** A DHCP server can only service requests for a scope that has a network ID that is the same as the network ID of its IP address.

  Make sure that the DHCP server IP address falls in the same network range as the scope it is servicing. For example, a server with an IP address in the 192.168.0.0 network cannot assign addresses from scope 10.0.0.0 unless superscopes are used.

- **See also:** DHCP Best Practices; Using superscopes; Configuring scopes

- **Cause:** The DHCP clients are located across a router from the subnet where the DHCP server resides and are unable to receive an address from the server.

- **Solution:** A DHCP server can provide IP addresses to client computers on remote multiple subnets only if the router that separates them can act as a DHCP relay agent.

  Completing the following steps might correct this problem:

1. Configure a BOOTP/DHCP Relay Agent on the client subnet (that is, the same physical network segment). The relay agent can be located on the router itself, on a computer running Windows NT Server and the DHCP Relay Agent component, on a computer running Windows 2000 Server with the Routing and Remote Access service enabled and configured as a DHCP Relay Agent, or on a computer running a Windows Server 2003 operating system with the Routing and Remote Access service enabled and configured as a DHCP Relay Agent.

2. At the DHCP server, do the following:

   a. Configure a scope to match the network address on the other side of the router where the affected clients are

located.

b. In the scope, make sure that the subnet mask is correct for the remote subnet.

c. Use a default gateway on the network connection of the DHCP server in such a way that it is not using the same IP address as the router that supports the remote subnet where the clients are located.

d. Do not include this scope (that is, the one for the remote subnet) in superscopes configured for use on the same local subnet or segment where the DHCP server resides.

3. Make sure there is only one logical route between the DHCP server and the remote subnet clients.

- **See also:** DHCP Best Practices; DHCP/BOOTP Relay Agents; BOOTP and DHCP

- **Cause:** Multiple DHCP servers exist on the same local area network (LAN).

- **Solution:** Make sure that you do not configure multiple DHCP servers on the same LAN with overlapping scopes.

  You might want to rule out the possibility that one of the DHCP servers in question is a computer running Small Business Server. On a computer running Small Business Server, the DHCP Server service automatically stops when it detects another DHCP server on the LAN.

- **See also:** DHCP Best Practices; Configuring scopes

**The DHCP client appears to be affected by another problem not described above.**

- **Cause:** My problem is not described above.

- **Solution:** Search the Microsoft Web site for updated technical information that might relate to the problem you have observed. If necessary, you can obtain information and instructions that pertain to your current problem or issue.

  If you are connected to the Internet, the latest updates for the Windows Server 2003 family are available at the Microsoft Web site.

- **See also:** DHCP updated technical information; DHCP; Using the Windows Deployment and Resource Kits; Microsoft Web site

# Troubleshooting DHCP servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting DHCP servers**
What problem are you having?

- The DHCP server is stopped.
- The DHCP server is unable to provide service to clients.
- One of two DHCP servers on the same subnet is not servicing clients.
- The DHCP server appears to have suffered some data corruption or loss.
- The server appears to be affected by another problem not described above.

**The DHCP server is stopped.**

- **Cause:** The DHCP server has not been authorized to operate on the network.
- **Solution:** Authorize the DHCP server in the enterprise where it is being used.
- **See also:** Authorizing DHCP servers; Authorize a DHCP server in Active Directory; Delegate ability to authorize DHCP servers to a non-enterprise administrator
- **Cause:** Configuration details might be incorrect or missing at the server.
- **Solution:** If you have just completed setting up or administering the DHCP server, you might want to review the provided checklist to see if you have missed a crucial step in the installation process.

  To help prevent the most common types of problems, review DHCP best practices for tips on deploying and managing your servers.

  Because many DHCP failures are first detected as client-side errors, you might want to start by investigating the problem there.
- **See also:** Checklist: Installing a DHCP server; DHCP Best Practices; Troubleshooting DHCP clients
- **Cause:** The DHCP server has been stopped.
- **Solution:** Check the system event log and DHCP server audit log files for details.

  When the DHCP Server service either stops or cannot start, useful explanatory information about the source of the service failure or shutdown can generally be found in these logs.
- **See also:** Audit logging; Analyzing server log files; Using the Event Viewer snap-in; Search for specific events

**The DHCP server is unable to provide service to clients.**

- **Cause:** The server is a multihomed computer and is not providing service on one or more of its network connections.
- **Solution:** Review Windows Server 2003 DHCP binding defaults for network connections based on whether you have elected to either statically or dynamically configure TCP/IP for any or all installed connections on the server computer.

Also, review an example of multihomed DHCP server configuration to see if you have missed any critical details.

- **See also:** Multihomed DHCP servers; Selectively set DHCP server bindings for network connections

- **Cause:** Scopes or superscopes on the DHCP server have not been either configured or activated for use.

- **Solution:** Add scopes and make sure that they are correctly configured along with any DHCP scope options that need to be assigned for client use.

- **See also:** Configuring scopes; Create a new scope; Assign a scope-based option

- **Cause:** The server is located on a different subnet as some of its clients and is not providing service to clients on remote subnets.

- **Solution:** If you are using a DHCP server in a routed network, you might want to review issues related to DHCP relay agents and the appropriate use of superscopes.

- **See also:** DHCP/BOOTP Relay Agents; Using superscopes; Create a superscope

- **Cause:** The scope in use is full and can no longer lease addresses to requesting clients.

- **Solution:** If the DHCP server does not have IP addresses available to provide to its clients, it returns DHCP negative acknowledgment messages (DHCPNAKs) to them. When this occurs, consider the following possible solutions:

1. Expand the address range by increasing the **End IP address** for the current scope.

2. Create a new additional scope and a superscope, then add the current scope and the new scope to the superscope.

3. Create a new scope or extend the range. Optimally, you could renumber your current IP network. Deactivate the old scope as needed, and then configure and activate the new one.

4. Reduce the lease duration. This can help to expedite the reclaiming of lapsed scope addresses.

   Other DHCP-related procedures and techniques might also help to accelerate or ease the transition from an existing scope being retired to a new scope created to take its place at the server. These include deleting client leases from the scope being retired, excluding addresses from that scope, and then deactivating it once the new scope has been activated. This ensures that the DHCP client obtains leasing from the new scope.

- **See also:** Managing leases; Removing scopes; Delete a client lease; Exclude an address from a scope; Activate a scope; Deactivate a scope

- **Cause:** The range of IP addresses being offered by the DHCP server is in conflict with the range of addresses being offered by another DHCP server on the network.

  You can confirm that this is the likely cause if DHCP server logs still indicate that DHCP negative acknowledgment messages (DHCPNAKs) are being returned to requesting clients or if you have tried unsuccessfully at the client to renew its lease manually.

- **Solution:** Modify the scope address pool for the scopes at each DHCP server to ensure that scope IP addresses do not overlap. You can add exclusions to the scopes as necessary, delete client leases, and temporarily enable server-side conflict detection to assist in solving the problem.

- **See also:** Delete a client lease; Exclude an address from a scope; Enable address conflict detection; DHCP Best Practices

**One of two DHCP servers on the same subnet is not servicing clients.**

- **Cause:** The DHCP server is not authorized in Active Directory.

- **Solution:** If the DHCP server is a domain member, authorize the server in Active Directory.

  In some circumstances you might accidentally have a standalone server and a domain member server on the same subnet. When the standalone server detects the domain member server, it attempts to verify that it is authorized in Active Directory. Even if a domain controller resides on the same subnet as the standalone DHCP server, the DHCP server cannot verify its status with the domain controller because the DHCP server is not a domain member. When the standalone server is unable to access a domain controller to discover whether it is authorized, it stops servicing clients and displays the red icon in the DHCP console that indicates the server is unauthorized. If you want the standalone server to service clients on the subnet, remove the authorized DHCP server from the subnet.

- **See also:** Authorizing DHCP servers; Authorize a DHCP server in Active Directory; DHCP console icons reference

**The DHCP server appears to have suffered some data corruption or loss.**

- **Cause:** The DHCP server database has become corrupted or is missing server data, possibly reporting JET database errors.

- **Solution:** Use DHCP server data recovery options to restore the database and correct any of the reported errors. You can also use the Reconcile feature in the DHCP console to verify and reconcile any database inconsistencies that the server is able to find.

- **See also:** Restoring server data; The DHCP database; Reconciling scopes; Reconcile the DHCP database; Reconcile a scope

**The server appears to be affected by another problem not described above.**

- **Cause:** My problem is not described above.

- **Solution:** Search the Microsoft Web site for updated technical information that might relate to the problem you have observed. You can obtain information and instructions that pertain to your current problem or issue.

  If you have connection to the Internet, the latest updates for members of the Windows Server 2003 family are available at the Microsoft Web site.

- **See also:** DHCP updated technical information; DHCP; Using the Windows Deployment and Resource Kits; Microsoft Web site

# WINS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS**
Windows Internet Name Service (WINS) provides a dynamic replicated database service that can register and resolve NetBIOS names to IP addresses used on your network. The Microsoft® Windows Server 2003 family provides WINS, which enables the server computer to act as a NetBIOS name server and register and resolve names for WINS-enabled client computers on your network as described in the NetBIOS over TCP/IP standards.

- Before you begin using this computer as a WINS server, see Checklist: Installing a WINS server.
- To find features that have been moved in the Windows Server 2003 family, see New ways to do WINS tasks.
- For tips about using WINS, see WINS Best Practices.
- For help with specific tasks, see WINS How To....
- For general background information, see WINS Concepts.
- For problem-solving instructions, see WINS Troubleshooting.

# Checklist: Installing a WINS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Checklist: Installing a WINS server**

| Step | Reference |
|---|---|
| Review WINS concepts such as NetBIOS names, WINS servers, WINS clients, and replication partners. | Understanding WINS |
| Review best practices for implementing WINS on your network. | WINS Best Practices |
| Determine the number of WINS servers you need to install and where to locate each server on your network. | Planning WINS networks |
| Manually configure TCP/IP properties for the WINS server computer. | Configure TCP/IP for static addressing |
| Install a primary WINS server. | Install a WINS server |
| Open the WINS console. | Open the WINS console |
| Modify WINS server defaults, if needed. | Modifying WINS server defaults |
| Install a secondary WINS server. | Install a WINS server |
| Configure replication settings on both primary and secondary WINS servers. Choose among these replication partnership methods:<br>• Push partner only<br>• Pull partner only<br>• Push/pull partner (recommended) | Configuring WINS replication; Configure Replication |
| View and filter the WINS database view of active registrations as needed. | View WINS Records |
| Add and remove mappings in the WINS database as needed. | Manage Static Mappings; Delete or tombstone an entry in the WINS database |
| Back up, scavenge, and compact the WINS database regularly. | Manage the WINS Database |
| View WINS server statistics periodically to monitor performance. | View WINS server statistics |
| Update client configurations on your network to correctly specify primary/secondary WINS servers based on any WINS servers you have added.<br>Depending on whether you configure clients statically or dynamically for TCP/IP, either:<br>• Configure WINS-related settings in advanced TCP/IP properties.<br>• Configure and enable WINS-related options in DHCP scopes so that IP addresses of WINS servers and NetBIOS node types are provided to clients. | Assign a scope-based option; Configure TCP/IP to use WINS |
| Verify registration of client NetBIOS names in WINS as needed. | Verify WINS registration of client NetBIOS names |

| | |
|---|---|
| Troubleshoot common WINS-related problems. | WINS Troubleshooting |

# New ways to do WINS tasks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**New ways to do familiar tasks**

The following table lists common tasks for managing WINS servers. The user interface for performing these tasks is different in this version of Windows from the way it was in Windows NT 4.0.

**Note**

- There are no significant user interface differences between Windows 2000, Windows XP, and the Windows Server 2003 family for this component.

| If you want to | In Windows NT 4.0 use | In this version of Windows use |
|---|---|---|
| Install a WINS server on this computer | **Network** in Control Panel | Windows Components Wizard.<br><br>For more information, see Install a WINS server. |
| Start WINS management tool | **Start** menu shortcut to WINS Manager listed in **Administrative Tools** | WINS.<br><br>For more information, see Open the WINS console. |
| Start or stop a WINS server | **Services** in Control Panel | Computer Management.<br><br>For more information, see Start or stop a WINS server. |
| Add a server to WINS management tool and manage it | **Add WINS Server** on the **Server** menu in WINS Manager | See Add a WINS server to the console. |
| Add and configure a replication partner for a WINS server | **Replication Partners** on the **Server** menu in WINS Manager | See Add a replication partner. |

# WINS Best Practices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Best practices**

- **Use default settings to configure WINS servers.**

  The preconfigured WINS settings provide the optimal configuration for most conditions and should be used in most WINS network installations. If you modify the default settings, be sure that the need to do so is clear and necessary, and that you understand all of the implications.

- **Avoid using static WINS entries for anything other than mission-critical servers.**

  Static WINS entries require further administrative action to ensure their successful and intended use. However, static entries can be useful for specific purposes, such as to safeguard against WINS registration of the names used by critically important servers.

  For example, a static entry in WINS can be used to prevent other computers from taking over the use of the name of a critical server while that server is unavailable.

  The biggest disadvantage of using static WINS entries is that it complicates administration of name and address changes in your network. For example, if either the IP address or the computer name of a static WINS entry changes, you might have to manually update other configurations also, such as DHCP servers, DNS servers, end systems, and Lmhosts files.

  If you decide to use static WINS entries, the following are suggestions for configuring other WINS and DHCP service properties and avoiding common problems:

  - For each IP address used in static WINS mapping, consider using a corresponding client address reservation to reserve the IP address at the DHCP server. For more information, see Using client reservations.

  - If you use static WINS entries only to support temporary changes on your network, keep the default **Overwrite unique static mappings at this server (migrate on)** setting selected in the WINS console.

    When **Overwrite unique static mappings at this server (migrate on)** is selected, any temporary unique or multihomed static entries that you add can be challenged and dynamically updated by clients. An attempt later by any client to dynamically register a unique or multihomed name entry over an existing static entry of the same name results in a challenge process.

    In the challenge, the IP address in the static mapping is compared to any IP address that the named client attempts to dynamically register in WINS. If the two addresses are different, and the static IP address is determined to no longer be active or in use, the IP mapping can be migrated (from a static to dynamic mapping), and the IP address is updated in WINS.

  - If you use static WINS entries on a permanent basis, you can disable **Overwrite unique static mappings at this server (migrate on)**. This prevents a dynamic WINS entry from overriding a static WINS entry that maps to the name and address of a critical server on your network.

- **Schedule consistency checking for an off-peak time.**

  For the Windows Server 2003 family, WINS consistency checking is available through the WINS console. Periodically, you should use this feature to check the WINS database for consistency. However, consistency checking is network and resource intensive for the WINS server computer. For this reason, run WINS consistency checks during times of low traffic, such as at night or on weekends.

- **Select Push/Pull when configuring replication partners.**

  In general, Push/Pull is a simple and effective way to ensure full WINS replication between partners. For most WINS installations, avoid the use of limited replication partnerships (Push Only or Pull Only) between WINS servers. In some large enterprise WINS networks, limited replication partnering can effectively support replication over slow wide area network (WAN) links. However, when you plan limited WINS replication, note the design and configuration when choosing to use limited replication partnerships.

- **For best results in WINS replication and convergence time, use a hub-and-spoke design model.**

  Convergence time is a critical part of WINS planning. Convergence time is the time needed to replicate a new entry in a WINS database from the WINS server that owns the entry to all other WINS servers on the network. To review the convergence time for your WINS network design, ask the following question for each of your WINS servers:

  *How long does it take for a change in WINS data at one WINS server to replicate and appear at other WINS servers in the network?*

  In most cases, the hub-and-spoke model provides a simple and effective planning method for organizations that require full and speedy convergence with minimal administrative intervention. For example, you can use this model for organizations with centralized headquarters or a corporate data center (the *hub*) and several branch offices (the *spokes*). A second, redundant hub (that is, a second WINS server in the central location) can increase the fault tolerance for WINS.

  For more information on how to configure a simple hub-and-spoke model, view the following graphic.

- **Use only as many WINS servers as you need.**

  Too many WINS servers on a network can complicate any problems that arise. Be conservative when adding WINS servers to your network, using the least number of WINS servers to support all clients while maintaining acceptable performance from each server. If you are currently designing a WINS installation that includes more than 20 WINS servers, seek assistance from Microsoft Product Support Services before finalizing your plans.

  By default, most WINS clients first try to communicate using directed point-to-point datagrams with their configured primary WINS servers. One WINS server adequately supports a small routed internetwork. However, at least two WINS servers are recommended, to provide a fault-tolerant WINS installation.

  For more information on WINS server planning, see Planning WINS networks.

- **To maximize server performance, purchase hardware with optimal disk performance characteristics to handle WINS.**

WINS causes frequent and intensive activity on server hard disks. To provide for the best performance, consider RAID solutions that improve disk-access time when you purchase new hardware to use as a WINS server. You should view WINS as part of a full performance evaluation of the server. By monitoring system hardware performance in the most demanding areas of utilization (that is, CPU, memory, and disk input/output) you make the best assessments of when a WINS server is overloaded and should be upgraded.

- **When using multihomed servers, follow well-known considerations for configuring WINS and TCP/IP properties.**

  When using multihomed WINS servers, it is best to configure all server IP addresses as replication partners with other WINS servers. Using a multihomed WINS server as a router or gateway between disjointed networks is not recommended.

- **Monitor and perform regular, offline compaction.**

  Although manual compaction of the WINS server database is not as important for the Windows Server 2003 family as it was for earlier versions, it is still useful. For disk defragmentation and improved server disk performance, use offline WINS compaction regularly (such as monthly or weekly). Then, monitor any changes to the size of the server database file, Wins.mdb, which is located by default in the *systemroot*\System32\WINS\ folder.

  At each offline compaction, it is useful to check the file size of Wins.mdb both before and after compaction, to measure growth and reduction. This information can be helpful in determining the actual benefits to using offline compaction. Based on this information, you can then gauge how often to repeat offline compaction for measurable gains.

- **Perform regular backups of the WINS database.**

  Besides using server tape backup of the WINS server computer, the WINS console offers a backup option which you can use to restore a server database if corruption occurs. For more information, see Troubleshooting WINS databases.

- **Configure clients with more WINS server IP addresses.**

  In earlier versions of Windows NT, you could manually configure clients to use only a primary and secondary WINS server. For the Windows Server 2003 family, you can configure WINS clients (either manually or through DHCP) to use up to 12 WINS servers, two of which can be used to register clients. You can either statically configure this list (using the **Internet Protocol (TCP/IP) Properties** dialog box) or distribute it to DHCP clients (using option 44). A larger list of WINS servers gives clients additional fault tolerance for WINS when their configured primary WINS server is not available.

- **Use NBTSTAT -RR to register and troubleshoot client connectivity.**

  For the Windows Server 2003 family, the NBTSTAT -RR command-line option forces immediate release and renewal of local client names. You can use this command-line option to refresh the client entries in WINS and replicate them to other replication partners without requiring a client reboot.

- **Configure each WINS server computer to point to itself.**

  Each WINS server that you install on your network must register its own set of NetBIOS unique and group names in WINS. To prevent WINS service problems that can occur when a WINS record becomes split (that is, when names registered for a particular WINS server are owned by different WINS servers), each WINS server computer should point only to its own IP address when configuring its TCP/IP properties.

# WINS How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**How to...**

- Install and Manage WINS Servers
- Modify Server Properties
- Manage WINS Console Data
- Manage WINS Clients
- View WINS Records
- Manage the WINS Database
- Configure Replication
- Manage Replication
- Use Persistent Connections
- Manage Static Mappings
- Use WINS Command-line Tools

# Install and Manage WINS Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Install and manage WINS servers**

- Install a WINS server
- Open the WINS console
- Add a WINS server to the console
- Remove a WINS server from the console
- Start or stop a WINS server
- Decommission a WINS server
- Remove or uninstall WINS

# Install a WINS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To install a WINS server**

1. Open Windows Components Wizard.
2. Under **Components**, scroll to and click **Networking Services**.
3. Click **Details**.
4. Under **Subcomponents of Networking Services**, click **Windows Internet Name Service (WINS)**, click **OK**, and then click **Next**.
5. If prompted, type the full path to the Windows Server 2003 distribution files and click **Continue**.

   Required files are copied to your hard disk, and server software can be used after restarting the system.

## Notes

- To open the Windows Components Wizard, click **Start**, click **Control Panel**, double-click **Add or Remove programs**, and then click **Add/Remove Windows Components**.
- It is strongly recommended that you manually configure the computer to use a static IP address.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

WINS How To...

# Open the WINS console

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To open the WINS console**

- Open WINS.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- The WINS console is an administrative tool for managing WINS servers. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

WINS How To...

# Add a WINS server to the console

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To add a WINS server to the console**

1. Open WINS.
2. In the console tree, click **WINS**.
3. On the **Action** menu, click **Add Server**.
4. In **Add Server**, under **WINS Server**, type the appropriate server information.

   Optionally, click **Browse** to locate the WINS server computer by name on your network.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- If WINS is locally installed on a server, the local WINS server is added to the console automatically. For remote WINS servers, you must add them to the console, and then save the file.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Install and Manage WINS Servers

# Remove a WINS server from the console

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To remove a WINS server from the console**

1. Open WINS.
2. Click the WINS server that you want to remove.
3. On the **Action** menu, click **Delete**.
4. When prompted "Are you sure you want to remove WINS server *servername* from this list?," click **Yes**.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- This procedure affects only the management console at which you are working, not the WINS server itself which continues to provide service and registration on the network.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Add a WINS server to the console

# Start or stop a WINS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To start or stop a WINS server**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, point to **All Tasks**, and then click one of the following:

   - To start the service, click **Start**.
   - To stop the service, click **Stop**.
   - To interrupt the service, click **Pause**.
   - To stop and then automatically restart the service, click **Restart**.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- After you pause or stop the service, the **Resume** option appears and can be clicked to immediately resume WINS service.
- You can also perform most of these tasks at a command prompt by using the following commands:
  - **net start wins**
  - **net stop wins**
  - **net pause wins**
  - **net continue wins**

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Decommission a WINS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To decommission a WINS server**

1. Before decommissioning a WINS server, make sure that any computers previously configured to be WINS clients of this server are reconfigured to point to other servers as their primary or secondary WINS servers. Reconfiguration is necessary only if these clients are to continue using WINS to register and resolve network names.

2. Open WINS.

3. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

4. On the **Action** menu, click **Delete Owner**.

5. In **Delete Owner**, in **Delete this owner**, click the IP address for the WINS server you want to decommission.

   If the WINS server is not running locally on this computer, it might take awhile to load the records for the selected server.

6. In **Use this operation to delete the selected owner and its records**, click **Replicate deletion to other WINS servers (tombstone)**, and then click **OK**.

   When prompted to confirm tombstoning, click **Yes**.

7. In the console tree, click **Replication Partners**.

8. On the **Action** menu, click **Replicate Now**.

9. Once you have verified that records tombstoned in step 6 have been replicated to other partner servers, stop and remove WINS on the decommissioned server.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.

- If the WINS server you want to decommission does not appear in the console tree, you can add it. For more information, see Related Topics.

- *Tombstoning* ensures that the WINS servers that are replication partners with the decommissioned WINS server are updated properly so that they delete the records. If tombstone status is not properly replicated, you can manually delete the records at each WINS server on which tombstone replication failed.

- WINS supports remote record deletion for servers running Windows NT Server 4.0, if updated to Service Pack 4 (SP4) or later.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove or uninstall WINS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To remove or uninstall WINS**

1. Stop the WINS service on this computer. For more information, see Related Topics.
2. Open **Add or Remove Programs**.
3. Click **Add/Remove Windows Components**.
4. In **Windows Components**, select the **Networking Services** check box in the list of components, and then click **Details**.
5. In **Subcomponents of Networking Services**, scroll to **Windows Internet Name Service (WINS)**, and clear the check box.

## Notes

- To open Add/Remove Windows Components, click **Start**, click **Control Panel**, double-click **Add or Remove programs**, and then click **Add/Remove Windows Components**.
- When you remove WINS, all WINS files are deleted from the server except program files that are in use. When the system is restarted, these files are removed as well.
- If you do not stop the WINS service in step 1, this procedure only deletes the WINS server registry entries.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify Server Properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Modify server properties**

- Modify backup settings
- Modify name record settings
- Modify WINS logging properties
- Modify burst handling properties
- Set the WINS database backup path
- Set the WINS database path
- Increase the starting version count
- Disable LAN Manager compatibility

# Modify backup settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To modify backup settings**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. On the **General** tab, under **Database backup**, modify default backup settings as needed.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**

### Note

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**

# Modify name record settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To modify name record settings**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Intervals** tab.
5. Modify default settings as needed.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- For most networks the default interval settings, **Renewinterval**, **Extinction interval**, **Extinction timeout**, and **Verificationinterval**, are acceptable and do not require modification.
- As an option, you can click **Restore Default** to restore WINS default intervals used for registering, renewing, and verifying name records in the database.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify WINS logging properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To modify WINS logging properties**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. Select the **Log detailed events to Windows event log** check box.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- When **Log detailed events to Windows event log** is checked, WINS logs additional detailed information to the system event log, which can be viewed by using Event Viewer. Because this feature can degrade system performance when enabled, it is turned off by default.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify burst handling properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To modify burst handling properties**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. In **Enable burst handling**, modify default settings as needed.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, burst handling is enabled and the burst queue sized to **Medium**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set the WINS database backup path

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To set the WINS database backup path**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. On the **General** tab, in **Database backup**, select **Default backup path**, and type the path to the folder where you want to back up the WINS database. Or, use **Browse** to select a location.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- You can also set the WINS database backup path while performing a backup. For more information, see Related Topics.
- There is not a default database backup path, and database backups do not occur by default. After a database backup path is set, backups occur every twenty four hours.
- When you choose a backup folder location by typing a path or using the **Browse** button, WINS automatically adds two subfolders to the path, Wins_bak and New. For example, if you type C:\Backups, the folder where WINS stores the backup database is C:\Backups\Wins_bak\New.
- This procedure describes how to specify the path that WINS uses when backing up the database. It does not set the path used by WINS to store the primary database on the applicable server. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set the WINS database path

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To set the WINS database path**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. In **Database path**, modify the database path as needed.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**.

## Caution

- This setting affects WINS back up and restore operations. If you change the path used here, be sure to run WINS backup again to archive the database with the updated path information. Otherwise, WINS cannot restore previously archived copies of the database where another path was specified, for either the WINS database path or the WINS database backup path.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- This procedure describes how to set the path used by WINS to store the database on the applicable server. It does not specify the path that WINS uses when backing up the database. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Increase the starting version count

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To increase the starting version count**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. For **Starting version ID (hexadecimal)**, enter a new number to be used by WINS as the new starting version ID when WINS is next restarted.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Because a higher version ID is used by WINS during replication to determine between two servers storing the same record which version is more recent, increasing the starting version ID count can be useful in some cases where you are attempting to affect a forced update and replication of names between servers. For more information, see Related Topics.
- If you enter a number that is less than the actual value of the highest version ID currently in use by the selected server, WINS might increase the actual number used for its start version count when service is restarted.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Disable LAN Manager compatibility

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To disable LAN Manager compatibility**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. Click **Advanced**.
5. Clear the **Use computer names that are compatible with LAN Manager** check box.

**Note**

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage WINS Console Data

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Manage WINS console data**

- View WINS server statistics
- Reset WINS server statistics
- Modify auto-refresh of WINS statistics
- Export WINS console data to a text file
- Modify the WINS console view

# View WINS server statistics

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To view WINS server statistics**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Display Server Statistics**.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- To update the display while viewing WINS statistics, click **Refresh**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify auto-refresh of WINS statistics

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To modify auto-refresh of WINS statistics**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. Under the **Automatically update statistics every** check box, modify the refresh interval in hours, minutes, or seconds, as needed.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, statistics automatically refresh every 10 minutes. As an option, you can also disable this feature by clearing the **Automatically update statistics every** check box.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Export WINS console data to a text file

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To export WINS console data to a text file**

1. Open WINS.
2. In the console tree, click the node item for which you want to export all currently displayed console data.

   For example, if you want to export all console data about a specific WINS server, click this server in the console tree.
3. On the **Action** menu, click **Export List**.
4. Enter a name for the text (*.txt) file to be used to export the output of this operation.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- For the **Active Registrations** node, you need to use **Display Records** to query for and display records for the applicable server prior to performing this procedure. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Modifying WINS server defaults
Search for names that begin with a specified set of characters
Filter the WINS database view
Show all records in the WINS database

# Modify the WINS console view

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To modify the WINS console view**

1. Open WINS.
2. In the console tree, click **WINS**.
3. On the **Action** menu, click **Properties**.
4. Modify console defaults to specify how WINS servers added to the console are displayed.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, the WINS console orders servers by name and uses only short (host-only) DNS names when displaying WINS servers that are added to the console. In addition, WINS does not validate its cache of WINS servers, which can prolong the length of time needed to load the WINS console when started.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage WINS Clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Manage WINS clients**

- Configure WINS for non-DHCP clients
- Configure WINS for DHCP-enabled clients
- Disable WINS/NetBT name resolution
- Verify WINS registration of client NetBIOS names

# Configure WINS for non-DHCP clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To configure WINS for non-DHCP clients**

- WINS servers must be manually added for each network connection that does not use DHCP. For more information, see Related Topics.

## Notes

- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.
- If you manually configure a list of WINS servers for the connection that later leases and obtains its IP address using DHCP, the list you configure supercedes any WINS servers returned in an options list provided by the DHCP server.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Configure TCP/IP to use WINS

# Configure WINS for DHCP-enabled clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To configure WINS for DHCP-enabled clients**

- Clients running Windows 2000, Windows XP, or the Windows Server 2003 family are configured by default to use a DHCP server to obtain an IP address. No further client-side configuration is needed.

  Instead, configure your DHCP server to assign WINS-related options needed to enable DHCP-enabled clients on your network to use WINS. For more information, see Related Topics.

**Note**

- In most cases, WINS clients only need to be provided the following NetBIOS over TCP/IP (NetBT) option types for basic WINS configuration: 44 (WINS servers) and 46 (WINS node type). These options must be configured at the DHCP server providing each client its dynamically leased IP address.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Disable WINS/NetBT name resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To disable WINS/NetBT name resolution**

1. Open Network Connections.
2. Click the Local Area Connection to be statically configured and then, from the **File** menu, click **Properties**.
3. In the list of components, click **Internet Protocol (TCP/IP)**, and then click **Properties**.
4. Click **Advanced**.
5. Click the **WINS** tab.
6. Click **Disable NetBIOS over TCP/IP**.

   Optionally, you can select **Use NetBIOS setting from the DHCP server** if you are using a DHCP server that can selectively enable and disable NetBIOS configuration through DHCP option types.

## Notes

- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.
- NetBIOS over TCP/IP can also be disabled for computers running Windows XP using DHCP option types supported by the Windows Server 2003 DHCP Server service. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Verify WINS registration of client NetBIOS names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To verify WINS registration of client NetBIOS names**

1. On the WINS client computer, at the command prompt, type **nbtstat -n**.

   The local NetBIOS names table for the WINS client computer is listed. Verify that each name indicates **Registered** in the **Status** column.

2. The **Status** column should indicate a status of either Registered, Registering, or Conflict.

   For cases where the name is shown to be either Registered or Registering, you can type **nbtstat -RR** to release and refresh registration of the local NetBIOS names of the client with WINS.

   For cases where the Status column indicates a conflict for the name, try either of the following to resolve the conflicted name state at the client computer:

   - For WINS clients running Windows 2000, Windows XP, or the Windows Server 2003 family, you can selectively disconnect and reconnect the network connection in the Network Connections folder to force release and refresh of all client NetBIOS names in WINS.

     For more information, see Related Topics.

   - For earlier versions of Windows, shut down and restart the system to achieve similar results.

3. After the release/refresh process is completed, repeat **nbtstat -n** to verify that all local names have a status of Registered in WINS.

### Notes

- For name conflicts, you may only need to perform step 2 if the name in conflict is critically necessary for the WINS client to maintain visibility or locate other computers on the network. Names that fit this description might include the [00h] and [20h] type names, if they match the client NetBIOS computer name. The need to resolve a name conflict for other types of names might be less critical to support needs.

- The **nbtstat** command can also be used to perform other useful procedures related to WINS client support. For more information, see Related Topics.

- When you type **nbtstat -n** at a command prompt and the local NetBIOS name table is displayed, the status column should indicate that each name is registered, such as shown in the sample command output below:

```
Node IpAddress: [10.0.0.1] Scope Id: []

NetBIOS Local Name Table
Name                Type         Status
---------------------------------------------------
MY_PC           <20>  UNIQUE      Registered
MY_PC           <00>  UNIQUE      Registered
WORKGROUP       <00>  GROUP       Registered
MY_PC           <03>  UNIQUE      Registered
ADMINISTRATOR   <03>  UNIQUE      Registered
WORKGROUP       <1E>  GROUP       Registered
WORKGROUP       <1D>  UNIQUE      Registered
```

```
..__MYBROWSE__. <01>  GROUP       Registered
```

**Information about functional differences**

# View WINS Records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**View WINS records**

- Start a record search
- Stop a record search
- Search for names that begin with a specified set of characters
- Search for records by IP address and subnet mask
- Show all records in the WINS database
- View properties for a selected WINS record
- View or download the WINS database by owner
- Filter the WINS database view
- Clear all WINS data filters
- Add, modify, or remove a filter type

# Start a record search

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To start a record search**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display Records**.
4. Select the appropriate filters and type in search criteria, if necessary.
5. Click **Find Now**.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, in the **Display Records** dialog box, all NetBIOS name record owners are selected on the **Record Owners** tab, and all NetBIOS name suffix record types are selected on the **Record Types** tab. If you have a large network or a large number of WINS servers, running a query without refining these selections could cause degradation of network performance due to the large data load transfer.
- You must select at least one record owner and at least one record type in order for any search operation to successfully return one or more name records.
- If you select the **Enable result caching** check box, the search results will be downloaded from the WINS server and stored in local random access memory (RAM). Because search results are stored in RAM, subsequent record searches on this name pattern will be faster. If a large number of records are returned, however, caching of records might take a long time and could adversely affect overall network performance.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Stop a record search

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To stop a record search**

1. On the **Action** menu, click **Stop Loading Records**.

   A message box will ask, "Are you sure you want to stop downloading the records from the database?"

2. Click **Yes**.

## Notes

- This procedure assumes that both the WINS console and the **Display Records** dialog box are open.
- A record search must be currently operating in order for this procedure to work.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Search for names that begin with a specified set of characters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To search for names that begin with a specified set of characters**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display Records**.
4. Select the **Filter records matching this Name pattern** check box.
5. In **Filter records matching this Name pattern**, type one or more characters to be used in the search.
6. Click **Find Now** to begin the search.

   WINS searches the server database and displays any names that begin with the specified characters in uppercase.

**Notes**

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Any lowercase text entered in **Filter records matching this Name pattern** is converted to uppercase when WINS performs the record search. WINS does uppercase searches only and does not display any records that contain lowercase characters.
- By default, in the **Display Records** dialog box, all NetBIOS name record owners are selected on the **Record Owners** tab, and all NetBIOS name suffix record types are selected on the **Record Types** tab. If you have a large network or a large number of WINS servers, running a query without refining these selections could cause degradation of network performance due to the large data load transfer.
- You must select at least one record owner and at least one record type in order for the search operation to successfully return one or more name records.
- If you select the **Enable result caching** check box, the search results will be downloaded from the WINS server and stored in local random access memory (RAM). Because search results are stored in RAM, subsequent record searches on this name pattern will be faster. If a large number of records are returned, however, caching of records might take a long time and could adversely affect overall network performance.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Search for records by IP address and subnet mask

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

#### To search for records by IP address and subnet mask

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display Records**.
4. Select the **Filter records matching this IP address** check box.
5. In **Filter records matching this IP address**, type a valid IP address.
6. Select the **Match the IP address based on this subnet mask** check box.
7. In **Match the IP address based on this subnet mask**, type a valid subnet mask.
8. Click **Find Now** to begin the search.

   WINS searches the server database and displays any records in which the network ID portion of the IP address matches the parameters entered into the **Display Records** dialog box.

### Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, in the **Display Records** dialog box, all NetBIOS name record owners are selected on the **Record Owners** tab, and all NetBIOS name suffix record types are selected on the **Record Types** tab. If you have a large network or a large number of WINS servers, running a query without refining these selections could cause degradation of network performance due to the large data load transfer.
- You must select at least one record owner and at least one record type in order for the search operation to successfully return one or more name records.
- If you select the **Enable result caching** check box, the search results will be downloaded from the WINS server and stored in local random access memory (RAM). Because search results are stored in RAM, subsequent record searches on this name pattern will be faster. If a large number of records are returned, however, caching of records might take a long time and could adversely affect overall network performance.

#### Information about functional differences

# Show all records in the WINS database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To show all records in the WINS database**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display Records**.
4. Click **Find Now**.

   The entire WINS database appears in the details pane.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, in the **Display Records** dialog box, all NetBIOS name record owners are selected on the **Record Owners** tab, and all NetBIOS name suffix record types are selected on the **Record Types** tab. If you have a large network or a large number of WINS servers, running a query without refining these selections could cause degradation of network performance due to the large data load transfer.
- You must select at least one record owner and at least one record type in order for the search operation to successfully return one or more name records.
- If you select the **Enable result caching** check box, the search results will be downloaded from the WINS server and stored in local random access memory (RAM). Because search results are stored in RAM, subsequent record searches on this name pattern will be faster. If a large number of records are returned, however, caching of records might take a long time and could adversely affect overall network performance.

# View properties for a selected WINS record

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To view properties for a selected WINS record**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display records**.
4. To display records in the details pane, perform one of the following actions:

   - To find a record by NetBIOS name, select the **Filter records matching this Name pattern** check box, type the leading characters for the name or names that you want to view, and then click **Find Now**.
   - To find a record by IP address, select the **Filter records matching this IP address** check box, type the IP address, and then click **Find Now**.
   - To find a record by owner, click the **Record Owners** tab. In the **Display records for these owners** list, select the check box for any of the name record owners that you want included in filtered viewing of the WINS database, clear the check box for any name record owners you want excluded from filtered viewing of the WINS database, and then click **Find Now**.

5. In the details pane, click the record that you want to view.
6. On the **Action** menu, click **Properties**.

**Notes**

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, in the **Display Records** dialog box, all NetBIOS name record owners are selected on the **Record Owners** tab, and all NetBIOS name suffix record types are selected on the **Record Types** tab. If you have a large network or a large number of WINS servers, running a query without refining these selections could cause degradation of network performance due to the large data load transfer.
- You must select at least one record owner and at least one record type in order for the search operation to successfully return one or more name records.
- If you select the **Enable result caching** check box, the search results will be downloaded from the WINS server and stored in local random access memory (RAM). Because search results are stored in RAM, subsequent record searches on this name pattern will be faster. If a large number of records are returned, however, caching of records might take a long time and could adversely affect overall network performance.

# View or download the WINS database by owner

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To view or download the WINS database by owner**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display Records**.
4. Click the **Record Owners** tab.
5. In the **Display records for these owners** list, perform one or more of the following actions:

   - Select the check box for any name record owners that you want to include in the filtered view of the WINS database.
   - Clear the check box for any name record owners that you want to exclude from the filtered view of the WINS database.
   - Click **Select Local** to query records only for local owners.
   - Click **Select All** to query records for all owners.

6. Click **Find Now**.

   After you click **Find Now**, the filtered WINS database appears in the details pane and shows only the records that are registered to the selected owners.

**Notes**

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, in the **Display Records** dialog box, all NetBIOS name record owners are selected on the **Record Owners** tab, and all NetBIOS name suffix record types are selected on the **Record Types** tab. If you have a large network or a large number of WINS servers, running a query without refining these selections could cause degradation of network performance due to the large data load transfer.
- You must select at least one record owner and at least one record type in order for the search operation to successfully return one or more name records.
- If you select the **Enable result caching** check box, the search results will be downloaded from the WINS server and stored in local random access memory (RAM). Because search results are stored in RAM, subsequent record searches on this name pattern will be faster. If a large number of records are returned, however, caching of records might take a long time and could adversely affect overall network performance.

# Filter the WINS database view

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To filter the WINS database view**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display records**.
4. Click the **Record Types** tab.
5. Clear the check box for any name record types you want excluded from filtered viewing of the WINS database.

   When you click **Find Now**, the filtered WINS database appears in the details pane.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, in the **Display Records** dialog box, all NetBIOS name record owners are selected on the **Record Owners** tab, and all NetBIOS name suffix record types are selected on the **Record Types** tab. If you have a large network or a large number of WINS servers, running a query without refining these selections could cause degradation of network performance due to the large data load transfer.
- You must select at least one record owner and at least one record type in order for the search operation to successfully return one or more name records.
- If you select the **Enable result caching** check box, the search results will be downloaded from the WINS server and stored in local random access memory (RAM). Because search results are stored in RAM, subsequent record searches on this name pattern will be faster. # Clear all WINS data filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To clear all WINS data filters**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display Records**.
4. Click the **Record Types** tab.
5. Click **Clear All**.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, all predefined NetBIOS name type filters are included in the filter mask. To restore the default settings, click **Select all**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add, modify, or remove a filter type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To add, modify, or remove a filter type**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display Records**.
4. Click the **Record Types** tab.
5. Click either **Add**, **Edit**, or **Delete** to add, modify, or remove name type filters.
6. When adding a new filter type, click **Add**, and complete the following for **Add Record Type**:

   - For **ID (hexadecimal)**, specify a unique 2-digit hexadecimal number that can be used to identify a distinct set of records in the WINS database.
   - For **Description**, enter descriptive text that indicates how the new filter type is to be used.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Only user-defined filters can be modified or deleted. Predefined filters provided for default use by WINS cannot be modified or deleted.
- For any search operation to successfully return one or more name records, at least one record type must be selected.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage the WINS Database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Manage the WINS database**

- Scavenge the WINS database
- Back up the WINS database
- Restore the WINS database
- Delete or tombstone an entry in the WINS database
- Delete an owner from the WINS database
- Enable periodic consistency checking of the WINS database
- Manually check database consistency
- Check version number consistency between servers

# Scavenge the WINS database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To scavenge the WINS database**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Scavenge Database**.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Like other databases, you must periodically maintain the WINS database to remove outdated information. This process is called *scavenging*, which removes old and released entries that were registered at another WINS server and replicated to the server being maintained.
- WINS automatically scavenges the server database at intervals you specify in server properties.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Maintaining the WINS database

# Back up the WINS database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To back up the WINS database**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Back Up Database**. The **Browse for Folder** dialog box opens.
4. Select the location for the WINS database backup. Click **OK**.
5. After backup is completed, click **OK**.

### Important

- Do not specify a network drive as the backup location. In addition, if you change the WINS backup or database path in server properties, perform new backups to ensure successful future restorations of the WINS database.

### Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- The WINS console provides backup tools so that you can back up and restore the WINS database. After you specify a backup folder for the database, WINS performs complete database backups every twenty four hours, using the specified folder.
- WINS can also be configured to back up the database automatically when the service is stopped or the server computer is shut down properly. For more information, see Related Topics.
- When WINS backs up the server database, it creates a **\wins_bak\new** folder under the backup folder you have specified for **Default backup path** in ***Server* Properties**. Actual backups of the WINS database (Wins.mdb) are stored in this folder.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**

# Restore the WINS database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

#### To restore the WINS database

1. Stop WINS.

   For more information, see Related Topics.

2. Delete all files in the folder path on the WINS server computer where you are restoring the database.

   This path is determined by the current setting of **Database path**, which is located on the **Advanced** tab in ***Server* Properties**.

3. Open WINS.

4. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

5. On the **Action** menu, click **Restore Database**.

6. In the **Browse for Folder** dialog box, click the same folder (such as *C:*\) that was used previously to back up the local WINS database, and then click **OK**.

### Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- In step 1, wait for WINS to completely stop before proceeding. A busy server might require several minutes before it can stop WINS, and you can proceed with restoring the database.
- When restoring the database, WINS requires that the backup path used for restoration match the path that was originally specified in ***Server* Properties** as the **Backup path**.
- WINS does not permit you to restore the server databases remotely from another computer.
- The restore option is only available when viewing a computer on which WINS is stopped. In some cases, you might need to refresh the WINS console to activate the restore option. If necessary, click **Refresh** from the **Action** menu to refresh the server node so that the WINS console detects that WINS is stopped on the server.
- In case of database corruption, the WINS database can be restored from the backup. You can sometimes repair WINS database corruption by incrementing the starting version count for the WINS server and restarting the server.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete or tombstone an entry in the WINS database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To delete or tombstone an entry in the WINS database**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Display Records** to query for and display the names you want to delete from the database.
4. In the details pane, click the entry you want to delete.

   You can hold down the CTRL or SHIFT keys to select multiple entries.

5. On the **Action** menu, click **Delete**.
6. In the **Delete Record** dialog box, click one of the following options for deleting the selected records:

   - **Delete the record only from this server**.
   - **Replicate deletion of the record to other servers (tombstone)**.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- *Tombstoning* marks records as inactive for a period of time. When the WINS database on this server replicates these records to other WINS servers, the other servers preserve the tombstone state and can eventually remove these entries from a replicated WINS network of server databases.
- In step 6, if you click **Delete the record only from this server** and another WINS server owns the records, then deleted records can reappear after WINS replication occurs with other partner servers. To avoid this, click **Replicate deletion of the record to other servers (tombstone)**.
- Once an entry has been tombstoned and its status is replicated to other servers, the tombstoned entries can be removed from WINS, in either of two ways:

  - Automatically, using the **Extinction Interval**, which is set from the **Intervals** tab in WINS server properties.
  - Manually, by performing a scavenging operation.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete an owner from the WINS database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To delete an owner from the WINS database**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Delete Owner**.
4. In **Delete Owner**, click the owner you want to delete.
5. Select from the following options for deleting records in the WINS database associated with the owner you are deleting:

   - To delete the owner and all of its records from this WINS server only, click **Delete from this server only**.
   - To replicate deletion of the selected owner and all its records at this and other WINS servers, click **Replicate deletion to other servers (tombstone)**.

**Notes**

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- *Tombstoning* marks records as inactive for a period of time. When the WINS database on this server replicates these records to other WINS servers, the other servers preserve the tombstone state and can eventually remove these entries from a replicated WINS network of server databases.
- In step 5, if you click **Delete from this server only**, records first introduced by the deleted owner can reappear after WINS replication with other partner servers that have replicated these records. To avoid this, click **Replicate deletion to other servers (tombstone)**.
- Once an entry has been tombstoned and its status is replicated to other servers, the tombstoned entries can be removed from WINS, in either of two ways:

  - Automatically, using the **Extinction Interval**, which is set from the **Intervals** tab in WINS server properties.
  - Manually, by performing a scavenging operation.

  For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Deleting and tombstoning records

Scavenge the WINS database

Modify name record settings

# Enable periodic consistency checking of the WINS database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To enable periodic consistency checking of the WINS database**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Database Verification** tab.
5. In **Database Verification settings**, select the **Verify database consistency every** *number of hours* **hours** check box.
6. If necessary, modify default settings to be used when consistency checks are performed.

   To view a description of a dialog box item, right-click the item, and then click **What's This?**

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Because consistency checking might affect WINS server performance, this feature is not enabled by default.
- When enabled, the default settings for this feature provide for up to 30,000 records in the WINS server database to be checked on a daily basis, beginning at 2:00AM each night. During each of these scheduled consistency checks, the selected WINS server compares local copies of records it stores with the same record as stored at the WINS server listed as the owner for each record.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manually check database consistency

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To manually check database consistency**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Verify Database Consistency**.
4. When prompted if you want to continue, click **Yes** to start consistency checking.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Checking consistency can be resource-intensive when there is a large number of names to be checked or a large number of WINS servers involved. You might want to perform this only during off-peak hours to minimize the impact on your WINS servers and network.
- Consistency checking can also be scheduled through server properties. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Check version number consistency between servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To check version number consistency between servers**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click **Verify Version ID Consistency**.
4. When prompted if you want to continue, click **Yes** to start this operation.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- This operation gets the Owner-to-Highest-Version-ID mappings from different WINS servers. It checks the consistency of the WINS databases at all tested servers by ensuring that each server always has the highest version ID among the network of WINS servers for any records that it owns.
- Checking version ID number consistency can be resource-intensive when there are a large number of WINS servers tested.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Replication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Configure replication**

- Add a replication partner
- Delete a replication partner
- Enable replication with non-partner WINS servers
- Modify push partner properties
- Modify pull partner properties
- Enable automatic partner configuration

# Add a replication partner

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To add a replication partner**

1. Open WINS.
2. In the console tree, click **Replication Partners**.

   **Where?**

   - WINS/*applicable WINS server*/Replication Partners

3. On the **Action** menu, click **New Replication Partner**.
4. In **New Replication Partner**, type the name or IP address of the WINS server to add as a replication partner.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, replication partners are configured as push/pull type partners. Once you have added a partner, however, you can change it to be a Push only or Pull only type partner. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete a replication partner

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To delete a replication partner**

1. Open WINS.
2. In the console tree, click **Replication Partners**.

   **Where?**

   - WINS/*applicable WINS server*/Replication Partners

3. In the details pane, click the replication partner you want to remove.
4. On the **Action** menu, click **Delete**.
5. When prompted, click **Yes** to confirm that you want to delete the partner.

### Note

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable replication with non-partner WINS servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To enable replication with non-partner WINS servers**

1. Open WINS.
2. In the console tree, click **Replication Partners**.

   **Where?**

   - WINS/*applicable WINS server*/Replication Partners

3. On the **Action** menu, click **Properties**.
4. Clear the **Replicate only with partners** check box, and then click **Apply**.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, WINS only replicates with other WINS servers configured as replication partners.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Replication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Manage replication**

- Start replication immediately
- Send a replication trigger to a selected partner
- Send a replication trigger to any specified WINS server
- Accept replication of records owned by a specified server
- Block replication of records owned by a specified server
- Change a replication partner type

# Start replication immediately

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To start replication immediately**

1. Open WINS.
2. In the console tree, click **Replication Partners**.

   **Where?**

   - WINS/*applicable WINS server*/Replication Partners

3. On the **Action** menu, click **Replicate Now**.
4. When prompted, click **Yes** to start replication immediately.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- This operation queues replication requests for triggering replication with any of its push and pull partner servers. For this operation to have any affect, replication partners must already be added at this server.
- Using Event Viewer, you can monitor the system event log at this server for more information about the status of when actual replication is completed between this server and its partner servers.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Working with MMC console files
Add a replication partner
Delete a replication partner
Send a replication trigger to any specified WINS server

# Send a replication trigger to a selected partner

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To send a replication trigger to a selected partner**

1. Open WINS.
2. In the console tree, click **Replication Partners**.

   **Where?**

   - WINS/*applicable WINS server*/Replication Partners

3. In the details pane, click the partner that you want to start replication with.
4. On the **Action** menu, click either **Start Push Replication** or **Start Pull Replication** depending on whether you want to start push or pull replication to the selected partner.
5. Confirm starting of either push or pull replication to the selected partner.
6. If using pull replication, in **Start Pull Replication**, click **Yes** to confirm.
7. If using push replication, in **Start Push Replication**, choose a push replication method, and then click **OK**:

   a. Click **Start for this partner only** to start push replication for the selected partner only.

   b. Click **Propagate to all partners** to request that the selected partner in turn propagate a push replication request to its configured partners.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- When this procedure is completed, replication with the partner server might not start immediately. Actual replication depends on server activity and the priority of other requests queued at the selected partner.
- By default, WINS only enables replication between configured replication partners. To replicate with non-partners, see Related Topics.
- When a push replication is started using this procedure, actual replication requires the selected partner to complete a subsequent pull replication. This occurs because WINS replication is essentially a pull operation. For more examples and information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Send a replication trigger to any specified WINS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To send a replication trigger to any specified WINS server**

1. Open WINS.
2. In the console tree, click the applicable WINS server.

   **Where?**

   - WINS/*applicable WINS server*

3. On the **Action** menu, click either **Start Push Replication** or **Start Pull Replication**.
4. In Start Replication, for **WINS server**, type or browse for the specified WINS server with which you want to start replication, and then click **OK**.
5. Confirm starting of either push or pull replication.
6. If using pull replication, in **Start Pull Replication**, click **Yes** to confirm.
7. If using push replication, in **Start Push Replication**, choose a push replication method, and then click **OK**:

   a. Click **Start for this partner only** to start push replication for the selected server only.

   b. Click **Propagate to all partners** to request that the selected server in turn propagate a push replication request to its configured partners.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- By default, WINS only enables replication between configured replication partners. To use this procedure, first configure the server to enable it to replicate with non-partners. For more information, see Related Topics.
- When this procedure is completed, replication with the specified server might not start immediately. Actual replication depends on server activity and the priority of other requests queued at the server.
- When a push replication request is started using this procedure, actual replication requires the specified WINS server to complete a subsequent pull replication. This occurs because WINS replication is essentially a pull operation. For more examples and information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Accept replication of records owned by a specified server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To accept replication of records owned by a specified server**

1. Open WINS.
2. In the console tree, click **Replication Partners**.

   **Where?**

   - WINS/*applicable WINS server*/Replication Partners

3. On the **Action** menu, click **Properties**.
4. On the **Advanced** tab, click **Accept records only for these owners**, and then click **Add**.
5. In **Add Server**, type the NetBIOS name or IP address of the owner (a WINS server) from which you want to replicate records to this server.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Once a server has been added to the list of accepted partners, any records owned by the listed servers are entered into the local database during subsequent replication cycles with other partner servers.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Block replication of records owned by a specified server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To block replication of records owned by a specified server**

1. Open WINS.
2. In the console tree, click **Replication Partners**.

   **Where?**

   - WINS/*applicable WINS server*/Replication Partners

3. On the **Action** menu, click **Properties**.
4. On the **Advanced** tab, click **Block records for these owners**, and then click **Add**.
5. In **Add Server**, type the NetBIOS name or IP address of the owner (a WINS server) from which you want to block records from being replicated to this server.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Once a server has been added to the list of blocked partners, any records owned by the listed servers are not entered into the local database during subsequent replication cycles with other partner servers.
- This feature was previously implemented as a registry-only configuration in Windows NT Server, using the PersonaNonGrata registry parameter.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Use Persistent Connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Use persistent connections**

- Enable the use of persistent connections with a partner server
- Enable the use of persistent connections with pull partners
- Enable the use of persistent connections with push partners

# Enable the use of persistent connections with a partner server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To enable the use of persistent connections with a partner server**

1. Open WINS.
2. In the console tree, click **Replication Partners**.

   **Where?**

   - WINS/*applicable WINS server*/Replication Partners

3. In the details pane, click the partner server for which you want to enable the use of persistent connections for replication purposes.
4. On the **Action** menu, click **Properties**.
5. Click the **Advanced** tab.
6. Select the appropriate **Use persistent connection for replication** check box, depending on whether the partner server is a **Push**, **Pull**, or **Push/Pull** partner of this server.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- In step 6, if the partner is configured as a **Push/Pull** partner of this server, you can select both **Use persistent connection for replication** check boxes.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Static Mappings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Manage static mappings**

- Add a static mapping entry
- Edit a static mapping entry
- Import a file containing static mapping entries
- Enable static mappings to be overwritten during replication

# Add a static mapping entry

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To add a static mapping entry**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **New Static Mapping**.

   The **New Static Mapping** dialog box appears.

4. Enter the following information to complete the static mapping:

   - In **Computer name**, type the NetBIOS name of the computer.
   - In **NetBIOS scope (optional)**, you can type a NetBIOS scope identifier, if one is used, for the computer. Otherwise, leave this field blank.
   - In **Type**, click one of the supported types to indicate whether this entry is a **Unique**, **Group**, **Domain Name**, **Internet**, or **Multihomed** type entry.
   - In **IP address**, type the address for the computer.

5. Click **Apply** to add the static mapping entry to the database.
6. To add more static mapping entries, repeat steps 4 and 5. When you are done adding static mapping entries, click **OK**.

### Important

- Because each static mapping is added to the database when you click **Apply**, you cannot cancel work in the dialog box. If you make a mistake when typing a name or address for a mapping, delete the incorrect mapping, and add a new one using the correct information.

### Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- In general, only use static WINS mappings for computer names (not group names) that do not directly use WINS to register their names. Static mappings can overwrite dynamic mappings at other WINS servers and can be increasingly difficult to remove from all servers once they are introduced into a replicated WINS environment.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your

account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Edit a static mapping entry

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To edit a static mapping entry**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. In the details pane, double-click the static mapping you want to edit.
4. Edit the following information for the existing static mapping, as needed:

   - For **IP Address**, you can change the address or, for supported types, you can add or remove addresses from the address list and change the order of addresses.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Only the IP address for an entry can be edited. To change other properties for an entry, you must delete the existing entry and add a new entry.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Import a file containing static mapping entries

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To import a file containing static mapping entries**

1. Open WINS.
2. In the console tree, click **Active Registrations**.

   **Where?**

   - WINS/*applicable WINS server*/Active Registrations

3. On the **Action** menu, click **Import LMHOSTS File**.
4. In the **Open** dialog box, locate and click the Lmhosts-formatted file that you want to use to import static mappings, and then click **Open**.

   WINS immediately begins importing the file into the server database. Wait for WINS to finish this before you click **OK**.

## Notes

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.
- Typically, the Lmhosts file is stored in the *systemroot*\System32\Drivers\Etc folder.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable static mappings to be overwritten during replication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To enable static mappings to be overwritten during replication**

1. Open WINS.
2. In the console tree, click **Replication Partners**.

   **Where?**

   - WINS/*applicable WINS server*/Replication Partners

3. On the **Action** menu, click **Properties**.
4. If needed, click the **General** tab.
5. Select the **Overwrite unique static mappings at this server (migrate on)** check box, and then click **Apply**.

### Note

- To open WINS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **WINS**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Use WINS Command-line Tools

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Use WINS command-line tools**

- Use WINS commands interactively at the command prompt
- Use WINS commands non-interactively or in scripts

# Use WINS commands interactively at the command prompt

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To use WINS commands interactively at the command prompt**

1. Open **Command Prompt**.

2. Type **netsh**.

3. At the **netsh>** command prompt, type **wins**.

4. At the **wins>** command prompt, type:

   **server ** *ServerName*

   Or, type:

   **server** *ip_address*

   Where *ServerName* and *ip_address* are the server that you want to manage.

   Once a server that you have rights to manage has been successfully contacted, you should see "You have Read and Write access to the server *ServerName*."

5. Once you are connected to this WINS server, you can use any supported command.

   Type **/?** or **help** to display the immediate WINS subcommand menu. Or, type **list** to display all of the Netsh subcommands that are available for use with WINS.

## Notes

- You must be a member of the Administrators group to change configuration information on WINS servers using the WINS console or the **netsh wins** commands. Administrator group membership should be restricted to the minimum number of users necessary to administer the server.

- If there are users who need read-only access to the WINS console, add them to the WINS Users group instead of the Administrators group. WINS Users can search for WINS records and view replication partners and other configuration information, but they cannot change settings on the WINS server.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Use WINS commands non-interactively or in scripts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**To use WINS commands non-interactively or in scripts**

1. Open **Command Prompt**.

2. At the command prompt or in scripted form, you can use Netsh commands for WINS non-interactively by using the following fully qualified command syntax:

   **netsh wins server** [****_ServerName_] _subcommand_

## Notes

- You must be a member of the Administrators group to change configuration information on WINS servers using the WINS console or the **netsh wins** commands. Administrator group membership should be restricted to the minimum number of users necessary to administer the server.

- If there are users who need read-only access to the WINS console, add them to the WINS Users group instead of the Administrators group. WINS Users can search for WINS records and view replication partners and other configuration information, but they cannot change settings on the WINS server.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- The ****_ServerName_ parameter is optional when performing WINS commands locally on the same computer where the command is executed. If the WINS server being managed is on a remote computer, this parameter is required and the remote server name must be used.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Security information for WINS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Security information for WINS**

It is important to follow best practices for security when using WINS servers on your network. For more information, see Best practices for security.

The following are known security issues for WINS and related protocols:

- **The NetBIOS naming protocol is an unauthenticated protocol.**

  Although the NetBIOS naming protocol can be used with network protocols other than TCP/IP, WINS was designed specifically to support NetBIOS over TCP/IP (NetBT).

  When a user connects to the network, the user is not required to provide credentials before using NetBT or requesting a name service from WINS servers. Malicious users with physical access to the WINS-enabled network can instigate a denial-of-service attack on WINS servers by requesting many name resolution requests or name registration requests from the server, thereby depleting the ability of the WINS server to service requests from other, non-malicious clients.

  **Recommendations:**

  - Ensure that unauthorized persons do not have physical or wireless access to your network.
  - Enable WINS logging in the event log. When **Log detailed events to Windows event log** is selected, WINS logs additional detailed information to the system event log, which allows you to monitor events on the WINS server. For more information, see Modify WINS logging properties and Event Viewer overview.

- Monitor the system event log for burst handling events. Burst mode is enabled by default. If you have disabled burst handling, enable it. The following event messages are logged for name refresh requests by WINS clients:

  - WINS 4338: The WINS server started the burst handling of incoming requests. WINS does this to handle a sudden increase of incoming requests. WINS will also log an event indicating when the burst handling stops. If you see this event frequently, you may want to upgrade the WINS server to a faster computer. You can also try to adjust the burst handling count using the WINS Manager tool.
  - WINS 4339: The WINS server completed the burst handling of incoming requests because the queue length became a quarter of what it was when burst handling began.

    You can also use Event Viewer when you suspect that server performance might be degraded due to an attack. For more information, see Modify burst handling properties.

  - Use Network Monitor if you suspect an attack on your WINS server. You can use Network Monitor to detect networking problems by capturing and viewing the frames (or packets) that a computer receives or sends on a local area network (LAN). When you view incoming packets, you can discover essential information about an attacker, including the IP address of their computer. For more information, see Network Monitor.

- **WINS database and log files are not protected if you move them from the default location.**

  The default location of the WINS database and log files is the *systemroot*\System32\Wins folder. By default, the access control list on the Wins folder provides the best security for the WINS database and log files. The access control list is a list of users and groups that can access the folder. In addition, each object (user or group) is assigned specific permissions that dictate what actions the object can perform. For more information, see Access Control.

  If you change the location of the WINS database files, the new folder location is not protected by the proper access

control list by default, thereby creating a security risk. The same is true when you configure a WINS database backup path. The folder you create when you designate the backup path is not protected by the proper access control list by default, and a security risk is created.

**Recommendations:**

- If you move the WINS files to another folder or create a new folder for backup files, create an access control list for the new folders that contains only the Local System account and the Administrators group. In addition, ensure that the new folder does not inherit unwanted permissions from any folder above it in Windows Explorer.
- Do not store WINS files in a personal folders (My Documents or My Pictures) or in a subfolder of a personal folder.
- Store WINS database and backup files on a computer that is physically secured and protected from unauthorized access.
- Turn on file auditing for individual WINS files, to track the users and groups that access the files. For more information, see Apply or modify auditing policy settings for a local file or folder.
- Do not move the WINS files to a remote storage device or map the WINS files to an external drive or storage device for which no access control list can be created. Also, do not move or copy WINS files to an anonymous File Transfer Protocol (FTP) site or any other unprotected location.

For more information, see Set the WINS database path, Set the WINS database backup path, Modify WINS logging properties, and The WINS database.

- **Name records for mission-critical servers can be overwritten, causing network traffic to be redirected.**

  If a computer connected to the network has the same NetBIOS name as a mission-critical server, such as a domain controller, Web server, or email server, the name records that map the mission-critical server name to a different and incorrect IP address overwrite the WINS name records of the mission-critical server. This can occur when:

  - The original owner of the record is unresponsive, such as when the server is rebooting, the server is disconnected from the network, or when a denial of service attack is being performed against the server.
  - The original record was registered dynamically.

  When this occurs, the mission-critical server name maps to a different IP address, and all of the traffic that was intended for that server is redirected to the new computer, which might be operated by a malicious user.

  **Recommendation:**

  - Use static WINS entries for mission-critical servers to prevent other computers from taking over the use of the name of a critical server. Static WINS entries also prevent other computers from appending additional IP addresses to the name record of a mission-critical server or domain. For more information, see WINS Best Practices, Using static mappings, and Add a static mapping entry.

**Additional recommendations**

Before you install and configure WINS for your network, consider:

- **Restricting who can enable, configure, and disable WINS.**

  You must be a member of the Administrators group to change configuration information on WINS servers using the WINS console or the **netsh wins** commands. Restrict the membership of the Administrator group to the minimum number of users necessary to administer the server.

  If there are users who need read-only access to the WINS console, add them to the WINS Users group instead of to the

Administrators group. WINS Users can search for WINS records and view replication partners and other configuration information, but they cannot change settings on the WINS server. For more information, see WINS tools, Finding and viewing WINS records, and View WINS Records.

# WINS defined

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS defined**

Windows Internet Name Service (WINS) provides a distributed database for registering and querying dynamic mappings of NetBIOS names for computers and groups used on your network. WINS maps NetBIOS names to IP addresses and was designed to solve the problems arising from NetBIOS name resolution in routed environments. WINS is the best choice for NetBIOS name resolution in routed networks that use NetBIOS over TCP/IP.

NetBIOS names are used by earlier versions of Microsoft® Windows® operating systems to identify and locate computers and other shared or grouped resources needed to register or resolve names for use on the network.

NetBIOS names are a requirement for establishing networking services in earlier versions of Microsoft operating systems. Although the NetBIOS naming protocol can be used with network protocols other than TCP/IP, WINS was designed specifically to support NetBIOS over TCP/IP (NetBT).

WINS simplifies managing the NetBIOS namespace in TCP/IP-based networks. The following illustration shows a typical series of events involving WINS clients and servers.

In this example, the following occurs:

1. A WINS client, HOST-A, registers any of its local NetBIOS names with WINS-A, its configured WINS server.

2. Another WINS client, HOST-B, queries WINS-A to locate the IP address for HOST-A on the network.

3. WINS-A replies with the IP address for HOST-A, 192.168.1.20.

WINS reduces the use of local IP broadcasts for NetBIOS name resolution and enables users to locate systems on remote networks easily. Because WINS registrations are done automatically each time clients start and join the network, the WINS database is automatically updated when dynamic address configuration changes are made. For example, when a DHCP server issues a new or changed IP address to a WINS-enabled client computer, WINS information for the client is updated. This requires no manual changes to be made by either a user or network administrator.

**Notes**

- The WINS protocol is based on and is compatible with the protocols defined for NetBIOS name service specified in RFCs 1001 and 1002, so it is interoperable with any other implementations of these RFCs.

- Replication of NetBIOS names data in WINS is Microsoft proprietary technology and is not interoperable with other NetBIOS name servers.

# Benefits of using WINS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Benefits of using WINS**

WINS provides the following benefits for administering your TCP/IP-based network:

- A dynamic name-to-address database that maintains support for computer name registration and resolution.
- Centralized management of the name-to-address database, alleviating the need for managing Lmhosts files.
- Reduction of NetBIOS-based broadcast traffic on subnets, by permitting clients to query WINS servers to directly locate remote systems.
- Support for earlier Microsoft® Windows® and NetBIOS-based clients on your network, permitting these types of clients to browse lists for remote Windows domains without requiring a local domain controller to be present on each subnet.
- Support for DNS-based clients by enabling those clients to locate NetBIOS resources when WINS lookup integration is implemented.

# How WINS works

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**How WINS works**

By default, when a computer running Microsoft® Windows® 2000, Windows XP, or a Windows Server 2003 operating system is configured with WINS server addresses (either manually or through DHCP) for its name resolution, it uses hybrid node (h-node) as its node type for NetBIOS name registration unless another NetBIOS node type is configured. For NetBIOS name query and resolution, it also uses h-node behavior, but with a few differences.

For NetBIOS name resolution, a WINS client typically performs the following general sequence of steps to resolve a name:

1. Client checks to see if the name queried is its local NetBIOS computer name, which it owns.

2. Client checks its local NetBIOS name cache of remote names. Any name resolved for a remote client is placed in this cache where it remains for 10 minutes.

3. Client forwards the NetBIOS query to its configured primary WINS server. If the primary WINS server fails to answer the query--either because it is not available or because it does not have an entry for the name--the client will try to contact other configured WINS servers in the order they are listed and configured for its use.

4. Client broadcasts the NetBIOS query to the local subnet.

5. Client checks the Lmhosts file for a match to the query, if it is configured to use the Lmhosts file.

6. Client tries the Hosts file and then a DNS server, if it is configured for one.

**Notes**

- For a more detailed description of the default NetBIOS name resolution process as it is performed by computers running Windows XP or a Windows Server 2003 operating system, see Resolving names.

- In general, Windows operating systems support two major methods of performing network name resolution. These are:

    - **Host name resolution.** This is Windows sockets-based name resolution which implements the gethostbyname () API to search for a host IP address based on a queried host name. This method relies on either a Hosts file or querying DNS to perform resolution of the name.

    - **NetBIOS name resolution.** This is name resolution that uses the NetBIOS redirector to search for an address based on a queried NetBIOS name. This method relies on either an Lmhosts file or querying WINS to perform resolution of the name.

  WINS clients running Windows 2000, Windows XP, or a Windows Server 2003 operating system are configured by default to first use DNS to resolve names that are longer than 15 characters or that make use of periods (".") within the name. For names that are less than 15 characters and do not use periods, DNS is also used again as a final option after a WINS query fails if the client is configured to use a DNS server.

# WINS tools

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS tools**
The primary tools that you use to manage WINS servers are the WINS console and the Netsh WINS commands.

**The Netsh WINS commands**
You can type the Netsh WINS commands in a command prompt window at the **netsh wins>** command prompt, or you can execute the Netsh WINS commands in batch files and other scripts. All of the functionality that is available in the WINS console is available at the **netsh wins>** command prompt.

For more information, see Use WINS Command-line Tools. For a simple list of Netsh WINS commands, see Managing WINS from the command line.

For a comprehensive Netsh WINS command reference (including syntax, parameters and examples), see Netsh commands for WINS.

For an example of how to use Netsh WINS commands in batch files and scripts, see Netsh WINS example.

**The WINS console**
The WINS console is added to the Administrative Tools folder in Control Panel when you install a WINS server running a Microsoft® Windows Server 2003 server operating system. The WINS console appears as a Microsoft Management Console (MMC) snap-in, to further integrate WINS administration into your total network management.

After you install a WINS server, you can use the WINS console or the Netsh WINS commands to perform these basic administrative server tasks:

1. View and filter NetBIOS name registrations stored at the WINS server for client names used on your network.
2. Add and configure replication partners for the WINS server.
3. Perform maintenance-related tasks, including back up, restoration, compaction, and scavenging, on the WINS server database.

In addition, you can also use the WINS console to perform the following optional or advanced setup tasks:

- View and modify WINS properties, such as the **Renew Interval** and other intervals that are used when registering, renewing, and verifying name records stored in the server database.
- Add and configure static WINS mappings, if they are needed for use on your network.
- Delete or tombstone WINS records that appear in WINS server data used throughout your network.

## Notes

- The Windows Server 2003 family includes new features beyond those provided in earlier versions. For more information, see New features for WINS.
- The WINS console provides new ways to perform familiar WINS administrative tasks previously performed in Windows NT® 4.0 using WINS Manager. For more information, see New ways to do WINS tasks.

# New features for WINS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**New features for WINS**

Microsoft® Windows Server 2003 Windows Internet Name Service (WINS) provides the following new features:

- **Advanced WINS database search and filtering capabilities**

  Improved filtering and new search functions help you locate records by showing only those records that fit the criteria you specify. These functions are particularly useful in analyzing very large WINS databases. You can use multiple criteria to perform advanced searches for WINS database records. This improved filtering capability allows you to combine filters for customized and precise query results. Available filters include: record owner, record type, NetBIOS name, and IP address with or without subnet mask.

  Because you can now store query results in the cache of the random access memory (RAM) on your local computer, the performance of subsequent queries is increased, and network traffic is reduced. For more information, see Finding and viewing WINS records and View WINS Records.

- **Accepting replication partners**

  When determining a replication strategy for your organization, you can define a list that controls the source of incoming name records during pull replication between Windows Internet Name Service (WINS) servers.

  In addition to blocking name records from specific replication partners, you can also choose to accept only name records owned by specific WINS servers during replication, excluding the name records of all servers that are not on the list. For more information, see Accepting replication partners and Accept replication of records owned by a specified server.

The following features were new for Windows 2000 Server and are also provided with the Windows Server 2003 family:

- **Command-line administration of WINS servers using Netsh**

  In addition to a full graphical user interface for managing WINS servers, the Windows Server 2003 family provides a fully equivalent WINS command-line based tool called Netsh. For more information, see Managing WINS from the command line. For a comprehensive netsh WINS command reference (including syntax, examples, and parameters) see Netsh commands for WINS. For an example of how to use Netsh WINS commands in batch files and scripts, see Netsh WINS example.

- **Persistent connections**

  You can now configure each WINS server to maintain a persistent connection with one or more replication partners. This increases the speed of replication and eliminates the overhead of opening and terminating connections. For more information, see Persistent connections.

- **Manual tombstoning**

  You can manually mark a record for eventual deletion (*tombstoning*). The tombstone state of the record replicates to other WINS servers, preventing any replicated copies of the deleted records from reappearing at the same server where they were originally deleted. For more information, see Deleting and tombstoning records.

- **Improved management utility**

  The WINS console is fully integrated with the Microsoft Management Console (MMC), a powerful and user-friendly environment you can customize for your efficiency. Because all server administrative utilities included for use in the Windows Server 2003 family are part of MMC, new MMC-based utilities are easier to use as they operate more

predictably and follow a common design.

- **Improved ease of use for both using and managing advanced WINS features**

  WINS now includes the ability to block records by a specific owner or WINS replication partner (formerly known as Persona Non Grata), and to use the feature **Overwrite unique static mappings at this server** (formerly known as **migrate on**). For more information, see either Blocking replication partners or Using static mappings.

- **Dynamic record deletion and multi-select**

  These features help you more easily manage the WINS database. With the WINS snap-in, you can simply point, click, and delete either one or more WINS static or dynamic-type entries. Previously, this functionality was only available when using command-based utilities, such as Winscl.exe, designed for earlier versions of WINS. It is also possible now to delete records that use names based on non-alphanumeric characters.

- **Record verification and version number validation**

  These features quickly check the consistency of names stored and replicated on your WINS servers. Record verification compares the IP addresses returned by a NetBIOS name query of different WINS servers. Version number validation examines the owner address-to-version number mapping tables. For more information, see Checking the WINS database for consistency.

- **Export function**

  When you *export*, you place WINS data in a comma-delimited text file. You can export this file to Microsoft Excel, reporting tools, scripting programs, or similar programs for analysis and reporting. For more information, see Export WINS console data to a text file.

- **Increased fault tolerance for clients**

  Clients running Windows 98, Windows 2000, Windows Millennium Edition, Windows XP, or a Windows Server 2003 operating system can specify more than two WINS servers (up to a maximum of 12 addresses) per interface, using the first two servers in the list for NetBIOS name registration. The extra WINS server addresses are used only if the primary and secondary WINS servers fail to respond. WINS clients also benefit from the use of burst handling, which is enabled by default. For more information, see Burst handling and "Primary/Secondary WINS servers" in WINS servers.

- **Dynamic re-insertion of client names**

  WINS clients no longer have to be restarted after they use WINS to force re-insertion and update of local NetBIOS names. The Nbstat command includes a new option, **-RR**, which provides this functionality. If WINS clients are running Windows NT® 4.0, updated to Service Pack 4 or later, the **-RR** option can also be used with those clients. For more information, see Verify WINS registration of client NetBIOS names.

- **Read-only console access to the WINS console.**

  This feature provides a special purpose local users' group, the WINS Users group, which is automatically added when WINS is installed. By adding members to this group, you can provide read-only access in the WINS console to WINS-related information on this server computer for users that are not administrators. You can allow a user in this group to view, but not modify, information and properties stored at a specific WINS server. For more information, see Default groups.

- **Improved database engine.**

  WINS uses the same performance-enhanced database engine technology that is also used in Active Directory®.

# Planning WINS networks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Planning WINS networks**

Before you install WINS servers on your network, plan the following tasks:

1. *Determine the number of WINS servers that you need.*

   One WINS server can handle NetBIOS name resolution requests for a large number of computers. However, consider the location of routers on your network and the distribution of clients in each subnet when you decide how many WINS servers are actually required.

2. *Plan the replication partnerships.*

   Determine whether to configure WINS servers as either pull or push partners, and set partner preferences for each server. For more information, see Configuring WINS replication.

3. *Assess the impact of WINS communication traffic on slower links.*

   Although WINS is designed to help reduce broadcast traffic between local subnets, it does create some traffic between servers and clients. This can be particularly important if you use WINS on routed TCP/IP networks.

   Also consider the effects of slower speed links (such as those typically used for wide area networks) on both replication traffic between WINS servers and NetBIOS registration and renewal traffic required for WINS clients.

4. *Assess the level of fault tolerance within your network for WINS.*

   Consider how shutting down a WINS server (even temporarily) affects your network. Use additional WINS servers for failure recovery, backup, and redundancy.

5. *Test and revise your planned WINS installation.*

   By testing the performance of your network installation of WINS, you can better identify potential problems before they occur. Use WINS server performance counters, which are available through the use of System Monitor.

**Planning how many WINS servers to use**

On a smaller network, a single WINS server can adequately service up to 10,000 clients for NetBIOS name resolution requests. To provide additional fault tolerance, you can configure a second computer running a Microsoft® Windows Server 2003 server operating system as a secondary (or backup) WINS server for clients. If you use only two WINS servers, you can easily set them up as replication partners of each other. For simple replication between two servers, one server should be set as a pull partner and the other as a push partner. Replication can be either manual or automatic, which you can configure by selecting the **Enable automatic partner configuration** check box on the **Advanced** tab of the **Replication Partner Properties** dialog box.

A larger network sometimes requires more WINS servers for several reasons including, most importantly, the number of client connections per server. The number of users that each WINS server can support varies with usage patterns, data storage, and the processing capabilities of the WINS server computer. Some enterprise network environments require more robust hardware to handle WINS activity, so you might benefit from upgrading the server computer.

When planning your servers, remember that each WINS server can simultaneously handle hundreds of registrations and queries per second. The WINS development and testing team compiled the following statistics as a profile of WINS performance during preliminary testing of Windows Server 2003 operating systems:

| | |
|---|---|
| Average registrations/second | 300 |

| | |
|---|---|
| Average queries/second | 350 |

These measurements were based on a server computer running WINS with no other additional services running and installed on currently available hardware. The specific hardware used includes the following: a single Intel Pentium II 350 MHz processor, 128 MB of RAM, and a standard IDE hard drive, which was used to store the WINS database. As a point of reference, WINS records data exchanged between servers and clients is typically small. On average, WINS records are about 40 bytes in size.

A conservative recommendation for large networks is to install one WINS server and a backup server for every 10,000 computers on the network. This reflects the previously suggested baseline performance and provides for large-scale power outages that could cause many WINS computers to restart simultaneously. Capacity is dependent upon server and network resources. Processor speed, available RAM, database storage space, and network resources can have a significant impact.

Two factors can enhance WINS server performance:

- Using two installed processors on the computer running WINS. This can increase performance by almost 25 percent.
- Using a dedicated high-performance disk drive, separate from the system drive, for the WINS database.

### Notes

- After you establish WINS servers on your intranet, you can adjust the *renew interval*, which is the time between a WINS client name registration and name renewal. By using this setting to reduce the number of registrations, you can tune server response time.

  For more information, see Modify name record settings and Modifying WINS server defaults.

- The default WINS database location is *systemroot*\System32\Wins. If you choose to move the WINS database to another location, you can change the database path using the WINS console.

  For more information, see Set the WINS database path.

**Planning for fault tolerance**

To ensure you are planning a fault-tolerant WINS design, ask the following question for each server on your network: *What happens to WINS if this server shuts down or if clients cannot reach it?*

To help answer the question, consider the two common scenarios in which a WINS server could fail to perform in its role on a network:

1. Hardware or power failures that require downtime for server repair or maintenance.
2. A network link or router failure that isolates a WINS server from clients.

To plan for these, determine the maximum length of time any given WINS server could be out of service on your network, factoring in the length of both planned and unplanned outages.

Also consider what happens to your WINS clients if their primary WINS server is shut down. By maintaining and assigning secondary WINS servers for clients, you can reduce the effects of a single WINS server being offline.

**Planning for network performance**

Begin planning by estimating the amount of network traffic between WINS clients and WINS servers under normal conditions. You should predict and monitor the following:

- NetBIOS names commonly registered by WINS clients.
- WINS registration and renewal caused by daily startup of clients.
- Roving users and their effect when moving within a routed network.

- WAN links and their effect on replication performance and convergence.

When planning for WINS network performance, it is important to understand the types of traffic that WINS clients typically generate on a network, as listed below.

- **Name registration**

  For more information, see Registering names.

- **Name refresh**

  For more information, see Renewing names.

- **Name release**

  For more information, see Releasing names.

- **Name query**

  For more information, see Resolving names.

**Daily start up of WINS clients**
When a WINS-enabled client starts on the network, it sends a name registration request for the computer name, user name, domain name, and any additional Windows NT® network client services running on the computer.

A WINS client running Windows XP usually registers more NetBIOS names than other WINS-enabled clients. The name registration requests generated by a computer running under these versions of Windows can include the following: File Server, Domain, the Replicator service, the Messenger service, the Computer Browser service, and additional network service names.

An active WINS client name registration in a WINS server database replicates to all pull partners configured on that WINS server. Eventually, the active name registration replicates to all WINS servers on the network.

When a WINS client is shut down at the end of a workday, it releases the name. When the computer is restarted at the beginning of next workday, the WINS client registers the name again with the WINS server and receives a new version ID. This new, active name registration entry replicates to the pull partners of the WINS server.

Assuming that this cycle occurs each day for each computer, the number of name registration entries replicated each day is approximately the number of computers that start each day multiplied by the number of NetBIOS names registered at each computer.

On large networks (50,000 or more computers), the biggest traffic load represents the name registration requests generated when WINS clients start on the network.

**Planning considerations for routed WINS networks**
When planning for WINS client traffic on large routed networks, consider the effect of name query, registration, and response traffic routed between subnets. Name requests and responses that occur at the daily startup of computers must pass through the traffic queues on the routers, and can cause delays at peak times.

Roving or mobile users also present challenges for planning WINS in routed networks. When a user stops a computer and then moves it to another location--starting the computer on a different subnet with a different primary WINS server--the resulting changes can generate name-challenge traffic for WINS.

Typically, the name registration request is answered with a brief "Wait for Acknowledgment" message. Assuming the name being registered was previously replicated to the new server, it challenges the IP address currently in its database for this name with a brief query. When, as expected, there is no reply, the WINS server retries the challenge two more times for a total of three attempts. If all three attempts fail, the challenge is successful and the new WINS server updates the name registration entry in its database with the new IP address, incrementing the version ID. The new version ID indicates that the entry must be replicated from its new owner--the new WINS server--to other WINS servers on the network.

You can estimate WINS client traffic based on the behavior of the WINS clients, as described in the preceding sections. However, when estimating WINS client traffic, also consider the network topology and the design or configuration of the

network routers. In some cases, it is not possible to predict the traffic load on a specific network router because the routers are configured to autonomously route traffic based on factors other than traffic load.

# WINS servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS servers**

WINS consists of two main components, the WINS server and WINS clients.

The WINS server handles name registration requests from WINS clients, register their names and IP addresses, and responds to NetBIOS name queries submitted by clients, returning the IP address of a queried name if it is listed in the server database.

Also, as the following graphic shows, WINS servers can replicate the contents of their databases (which contain NetBIOS computer name mappings to IP addresses) to other WINS servers. When a WINS-enabled client computer (such as a workstation computer on either Subnet 1 or Subnet 2) starts on the network, its computer name and IP address are sent in a registration request directly to its configured primary WINS server, WINS-A. Because WINS-A is the server that registers these clients, it is said to be the *owner* for the records of the clients in WINS.

In this example, server WINS-A has clients registering with it that are both local (that is, clients on Subnet 2 where it resides) and remote (clients located across a router on Subnet 1). A second WINS server, WINS-B, is located on Subnet 3 and only owns mappings for local clients registering from its same subnet. WINS-A and WINS-B can later complete replication of their databases so that records for clients on all three subnets are in the WINS database at both servers. For more information, see WINS Replication.

**Primary/Secondary WINS servers**

WINS servers are used by clients in one of two ways: either as a primary or secondary WINS server.

The difference between primary and secondary WINS servers is not based in any way on the servers (that for all functional purposes are the same in WINS). The difference occurs at the client which differentiates and orders the list of WINS servers when provided more than one WINS server to use.

For most cases, the client contacts the primary WINS server for all of its NetBIOS name service functions (name registration, name renewal, name release, and name query and resolution). The only case where secondary WINS servers are ever used is when the primary WINS server is either:

1. Unavailable on the network when the service request is made, or

2. Unable to resolve a name for the client (in the case of a name query).

In the case of a failure by the primary WINS server, the client requests the same service function from its secondary WINS servers. If more than two WINS servers are configured at the client, the additional WINS servers are tried until the list is exhausted or one of the secondary WINS server succeeds in processing and responding to the request. After a secondary WINS server is used, a client periodically tries to switch back to its primary WINS server for future service requests.

For most recent WINS clients (Windows XP and Windows 2000), a list of up to 12 secondary WINS servers can be configured (either manually through TCP/IP properties or dynamically by a DHCP server providing a list using DHCP option type 44). This feature is useful in an environment where there is a large number of mobile clients and NetBIOS-based resources, and services are used often. Because in these types of environments, the WINS database may not be consistent throughout the network of

WINS servers because of convergence issues, it can be helpful for clients to be able to query more than two WINS servers.

However, this option should not be overused needlessly as it produces a tradeoff in terms of the actual benefit for adding fault tolerance by listing additional WINS servers. The benefit of this feature must be weighed against the fact that for each additional WINS server listed, the time to process a query request fully in WINS takes incrementally longer to achieve. For example, if a WINS client tries three or more WINS servers before failing, it can substantially delay the processing of the name query before alternative methods for resolution are tried, such as searching of a local Hosts file or querying a DNS server.

# WINS clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS clients**

WINS clients attempt to register their names with a WINS server when they start or join the network. Clients thereafter query the WINS server to resolve remote names as needed.

WINS-enabled clients are computers that are able to be configured to make direct use of a WINS server. Most WINS clients typically have more than one NetBIOS name that they must register for use with the network. These names are used to publish various types of network services, such as the Messenger or Workstation service, that each computer can use in various ways to communicate with other computers on the network.

Microsoft supports WINS clients running on the following platforms:

- Windows Server 2003 operating systems
- Windows XP operating systems
- Windows Millennium Edition
- Windows 2000 operating systems
- Windows NT operating systems
- Windows 98
- Windows 95
- Windows for Workgroups
- Microsoft LAN Manager
- MS-DOS clients
- OS/2 clients
- Linux and UNIX clients (with Samba installed)

WINS-enabled clients communicate with the WINS server to:

- Register client names in the WINS database.
- Renew client names with the WINS database.
- Release client names from the WINS database.
- Resolve names by obtaining mappings from the WINS database for user names, NetBIOS names, DNS names, and IP addresses.

Clients that are not WINS-enabled can participate in these processes in a limited way by using WINS proxies. For more information, see WINS proxies.

# WINS proxies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS proxies**

A WINS proxy is a WINS client computer configured to act on behalf of other host computers that cannot directly use WINS. WINS proxies help resolve NetBIOS name queries for computers located on routed TCP/IP networks.

By default, most computers not able to use WINS use broadcasts to resolve NetBIOS name queries and register their NetBIOS names on the network. You can configure a WINS proxy to listen on behalf of these computers and to query WINS for names not resolved by broadcast.

WINS proxies are only useful or necessary on networks that include NetBIOS broadcast-only (or b-node) clients. For most networks, WINS-enabled clients are common and WINS proxies are typically not needed.

WINS proxies are WINS-enabled computers that listen for b-node NetBIOS name service functions (name registration, name release, and name query) and can respond for those names that are remote and not used on the local network. Proxies communicate directly with a WINS server to retrieve the information necessary to respond to these local broadcasts.

WINS proxies are used in the following ways:

- When a b-node client registers its name, the proxy checks the name against the WINS server database. If the name exists in the WINS database, the proxy might send a negative registration response back to the b-node client attempting to register the name.
- When a b-node client releases its name, the proxy deletes the client name from its remote name cache.
- When a b-node client sends a name query, the proxy attempts to resolve the name using information either locally contained in its cache of remote names or through the use of information it obtains from the WINS server.

**How WINS proxies resolve names**

The following graphic illustrates the use of a WINS proxy, HOST-B, for a subnet containing a b-node client, HOST-A.

In this example, the following steps are used by the WINS proxy to resolve names for the b-node computer:

1. HOST-A broadcasts a NetBIOS name query to the local subnet.
2. HOST-B accepts the broadcast and checks its cache for the appropriate NetBIOS computer name-to-IP address mapping.
3. HOST-B processes the request.

   If HOST-B has a name-to-IP address mapping cached that matches the one HOST-A requested, it returns this information to HOST-A. If not, HOST-B queries a WINS server for the mapping requested by HOST-A.

4. When HOST-B receives the requested name-to-IP address mapping from its configured WINS server (in this example, WINS-A), it briefly caches this information.

   By default, a WINS proxy caches the remote name mappings that it queries in WINS for 6 minutes, but this value is configurable with a minimum value of 1 minute.

5. HOST-B can then use this mapping information to respond to subsequent NetBIOS name queries broadcast from either HOST-A or other b-node computers on the subnet.

**Notes**

- Because WINS servers do not respond to broadcasts, you should configure a computer as a WINS proxy on each subnet that contains non-WINS computers that must use broadcasts to resolve NetBIOS names.

- When a WINS proxy is used to answer a query for a multihomed client or a group record containing a list of IP addresses, only the first listed address is returned to the b-node client.

- For more in-depth information on configuring or using WINS proxy, see Updated technical information or "Windows Internet Name Service" at the Microsoft Windows Resource Kits Web site.

# The WINS database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**The WINS database**

The WINS database stores and replicates the NetBIOS name-to-IP address mappings for your network. In the Windows Server 2003 family, the WINS database uses the Extensible Storage Engine (ESE).

**Compacting the database**

There is no built-in limit to the number of records that a WINS server can replicate or store. The size of the database depends on the number of WINS clients on the network. The WINS database changes over time as clients log on and log off the network.

However, the size of the WINS database is not directly proportional to the number of active client entries. Over time, as some WINS client entries become obsolete and are deleted, the size of the WINS database grows larger than the actual space currently in use by the database. This is because the space used to store obsolete records is not automatically reclaimed by the server once the space is freed and no longer in use.

Compacting the WINS database recovers the unused space. Dynamic database compaction occurs on WINS servers as an automatic background process during idle time after a database update. Compaction can also be done manually offline. Windows NT Server 4.0, Windows 2000, and the Windows Server 2003 family support both dynamic and manual compaction. Windows NT Server 3.51 (or earlier) supports only manual compacting of the WINS server database.

Although dynamic compacting greatly reduces the need for offline compaction, offline compaction reclaims the space better and should be done periodically. How frequently you manually compact the WINS database depends on your network. For large, busy networks with 1,000 or more WINS clients, you should compact offline each month. Smaller networks usually require less frequent manual compaction.

Because the dynamic database compaction occurs while the database is in use, you do not need to stop the WINS server during this process. However, for manual compacting, you must stop the WINS server and take it offline.

**Backing up the WINS database**

The WINS console provides the tools you need to maintain, view, back up, and restore the WINS server database. You should back up the database whenever you back up other files on the WINS server.

**WINS database files**

WINS uses the Jet database format for storing its data. Jet produces the J<*n*>.log and other files in the *systemroot*\System32\Wins folder to increase the speed and efficiency of data storage.

The following table discusses the files that are created and used by the Jet database in each WINS server.

| File | Description |
|---|---|

| | |
|---|---|
| J50.log and J50#####.log | A log of all transactions done with the WINS database. This file is used by WINS to recover data if necessary.<br><br>To increase speed and efficiency of data storage, the Jet database writes current transactions to log files rather than directly to the database. Therefore, the most current view of the data includes both the database and any transactions in the log files. Both of these files are used for recovery if the WINS service abruptly or unexpectedly stops. If the service stops in an unexpected manner, the log files are automatically used to re-create the correct state of the WINS database.<br><br>Log files maintain a specific size; however, they can grow quickly on a busy WINS server. Inevitably, WINS writes more transactions to a log than the log size can accommodate. When a log file is filled, it is renamed, indicating that it is an older log and not in use. A new transaction log is created with the J<*n*>.log file name, where <*n*> is a decimal number, such as J50.log. The naming format of the previous log file is Jet*XXXXX*.log, where each *X* denotes a hexadecimal number from 0 to F. Previous log files are maintained in the same folder as the current log files.<br><br>The log files are processed (all entries written to the database) and deleted every three hours. Processing and deletion also occur upon successful WINS database backup or when the WINS server is shut down properly. If many J<*n*>.log files accumulate, you should schedule frequent backups to maintain the logs.<br><br>After the entries are processed, you can manually delete the log files; however, this prevents a successful recovery of the database if it should be needed. For this important reason, do not manually delete or remove the log files from the system until a backup has been performed. |
| J50.chk | A checkpoint file that indicates the location of the last information successfully written from the transaction logs to the database. In a data recovery scenario, the checkpoint file indicates where the recovery or replaying of data should begin. This checkpoint file is updated every time data is written to the database file (Wins.mdb). |
| Wins.mdb | The WINS server database file, which contains two tables: the IP address-to-Owner ID mapping table and the Name-to-IP address mapping table. |
| Winstmp.mdb | A temporary file that is created by the WINS server service. This file functions as a swap file during index maintenance operations and can remain in the *systemroot*\System32\Wins directory after a system failure. |
| Res#.log | These are reserved log files, which function in emergencies when the server runs out of disk space. If a server attempts to create another transaction log file, and there is insufficient disk space, the server flushes any outstanding transactions into these reserved log files. The service then shuts down and logs an event to Event Viewer. |

**Important**

- The J50.log, J50#####.log, Wins.mdb, Winstmp.mdb, and Res#.log files should not be removed or altered.

# WINS Replication

Updated: January 21, 2005

# WINS replication overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Replication overview**

Where multiple WINS servers are used on your network, they can be configured to replicate records in their databases to other servers. This process is shown in the following figure. Two WINS servers, WINS-A and WINS-B, are both configured to fully replicate their records with each other.

By using replication between these WINS servers, a consistent set of WINS information is maintained and distributed throughout the network. For example, in the previous figure a WINS client (HOST-1) on Subnet 1 registers its name with its primary WINS server, WINS-A. Another WINS client (HOST-2) on Subnet 3 registers its name with its primary WINS server, WINS-B. If either of these hosts later attempts to locate the other host using WINS--for example, HOST-1 queries to find an IP address for HOST-2--replication between the WINS servers (WINS-A and WINS-B) makes resolving this query possible.

For replication to work, each WINS server must be configured with at least one other WINS server as its replication partner. This ensures that a name registered with one WINS server is eventually replicated to all other WINS servers in the network. A replication partner can be added and configured as either a pull partner, a push partner or to use both types of replication as a push/pull partner. The push/pull partner type is the default configuration and is the type recommended for use in most cases.

When WINS servers replicate, a latency period exists before a client name-to-address mapping from any given server is propagated to all other WINS servers in the network. This latency is known as the *convergence time* for the entire WINS system. For example, a name release request by a client will not propagate as fast as a name registration request. This is intended by design because it is common for client names to be released and then reused with the same mapping as computers are restarted or periodically shut down. Replicating each of these name releases would unnecessarily increase the network load of replication.

Also, when a WINS client computer is shut down improperly, as in the case of an unexpected power outage, the registered names of the computer are not released as they normally would be by sending a name release request to the WINS server. Therefore, the presence of a name-to-address record in the WINS database does not necessarily mean that a client computer is still using the name or its associated IP address. It only means that at some recent time in the past, a computer by the registered name claimed the mapped IP address for its use.

**Notes**

- The primary and secondary WINS servers of any client should typically have a push and pull relationship with each other. However, a direct push/pull configuration is not required as long as similar results can be indirectly achieved during a normal replication cycle.

- WINS replication is always incremental, meaning that only changes in the database are replicated each time replication occurs, not the entire database.

# Pull partners

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Pull partners**

A pull partner is a WINS server that pulls or requests replication of updated WINS database entries from other WINS servers (those configured to use it as a push partner) at a configured interval. This is done by requesting entries with a higher version ID than the last entry received from its configured partner.

You can enable WINS to pull (request) a replication with its configured partners when one of the following events occurs:

- When the WINS server starts.
- When a set amount of time has elapsed.

The amount of time between pull replications is indicated in the **Replication interval**, which can be specified either globally for all pull partners or individually for specific partners. When the time has elapsed for each interval, WINS sends a pull replication trigger to its pull partners. The partners can then respond with incremental changes, if any have been made since the last time replication occurred.

To configure which of these options WINS uses, you need to configure pull parameters, either the default parameters that the server uses for all pull partners or the parameters in effect for a specific partner. For more information, see Modify pull partner properties.

Additionally, you have the administrative option of manually sending a pull replication trigger to another pull partner of the selected WINS server. For more information, see Send a replication trigger to a selected partner.

**How WINS determines which entries to pull replicate**

Because push-based replication uses notification, it does not transfer any records until a subsequent pull trigger is returned by the notified partner. For this reason, pull replication can be viewed as the single process used to replicate WINS data between servers.

All WINS servers maintain an internal mapping table--an owner-version mapping table--which is used to complete the replication process. This table is built dynamically at startup by the server and is held in memory.

The owner-version mapping table contains the following:

1. An owner ID that maps to the IP address for each WINS server that appears in the database as an owner for records currently stored there.

   For practical purposes, WINS automatically assigns and increments an integer value for the owner ID and then maps that value to a corresponding server IP address. However, when you examine this information in the WINS console, only the owner IP address is actually displayed.

2. When replication occurs with another WINS server, the version ID field for all records currently in the database is scanned for the highest version ID associated with each identified distinct owner.

A sample Owner/Version ID table for WINS-A when it is started might look like the following, if viewed using **View Records** in the WINS console:

| Owner ID (not displayed) | Owner | Name | Highest ID |
|---|---|---|---|
| (0) | 192.168.1.5 | WINS-A | 1F |
| (1) | 192.168.2.5 | WINS-H | 125 |
| (2) | 192.168.3.5 | WINS-B | 31 |

| | | | |
|---|---|---|---|
| (3) | 192.168.4.5 | WINS-C | 100 |
| (4) | 192.168.5.5 | WINS-D | 200 |

The owner-version mappings are used by WINS to determine the state of the database at any point in time before or after replication. The following example provides more detailed information about how WINS manages replication.

**Example: How pull replication works**

The following graphic demonstrates how four WINS servers--WINS-A, WINS-B, WINS-C, and WINS-D--are all configured to be spokes (push/pull partners) of a central hub server, WINS-H.

Before replication with WINS-H, the owner-version mapping table at WINS-A contains a set of highest version IDs for all owners in its database. For the purpose of this example, assume these values are the same as those shown in the sample table provided in the previous section.

In reality, pull replication might be occurring dynamically between all four spokes at various times with WINS-H, so this table might not remain static for long. For a basic understanding of the details of an individual pull replication cycle, however, it is easier to focus on what might happen when just one of the spokes--for example, WINS-A--replicates its database with WINS-H.

In the graphic shown, the following changes in the replicated WINS network occur:

1. The three other spokes (WINS-B, WINS-C and WINS-D) each replicate with WINS-H, based on the highest version ID.

    a. WINS-B has added or updated one new record since its last replication cycle, which WINS-H replicates and adds to its database.

    b. WINS-C has the same version ID and does not have any new records to be replicated at WINS-H.

    c. WINS-D has updated a total of 20 records since its last replication cycle, which WINS-H replicates and adds to its database.

2. WINS-H sends a trigger to WINS-A initiating replication.

    The updated owner-version mapping table information is provided as part of the trigger.

3. WINS-A responds by pulling entries from WINS-H.

    WINS-A determines which owner servers to pull from based on the difference between its locally held highest version ID for each owner and the corresponding updated highest version IDs provided by WINS-H. WINS-A specifies the range of records to be pulled and replicated by comparing versions.

**Notes**

- In the case where another pull replication to the same partner is already queued, WINS sees the subsequent request as further down in the queue and discards it in favor of keeping the one with a higher placement in the service process queue.

- In addition to modifying settings for pull replication properties, WINS also provides the option to enable the use of persistent connections with either a specified pull partner or all pull partners of a WINS server.

  For more information, see either Persistent connections or Enable the use of persistent connections with a partner server.

# Push partners

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Push partners**

A push partner is a WINS server that pushes or notifies other WINS servers (those configured to use it as a pull partner) of the need to replicate their database entries at a configured interval. To configure a WINS server to use push replication, you can choose from several WINS console configurable options. For example, you can enable WINS to push notify configured partners when one of the following events occurs:

- When the WINS server starts.
- Whenever an IP address change occurs for a name-to-address mapping in the WINS server database.
- When a value for **Number of changes in version ID before replication** is specified--either globally for all push partners or individually for specific push partners--WINS can use this value as a threshold for determining how many incremental changes must be made to the database before it starts push replication to its partners.

To configure any of these options for WINS use, you need to configure push parameters, either the default parameters that the server uses for all push partners or the parameters in effect for a specific partner. For more information, see Modify push partner properties.

Additionally, you can manually start push replication to other WINS servers. For more information, see Send a replication trigger to a selected partner or Send a replication trigger to any specified WINS server.

**How updates and WINS settings affect push replication**

By default, WINS does not perform push replication unless other related settings are also configured on the **Push Replication** tab in **Replication Partners Properties**. For example, WINS uses an *update count* value of 0. This is set using **Number of changes in version ID before replication**.

Push replication only occurs at configured replication intervals, unless other push replication settings are configured as well, such as:

- For **Start push replication**, selected events such as the **At service startup** or the **When address changes** check boxes are selected.
- The **Use persistent connections for push replication partners** check box is selected, which can affect how the value of **Number of changes in version ID before replication** is handled by WINS.

Persistent connections are enabled by default, and replication with partners occurs dynamically as records are updated in the local WINS database. A persistent connection alleviates the need for connections to be opened and closed with each update of the WINS database between WINS server replication partners. Replication with partners occurs at a rate specified by the **Number of changes in version ID before replication** parameter. With this value set to the default of zero, replication takes place as soon as a change occurs. This default can be changed so that replication occurs at longer intervals.

With persistent connections enabled for push replication, the default value of 0 causes the local WINS server to send a push trigger and notify its push partners each time an update occurs. An update is defined as an incremental increase to the highest version ID in the local WINS database for records the server owns. This can occur when a new name record is registered and added locally or if an IP address change occurs for an existing record.

With persistent connections, you can reduce the update frequency for push notifications, by specifying a non-zero value instead. If a value greater than zero is used, WINS only starts push replication when the highest ID for records it owns has increased an equal number of times.

For example, the current highest version ID for an example server, WINS-A, is currently 1C4 (which is 452 in converted decimal notation). WINS-A also has its **Number of changes in version ID before replication** set to 2 for either all or some of its push partners.

Suppose that the following four distinct sets of database changes are then made to the WINS server database at WINS-A:

1. HOST-A refreshes its previously registered name record, though it does not change its IP address.

2. HOST-B registers a name record, creating a new dynamic name-to-address mapping to the database.

3. HOST-C registers a previously released name record and, in the process, reports an updated change of IP address for this record.

4. A pull replication occurs at a specified interval with another WINS server.

Once these changes are entered into the database, the newly revised highest version ID for WINS-A is 1C6 (454 decimal). This is because the changes made to WINS server data that were caused by items 2 and 3 (either a client registering a new mapping or updating the IP address used with a previous mapping) each caused the version ID at that server to increment.

For items 1 and 4 in the previous list of changes, the highest version ID at the WINS server does not increase.

After these changes occur, any or all partners of WINS-A that are configured with a **Number of changes in version ID before replication** of 2 would then be push notified by WINS sending a replication trigger to those servers.

**Example: How push with propagation works**
The following figure shows an example of the use of push partners in a replicated WINS network of four servers. In this example, two of the servers--WINS-A and WINS-B--are located at regional data center locations.

These servers are both central hub servers in a multiple hub-and-spoke enterprise WINS replication design. In order to ensure frequent convergence of names data between the separate regional hubs, both WINS-A and WINS-B maintain a full push/pull relationship with each other.

WINS-C and WINS-D are site or branch-level spoke servers used on the same replicated WINS network. Respectively, they are both configured as push-only partners of WINS-A and WINS-B.

If updates occur at one hub WINS-A, it is unlikely a remote spoke operating as a push-only partner (WINS-D) would receive those updates in a timely or predictable manner. Although replication between the hubs might occur frequently enough to pose no significant issues, setting the update count to an arbitrarily high value at WINS-B might delay convergence at WINS-D until more than one replication cycle has been completed.

To administratively correct this delay, you can initiate a push replication trigger at WINS-A to be sent to WINS-B, which would queue a replication immediately between the hubs. In doing so, if you also chose the **Propagate to all partners** when manually starting push replication, then WINS-B would propagate the push replication trigger to WINS-D. This would result in an early notification to WINS-D of the need to use a pull replication to WINS-B, obtaining any interim updates from WINS-A.

**Note**

- In addition to modifying settings for push replication properties, WINS also provides you the option to enable the use of persistent connections with either a specified push partner or all push partners of a WINS server.

  For more information, see either Persistent connections or Enable the use of persistent connections with a partner server.

# WINS Resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS resolution**

- Registering names
- Releasing names
- Renewing names
- Resolving names

# Resolution overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Resolution overview**

WINS is used to resolve NetBIOS names, but in order for name resolution to be effective, clients need to be able to dynamically add, remove, or update their names in WINS. The following sections provide a functional description of each of these processes, specifically how names are registered, renewed, released, and resolved for clients on a WINS-based network.

This process of WINS client/server communications is outlined in the following graphic:

In a WINS system, all names are registered with a WINS server. The names are stored in a database on the WINS server which answers requests for name-to-IP address resolution based on the entries in this database.

Redundancy and load balancing are maintained with more than one WINS server in the network. Periodically, servers replicate their database entries among one another in order to maintain a consistent view of the NetBIOS namespace.

Each name has an entry in the database. It is owned by the WINS server it registered with and is a replica on all other WINS servers. Each entry has a state associated with it--the entry can be in the active, released, or extinct (also known as tombstone) state. Entries are also assigned a version ID. This number is used in the replication process and is discussed in more detail in **WINS replication**. For more information, see Push partners.

WINS also allows the registration of static names. This enables the administrator to register names for servers running operating systems that are not capable of dynamic name registration. WINS distinguishes between dynamic and static entries. Static names are treated somewhat differently than dynamic names. For more information, see Using static mappings.

# Registering names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Registering names**

Name registration is a WINS client requesting the use of a NetBIOS name on the network. The request may be for a unique (exclusive) or a group (shared) name. NetBIOS applications can also register one or more names.

As illustrated in the following figure, a WINS client (HOST-C) sends a Name Registration Request directly to its configured WINS server, WINS-A.

WINS-A can accept or reject the name registration request by issuing either a positive or negative name registration response to HOST-C. The action taken by WINS-A depends on several factors:

- Whether the name already exists in the server database at WINS-A
- If a record of the name exists, the state in the server database of the record at WINS-A might make a difference. Also, if the recorded IP address for the name is the same or different from the IP address of the requesting client, HOST-C.
- Whether the request is for a unique or group name entry.

If the name does not exist in the database, it is accepted as a new registration and the following steps occur:

1. The name for HOST-C is entered with a new version ID, given a time stamp, and marked with the owner ID of the WINS server.

   The time stamp is calculated based on adding the value of the **Renew interval** (which by default, is 6 days) set on the WINS server to the current date and time of the server.

2. A positive registration response is sent back to HOST-C with a Time-to-Live (TTL) value equal to the time stamp recorded for the name at WINS-A.

**Name registered for same IP address**

If the name HOST-C is already entered in the database with the same IP address as that being requested, the action taken depends on the state and ownership of the existing name.

1. If the entry is marked as *active* and the entry is owned by the server (WINS-A), the server updates the time stamp for the record and returns a positive Response back to the client.

2. If the entry is marked as being either *released* or *tombstoned*, or if the entry is owned by another WINS server, the registration is treated as a new registration. Time stamp, version ID, and ownership are all updated and a positive response is returned.

**Name registered for different IP address**

In the case where the name exists in the WINS database but with a different IP address than that being requested, the WINS

server is expected to avoid duplicate names. If the database entry is in the released or tombstone state, the WINS server is free to assign that name.

If, however, the entry is in the active state, the node holding the name is challenged to determine if it still exists on the network. In this case, the WINS server (WINS-A) could perform a challenge of the name and do the following:

1. WINS-A sends a Wait for Acknowledgment (WACK) response to the requesting client (HOST-C), specifying a time in the TTL field that the client should be prepared to wait for a response.

2. WINS-A then issues a name query request to the node currently registered for this name in the server database.

3. If the node still exists, it sends a positive response back to WINS-A.

4. WINS-A, in turn, sends a negative name registration response back to the requesting client (HOST-C), rejecting the name registration.

5. If a positive response is not received back from the first challenge query made by WINS-A, two subsequent name query requests are made. After three attempts with no response, the challenge process is complete and a positive registration response is returned to the requesting client (HOST-C) and the name updated in the server database for the new client registration.

**Notes**

- Unlike WINS-enabled clients, which can directly contact a WINS server, non-WINS clients (such as NetBT b-node clients) must register and then continuously defend their names by sending and replying to broadcast name queries within the local network.

- NetBIOS names are registered with the Windows Internet Name Service (WINS) and are normally released when the computer is properly shutdown. If the computer was not properly shutdown, or the computer was not able to contact a WINS server during shutdown, the **nbtstat** command can be used to refresh in WINS the local names for this computer. This can be useful for mobile or portable computers that are moved between different locations on a network.

  For more information, see Verify WINS registration of client NetBIOS names.

# Releasing names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Releasing names**

Name release occurs when a WINS client computer finishes using a particular name, when a proper shutdown occurs. In releasing its name, a WINS client notifies its WINS server (or potentially other computers on the network) that it is no longer using its registered name.

As shown in the following figure, when a WINS-enabled client (HOST-C) releases its name, the following steps occur:

1. The computer named HOST-C either shuts down properly or a user enters the **nbtstat -RR** command, initiating a name release request to be sent to the WINS server, WINS-A.

2. WINS-A marks the related database entry for HOST-C as *released*.

   If the entry remains released for a period of time, WINS-A marks the entry as *tombstoned*, updates the version ID for the entry, and notifies other WINS servers of the change.

3. WINS-A returns a release confirmation message to the WINS client, HOST-C.

If a name entry is marked as released, the WINS server can immediately update or revise a marked name entry when a new registration request arrives from a WINS client with the same name but with a different IP address. This is possible because the WINS database shows that the WINS client at the old IP address is no longer using that name. For example, this can happen when a DHCP-enabled laptop changes subnets.

Name release is most often used to simplify WINS registration for clients that shut down and restart on the network. If a computer released its name during a normal shutdown, the WINS server does not challenge the name when the computer reconnects. If a proper shutdown did not occur, the name registration with a new IP address causes the WINS server to challenge the previous registration. When the challenge fails (because the client computer is no longer using the old IP address), the registration succeeds.

In some cases, a client is not able to release its name by contacting the WINS server, so broadcasts must be used to release a name. This can happen when a WINS-enabled client shuts down without receiving confirmation of its name release by the WINS server.

# Renewing names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Renewing names**

Periodic name renewal is required for WINS client computers to renew their NetBIOS name registrations with the WINS server. The WINS server treats name renewal requests similarly to new name registrations.

When a client computer first registers with a WINS server, the WINS server returns a message with a Time-To-Live (TTL) value that indicates when the client registration expires or needs to be renewed. If renewal does not occur by that time, the name registration expires on the WINS server and the name entry is eventually removed from the WINS database. However, static WINS name entries do not expire, and therefore, do not need to be renewed in the WINS server database. For more information, see Using static mappings.

The default **Renew interval** for entries in the WINS database is six days. Renewal occurs every three days for most WINS clients because WINS clients attempt to renew their registrations when 50 percent of the TTL value has elapsed.

A name must be refreshed before this interval ends or it will be released. Names are refreshed by sending a name refresh request to the WINS server, as shown in the following figure.

It is the responsibility of the client (HOST-C) to refresh its name before the **Renew interval** expires. If the WINS server, WINS-A, does not respond to the refresh request, the client (HOST-C) can increase the rate at which it attempts to refresh its name.

**Important**

- In most cases, the default value is the appropriate **Renew interval**. You should always set the same **Renew interval** for all server replication partners whenever multiple WINS servers are used.

- Incorrectly adjusting the **Renew interval** can adversely affect system and network performance.

# Resolving names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Resolving names**

Name resolution for WINS clients is an extension of the same name resolution process used by all Microsoft NetBIOS over TCP/IP (NetBT) clients to resolve NetBIOS name queries on your network. The actual method of name resolution is transparent to the user.

For Windows XP and Windows 2000, WINS clients use the following sequential flow of options for resolving a name once the query has been made by using **net use** or a similar NetBIOS-based application.

1. Determine if the name is longer than 15 characters or if it contains periods ("."). If so, query DNS for the name.
2. Determine if the name is stored in the remote name cache at the client.
3. Contact and try configured WINS servers to attempt to resolve the name using WINS.
4. Use local IP broadcasts to the subnet.
5. Check an Lmhosts file if **Enable LMHOSTS Lookup** is enabled in the **Internet Protocol (TCP/IP)** properties for the connection.
6. Check a Hosts file.
7. Query a DNS server.

For a more detailed explanation and flowchart of this process, see the *Microsoft Windows Server 2003 Resource Kit*.

# WINS Features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS features**

- Persistent connections
- Burst handling
- Deleting and tombstoning records
- Accepting replication partners
- Blocking replication partners

# Persistent connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Persistent connections**

WINS includes persistent connections between WINS server replication partners. This feature is helpful because WINS servers typically disconnect from their replication partners each time replication is completed. In many cases, where WINS servers are interconnected through high speed local area network (LAN) links it is preferable to keep connections open, instead of closing them after replication is completed.

For earlier versions of WINS, servers had to establish new WINS-server connections each time replication was performed. Each connection required a modest number of processor cycles. For efficiency, network managers often configured systems to accumulate a larger number of changes before connecting for replication. These reconnections sometimes caused delays (perhaps as long as several minutes) in the replication process, which meant that inconsistencies in server data commonly existed when WINS was updated.

Persistent connections increase the speed of replication because a server can immediately send records to its partners, without incurring the cost of establishing temporary connections each time. Every record is immediately updated across the network upon registration in WINS, making replication more consistent. The bandwidth used by persistent connections is minimal because the connection is usually idle.

# Burst handling

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Burst handling**

WINS servers can now support handling of high-volume (*burst*) server loads. Bursts occur when a large number of WINS clients actively and simultaneously try to register their local names in WINS, such as when a power failure occurs. When power is later restored, many users start and register their names simultaneously on the network, which creates high levels of WINS traffic. With burst-mode support, a WINS server can respond positively to these client requests, even before it processes and physically enters those updates in the WINS server database.

**How burst handling works**

Burst mode uses a burst-queue size as a threshold value. This value determines how many name registration and name refresh requests sent by WINS clients are processed normally before burst-mode handling is started. By default, the value is 500. A WINS server initiates burst handling whenever the number of WINS client registration requests exceeds the burst queue size.

In burst handling, additional client requests are immediately answered with a positive response by the WINS server. The response also includes a varied Time-To-Live (TTL) to clients, which helps regulate the client registration load and distribute processing of the requests over time. This slows the refresh and retry rate for new WINS clients and regulates the burst of WINS client traffic.

For example, if the burst queue size is 500 entries and more than 500 requests are active, the WINS server replies immediately to the next 100 WINS client registration requests by sending early success responses with a starting TTL value of 5 minutes. For each additional round of 100 client requests, 5 minutes more are added to the TTL up to a maximum of 50 minutes. If WINS client traffic still arrives at burst levels, the next round of 100 client requests are answered with the initial TTL value of 5 minutes, and the entire process for incrementing the response TTL is repeated.

This behavior continues until the WINS server reaches its maximum intake level of 25,000 name registration and refresh queries. At this point, the WINS server begins dropping queries.

Using the WINS console, you can choose to configure the level of burst handling used by the server which modifies the size of the burst queue to accommodate either a low, medium or large burst situation.

### Note

- Any WINS server running Windows NT Server 4.0 (with Service Pack 3 or later installed), Windows 2000, or Windows Server 2003 can use burst handling.

# Deleting and tombstoning records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Deleting and tombstoning records**
WINS now provides improved database management through support for the following deletion operations:

- Simple deletion, for deleting WINS database records stored on a single server database.
- Tombstoned deletion, for deleting WINS database records replicated to databases on other WINS servers.
- Multiple-group selection of displayed database records, for either simple or tombstoned deletion.

The WINS console also provides a simple and convenient utility for administratively removing records of any type, regardless of whether they are statically or dynamically added. In previous releases of Windows NT Server, other available WINS management tools could only administratively delete entries (such as static mappings) that were added in the same way.

**How simple deletion works**
Simple deletion removes the records that are selected in the WINS console only from the local WINS server you are currently managing. If the WINS records deleted in this way exists in WINS data replicated to other WINS servers on your network, these additional records are not fully removed. Also, records that are simply deleted on only one server can reappear after replication between the WINS server where simple deletion was used and any of its replication partners.

**How tombstoning works**
Tombstoning marks the selected records as *tombstoned*, that is, marked locally as *extinct* and immediately released from active use by the local WINS server. This method allows the tombstoned records to remain present in the server database for purposes of subsequent replication of these records to other servers.

When the tombstoned records are replicated, the tombstone status is updated and applied by other WINS servers that store replicated copies of these records. Each replicating WINS server then updates and tombstones these records. When all WINS servers complete replication of these records and a specified length of time (determined by the **Verification Interval** for each WINS server) elapses, then the records are automatically removed from WINS.

In most cases, WINS records should be tombstoned at the WINS server that originally owned them, to prevent deleted records from reappearing in WINS after subsequent replication with other servers.

The owner of a given WINS server record is typically the first server contacted by the WINS client during the registration process and the server first actually used to register the local names of the client in WINS. In most cases, the WINS server that owns a client name record in WINS corresponds to the primary WINS server configured on the WINS client computer. If the configured primary WINS server is not available during client registration, a configured secondary WINS server can perform the actual registration of the client name and become the owner.

**Example: Tombstoned deletion in replicated WINS**
Where tombstoned deletion is used at an owner WINS server in a replicated WINS network, the following sequence of events occurs to effect full removal of the selected records from all WINS servers that replicate the selected records.

1. The owner WINS server marks and changes the status of the selected WINS records in its local WINS server database from Active to Tombstoned.

   WINS then treats the records as inactive and released from use. When these records are tombstoned locally, the owner WINS server does not respond to or resolve NetBIOS name queries for these names unless the records are registered again by the WINS client.

2. The owner WINS server replicates the selected records as tombstoned at subsequent replication cycles.

   The records are not forcibly and immediately removed from WINS, but are flagged or marked for eventual deletion. The exact replication cycle interval is configured by the server **Intervals** properties, which you set in the WINS console. Records are not removed from WINS data until the time specified in the **Extinction Interval** has elapsed. This allows

other WINS servers to be notified that these records are no longer in use, update their replicated mappings for these records, and further replicate this updated WINS data to other servers.

3. Records become extinct on all replicated WINS servers and are eventually removed physically from all WINS servers.

   After all WINS servers that participate in replication complete a full replication cycle and arrive at a consistent state, the tombstoned records expire and are removed from the WINS database of each server at the next database scavenging operation. After scavenging occurs on all servers, the records no longer appear in the WINS console and are no longer physically stored in the WINS database.

**Note**

- Even if records are manually tombstoned (or otherwise marked as released by WINS), released records remain in the WINS database for some time before being completely removed during subsequent scavenging operations. Typically, the period before records extinction is the sum of the following settings:

  - Extinction interval
  - Extinction time-out
  - Verification interval

  You can view and configure these settings on the **Intervals** tab, located in the **WINS <*Server name*> Properties** dialog box. By default, the sum of these settings is 36 days.

# Accepting replication partners

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Accepting replication partners**

When determining a replication strategy for your organization, you can define a list that controls the source of incoming name records during pull replication between Windows Internet Name Service (WINS) servers.

In addition to blocking name records from specific replication partners, you can also accept name records owned by specific WINS servers during replication, thereby excluding the name records of all servers that are not on the list. Although both options exist, only one can be used. You can either block replication of records from specified servers or accept replication of records from specified servers.

Pull replication based on a list of accepted WINS servers can occur either during normal pull replication or in response to push replication.

To use the **Accept records only for these owners** feature, see Accept replication of records owned by a specified server.

**Deciding whether to block or accept name records**

When using multiple WINS servers, you can either block or accept records owned by specific servers. For example, when you remove a WINS server from service, you can block the server records from pull replication. For more information, see Blocking replication partners.

If your WINS server topology is designed around the recommended hub-and-spoke model, you can use **Accept records only for these owners**. In this way, you can maintain push-pull replication between key WINS servers (hubs) without replicating the name records for other replication partners (spokes) of each individual server.

### Note

- When choosing between blocking or accepting WINS server name records, it is useful to use the shorter of two lists. For example, if you have twenty WINS servers and you want to replicate records owned by only five of them, you can choose **Accept records only for these owners** instead of **Block records for these owners**. In doing so, you need only to create a list of five servers instead of 15.

# Blocking replication partners

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Blocking replication partners**

After a WINS server is removed from a network, records it owns often continue to be distributed to other servers in a replicated WINS environment. In some cases, WINS either does not delete entries owned by servers no longer active on the network or, by default, preserves stale mappings for an extended period of time. The reasons for this can include:

- Static mappings originally made at the inactive WINS server replicate indefinitely among the other active WINS servers in the network, unless manually deleted or tombstoned.

  By default, WINS servers preserve static name-to-address mappings whenever such mappings are challenged. This can occur when a WINS client attempts to register or update a static mapping with a dynamic-type mapping of the same name. This behavior, however, can be modified. For more information, see Using static mappings.

- Dynamic mappings originally registered at the inactive WINS server are not immediately removed from the WINS database.

  In the case of dynamic entries, WINS must check with an owner server before entries are deleted. If a WINS server is no longer in use, other WINS servers conservatively retain records they cannot verify as expired on an owner server. For example, even if an owner is deleted in the WINS console for a particular server, these unwanted or stale names can continue to be replicated throughout the WINS network from other servers storing replica entries of these names.

  WINS processes removal of dynamic-type records according to the **Intervals** tab settings for **WINS Server Properties**, which can be configured at each server. In most default cases, a typical extinction period of 36 days passes before a record is fully removed from the database through the scavenging process.

For the Windows Server 2003 family, the **Block records for these owners** feature (formerly known as PersonaNonGrata) provides a way to block further replication of entries owned by inactive servers. It allows you to specify the IP addresses of inactive WINS servers that own records you want to assure are removed from WINS in a timely manner.

Because it can prevent any further replication of unwanted or stale mappings between active WINS servers remaining on the network, this feature is most useful when you need to remove WINS servers from your network.

**Example: Blocking records owned by a WINS server**

The following graphic shows a typical WINS replication design based on the recommended hub-and-spoke WINS replication design model.

In the example replicated WINS network, WINS-D, is an inactive spoke server in the process of being removed from the network. Because WINS-A is the hub in this design, it must be configured to block records for WINS-D in order to prevent

replica entries for WINS-D that are present at other spokes from replicating back to WINS-A and reappearing throughout the network.

When WINS-D server is given blocked partner status, it can be deleted as an owner in the WINS console at WINS-A and its entries will not be replicated back from other spoke servers, such as WINS-B, WINS-C or WINS-E. For more information, see Delete an owner from the WINS database.

**Notes**

- You can also choose to accept name records only from specific WINS servers during pull replication. For more information, see Accepting replication partners.

- If you are not using a hub-and-spoke WINS replication model, it might be necessary to enforce blocking at other servers in your network. If this is the case, you might need to list the blocked partner by blocking records owned by servers or for WINS running on earlier versions, add and configure the PersonaNonGrata registry parameter at each server. These steps can help achieve the intended results of full replication for records owned by the partner to other WINS servers in the network.

- After adding IP addresses to the list of blocked partners at a WINS server, it is recommended to stop and restart WINS to ensure that the change is in effect the next time replication at that WINS server occurs. For more information, see Start or stop a WINS server.

# Administering WINS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Administering WINS**

This section provides information about administering WINS:

- Managing WINS from the command line
- Configuring WINS replication
- Using static mappings
- Modifying WINS server defaults
- WINS interoperability issues
- WINS Database Management

# Managing WINS from the command line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Managing WINS from the command line**
The Netsh commands for WINS offer a fully equivalent command-line tool for administering WINS servers that can be used as an alternative to console-based management. This is useful in the following situations:

- When managing WINS servers in wide area networks (WANs), commands can be used in interactive mode at the netsh command prompt to better manage over slow-speed network links.

- When managing a large number of WINS servers, commands can be used in batch mode to script and automate recurring administrative tasks that need to be performed for all WINS servers.

For more information about how to use netsh commands provided for WINS, see Use WINS Command-line Tools.

**Notes**

- For a comprehensive netsh WINS command reference (including syntax and parameters), see Netsh commands for WINS.

- For an example of how to use netsh WINS commands in batch files and scripts, see Netsh WINS example.

- The terms Persona Non Grata and Persona Grata refer to the Windows WINS server features **Block records for these owners** and **Accept records only for these owners**, respectively.

- For more information about netsh, see The Netsh Command-Line Utility.

# Configuring WINS replication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Configuring WINS replication**

Before configuring replication, you should first carefully design and review your WINS replication topology. For wide area networks (WANs), this planning can be critical to the success of your deployment and use of WINS. In general, WINS offers you the following options and possibilities to choose from when you are configuring replication:

- You can manually configure WINS replication for a WAN environment.
- For some larger campus networks, you might also configure WINS to replicate within a LAN environment.
- In smaller or bounded LAN installations, you might consider enabling and using WINS automatic partner configuration for simplified setup of WINS replication.
- In some larger or more global installations, you might have to configure WINS across untrusted Windows NT domains.

**Replication across wide area networks**

When configuring WINS replication, the two most important planning issues are:

- Whether your WINS replication occurs over slower WAN links.
- The length of time required for all replicated changes in the WINS database to converge and achieve consistency on the network.

The frequency of WINS database replication between WINS servers is a major planning issue. The WINS server database should be replicated frequently enough to prevent the downtime of a single WINS server from affecting the reliability of the mapping information in other WINS servers. However, the time interval between replications should not be so small that it interferes with network throughput.

Network topology can influence your decision on replication frequency. For example, if your network has multiple hubs connected by relatively slow WAN links, you can configure WINS database replication between WINS servers on the slow links to occur less frequently than replication on the local area network or on fast WAN links. This reduces traffic across the slow link and reduces contention between replication traffic and WINS client name queries.

For example, as shown in the following figure, the intervals used for configuring pull replication for WINS servers could be set according to proximity between servers and the likelihood of a high-speed link connecting servers configured as replication partners of each other.

In this example, two WINS servers--SEA-WINS and ATL-WINS--are located in Seattle and Atlanta. Another two servers--MEX-WINS and SYD-WINS--are located outside the United States in Mexico City and Sydney. Because SEA-WINS and ATL-WINS are located across a higher-speed WAN link, they are configured to replicate once every hour. For the servers outside the United States, replication intervals might be set higher, such as either 3 or 12 hours, because lower-speed links are associated with these connections.

**Planning the convergence time**

*Convergence time* is the time needed to replicate a new entry in a WINS database from the WINS server that owns the entry to all other WINS servers on the network. When planning for WINS servers, you must decide what is acceptable as the convergence time for your network.

Using the previous example, if a WINS client in Seattle registers its name with the WINS server in the figure labeled SEA-WINS, other WINS clients in remote locations might query for the client name and not find it in WINS. In some cases, if the address of the client has been changed, the remote locations would only have a mapping for the previous IP address of the client in their local server databases.

WINS clients that query any of the other WINS servers in the figure (that is, ATL-WINS, MEX-WINS, SYD-WINS) only receive a positive and correct response when the new or updated mapping for the client has been fully replicated from the owning WINS server, SEA-WINS, to all of the other servers. Replications from SEA-WINS could be triggered in one of two ways:

- A push replication trigger is sent based on the frequency of updates made at SEA-WINS.
- A pull replication trigger is sent to other WINS servers based on the configured **Replication interval** set in **Replication Partners Properties** at SEA-WINS.

Given this configuration, a new or updated entry at SEA-WINS is only replicated when the pull replication interval expires, but queries at remote sites for the new name mapping might not succeed until later. This is because the time interval for replication to ATL-WINS is one hour; it is three hours for MEX-WINS; and it is 12 hours for SYD-WINS. In this case, WINS convergence time is calculated as:

```
12 hours + 2 * (1 hour) = 14 hours
```

In reality, name query requests can succeed before the convergence time elapses. This happens when the entries replicate over a shorter path than the worst-case path. It also happens when the **Number of changes in version ID before replication** threshold in push replication settings passes before the **Replication Interval** expires in pull replication settings. This results in earlier replication of the new entry. The longer the replication path, the longer the convergence time.

**Notes**

- After each administrator configures the respective WINS server, you can use **Replicate Now** (in the WINS console) to start immediate replication between the configured WINS servers.
- When replication occurs, you can use **Display Records** to view records for the remote WINS server database. However, to make changes to the remote WINS database, you must be logged on under an account with required user rights in the respective domains for both servers involved.

- Replication can also occur between two separate stand-alone servers that participate in a workgroup.

**Replication across local area networks**
When configuring WINS replication for local area networks (LANs), the issues are similar to those that occur in WAN environments, although less critical.

Because the speed of the underlying network links for LANs are much greater than for WANs, it might be acceptable to increase the frequency of WINS database replication, by optimizing push and pull parameters for LAN-based replication partners. For push/pull partners, you can do this by decreasing the **Number of changes in version ID before replication** and **Replication interval** settings accordingly, from what you would use for WAN-based partners on slower links.

For example, between LAN-based replication partners it often works to enable WINS to use a persistent connection between the servers. If a persistent connection was not used, the normal update count threshold would default to a minimum of 20. With persistence, a smaller update count value can be specified.

Next, you could specify a much smaller number, such as a value of one to three in **Number of changes in version ID before replication** before WINS sends a push replication trigger to the other partner. For pull partners, you might also consider setting the **Replication interval** to a value in minutes, instead of hours.

As in WAN replication planning, the WINS server database should be replicated frequently enough to prevent the downtime of a single WINS server from affecting the reliability of the mapping information in other WINS servers. However, the time interval between replications should not be so small that it interferes with network throughput.

For network-intensive environments, it is a good idea to use a network monitoring tool such as Network Monitor to help measure and determine how to optimize your WINS replication strategy.

**Automatic partner configuration**
You can configure a WINS server to automatically configure other WINS server computers as its replication partners. With this automatic partner configuration, other WINS servers are discovered when they join the network and are added as replication partners.

Automatic configuration is possible because each WINS server announces its presence on the network through periodic multicasts. These announcements are sent as IGMP messages for the multicast group address of 224.0.1.24 (the well-known multicast IP address reserved for WINS server use).

Automatic replication configuration monitors multicast announcements from other WINS servers and automatically performs the following configuration steps:

- Adds the IP addresses for the discovered servers to its list of replication partner servers.
- Configures the discovered servers as both push and pull partners.
- Configures pull replication at two-hour intervals with the discovered servers.

If a remote server is discovered and added as a partner through multicasting, it is removed as a replication partner when WINS shuts down properly. To have automatic partner information persist when WINS restarts, you must manually configure the partners.

To manually configure replication with other WINS servers, use the WINS console to specify roles for each partner and any related information.

### Notes

- Automatic partner configuration is typically useful in small networks, such as single subnet LAN environments. It can, however, be used in routed networks. For WINS multicast support in routed networks, the forwarding of multicast traffic is made possible by configuring routers for each subnet to forward multicast traffic for the reserved WINS server multicast group. The destination IP address for this group is 224.0.1.24 between routed subnets.
- Because periodic multicast announcements between WINS servers can add traffic to your network, automatic partner configuration is recommended only if you have a small number of installed WINS servers (typically, three or fewer) on the reachable network.

**Replication between untrusted domains**

It is possible to set up WINS replication between one or more WINS servers in domains that do not have a trust relationship. You can do this without a valid user account in the untrusting domain. To configure replication, an administrator for each WINS server must use the WINS console to manually configure that server to permit this replication.

# Using static mappings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Using static mappings**

Mapped name-to-address entries can be added to WINS in either of two ways:

- Dynamically, by WINS-enabled clients directly contacting a WINS server to register, release, or renew their NetBIOS names in the server database.
- Manually, by an administrator using the WINS console or command-line tools to add or delete statically mapped entries in the server database.

Static entries are only useful when you need to add a name-to-address mapping to the server database for a computer that does not directly use WINS. For example, in some networks, servers running other operating systems cannot register a NetBIOS name directly with a WINS server. Although these names might be added to and resolved from an Lmhosts file or by querying a DNS server, you might consider using a static WINS mapping instead.

**Migrating static mappings to dynamic mappings**

Unlike dynamic mappings, which can age and be automatically removed from WINS over time, static mappings can remain in WINS indefinitely unless administrative action is taken.

By default, if during an update process WINS is presented with both a static and dynamic-type entry for the same name, it preserves the static-type entry. You can, however, use the **Overwrite unique static mappings at this server (migrate on)** feature provided with WINS to change this behavior.

For example, the following graphic shows the default migration behavior for a WINS server, WINS-A, when presented with a registration request by a WINS client, Host C, that challenges a static mapping already in the server database.

In this example, WINS-A prevents the client from registering and updating the statically mapped information for Host C. In the next graphic, the same situation is repeated but in this example, the Migrate feature has been turned on at WINS-A.

As shown in the revised graphic, enabling the Migrate feature at WINS-A permits previously entered static mappings for Host B and C to be overwritten by WINS client computers that attempt to register dynamically and update entries for these same

names. This feature is useful in simplifying the update of legacy NetBIOS b-node (broadcast-only) type clients that are later upgraded to support WINS.

**Important**

- Never add static mappings for computers that can directly use WINS. Doing so can cause undesirable problems, such as demanding additional work to migrate, delete, or tombstone these mappings in a replicated WINS environment.

**Notes**

- You can add static entries either interactively using the WINS console or command-based tools, or by importing an Lmhosts file.

- The **Overwrite unique static mappings at this server (migrate on)** feature was designed primarily to migrate records for older non-WINS clients that do not dynamically register themselves in WINS. Some special group names, such as domain [1Ch] names are not affected by this setting.

# Modifying WINS server defaults

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Modifying server defaults**

WINS uses several default server configuration parameters that determine how NetBIOS name records are managed in the WINS server database. These parameters affect the default settings applied by each WINS server for any records stored locally.

The following sections describe the default, minimum, and maximum settings that can be applied for database records. Included is the examination of behavior differences in servers running under each of the released versions of WINS. In most cases, default values are acceptable. In some cases, you might choose to modify the defaults to accommodate special circumstances, such as when a host name change must be made or when you renumber your network so that hosts use different IP addresses.

All of these settings are configured on the **Intervals** tab of the **WINS <*Server name*> Properties** dialog box.

**Renew interval**

The WINS renew interval setting specifies how often a client renews registration of its names. The following table shows the supported range of values for **Renew interval**:

| | |
|---|---|
| **Default:** | 5 hours (Windows NT Server 3.5)<br>4 days/96 hours (Windows NT Server 3.51)<br>6 days/144 hours (Windows NT Server 4.0, Windows 2000 Server, and the Windows Server 2003 family) |
| **Maximum:** | 999 hours (Windows NT Server 3.5, 3.51, and 4.0)<br>365 days (Windows 2000 Server and the Windows Server 2003 family) |
| **Minimum:** | 40 minutes (all versions of Windows NT Server, Windows 2000 Server, and the Windows Server 2003 family) |

When adjusting this value from its service default, consider the following guidelines:

| **Increasing the renew interval ...** | **Decreasing the renew interval ...** |
|---|---|
| Causes client names to be renewed with WINS less often. | Causes client names to be renewed with WINS more often. |
| Reduces client registration activity and performance loads on the WINS server. | Increases client registration activity and performance loads on the WINS server. |
| Allows WINS data to become less consistent with the current state of the network (when WINS names are changed or modified, changes are reflected less quickly in the WINS database). | Allows WINS data to become more consistent with the current state of the network (when WINS names are changed or modified, changes are reflected more quickly in the WINS database). |

**Important**

- Any changes made to the WINS renew interval also directly affect the extinction interval and extinction time-out values, which are dependent on this setting.

**Extinction interval**

The WINS extinction interval specifies the time interval between when an entry is marked as Released and when it is marked as Extinct in the WINS database. The default value is dependent on the renew interval and, if the WINS server has replication partners, on the maximum replication time interval. The following table shows the supported range of values for **Extinction interval**:

| | |
|---|---|
| **Default:** | (Dependent on **Renew interval**) |

| | |
|---|---|
| **Maximum:** | 999 hours (Windows NT Server 3.5, 3.51, and 4.0)<br><br>365 days (Windows 2000 Server and the Windows Server 2003 family) |
| **Minimum:** | 40 minutes (Windows NT Server 3.5, 3.51, Windows 2000 Server, and the Windows Server 2003 family)<br><br>1 hour (Windows NT Server 4.0) |

**Extinction timeout**

The WINS extinction timeout specifies the interval between when an entry is marked extinct and when the entry is scavenged from the database. The default value is dependent on the renew interval and, if the WINS server has replication partners, on the maximum replication time interval. The following table shows the supported range of values for **Extinction time-out**:

| | |
|---|---|
| **Default:** | (Dependent on **Renew interval**) |
| **Maximum:** | 999 hours (Windows NT Server 3.5, 3.51, and 4.0)<br><br>365 days (Windows 2000 Server and the Windows Server 2003 family) |
| **Minimum:** | 24 hours (all versions of Windows NT Server, Windows 2000 Server, and the Windows Server 2003 family) |

**Verification interval**

The WINS verification interval specifies the time after which the WINS server must verify that old names that it does not own are still active. The default is dependent on the extinction interval. The following table shows the supported range of values for **Verification interval**:

| | |
|---|---|
| **Default:** | (Dependent on **Renew interval**) |
| **Maximum:** | 9999 hours (Windows NT Server 3.5, 3.51, and 4.0)<br><br>365 days (Windows 2000 Server and the Windows Server 2003 family) |
| **Minimum:** | 24 days (all versions of Windows NT Server, Windows 2000 Server, and the Windows Server 2003 family) |

# WINS interoperability issues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Interoperability issues**

**Using DHCP with WINS**
When using DHCP and WINS together on your network, consider the following options for interoperation:

- **Use additional DHCP scope options.**

  Specifically, use DHCP options to assign WINS node types (option type 46) and to identify WINS servers for use by DHCP clients (option type 44). In some cases, this can involve adjusting these option types for each physical subnet in which DHCP and WINS are implemented.

- **Assign a length of time for DHCP lease durations comparable to the time WINS uses for renew intervals, when both services are deployed.**

  By default, DHCP leases are eight days in length and the WINS renew interval is six days. If lease lengths for DHCP widely differ from WINS renew intervals, the effect on your network can be an increase in lease-management traffic and might cause a WINS registration for both services. If you shorten or lengthen the DHCP lease time for clients, then modify the WINS renew interval accordingly.

**Using DNS with WINS**
If a large percentage of clients use NetBIOS and you are using DNS, consider using **WINS lookup on your DNS servers.** If WINS lookup is enabled on Microsoft DNS Service, WINS is used for final resolution of any names that are not found using DNS resolution. The WINS forward lookup and WINS-R reverse lookup records are supported only by DNS. If you use servers on your network that do not support DNS, use the DNS console to ensure that these WINS records are not propagated to DNS servers that do not support WINS lookup.

**Multihomed WINS servers**
For multihomed WINS servers, where more than one local network connection is present and active, WINS does not guarantee the binding order for NetBIOS. Therefore, for a multihomed WINS server to function properly, all installed connections should be configured as routable interfaces.

All multihomed WINS servers should have their primary IP addresses assigned to each network connection, configured as push and pull replication partners at other servers that can be reached through each of the respective connections. When configuring replication partners, you can ensure that a specific network connection is used by specifying an IP address for the remote multihomed server you are adding at a WINS server.

Otherwise, when replication partners are specified and resolved by a name entered in the WINS console, it is possible that a packet generated by WINS could use any of the installed interfaces and their respective IP addresses. This seemingly random behavior results from WINS referring to its local IP routing table, which contains all of the installed IP interfaces, before it sends packets to the remote server.

# WINS Database Management

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS database management**

- Finding and viewing WINS records
- Maintaining the WINS database
- Checking the WINS database for consistency

# Finding and viewing WINS records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Finding and viewing WINS records**

The WINS console provides many methods for filtering and displaying WINS database records. Record searches are initiated in the WINS console **Display Records** dialog box. When WINS database records match search parameters, one or more records are displayed in the details pane of the WINS console. While a search is in progress, search statistics are dynamically displayed in the status bar above the details pane. Search statistics include the number of records scanned and filtered. When no WINS database records match search parameters, no records are displayed in the details pane. The methods of filtering WINS database records are detailed in the paragraphs that follow.

For information on how to access the **Display Records** dialog box, see Start a record search.

**Filtering records for display**

When you create a search filter, you choose from three categories of filters:

- Record owners - A record query can be based on the name records of one or more name record owners.
- Record types - A record query can be based on one or more NetBIOS name suffix record types.
- NetBIOS name and IP address - A record query can be based on all or part of a NetBIOS name, on IP address, or it can be based on NetBIOS name and IP address, including or excluding subnet mask as a search parameter.

You can shape a record filter from all three categories above. For example, in one filter you can specify one or more record types, one or more record owners, a partial or complete NetBIOS name, and IP address.

The properties of each returned record are displayed in the details pane. In addition to displaying the Record Name, Type, IP Address and Owner, the details pane also displays State (Active, Released or Tombstoned), Static (x for static, null or blank for not static), Expiration (date and time of record expiration), and Version information for each record.

Because most names in the database are computer names and computer names are always registered as uppercase, WINS only does uppercase searches. If you type lowercase letters in **Filter records matching this Name pattern**, WINS converts lowercase letters to uppercase letters before it performs the search.

You can alter this behavior, however, by using the **Case sensitive match** check box. When checked, the record search is performed matching the supplied criteria, including capitalization.

**Record owners**

For a search operation to successfully return one or more name records, you must select at least one record owner. You can select any combination of record owners or all record owners.

This filter is ideal for doing full display searches and obtaining either a full or filtered view of the WINS database for one or more servers that own records registered in the database.

Because full database views potentially require WINS to download large amounts of data from one or more servers, its use should be handled carefully, especially on WINS networks where a large number of WINS servers are deployed. However, for in-depth troubleshooting and close viewing of local WINS databases (either local viewing on the same WINS server or viewing a WINS server that is on the same local area network), this feature should not present an overly demanding load for either the WINS server or the local area network involved.

However, if multiple servers are selected in **Display records for these owners**, or if a remote owner is selected (such as another WINS server that is located on a wide area network), a substantial or undesirable increase in network traffic can occur. For this reason, you should test the impact of a multiple-server search on network traffic before you use it during peak periods, or you should use a multiple-server search during off-peak hours only.

If a search generates considerable undesired network traffic, the search can be stopped before it completes. For more information, see Stop a record search.

When viewing records by owner, you can additionally filter WINS data to be included in the view by selecting and using

NetBIOS name suffix types as criteria.

**Record types**
For a search operation to successfully return one or more name records, you must select at least one NetBIOS name suffix type. You can select any combination of record types or all record types.

The WINS console provides you with the ability to add, edit, and remove your own NetBIOS name suffix filter types. It also provides a predefined list that is sufficient for typical use.

Filtering records by suffix type allows for more precise network troubleshooting. For example, to isolate browsing problems associated with the Computer Browser service when WINS clients are using browsing on a WAN, you can filter WINS data by including only those records that use the [1Bh] suffix type, which maps the domain master browser record for each primary domain controller (PDC) in a Windows NT domain environment.

For more information, see Add, modify, or remove a filter type.

**NetBIOS name and IP address filters**
Following are some of the methods used for filtering and displaying records based on NetBIOS name and IP address. These filters can be used in different combinations to achieve varying results; however, you must use at least one record type and one record owner for the NetBIOS name and IP address filters to function properly.

**Filter records matching this Name pattern** is used to query the WINS database and filter displayed results to a limited number of NetBIOS name records that start with a specified set of one or more characters. This filter is ideal for targeting either a known name or similar names that are located on a specific WINS server. For example, you can use this filter to troubleshoot WINS name resolution problems in a wide area network (WAN) by verifying that a known NetBIOS name exists in the data that is stored at any one of your remote WINS servers. This filter typically generates minimal network traffic and can be used routinely for locating the source of "name not found" errors that can result from NetBIOS name resolution.

**Filter records matching this Name pattern** locates records through either a full NetBIOS name or a specified set of matching characters. For WINS to include a targeted name in the results of a find operation, the name must begin with the exact characters that are specified in **Filter records matching this Name pattern**. However, names that match the specified search criteria can contain additional characters after the specified string. For example, if "A," "AB," and "AXB" are all NetBIOS name records that begin with the letter "A" in the WINS database, then entering "A" as the search string finds all three records. If you enter "AB" as the search string, only the record "AB" is found. If you enter "ABC" as the search string, none of the three example records are found or returned in your search results.

**Filter records matching IP address** searches for and displays records that have a specific IP address.

**Filter records matching this Name pattern** and **Filter records matching IP address** can be used together to search for and display only records in which the name and IP address match the search criteria.

**Filter records matching IP address** and **Match the IP address based on subnet mask** can be used together to search based on an IP address and subnet mask pair. The subnet mask indicates which sections of the IP address are interpreted as a network ID and which sections of the IP address are interpreted as a host ID. The search is performed for all records with a network ID that matches the IP address search criteria. For example, if the IP address search criteria is 192.168.0.1, and the subnet mask search criteria is 255.255.0.0, the first two sections of the IP address are interpreted as network ID, and all of the name records that have an IP address of 192.168.*x.y* -- where *x* is any number between 1 and 254 and *y* is any number between 1 and 254 -- are returned to the details pane. In another example, if the IP address search criteria is 192.168.0.1, and the subnet mask search criteria is 255.255.255.0, the first three sections of the IP address are interpreted as network ID, and all name records that have an IP address of 192.168.0.*x* -- where *x* is any number between 1 and 254 -- are returned to the details pane.

For more information about IP addressing and subnet masks, see IP addressing and Subnet masks.

For more information about using NetBIOS name filtering, see Search for names that begin with a specified set of characters.

**Result caching**
Result caching allows you to download the records of WINS name record owners to the local computer. This provides faster performance during subsequent query operations on the record set. The record set that is returned to the local computer is stored in local random access memory (RAM). If a large record set is stored in RAM, performance on the local computer might suffer, depending on the amount of RAM and the size of the record set.

If your network has large WINS databases and many WINS servers, it is recommended that you test the performance of **Enable result caching** during off-hours, before you use it during peak network hours.

When **Enable result caching** is checked, caching behavior varies depending on the selected search criteria.

**Queries for records from one WINS server**
If you query for the records of one name record owner, with or without additional query parameters, all records for that owner will be returned and cached in RAM. The additional parameters, if any -- such as name or IP address -- will cause the records to be filtered so that only records matching the detailed query parameters are displayed for view in the details pane. New record searches on the same owner's records with the same or different parameters will cause the locally cached record set to be queried, not the WINS server. The performance of these subsequent queries should be high, depending on the size of the record set and the amount, type and speed of RAM.

**Queries for records from more than one WINS server**
If the query includes requests for records from more than one name record owner:

- The entire WINS database is downloaded to the local RAM cache if no other parameters (such as NetBIOS name or IP address) are specified. All subsequent queries run on the locally cached record set, not on the WINS server.

- Only records containing the additional query parameters are downloaded to the local computer's RAM cache if the query contains other parameters, such as NetBIOS name or IP address.

When you close the WINS console, all records in the RAM cache are cleared. If you reopen the console and initiate a new search, unless you select **Enable result caching**, all queries will be made to the selected WINS server, and only the records that match the query parameters are returned to the local computer and displayed in the details pane. No records will be cached in RAM, and each subsequent query will go to the server, regardless of the query parameters that you have selected.

# Maintaining the WINS database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Maintaining the WINS database**

The WINS console provides tools for maintaining the WINS server database. For example, you can use the WINS console to back up and restore WINS server database files. This should be done periodically in a way that is similar to other backup operations that are planned and used for saving files on a server computer.

Scavenging and compaction are additional maintenance operations that can be used selectively to help reduce database size and reclaim disk space that is no longer used by the database. Dynamic compaction is performed automatically by WINS at periodic intervals; manual compaction is not generally necessary.

**Backing up the database**

The WINS console provides its own backup feature for backing up the WINS server database during normal operation. After you specify a backup directory for the database, WINS performs complete database backups every twenty four hours, by default.

You should also periodically back up the registry entries for the WINS server.

**Scavenging the database**

*Scavenging* the WINS server database is the process of deleting and removing obsolete information that remains after changes occur. Like any database, the WINS server database of address mappings needs to be periodically scavenged and backed up.

The local WINS server database sometimes retains both released and old entries that were registered at another WINS server (and replicated to the local WINS server). Automatic scavenging takes place at intervals defined by the relationship between the Renewal and Extinct intervals you define. You can also manually clean the database.

The following table describes the results of scavenging the WINS database for a WINS server. The first column shows the record criteria and state of any database entries before scavenging is started. The second column indicates the state of the same entries after the scavenging process.

| Entry state before scavenging | Entry state after scavenging |
|---|---|
| Active names owned by this WINS server for which the **Renew Interval** has expired | Marked as Released. |
| Released names owned by this WINS server for which the **Extinction interval** has expired | Marked as Tombstoned. |
| Tombstoned names for which the **Extinction timeout** has expired | Deleted and removed from the database. |
| Tombstoned names, replicated from other servers for which the **Extinction timeout** has expired | Deleted and removed from the database. |
| Active names replicated from other servers for which the **Verification interval** has expired | Revalidated. |
| Tombstoned or deleted names replicated from other servers | Removed from the database. |

# Checking the WINS database for consistency

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Checking the WINS database for consistency**

Consistency checking helps maintain database integrity among WINS servers in a large network. When you initiate consistency checking at the WINS console, all records are pulled from each owner listed in the current server database, including other WINS servers that are indirect (not directly configured) replication partners.

All records pulled from remote databases are compared to records in the local database, using the following checks for consistency:

- If the record in the local database is identical to the record pulled from the owner database, its time stamp is updated.
- If the record in the local database has a lower version ID than the record pulled from the owner database, the pulled record is added to the local database, and the original local record is marked for deletion.

**Verifying registered name records on WINS servers**

The WINS console provides a **Check Registered Names** command that enables you to perform the following verification process among WINS servers on your networks:

- A NetBIOS name records list, that can be specified either manually or within a stored file called Names.txt, that contains names to be used for testing and verification.
- A WINS server list, that can be specified either manually or within a stored file called Servers.txt, that contains a list of WINS servers to be used in verifying NetBIOS names you specify for testing and verification checking.

WINS uses a NetBIOS names list (such as Names.txt) to build a query and test for those records with any matched records currently registered and stored in local databases at other WINS servers. The list of WINS servers used for checking the specified names is determined by the IP addresses of WINS servers included in a server list (such as Servers.txt) which is the list of WINS servers to query.

Once initiated, WINS completes the name verification check as follows:

1. The names list is used to build a name query list.
2. Names are verified by query for the first listed name, starting with the WINS server specified in the server list.
3. For each name in the names list, WINS queries each server to verify that the name is registered.

   If a failure is encountered, WINS can retry the query up to three times at the same server.
4. Once the first listed name has been queried and checked at all servers, WINS proceeds to the next name in the list.

The process is repeated until all listed names have been checked at all listed servers. The results and outcome of each name/server query are displayed in **Checking Name Registrations**.

Typical results include the following:

| Status | Description |
|---|---|
| ok | Indicates both that the query was successfully completed and that the specified name was verified at the current WINS server. |
| no response | Indicates that the current WINS server did not respond to the NetBIOS name query. |

| | |
|---|---|
| name not found | Indicates that the current WINS server responded to the NetBIOS name query but could not resolve the specified name. |

When all specified names have been queried at all specified servers, a summary is provided, which includes the following information:

- Any specified NetBIOS names that were verified to their mapped IP address.
- Specified NetBIOS names for which not all WINS servers resolved to the same IP address, indicating that the name is stored and used inconsistently in WINS.
- WINS servers that generated an incomplete response, indicating that they did not have all of the names specified for verification.
- WINS servers that did not respond.
- Specified names for which an IP address could not be verified.

**Notes**

- If a WINS database is extremely large, the consistency checking process can be highly resource intensive, affecting network, disk, and processor usage. For this reason, consider doing this during off-peak hours when other network traffic loads and usage are minimal.
- If the **Verify name records with all partners of each selected server** check box is cleared, listed names are only verified at each of the specified servers. When this option is selected, replication partners of each listed server are additionally queried for any specified names.
- For Windows 2000 and the Windows Server 2003 family, use the WINS console to perform consistency checking. For earlier versions, consistency checking must be enabled, either through changes to the Windows NT registry or triggered through use of the WINSCL utility, provided as part of the *Windows NT 4.0 Server Resource Kit*.

# WINS Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

# NetBIOS names reference

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**NetBIOS names reference**

For all Microsoft operating systems that support and use NetBIOS names, the first 15 characters of a name can be specified by a user. However, the 16th character of the name (00-FF hex) always indicates a resource type.

This section contains additional information and examples of NetBIOS names used by Microsoft networking components.

**NetBIOS name types: an overview**

The following are the most common types of NetBIOS names that can be used in the WINS database. When creating static mappings, these general types are available for selected use.

| Type | Description |
|---|---|
| Unique | Used to associate the computer specified by name in Computer name and a single IP address in IP address for this static mapped entry. When this type is selected, three types of records are statically added to the WINS database for the specified computer name. These are the [00h]WorkStation, [03h]Messenger and [20h] File Server types. |
| Group | Also referred to as a normal group. This type is used to add a static entry for the computer, specified by name in a static mapping, to a workgroup used on your network. If this type is used, the IP address for the computer is not stored in WINS, but is resolved through local subnet broadcasts. |
| Domain Name | Indicates a *domain name* [1C] mapped entry for locating Windows NT domain controllers. |
| Internet Group | Used for special user-defined administrative groups. You can use this to group resources. For example, you can indicate a group of file or print servers for organizing shared resources that are visible when browsing your network places. Each Internet group is represented by a shared *group name* of [20h] type in the WINS database. |
| Multihomed | Used to register a unique name for a computer that has more than one IP address (either multiple adapters each using a single address or one network adapter configured with multiple IP addresses). |

**NetBIOS Unique Names**

| Format | Description |
|---|---|
| *computer_name*[00h] | Registered by the Workstation Service on the WINS client. In general, this name is called the *NetBIOS computer name*. |
| *computer_name*[03h] | Registered by the Messenger service on the WINS client. This service is used by the client when sending and receiving messages. This name is usually appended to both the NetBIOS computer name for the WINS client computer and the name of the user currently logged on to that computer when sending messages on the network. |
| *computer_name*[06h] | Registered by the Routing and Remote Access service on the WINS client (when the service is started). |
| *domain_name*[1Bh] | Registered by each Windows NT Server 4.0 domain controller running as the domain master browser. This name record is used to allow remote browsing of domains. When a WINS server is queried for this name, a WINS server returns the IP address of the computer that registered this name. |
| *computer_name*[1Fh] | Registered by the Network Dynamic Data Exchange (NetDDE) services. This appears only if the NetDDE services are started on the computer. |
| *computer_name*[20h] | Registered by the Server service on the WINS client. This service is used to provide points of service to the WINS client to provide sharing of its files on the network. |
| *computer_name*[21h] | Registered by the RAS Client service on the WINS client (when the RAS Client is started). |

| | |
|---|---|
| *computer_name*[BEh] | Registered by the Network Monitoring Agent Service and appearing only if the service is started on the WINS client computer. If the computer name has fewer than 15 characters, the remaining character spaces are padded with plus (**+**) symbols. |
| *computer_name*[BFh] | Registered by the Network Monitoring Utility (included with Microsoft Systems Management Server). If the computer name has fewer than 15 characters, the remaining character spaces are padded with plus (**+**) symbols. |
| *username*[03h] | User names for currently logged-on users are registered in the WINS database. Each user name is registered by the Server service component so that users can receive any **net send** commands sent to the user name. If more than one user logs on with the same user name, only the first computer logged on with that name registers the name. |

**NetBIOS Group Names**

| Format | Description |
|---|---|
| *domain_name*[00h] | Registered by the Workstation Service so that it can receive browser broadcasts from LAN Manager-based computers. |
| *domain_name*[1Ch] | Registered for use by the domain controllers within the domain. These contain up to 25 IP addresses. |
| *domain_name*[1Dh] | Registered for use by master browsers, of which there is only one per subnet. Backup browsers use this name to communicate with the master browser, retrieving the list of available servers from the master browser. WINS servers always return a positive registration response for *domain_name*[1D], even though the WINS server does not *register* this name in its database. Therefore, when a WINS server is queried for the *domain_name*[1D], the WINS server returns a negative response, which forces the client to broadcast for name resolution. |
| *group_name*[1Eh] | A normal group name. Any computers configured to be network browsers can broadcast to this name, and listen for broadcasts to this name, to elect a master browser. A statically mapped group name uses this name to register itself on the network. When a WINS server receives a name query for a name ending with [1E], the WINS server always returns the network broadcast address for the local network of the requesting client. The client can then use this address to broadcast to the group members. These broadcasts are for the local subnet and should not cross routers. |
| *group_name*[20h] | A special group name called the *Internet Group* is registered with WINS servers to identify groups of computers for administrative purposes. For example, "printersg" could be a registered group name used to identify an administrative group of print servers. |
| --__MSBROWSE__[01h] | Registered by the master browser for each subnet. When a WINS server receives a name query for this name, the WINS server always returns the network broadcast address for local network of the requesting client. |

# WINS updated technical information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**WINS updated technical information**

Updated technical information for WINS can be obtained by searching technical articles available from the Personal Support Center at the Microsoft Web site. For more information, see Updated technical information.

You can also obtain additional in-depth information on WINS in the Microsoft Windows Server 2003 Resource Kit:

- For more information about WINS, see "Windows Internet Name Service" at the Microsoft Windows Resource Kits Web site.
- For more information about LMHOSTS files, see "LMHOSTS File" at the Microsoft Windows Resource Kits Web site.

# WINS Troubleshooting

# Troubleshooting WINS clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Troubleshooting WINS clients**
What problem are you having?

- Name resolution failed at client computer.
- Clients do not use load balancing when connecting to a multihomed server.

**Name resolution failed at client computer.**
**Cause:** The type of name resolution used is not appropriate. Determine whether WINS or DNS is being used for name resolution and if the name failure is occurring for a NetBIOS or fully qualified domain name (FQDN).

**Solution:** NetBIOS names are 15 characters or less and are typically used to provide named access to NetBIOS services based on a computer or group name, such as Messenger, Server, or Workstation. For example, the short NetBIOS name "PRINT-SRV1" might refer to a computer used for print and file sharing. It might also be known by a full DNS computer name "print-srv1.example.microsoft.com" when referring to this same computer as a Windows Server 2003 family shared or published printer resource.

For the DNS example name used above, Winsock-based host name resolution is used to associate an IP address to a named computer and further identify it in a system of domains, either on an intranet or the Internet. This is needed for an entirely different set of applications such as to access Web, SMTP mail, FTP, or LDAP servers.

The key point is that each of these name schemes, WINS or DNS, require name resolution for different names used in different applications, and for locating different types of network services. NetBIOS has its own set of applications that demand NetBIOS name resolution, the absence of which can cause network failures. These can be repaired or detected through an Lmhosts file used temporarily to troubleshoot or correct the name resolution failure.

DNS and FQDNs use Winsock-style host name resolution and are primarily used for Active Directory and Internet use. For this type of name resolution, you can also repair or detect most problems through a Hosts file used temporarily to troubleshoot or correct the name resolution failure.

Verify the exact form of the name that has failed during resolution and determine whether the correct type of name resolution was involved.

**See also:** NetBIOS name resolution; Host name resolution

**Cause:** The client could be using an application or version of Windows that requires the use of WINS to resolve names.

**Solution:** Not all Windows computers or applications require WINS or NetBIOS over TCP/IP (NetBT). For example, if the failed name resolution occurred as part of a URL entered in a Web browser or FTP program or as part of an address in an Internet e-mail program, the problem is more likely related to DNS.

Name resolution could fail when any clients need access to shared resources not published through Active Directory. Resources such as these could include legacy file servers, print servers, domain controllers or member servers used to complete logon or browsing of Windows NT domains. Some examples of applications that a client might use and need WINS to assist in name resolution include My Network Places, the **Map Network Drive** feature in Windows Explorer, or the **net** command (Net.exe) and any of its supported options, such as **net use** or **net view**.

**Cause:** The client computer may not be correctly configured, or may not be able to use WINS.

**Solution:** First, determine whether the client is configured or enabled to use both TCP/IP and WINS. Client configuration of WINS-related settings can be done in one of the two following ways:

1. Manually, by an administrator setting the client TCP/IP configuration.
2. Dynamically, by a DHCP server providing the client with TCP/IP configuration.

In most cases, computers running earlier versions of Microsoft operating systems are already able to use WINS once TCP/IP is installed and configured for the client. For Windows XP, administrators can optionally disable NetBIOS over TCP/IP (NetBT) for each client. By disabling NetBT, WINS cannot be used at the client.

In addition, determine whether the client has a valid IP configuration. To check a client IP configuration, use the **ipconfig /all** command. You can use **ipconfig /all|more** as a way to slow or pause viewing of the output of this command for screen-by-screen review.

In the command output, verify that the client computer has the following configured for the network where it is connected:

- a valid IP address
- a valid subnet mask
- a default gateway
- Primary and secondary WINS servers

If the client does not have a valid configuration, you can either use the **ipconfig /renew** command to force the client to obtain a renewal of its IP configuration with the DHCP server or you can update the TCP/IP configuration for the client manually.

**See also:** Configure WINS for non-DHCP clients; Configure WINS for DHCP-enabled clients

**Cause:** The client may not have basic connectivity with its configured WINS servers.

**Solution:** To verify whether a client has basic TCP/IP access to the WINS server, first try pinging the WINS server by its IP address.

For example, if the client uses a primary WINS server of 10.0.0.1, type **ping 10.0.0.1** at the command prompt on the client computer. If you are not sure what the IP address is for the WINS server, you can usually learn it by repeating the previous command, using **ipconfig /all|more** if necessary to pause the displayed command output so you can read the WINS server information.

If the WINS server responds to a direct ping of its IP address, try using the **nbtstat -RR** command at both the client and also at the resource server that the client is attempting to locate by name. This command forces the WINS client services on each computer to send name release and refresh requests to the WINS server and re-register their names.

If the WINS server does not respond to direct pinging of its IP address, this indicates that the source of the problem more likely stems from network connectivity issues between the client and WINS server. If this is the case, follow basic TCP/IP network troubleshooting steps to fix the problem.

**See also:** Verify WINS registration of client NetBIOS names; Troubleshooting WINS replication

**Cause:** The primary or secondary WINS server may not be able to service the client.

**Solution:** At the primary or secondary WINS server for the client, use either Event Viewer or the WINS console to see if WINS is started and currently running. If WINS is running on the server, search for the name previously requested by the client to see if it is in the WINS server database. If the name does not appear in the server database, check whether replication is configured correctly and operational between your WINS servers.

**See also:** View Event Logs; Search for names that begin with a specified set of characters; Troubleshooting WINS replication

**Clients do not use load balancing when connecting to a multihomed server.**
**Cause:** The WINS server providing name resolution for the multihomed server name to network clients is running an earlier version of Windows NT Server that has not been updated.

For all versions of Windows that support NetBIOS over TCP/IP (NetBT), network clients configured to use WINS attempt to resolve any NetBIOS-based name for a computer to its IP address or addresses. To perform this resolution, clients query the WINS server for the address of the multihomed server and receive a list of addresses that are always in the same order. NetBT then takes and sorts the list, arranging multiple IP addresses according to the following three categories:

- Any IP addresses located on the same subnet as the client are given first priority in the list.
- Next, IP addresses located within the same network class are listed.

- Finally, any remaining addresses are listed.

Then, NetBT starts at the top of this list and pings the first address to make sure it is valid. If it gets a reply, it uses the address. If there is no reply, it goes on to the next address.

The problem is that for earlier versions of WINS, within these three categories, the order of addresses is left unchanged from the list provided by the WINS server. This means that, as long as the first address in the list is online, it will be the one that is always used by every WINS client. This does not provide load balancing or 'round-robin' rotation, as DNS servers can perform when more than one name-to-address mapping is available.

**Solution:** Upgrade WINS servers to a Windows Server 2003 operating system; or update servers running earlier versions of Windows 2000 and Windows NT Server to the most current Service Pack

# Troubleshooting WINS servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Troubleshooting WINS servers**
What problem are you having?

- Unable to send and receive data.
- The server intermittently loses its ability to resolve names.

**Unable to send and receive data.**
**Cause:** Configuration details might be incorrect or missing.

**Solution:** To help prevent the most common types of problems, review WINS best practices for deploying and managing your WINS servers. Most WINS-related problems start as failed queries at a client, so it is best to start there.

**See also:** WINS Best Practices; Troubleshooting WINS clients

**Cause:** The WINS server might not be able to service the client.

**Solution:** At the primary or secondary WINS server for the client that cannot locate a name, use **Event Viewer** or the WINS console to see if WINS is started and currently running. If WINS is running on the server, search for the name previously requested by the client to see if it is in the WINS server database.

**See also:** Search for names that begin with a specified set of characters

**Cause:** WINS server is failing or registering database corruption errors.

**Solution:** Use WINS database recovery techniques to help restore WINS operations.

**See also:** Troubleshooting WINS databases

**Cause:** The name does not appear in the server database.

**Solution:** Check whether replication is configured correctly and is operational between your WINS servers.

**See also:** Troubleshooting WINS replication

**Cause:** The WINS server answering clients might be returning stale or incorrect information to clients. The WINS server might be affected by a static mapping blocking the dynamic registration of a valid name-to-address mapping for the computer hosting the service or resource in question.

**Solution:** In general, static mappings are not recommended for clients that can dynamically use WINS to update their name and address information. If the information returned to a client during name resolution is incorrect or stale, check to see if the name entry in the WINS server database was entered statically. If the name was entered using a static type entry, you can choose from the following options to update WINS:

- Enable **Migrate (Overwrite unique static record with dynamic record)** in **Replication Partners Properties**.
- Edit the static mapping to update the mapped address information.
- Delete the static entry from WINS.

**See also:** Enable static mappings to be overwritten during replication; Edit a static mapping entry; Delete or tombstone an entry in the WINS database

**Cause:** Replication might not be occurring between all WINS servers.

**Solution:** In some WINS designs, the use of one-way replication partnerships, such as push-only or pull-only partners, can

create situations where WINS names data is not regularly replicated to all network servers.

**See also:** Troubleshooting WINS replication

**The server intermittently loses its ability to resolve names.**

**Cause:** There might be a split registration problem, where the WINS server is registering its names in WINS at two servers on the network. This is possible when the WINS server settings configured in TCP/IP properties at the server computer are pointing to IP address of remote WINS servers and are not configured to use the IP address of the local WINS server.

**Solution:** Re-configure client TCP/IP properties at the WINS server to have its primary and secondary WINS servers point to the IP address of the local server computer.

**See also:** Configure TCP/IP to use WINS; WINS Best Practices

# Troubleshooting WINS databases

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Troubleshooting WINS databases**
What problem are you having?

- WINS backups are failing consistently.
- My WINS database might be corrupt.

**WINS backups are failing consistently.**
**Cause:** The specified WINS backup directory might be a remote drive.

**Solution:** Make sure that the path for the WINS backup directory is on a local disk on the WINS server. WINS cannot back up its database files to a remote drive.

**See also:** Modify backup settings

**My WINS database might be corrupt.**
**Cause:** The WINS database might need to be deleted, either fully or partially, so its contents can be replaced from another WINS server to restore consistency and data integrity between WINS servers on your network.

**Solution:** Depending upon the extent of the corruption, and whether the corrupted records are at an owner or replica WINS server, you can rebuild the local WINS database through replication with another WINS server.

To remove corrupted data at a replica (non-owner) server, use the **Delete Owner** command option in the WINS console. When using this feature, you can delete the owner and any of its associated records in question from local WINS data.

For an owner WINS server, you can restore data integrity by starting WINS with a fresh database and then initiating replication with a configured replication partner. At the local WINS server that has ownership of corrupted records, perform the following steps:

1. Stop WINS.
2. Delete all current WINS database files.

   These files are located at the path currently set in **Database path** on the **Advanced** tab in *WINS server* **Properties** for the local WINS server.
3. Restart WINS.

When WINS is started with a blank database, it will replicate back all records (including those for which it is the registered owner) that are contained in data stored at other servers. This is because it starts with a fresh version ID that is lower than the highest version ID in use for data at any of the other WINS servers on your network.

WINS servers use record version IDs to keep track of which records are new and which need to be replicated to other WINS servers. Every record in a WINS database has an owner associated with it. This owner is generally the server with which the WINS client originally registered.

Normally, the owner (in this case, the local WINS server) does not receive its own records from its replication partners. For this reason, if records are lost from the local WINS database, it can typically be difficult to replace these records, even if they exist at other partners. In this solution, this difficulty is solved because records that exist on other WINS servers are certain to have higher version IDs than the local server after you delete the local database and restart WINS.

On a WINS network with many records, two registry entries affect the ability of WINS to perform local database replacement as described in earlier steps. The first value, InitTimeReplication, keeps the server from accepting queries or registrations until the database is reconstructed. The second, InitTimePause, causes WINS to pause while the replication takes place. The location

and configurable settings for these keys are discussed more in the following tables.

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**InitTimeReplication**

**Location:**

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\WINS\Partners\Push (or Pull)

**Type:**

REG_DWORD

**Default:**

1

**Values:**

1 = The WINS server pulls replicas of new WINS database entries from its partners when the system is initialized or when a replication-related parameter changes.

0 = Replication occurs only as often as specified in the value of **TimeInterval**.

**InitTimePause**

**Location:**

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\WINS\Parameters

**Type:**

REG_DWORD

**Default:**

0

**Values:**

0 = WINS does not start in paused state.

1 = WINS starts in paused state.

The value set determines whether WINS starts in a paused state and remains in that state until its first replication is completed. In the paused state, WINS does not accept any name registrations, releases, or queries. WINS remains in the paused state until it has replicated with its partners or until its first replication attempt has failed.

If the value of **InitTimePause** is set to **1**, then **InitTimeReplication** (in the Pull partners subkey) should either be set to **1** or deleted from the registry.

# Troubleshooting WINS replication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 8 Beta

**Troubleshooting WINS replication**
What problem are you having?

- I can't locate the source of "duplicate name" error messages.
- I need to locate the source of "network path not found" error messages on a WINS client.
- The WINS server cannot pull or push replications to another WINS server.
- I am having intermittent problems with WINS not replicating between servers on my network.

**I can't locate the source of "duplicate name" error messages.**
**Cause:** You might need to manually remove static records, or enable static mappings to be overwritten during replication.

**Solution:** If the duplicate name exists already as a static mapping, you can tombstone or delete the entry. If possible, this should be done at the WINS server that owns the static mapping for the duplicate name record. As a preventive measure, in cases where a static mapping needs to be replaced and updated by a dynamic mapping, you can also enable **Overwrite unique static mappings at this server (migrate on)** in **Replication Partners** Properties.

**See also:** Delete or tombstone an entry in the WINS database; Enable static mappings to be overwritten during replication

**I need to locate the source of "network path not found" error messages on a WINS client.**
**Cause:** The network path might contain the name of a server computer configured as a p-node, m-node, or h-node and its IP address is different from the one in the WINS database. In this case, the IP address for this computer might have changed recently and the new address has not yet replicated to the local server.

**Solution:** Check the WINS database for the name and IP address mapping information. If they are not current, you can start replication at the WINS server that owns the name record requiring an update at other servers.

**See also:** Manage Replication

**Cause:** If the computer name is configured as b-node, its name might be missing in the WINS database.

**Solution:** Check the WINS database for the name. If the name is not present in WINS and clients on other subnets need to locate the b-node computer by name, you can add a static mapping in WINS for the computer name and IP address.

**See also:** Manage Static Mappings

**The WINS server cannot pull or push replications to another WINS server.**
**Cause:** If the other WINS server is located across a router, there might be a failed router or other network problem.

**Solution:** Check for network connectivity to the server. Ping the other WINS server and troubleshoot any network or TCP/IP-related problems.

**See also:** Troubleshooting TCP/IP

**Cause:** If the other WINS server is located on the same network or can be successfully pinged, the server might not be configured correctly as either a push or pull partner of the other server.

For example, suppose the two WINS servers are called WINS-A and WINS-B. If WINS-A needs to perform pull replications with WINS-B, make sure it is a push partner of WINS-B. Likewise, if WINS-A should push replications to WINS-B, it should be a pull partner of WINS-B.

**Solution:** Determine the current configuration of replication partners between the servers. If partnerships are missing at either server, add the missing partner IP addresses as needed for the appropriate server. If needed, you can also change the replication partner type, such as from either **Pull only** or **Push only**, to **Push/Pull**.

**See also:** Configure Replication; Change a replication partner type

**I am having intermittent problems with WINS not replicating between servers on my network.**
**Cause:** The replication pattern in use on your network might not be correct or appropriate to use.

**Solution:** In general, deployments of more than 20 WINS servers are strongly discouraged. Also, for best results and simpler administration, follow a hub-and-spoke replication topology when designing your replicated WINS network that utilizes push/pull partnerships between each WINS hub server and its member spoke servers.

If a single hub-and-spoke exceeds the recommended total of 20 WINS servers for a single enterprise, you should contact Microsoft Consulting Services or Microsoft Product Support Services about how to better revise or reduce your current WINS installation. For larger or enterprise installations, multiple hub-and-spoke designs are acceptable to use.

In rare cases, the limited use of push-only and pull-only partner relationships might be needed. You should, however, carefully review added WINS administration issues when these configurations are deployed. At a minimum, establish reliable support procedures for occasions when you might need to manually trigger replication between WINS servers configured to operate using these types of limited replication partnering.

**Cause:** The version ID might not be incrementing for WINS entries when replicating on all servers.

**Solution:** The version ID is incremented in the WINS database by each server that owns and registers a name record. This identifier is a hexadecimal value stored with each name record in the database and is used for version tracking when the record is replicated to other servers.

Version IDs are only incremented for certain types of record changes. For example, a typical refresh of a name in WINS does not increment the version ID, but other changes, such as an updated IP address, can cause the version ID to increment in most cases.

When the version ID is not consistently incrementing for a name record at all servers in the replicated WINS network, you can use either the WINS console or command-line options to administratively increase the starting version count for the server and correct the problem.

**See also:** Increase the starting version count; WINS Best Practices

# Help: Windows Firewall

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windows Firewall**
Windows Firewall is a host firewall technology that replaces Internet Connection Firewall in Windows Server 2003 with Service Pack 1 (SP1) and Windows XP with Service Pack 2 (SP2). Windows Firewall provides stateful inspection of incoming Internet Protocol version 4 (IPv4) and Internet Protocol version 6 (IPv6) traffic and is designed to protect you from network attacks that pass through your perimeter network or originate inside your organization, such as Trojan horse attacks, port scanning attacks, and worms. You should run Windows Firewall on each of your clients and servers, thereby extending your defense-in-depth strategy to the innermost layer of your security architecture.

- To learn about differences between Windows Firewall and its predecessor, Internet Connection Firewall, see Help: Windows Firewall features.
- For help with specific Windows Firewall tasks, see Help: Windows Firewall How To....
- For general background information, see Help: Windows Firewall Concepts.

# Help: Windows Firewall overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windows Firewall overview**

To protect your network from the growing number of malicious network attacks, you need to adopt a defense-in-depth strategy. A defense-in-depth strategy incorporates a variety of network security technologies into your security architecture and implements those technologies in a layered structure that extends from your perimeter network (outer layer) to every computer in your organization (inner layer). By providing host firewall protection on the innermost layer of your network, Windows Firewall, a new security component in Windows XP with Service Pack 2 and Windows Server 2003 with Service Pack 1, can be an effective part of your defense-in-depth security strategy.

**What is Windows Firewall?**

Windows Firewall is a host firewall technology, so it runs on each of your clients and servers, providing protection from network attacks that pass through your perimeter network or originate inside your organization, such as Trojan horse attacks, port scanning attacks, and worms. Like many firewall technologies, Windows Firewall is a stateful firewall, so it inspects and filters all TCP/IP version 4 (IPv4) and TCP/IP version 6 (IPv6) traffic. Unsolicited incoming traffic is dropped unless it is a response to a request by the host (solicited traffic) or it is specifically allowed (that is, has been added to the exceptions list). You can specify traffic to be added to the exceptions list according to port number, application name, or service name by configuring Windows Firewall settings. With the exception of some Internet Control Message Protocol (ICMP) messages, Windows Firewall allows all outgoing traffic.

You cannot use Windows Firewall as a perimeter firewall solution and you should not use it as a substitute for other network security technologies. Windows Firewall is designed to be a supplemental security solution; it should be part of a security architecture that implements a variety of security technologies, such as border routers, perimeter firewalls, virtual private networking (VPN), and Internet Protocol security (IPSec).

**How does Windows Firewall work?**

When an incoming packet reaches your computer, Windows Firewall inspects the packet and determines whether it meets criteria specified on the exceptions list. If the packet matches an entry in the list, Windows Firewall passes the packet to the TCP/IP protocol for further processing. If the packet does not match an entry in the list, Windows Firewall silently discards the packet and creates an entry in the Windows Firewall logging file (if the logging file is enabled). The entries in the exceptions list can consist of program names, system service names, TCP ports, and UDP ports. There is no way to create an entry in the exceptions list based on the IP Protocol field in the IP header.

There are only two conditions under which traffic can pass through Windows Firewall:

- When the incoming traffic corresponds to a recent outgoing request, in which case the response traffic is then considered incoming solicited traffic.

  An example of this occurs when a Domain Name System (DNS) Name Query Request message is sent to a DNS server. Windows Firewall adds an entry to the state filter table so that the corresponding DNS Name Query Response message sent by the DNS server can be passed to the TCP/IP protocol for further processing.

- When you configure Windows Firewall for exceptions, in which case you allow a computer using Windows Firewall to accept unsolicited incoming traffic when acting as a server, a listener, or a peer.

  An example of this occurs when your computer is acting as a Web server. In this case, you must configure Windows Firewall to allow Web traffic so that the computer can respond to requests from Web clients. You can configure exceptions based on programs, in which case the ports opened by the program are added to the exceptions list automatically, or on TCP or UDP ports, in which case the ports are opened whether the application or services using them is active or not.

**Common Windows Firewall scenarios**

With a few exceptions, Windows Firewall can be enabled on all configurations of Windows XP with SP2 or Windows Server 2003 with SP1. Therefore, it is recommended that you enable Windows Firewall on every client and server in your organization, including bastion hosts and other servers in your perimeter network, mobile and remote clients that connect to your network, and all clients and servers in your internal network. In addition, Windows Firewall can be enabled for any network architecture. Therefore, it is also recommended that you enable Windows Firewall regardless of how you have

designed and implemented your perimeter network or your internal network.

There are a few circumstances that might require you to disable Windows Firewall.

**Servers that are running Routing and Remote Access**
You should not enable Windows Firewall on a server that is running Routing and Remote Access. Routing and Remote Access has its own firewall, which makes Windows Firewall redundant and unnecessary, and Routing and Remote Access might not run if you have Windows Firewall enabled.

**Servers that are running perimeter firewalls**
You should not run Windows Firewall on a server that is running a perimeter firewall, such as Microsoft Internet Security and Acceleration (ISA) Server 2004. The protection that Windows Firewall provides in this situation is redundant and unnecessary. In addition, Windows Firewall can cause perimeter firewalls such as ISA Server to function improperly.

**Computers that are running non-Microsoft host firewalls**
You should disable Windows Firewall on a computer that is running a non-Microsoft host firewall. Although it is possible to run two host firewalls on a single computer, it is not recommended that you do so. Host firewall implementations vary widely and there is no guarantee that a non-Microsoft host firewall and Windows Firewall will work well together. Also, using multiple host firewalls on a single computer does not necessarily decrease your attack surface because the configuration settings (traffic rules) for each firewall would likely be the same and therefore redundant. Also, the use of multiple host firewalls on a single computer increases your operational overhead without any substantial gain in security.

In addition, you might want to disable Windows Firewall if a client or server requires you to open numerous ports or allow a large number of applications and services to receive unsolicited traffic. Because a significant volume of network traffic will be allowed to pass through Windows Firewall anyway, by disabling Windows Firewall, you eliminate the operational overhead associated with Windows Firewall configuration and maintenance. You also avoid any performance impact related to Windows Firewall. However, you should closely evaluate the design of any client or server that requires you to open numerous ports. Clients and servers that are configured for numerous roles or are configured to provide numerous services can be a critical point of failure in your organization and usually indicate poor infrastructure design.

**Windows Firewall impacts**
When it is enabled in its default configuration, Windows Firewall blocks all unsolicited incoming network traffic on all network connections. While blocking unsolicited incoming traffic reduces your attack surface and increases your level of security, it can cause some applications and services to stop working properly. For this reason, you might need to configure Windows Firewall so that unsolicited incoming traffic is allowed on certain ports or for certain applications and services. Configuration changes are usually not required on clients that are running Windows XP because the applications and services that run on a client do not often need to receive unsolicited incoming traffic. However, configuration changes are usually required on servers that are running Windows Server 2003 because many of the applications and services that run on servers, by their nature, need to receive and process unsolicited incoming traffic.

**Impacts on Windows XP**
Windows Firewall affects only the applications and services that listen for and respond to unsolicited incoming network traffic. There are not many applications and services that do this on clients because clients are typically configured as service consumers, not service providers. In other words, most of the network traffic that passes through a client computer is initiated by the client in the form of an outgoing request to another computer. Therefore, on clients, you usually do not need to configure Windows Firewall settings. There are, however, some scenarios for which you might have to create Windows Firewall exceptions:

**File and Printer Sharing**
If you want to share files, folders, or printers so that other computers can access these resources on a client computer, you need to configure Windows Firewall on the client computer so that unsolicited incoming traffic is allowed on TCP ports 139 and 445, and UDP ports 137 and 138.

**Remote Assistance**
If you want administrators and help desk technicians to use Remote Assistance to administer clients, you need to configure Windows Firewall on your clients so that the Remote Assistance application is allowed to process unsolicited incoming traffic.

**Remote Desktop**
If you want administrators and help desk technicians to use Remote Desktop to administer clients, you need to configure Windows Firewall on your clients so that unsolicited incoming traffic is allowed on TCP port 3389.

**UPnP**
If your clients need to process UPnP requests from other computers, you need to configure Windows Firewall on your clients so that unsolicited incoming traffic is allowed on TCP port 2869 and UDP port 1900.

In addition, you might have to configure Windows Firewall settings on clients that run certain types of e-mail and antivirus

programs. E-mail programs that connect to an Exchange server typically receive unsolicited incoming traffic when the Exchange server sends a message to the client informing the client that new mail has arrived. Centrally-managed antivirus programs typically receive unsolicited traffic when new virus signatures are pushed down to clients from a server.

**Impacts on Windows Server 2003**

Unlike clients, servers typically run numerous applications and services that listen for and respond to unsolicited incoming network traffic. Therefore, on servers, you usually need to configure some Windows Firewall settings so that unsolicited traffic is not blocked by Windows Firewall. The configuration changes that you need to make to Windows Firewall vary according to the server role and the applications and services that are running on the server. The following are some common server roles that require you to configure Windows Firewall settings:

| Server role | Configuration required |
|---|---|
| DHCP server | Allow unsolicited traffic through TCP port 67. |
| DNS server | Allow unsolicited traffic through TCP port 53. |
| POP3 server | Allow unsolicited traffic through TCP port 110. If you are securing POP3 traffic with Secure Sockets Layer (SSL), allow unsolicited traffic through TCP port 995. |
| Telnet server | Allow unsolicited traffic through TCP port 23. |

In addition to configuring Windows Firewall for various server roles, applications, and services, you need to configure Windows Firewall settings on every server that you intend to manage remotely. If you are managing the server by using the Administration Tools Pack on a client running Windows XP, then you need to configure Windows Firewall settings on the server to ensure that Windows Firewall allows the unsolicited traffic from the remote computer to reach the applications and services that are running on the server.

## Notes

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- Internet Connection Firewall is included only in the original releases of Windows Server 2003, Standard Edition, and Windows Server 2003, Enterprise Edition.

# Help: Windows Firewall features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windows Firewall features**
Windows Firewall has several features and functional differences that make it different from its predecessor, Internet Connection Firewall (ICF). Some of the features and functional differences between Windows Firewall and Internet Connection Firewall include:

- Global configuration options that apply to all connections
- New Windows Firewall component in Control Panel
- New Don't Allow Exceptions operating mode
- Startup security
- Incoming traffic scoping for Internet Protocol version 4 (IPv4)
- Exceptions that can be specified by program or system service name
- Built-in support for Internet Protocol version 6 (IPv6)
- New configuration options

**Global configuration options that apply to all connections**
Windows Firewall allows you to configure settings that apply to all the connections of the computer. In Windows Server 2003 with no service packs installed, ICF settings are configured per connection, which means that if you want to enable ICF on multiple connections and configure exceptions, you must configure each connection separately. When you change a global Windows Firewall setting, the change is applied to all the connections on which Windows Firewall is enabled. Windows Firewall does allow per-connection configuration; however, connection-specific configuration overrides global configuration.

**New Windows Firewall component of Control Panel**
To enable or disable ICF, you select or clear the **Protect my computer and network by limiting or preventing access to this computer from the Internet** check box, which appears on the **Advanced** tab of a connection's properties dialog box. You can also click the **Settings** button on a connection's properties dialog box and configure general exceptions, logging settings, and ICMP exceptions.

In Windows Firewall, the check box on the **Advanced** tab of a connection's properties dialog box has been replaced with a **Settings** button, which launches the new Windows Firewall component in Control Panel. You can also start Windows Firewall by clicking **Windows Firewall** in Control Panel. The Windows Firewall dialog box allows you to configure general settings, exceptions for programs (applications and services), connection-specific settings, log settings, and ICMP exceptions. You can also reset Windows Firewall to its default configuration.

**New operating mode**
ICF is either enabled (that is, allows only solicited traffic and traffic that is specified in the exceptions list) or disabled (allows all traffic). Windows Firewall has these same operating modes, but allows you to select a new operating mode that enables Windows Firewall and ignores all exceptions. When Windows Firewall is running in this new mode, all unsolicited incoming traffic is dropped, including traffic that is specified in the exceptions list. This new mode can be used when connecting to the Internet from a public location, such as a hotel or airport, or inside an organization's network to temporarily lock down computers during a network attack or when a malicious program is spreading. After the network attack is over and appropriate updates have been installed to prevent future attacks, Windows Firewall can be returned to the normal operating mode that allows exceptions. All of the original settings for exceptions are maintained.

**Startup security**
ICF is active only on the connections on which it is enabled when the Internet Connection Firewall/Internet Connection Sharing (ICS) service starts successfully. Therefore, there is a delay between when the computer is active on the network and when the connections are protected with ICF. This delay makes the computer accessible to attacks during startup.

In Windows Firewall, there is a startup policy that performs stateful packet filtering, thereby allowing the computer to perform basic networking startup tasks using Dynamic Host Configuration Protocol (DHCP) and the Domain Name System (DNS) protocol to configure the computer and communicate with a domain controller to obtain Group Policy updates. The startup policy does not include any settings that you have configured for Windows Firewall, including settings that you have configured in Group Policy. After the Windows Firewall/ICS service is started, Windows Firewall uses the settings that you configured for Windows Firewall and removes the startup policy. The startup policy settings cannot be configured.

**Incoming traffic scoping**
In ICF, allowed traffic can originate from any IPv4 address. In Windows Firewall, you can specify where allowed traffic originates. This configuration setting is known as the scope option and it allows you to limit the scope of an exception to traffic that originates from any IPv4 address; originates from an IPv4 address that can be reached directly (based on IPv4 routing table entries); originates from one or more specific IPv4 addresses or from one or more ranges of IPv4 addresses.

For incoming IPv6 traffic, Windows Firewall allows you to specify whether exceptions allow traffic that originates from any IPv6 address or from an IPv6 address that can be reached directly (based on IPv6 routing table entries).

**Exceptions can be specified by program name**
In ICF, you manually configure exceptions by specifying the set of TCP and UDP ports that correspond to the traffic of a specific program, which can be either an application or service. This can make configuration difficult for users who do not know the set of TCP and UDP ports for the application or service. Also, this configuration does not work for applications that do not listen on a specific set of UDP or TCP ports.

To make it easier to configure exceptions, Windows Firewall allows you to specify the set of TCP or UDP ports or the file name of the program. When the program runs, Windows Firewall monitors the ports on which the program listens and opens the ports.

To allow you to quickly enable exceptions for commonly allowed, incoming unsolicited traffic, Windows Firewall has predefined exceptions, such as File and Printer Sharing and Remote Desktop. In addition, the notification mechanism in Windows Firewall prompts local administrators with a Windows Security Alert message to allow them to add new programs to the program exceptions list automatically.

**Built-in support for IPv6**
IPv6 support is included with Windows Firewall and is automatically enabled on all IPv6 connections. Both IPv4 and IPv6 share the same settings for traffic that is on the exceptions list. For example, if you allow file and print sharing traffic, then both IPv4- and IPv6-based unsolicited incoming file and printer sharing traffic is allowed.

### Note

Windows Firewall does not support the same scope options for IPv6 traffic as IPv4 traffic.

**New configuration options**
The only way to enable or disable ICF is through the Network Connections folder, the Network Setup Wizard, or the Internet Connection Wizard. To configure exceptions, you must either use the Network Connections folder or your application must be ICF-aware, in which case it adds exceptions to the exceptions list automatically.

In Windows Firewall, there are several ways to configure settings and options, including the following:

**Netsh commands**
Netsh is a command-line tool that you can use to configure settings for network components. However, to configure a component, the component must support a set of commands through a **netsh** context. Windows Firewall provides the **firewall** context, which can be used to configure Windows Firewall settings through a suite of commands. Using **netsh firewall**, you can create scripts to automatically configure a set of Windows Firewall settings for both IPv4 and IPv6 traffic. You can also use **netsh firewall** commands to display the configuration and status of the Windows Firewall.

**Group Policy settings**
Windows Firewall provides several new Group Policy settings so you can centrally configure and manage large numbers of computers in an organization that uses the Active Directory directory service. These new Group Policy settings allow you to configure Windows Firewall operational modes, exceptions, and other settings.

**Profile-based settings**
Windows Firewall allows you to configure settings in two different profiles: a domain profile and a standard profile. The domain profile is the set of Windows Firewall settings that are needed when the computer is connected to the network that contains the domain controllers of the organization. For example, the domain profile might contain exceptions for the applications needed by a managed computer in an enterprise network. The standard profile is the set of Windows Firewall settings that are needed when the computer is not connected to the network that contains the domain controllers of the organization (for example, when an employee uses the organization's laptop on the road and connects to the Internet using a

public broadband or wireless Internet service provider). Because the organization's laptop is directly connected to the Internet, the standard profile should contain more restrictive settings than the domain profile.

### Notes

- Internet Connection Firewall is included only in the original releases of Windows Server 2003, Standard Edition, and Windows Server 2003, Enterprise Edition.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

# Help: Understanding Windows Firewall notifications

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding Windows Firewall notifications**

By default, Windows Firewall displays a **Windows Security Alert** dialog box (referred to as a notification) when a program attempts to listen for unsolicited incoming traffic. If you are a member of the Administrators group on the computer, the notification gives you the ability to add the program to the exceptions list. If you are not a member of the Administrators group on the computer, the notification informs you that a program attempted to listen for incoming traffic but was blocked. You are not given the ability to add the program to the exceptions list if you are not a member of the Administrators group on the computer.

Windows Firewall does not display a notification in the user interface (UI) when a system service attempts to listen for incoming traffic on a port. This is also true for any program that runs like a system service (that is, a program that runs under an account that has higher privilege than a user account, for example, the Local System account, or a program that runs while there is no user logged onto the computer). However, you can use the security event log to determine whether a system service, or a program that runs like a system service, attempts to listen for incoming traffic. To do this you must enable the **Audit process tracking** policy and the **Audit policy change** policy. When you do this, Windows Firewall will write a Failure Audit with Event ID 861 to the security event log any time a program or system service attempts to listen for incoming traffic.

You can disable the notification feature in Windows Firewall by using the **Exceptions** tab in Windows Firewall in Control Panel, the **netsh firewall set notifications** command, or the **Windows Firewall: Prohibit notifications** policy setting. This might be necessary on servers that are remotely managed.

# Help: Understanding Windows Firewall exceptions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding Windows Firewall exceptions**

When you first turn on Windows Firewall or you restore Windows Firewall default settings, all unsolicited incoming traffic is blocked on all network connections. This means that any program or system service that attempts to listen for traffic on a TCP or UDP port will be unable to receive network traffic. To allow programs and system services to receive unsolicited traffic through these ports, you need to add the program or system service to the Windows Firewall exceptions list, or you need to determine which port or ports the program or system service uses and add the port or ports to the Windows Firewall exceptions list. Adding programs, system services, and ports to the exceptions list is the most commonly used way to control which traffic is allowed to pass through Windows Firewall.

**Note**

You can also control which traffic is allowed to pass through Windows Firewall by configuring the **Windows Firewall: Allow authenticated IPSec bypass** Group Policy setting. However, this is not a commonly used method of controlling the traffic that passes through Windows Firewall.

**Configuring exceptions**

You can add exceptions to the Windows Firewall exceptions list on a global basis or on a per-connection basis. Global exceptions are applied to all of the network connections on a computer, including new connections that you create. The recommended method for configuring global Windows Firewall exceptions is to use the Security Configuration Wizard (SCW).You can also add global exceptions for programs, system services, and ports to the Windows Firewall exceptions list by using the **Exceptions** tab in Windows Firewall in Control Panel. You can also add global exceptions for programs, system services, and ports by using the **netsh firewall** commands and the Windows Firewall Group Policy settings. Per-connection exceptions are applied to specific network connections. You can add per-connection exceptions for system services and ports by configuring **Network Connections Settings** on the **Advanced tab** in Windows Firewall in Control Panel and by using the **netsh firewall set portopening** and **netsh firewall set icmpsettings** commands. You cannot configure per-connection exceptions by using the Windows Firewall Group Policy settings.

You can also configure exceptions by enabling or disabling the preconfigured Windows Firewall exceptions by using the **Exceptions** tab in Windows Firewall in Control Panel, the **netsh firewall set** commands, or the Windows Firewall Group Policy settings. The following table lists the preconfigured exceptions, all of which are disabled by default:

| Exception | Description |
|---|---|
| File and Printer Sharing | Opens TCP ports 139 and 445 and UDP ports 137 and 138. Allows a computer to receive unsolicited traffic to shared files, folders, and printers. |
| Remote Desktop | Opens TCP port 3389. Allows a computer to be managed remotely with the Remote Desktop Connection feature. |
| UPnP Framework | Opens TCP port 2869 and UDP port 1900. Allows a computer to receive UPnP discovery requests from other computers and devices. |
| Remote administration | Opens TCP ports 135 and 445. Allows Svchost.exe and Lsass.exe to receive unsolicited incoming traffic and allows hosted services to open additional dynamically-assigned ports, typically in the range of 1024 to 1034. Allows a computer to be remotely managed with administrative tools such as the Microsoft Management Console (MMC) and Windows Management Instrumentation (WMI). |
| ICMP | Includes a suite of Internet Control Messages Protocol (ICMP) exceptions. ICMP exceptions allow you to control how a computer responds to and sends ICMP messages, including messages that are used by the **ping** command. |

**Note**

You can programmatically configure Windows Firewall exceptions by using the Windows Firewall application programming interface (API).

**Mitigating the risks associated with exceptions**

Each time you add a program, system service, or port to the exceptions list, you make your computer more accessible to attack. A common network attack uses port scanning software to identify computers that have open and unprotected ports. By adding numerous programs, system services, and ports to the exceptions list, you defeat the purpose of a firewall and increase the attack surface of your computer. This problem typically occurs when you configure a server for several different roles, and you need to open numerous ports to accommodate each of the server roles. You should closely evaluate the design of any server that requires you to open numerous ports. Servers that are configured for numerous roles or configured to provide numerous services can be a critical point of failure in your organization and usually indicate poor infrastructure design.

To help decrease your security risk, follow these guidelines:

**Create an exception only when you need it**
If you think a program or system service might require a port for unsolicited incoming traffic, do not add the program or system service to the exceptions list until you verify that the program or system service attempted to listen for unsolicited traffic. By default, Windows Firewall displays a notification when a program attempts to listen for unsolicited traffic. You can also use the security event log to determine whether a system service has attempted to listen for unsolicited traffic.

**Never allow an exception for a program that you do not recognize**
If Windows Firewall notifies you that a program has attempted to listen for unsolicited traffic, verify the name of the program and the executable (.exe) file before you add the program to the exceptions list. Likewise, if you use the security event log to identify system services that have attempted to listen for unsolicited traffic, verify that the service is a legitimate system service before you add a port to the exceptions list for the system service.

**Remove an exception when you no longer need it**
If you add a program, system service, or port to the exceptions list on a server, and then change the server's role or reconfigure the services and applications on the server, be sure to update the exceptions list and remove all of the exceptions that are no longer necessary.

**Best practices for creating exceptions**
In addition to the general guidelines for managing exceptions, use the following best practices when adding a program, system service, or port to the exceptions list.

**Adding programs**
Always try to add a program (.exe file) or a system service that runs within an .exe file to the exceptions list before you try to add a port. When you add a program to the exceptions list, Windows Firewall dynamically opens the required ports for the program. When the program is running, Windows Firewall allows incoming traffic through the required ports; when the program is not running, Windows Firewall blocks any incoming traffic that is sent to the ports.

**Adding system services**
Do not add system services to the exceptions list if the system service runs within Svchost.exe. Adding Svchost.exe to the exceptions list allows any system service running inside every instance of Svchost.exe to receive unsolicited incoming traffic. You should add system services to the exceptions list only if the system service runs within an .exe file or you can enable a preconfigured Windows Firewall system service exception, such as the UPnP Framework exception or the File and Printer Sharing exception.

**Adding ports**
You should add a port to the exceptions list as a last resort. When you add a port to the exceptions list, Windows Firewall allows incoming traffic through the port, regardless whether there is a program or system service listening on the port for incoming traffic.

# Help: Understanding Windows Firewall profiles

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding Windows Firewall profiles**

You can configure Windows Firewall settings in two different profiles: a domain profile and a standard profile. The domain profile settings are used when a computer is connected to a network in which the computer's domain account resides. The standard profile settings are used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network like the Internet. Both the domain profile and standard profile contain the same set of Windows Firewall settings. However, the standard profile settings are typically more restrictive than the domain profile because the standard profile settings do not need to include applications and services that are used in a managed domain environment only.

When you configure Windows Firewall in Control Panel, you are configuring settings in the profile that is currently in use. You cannot use Windows Firewall in Control Panel to configure settings in the profile that is not currently in use. You can tell which profile is currently in use by looking at the bottom of the **General** tab. You can also use the **netsh firewall show currentprofile** command to determine which profile is currently in use.

When you configure Windows Firewall Group Policy settings, you can configure individual policy settings in either the domain profile or the standard profile. Likewise, when you use the **netsh firewall** commands to configure Windows Firewall settings, you can choose to configure settings in either the domain profile or the standard profile.

If you do not configure standard profile settings, their default values are applied whenever Windows Firewall uses the standard profile. Therefore, it is highly recommended that you configure both domain and standard profile settings and that you enable the Windows Firewall for both profiles.

# Help: Understanding Windows Firewall scope options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding Windows Firewall scope options**
When you configure a program or port exception, you can also configure the scope options for the exception. Scope options are used to define which computers are allowed to send traffic through an exception. You can access the scope options by pressing the **Change Scope** button in the **Add a Port**, **Add a Program**, **Edit a Port**, or **Edit a Program** dialog boxes. There are three scope options:

**Any computer (including those on the Internet)**
This setting allows traffic from any Internet Protocol version 4 (IPv4) or Internet Protocol version 6 (IPv6) address through the exception. This setting might make your computer more accessible to malicious users or programs on the Internet.

**My network (subnet) only**
This setting allows traffic only from IPv4 or IPv6 addresses that can be reached directly by your computer. Windows Firewall determines whether the source IPv4 or IPv6 address of the incoming packet can be reached directly by querying the IPv4 and IPv6 routing tables. You can see all destinations that are considered directly reachable by typing the **route print** command at a command prompt. For the IPv4 routing table, all IPv4 addresses that match the routes in which the IPv4 address of the **Gateway** column equals the IPv4 address of the **Interface** column are considered directly reachable. For the IPv6 routing table, all IPv6 addresses that match routes in which the **Gateway** column is set to **On-link** are considered directly reachable. Therefore, the set of directly reachable addresses depends on your networking configuration, as specified by the IPv4 and IPv6 configuration of LAN-based connections (such as Ethernet and 802.11 wireless), dial-up connections, and broadband Internet connections. In some Internet configurations, all destinations are considered directly reachable.

For example, for a computer that is only directly connected to a private home network, the set of directly reachable unicast addresses is confined to those that match the IPv4 network ID of the private subnet. If the network connection is configured with an IPv4 address of 192.168.0.99 with a subnet mask of 255.255.0.0, only traffic from IPv4 addresses in the range 192.168.0.0 to 192.168.255.255 is allowed.

In another example, for a computer that is directly connected to both a private home network and the Internet through a cable modem, the set of directly reachable unicast addresses are those that match either the network ID of the private subnet or the cable modem provider subnet. For example, if the private network connection is configured with an IPv4 address of 192.168.0.1 and a subnet mask of 255.255.0.0 and the cable modem connection is configured with an IPv4 address of 131.107.17.211 and a subnet mask of 255.255.255.0, traffic received by either network connection is allowed from IPv4 addresses in the ranges from 192.168.0.0 to 192.168.255.255 and from 131.107.17.0 to 131.107.17.255.

**Custom list**
This setting allows you to specify one or more IPv4 addresses or IPv4 address ranges separated by commas. IPv4 address ranges typically correspond to subnets. For IPv4 addresses, type the IPv4 address in dotted decimal notation. For IPv4 address ranges, you can specify the range using a dotted decimal subnet mask or a prefix length. When you use a dotted decimal subnet mask, you can specify the range as an IPv4 network ID (such as 10.47.81.0/255.255.255.0) or by using an IPv4 address within the range (such as 10.47.81.231/255.255.255.0). When you use a network prefix length, you can specify the range as an IPv4 network ID (such as 10.47.81.0/24) or by using an IPv4 address within the range (such as 10.47.81.231/24). The following is an example custom list: 10.91.12.56,10.7.14.9/255.255.255.0,10.116.45.0/255.255.255.0,172.16.31.11/24,172.16.111.0/24

You cannot specify a custom list for IPv6 traffic.

### Note

When you configure and enable an exception, you are instructing Windows Firewall to allow specific unsolicited incoming traffic sent from the specified scope (from any address, from an address that can be reached directly, or from a custom list). For any scope, enabling an exception makes the computer accessible to attacks based on incoming unsolicited traffic from computers that are assigned the allowed addresses and from malicious computers that spoof traffic. There is no way to prevent spoofed attacks from the Internet on connections assigned public IPv4 addresses except by disabling the exception. Therefore, you should try to configure scope options so that the number of computers that are allowed to send unsolicited traffic through an exception is kept to a minimum. This will reduce, but not eliminate, the likelihood of a spoof attack.

# Help: Administering Windows Firewall with Group Policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Windows Firewall with Group Policy**
If your organization uses the Active Directory directory service, you can configure and manage Windows Firewall with the new Windows Firewall Group Policy settings. When you use Group Policy to configure Windows Firewall, local administrators and users will be unable to locally configure some Windows Firewall configuration settings by using Windows Firewall in Control Panel. Specifically, when a Windows Firewall setting is configured through Group Policy, the equivalent setting appears dimmed in Windows Firewall in Control Panel.

**Windows Firewall Group Policy Settings**
There are two sets of Windows Firewall policy settings:

- The domain profile settings, which are used when a computer is connected to a network that contains the organization's domain controllers.
- The standard profile settings, which are used when a computer is connected to a network that does not contain the organization's domain controllers.

If you do not configure profile settings, their default values are applied. Therefore, it is highly recommended that you configure both domain and standard profile settings so that you maintain your desired level of security in the event your computer changes from one profile to another. Also, the standard profile settings are typically more restrictive that the domain profile settings because the standard profile settings do not need to include applications and services that are used only in a managed domain environment. Both the domain profile and standard profile contain the same set of Windows Firewall configuration settings.

The following Group Policy settings are available for managing Windows Firewall. These settings can be found at the following location in the Group Policy Editor snap-in:

- Computer Configuration\Administrative Templates\Network\Network Connections\Windows Firewall\Domain Profile or Standard Profile

| Group Policy setting | Description |
|---|---|
| **Windows Firewall: Protect all network connections** | Used to specify that all network connections have Windows Firewall enabled. |
| **Windows Firewall: Do not allow exceptions** | Used to specify that all unsolicited incoming traffic is dropped, including traffic that has been added to the exceptions list. |
| **Windows Firewall: Define program exceptions** | Used to define by application file names traffic that has been added to the exceptions list. |
| **Windows Firewall: Allow local program exceptions** | Used to enable local configuration of program exceptions. |
| **Windows Firewall: Allow remote administration exception** | Used to enable remote procedure calls (RPC) and Distributed Component Object Model (DCOM), which are necessary for many remote administration using tools such as Microsoft Management Console (MMC) and Windows Management Instrumentation (WMI). |
| **Windows Firewall: Allow file and printer sharing exception** | Used to specify whether file and printer sharing traffic is allowed. |
| **Windows Firewall: Allow ICMP exceptions** | Used to specify the types of unsolicited Internet Control Message Protocol (ICMP) traffic allowed. |

| | |
|---|---|
| **Windows Firewall: Allow Remote Desktop exception** | Used to specify whether the computer can accept a Remote Desktop-based connection request. |
| **Windows Firewall: Allow UPnP framework exception** | Used to specify whether the computer can participate in UPnP discovery. |
| **Windows Firewall: Prohibit notifications** | Used to disable notifications when an application uses new Windows Firewall application programming interfaces (APIs) to request traffic that has been added to the exceptions list. |
| **Windows Firewall: Allow logging** | Used to enable logging of discarded traffic, successful connections, and configure log file settings. |
| **Windows Firewall: Prohibit unicast response to multicast or broadcast requests** | Used to discard the unicast packets sent in response to a multicast or broadcast request. |
| **Windows Firewall: Define port exceptions** | Used to specify by TCP and UDP ports traffic that has been added to the exceptions list. |
| **Windows Firewall: Allow local port exceptions** | Used to enable local configuration of port exceptions. |

You can also configure the **Windows Firewall: Allow authenticated IPSec bypass police setting**, which can be found at the following location in the Group Policy Editor snap-in:

Computer Configuration\Administrative Templates\Network\Network Connections\Windows Firewall

This policy setting allows unsolicited incoming messages from specified systems that authenticate using IPSec.

**Notes**

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- You cannot use Group Policy to configure Windows Firewall per-connection settings.
- Group Policy settings must be refreshed before they take effect.

# Help: Administering Windows Firewall with Netsh

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Windows Firewall with Netsh**

Windows Firewall provides a **firewall** context, which you can use to configure Windows Firewall settings. To run Windows Firewall **netsh** commands, you must start **netsh** from the command prompt and then change to the **firewall** context by typing **firewall**. You can also run **netsh firewall** commands all on one line at the command prompt.

You cannot use the **netsh firewall** commands to remotely configure Windows Firewall settings, and you cannot use the **dump** command to create a script based on the current Windows Firewall configuration.

The following **netsh firewall** commands can be used in scripts or at the command line to configure Windows Firewall.

| Command | Description |
|---|---|
| **add allowedprogram** | Used to add a program-based exception. |
| **set allowedprogram** | Used to modify the settings of an existing program-based exception. |
| **delete allowedprogram** | Used to delete an existing program-based exception. |
| **set icmpsetting** | Used to specify Internet Control Message Protocol (ICMP) traffic that has been added to the exceptions list. |
| **set multicastbroadcastresponse** | Used to specify the unicast response to a multicast or broadcast request behavior. |
| **set notifications** | Used to specify the notification behavior. |
| **set logging** | Used to specify logging options. |
| **set opmode** | Used to specify the operating mode of Windows Firewall either globally or for a specific connection (interface). |
| **add portopening** | Used to create a port-based exception. |
| **set portopening** | Used to modify the settings of an existing port-based exception. |
| **delete portopening** | Used to delete an existing port-based exception. |
| **set service** | Used to enable or disable the predefined file and printer sharing, remote administration, Remote Desktop, and UPnP exceptions. |
| **show allowedprogram** | Displays the programs that have been added to the exceptions list. |
| **show config** | Displays the local configuration information. |
| **show currentprofile** | Displays the current profile. |
| **show icmpsetting** | Displays the ICMP settings. |
| **show logging** | Displays the logging settings. |
| **show multicastbroadcastresponse** | Displays multicast or broadcast response settings. |
| **show notifications** | Displays the current settings for notifications. |
| **show opmode** | Displays the operational mode. |
| **show portopening** | Displays the ports that have been added to the exceptions list. |

| | |
|---|---|
| **show service** | Displays the services. |
| **show state** | Displays the current state information. |

**Note**

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

# Help: Administering Windows Firewall through Control Panel

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Windows Firewall through Control Panel**

The most common way to configure Windows Firewall settings on a single computer is to use Windows Firewall in Control Panel. You must be a member of the Administrators group on the local computer to configure settings in Windows Firewall in Control Panel. If you are not a member of the Administrators group, all of the settings in Windows Firewall will appear dimmed.

The Windows Firewall user interface consists of three tabs: the **General** tab, the **Exceptions** tab, and the **Advanced** tab.

**General tab**

You can disable and enable Windows Firewall for all connections on the **General** tab. The settings can be configured as follows:

| Setting | Description |
|---|---|
| **On** | Enables Windows Firewall for all of the network connections that are selected on the **Advanced** tab. Windows Firewall is enabled to allow only solicited traffic and incoming traffic that has been added to the exceptions list. |
| **Don't allow exceptions** | Allows solicited incoming traffic only. Incoming traffic that has been added to the exceptions list is not allowed. The settings on the **Exceptions** tab are ignored and all of the network connections are protected, regardless of the settings on the **Advanced** tab. In addition, Windows Firewall does not display a notification when a program attempts to listen for unsolicited incoming traffic. |
| **Off** | Disables Windows Firewall. This is not recommended, especially for network connections that are directly accessible from the Internet, unless you are already using a non-Microsoft host firewall. |

On Windows Server 2003, the default setting for Windows Firewall is **Off** for all connections and all newly created connections. If you turn Windows Firewall on, Windows Firewall can affect the communications of programs or services that rely on unsolicited incoming traffic. In this case, you must identify those programs that are no longer working and add them to the exceptions list or determine which ports the programs use and add the ports to the exceptions list.

**Exceptions tab**

You can configure the following settings on the **Exceptions** tab:

| Setting | UI element | Description |
|---|---|---|
| Program and port exceptions | **Add Program** button | Used to display the **Add a Program** dialog box, which allows you to select a program from a list or browse for a program's executable (.exe) file. |
| | **Add Port** button | Used to display the **Add a Port** dialog box, which allows you to specify a name for the port exception, a port number, and a port type (TCP or UDP). |
| | **Edit** button | Used to display the **Edit a Port** or **Edit a Program** dialog box, which allows you to modify the exception settings for the port or program.<br><br>All of the programs or services enabled from the **Exceptions** tab are enabled for all of the connections that are selected on the **Advanced** tab.<br><br>For more information about program exceptions, see Help: Understanding Windows Firewall exceptions. |

| | | |
|---|---|---|
| Program and port scope options | **Change Scope** button | Available in the **Add a Port**, **Add a Program**, **Edit a Port**, or **Edit a Program** dialog boxes. There are three scope options:<br>• Any computer (including those on the Internet)<br>• My network (subnet) only<br>• Custom list<br><br>For more information about scope options, see Help: Understanding Windows Firewall scope options. |
| Windows Firewall notifications | **Display a notification when Windows Firewall blocks a program** check box | Select or clear to configure the way Windows Firewall handles notifications.<br><br>If selected, Windows Firewall displays a notification when a program that is not in the exceptions list attempts to listen for incoming traffic.<br><br>If cleared, notifications do not appear.<br><br>For more information about notifications, see Help: Understanding Windows Firewall notifications. |

**Advanced tab**

You can configure the following settings on the **Advanced** tab:

| Setting | Description |
|---|---|
| Network Connection Settings | Used to configure the following settings:<br>• Specify individual connection on which Windows Firewall is enabled. To enable Windows Firewall on a connection, select the check box next to the connection name. To disable Windows Firewall on a connection, clear the check box. By default, all of the network connections have Windows Firewall enabled. If a network connection does not appear in **Network Connection Settings**, then it is a non-standard networking connection, such as a custom dialer from an Internet service provider (ISP).<br><br>If you clear all of the check boxes in **Network Connection Settings**, then Windows Firewall is not protecting your computer even if, on the **General** tab, you have selected **On**. Also, the settings in **Network Connection Settings** are ignored if you have selected **Don't allow exceptions** on the **General** tab, in which case all interfaces are protected.<br><br>• Configure advanced settings for an individual network connection. Click the network connection name, and then clicking **Settings**. The **Advanced Settings** dialog box is displayed.<br><br>On the **Advanced Settings** dialog box, from the **Services** tab, you can configure specific services (by TCP or UDP port only). From the **ICMP** tab, you can enable specific types of ICMP traffic. |
| Security Logging | Configure Windows Firewall logging options by clicking **Settings** in **Security Logging**. When you do this, the **Log Settings** dialog box is displayed, which allows you to configure whether to log discarded (dropped) packets or successful connections and specify the name, location, and maximum size of the log file. By default, the log file is named pfirewall.log and it is saved in the systemroot folder. The default maximum size is 4096 kilobytes (KB). |
| ICMP Settings | Configure Internet Control Message Protocol (ICMP) exceptions by clicking **Settings** in **ICMP**. When you do this, the **ICMP** dialog box is displayed, which allows you to enable and disable the types of incoming ICMP messages that Windows Firewall allows for all the connections selected on the **Advanced** tab. ICMP messages are used for diagnostics, reporting error conditions, and configuration. By default, no ICMP messages in the list are allowed. |

| | |
|---|---|
| Restore Defaults | Restore Windows Firewall default settings. All of the entries in the exceptions list are deleted and all settings and options are restored to their original state. Clicking **Restore Defaults** also enables Windows Firewall on all connections, which can cause your programs and system services to behave improperly because this is not the standard. This might also cause Internet Connection Sharing (ICS) and Network Bridge to fail. |

**Note**

- If a setting is managed by Group Policy, or you do not have the administrative rights to configure a setting, the setting will appear dimmed when you open Windows Firewall in Control Panel.

# Help: Use SCW to start and configure Windows Firewall

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To use SCW to start and configure Windows Firewall**

1. Open the Security Configuration Wizard (SCW), and follow the steps in the wizard until you reach the **Network Security** page.

2. Clear the **Skip this section** check box, and click **Next**.

3. Under **Select the ports to open**, review the ports that SCW will add to the Windows Firewall exceptions list. To prevent SCW from adding a port to the exceptions list, clear the check box that is next to the port.

   If you want to add additional ports or applications to the Windows Firewall exceptions list, click **Add**, and do the following:

   - To add a port to the exceptions list, in **Port number**, enter the port number, select **TCP** or **UDP** or both **TCP** and **UDP**, and click **OK**.

   - To add an application to the exceptions list, click the **Approve Application** tab, and in **Application path**, enter the application path and name of the executable (.exe) file, and then click **OK**. Try to use environment variables for paths so that the administrative templates can be applied to any computer.

4. Click **Next**.

5. On the **Confirm Port Configuration** page, verify the port settings that SCW will use to configure Windows Firewall, and click **Next**.

6. On the **Registry Settings** page, select the **Skip this section** check box, and click **Next**.

7. On the **Audit Policy** page, select the **Skip this section** check box, and click **Next**.

8. On the **Internet Information Services** page, select the **Skip this section** check box, and click **Next**.

9. On the **Save Security Policy** page, click **Next**.

10. Enter a name and description for the security policy, and click **Next**.

11. Click **Apply now** to apply the security policy and configure Windows Firewall, and click **Next**.

12. When SCW has applied the security policy, click **Next**, and then click **Finish**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- SCW is an optional component in Windows Server 2003 with Service Pack 1 (SP1). SCW is not installed by default. You must install it before you can use it.

- SCW displays different pages depending on the configuration settings you choose.

- If you choose **Remote access/VPN server**, **Internet Connection Sharing server**, or **Microsoft Internet Security and Acceleration Server 2004** during the Role-Based Service Configuration portion of SCW, you will not be able to select Network Security portion of SCW, which is where you configure Windows Firewall settings.

# Help: Turn Windows Firewall on or off

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To turn Windows Firewall on or off**

- Open Windows Firewall.

  To turn Windows Firewall on, click **On**, and then click **OK**.

  To turn Windows Firewall off, click **Off**, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.
- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.
- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.
- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.
- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.
- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.
- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- If you start Windows Firewall after you start applications that are listed in the Windows Firewall exceptions list, you might have to restart your computer. Windows Firewall cannot track the state of a program's traffic if the program was started before Windows Firewall/Internet Connection Sharing service was started. This problem typically occurs when you start a program, and then try to start Windows Firewall for the first time.

# Help: Turn Windows Firewall on or off for a specific connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To turn Windows Firewall on or off for a specific connection**

1. Open Windows Firewall.

2. Click the **Advanced** tab.

   To turn Windows Firewall off for a connection, in **Network Connection Settings**, clear the check box next to the connection that you do not want to secure with Windows Firewall, and then click **OK**.

   To turn Windows Firewall on for a connection, in **Network Connection Settings**, select the check box next to the connection that you want to secure with Windows Firewall, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

# Help: Turn Windows Firewall on with no exceptions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To turn Windows Firewall on or off with no exceptions**

1. Open Windows Firewall.
2. Click **On**, select the **Don't allow exceptions** check box, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.
- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.
- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.
- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.
- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.
- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.
- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

# Help: Restore Windows Firewall default settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restore Windows Firewall default settings**

1. Open Windows Firewall.
2. Click the **Advanced** tab, click **Restore Defaults**, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.
- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.
- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.
- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- Restoring the default settings will undo all of the changes you have made to Windows Firewall. Restoring the default settings will also turn Windows Firewall on for all network connections, which might cause some programs to stop working. In addition, restoring the default settings might cause Internet Connection Sharing and Network Bridge to not work correctly.
- Internet Connection Sharing and Network Bridge are not included in Windows Server 2003, Web Edition; Windows Server 2003, Datacenter Edition; and the Itanium-based versions of the original release of the Windows Server 2003 operating systems.

# Help: Add a port to the Windows Firewall exceptions list

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a port to the Windows Firewall exceptions list**

1. Open Windows Firewall.
2. Click the **Exceptions** tab, and then click **Add Port**.
3. In **Name**, type a name for the port exception. This name will appear in the exceptions list.
4. In **Port number**, type the number of the port that you want to add to the exceptions list.
5. Click either **TCP** or **UDP**, depending on the type of traffic the port handles, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.
- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.
- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.
- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.
- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.
- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.
- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- Adding a port to the exceptions list can lessen the security of your computer because the port will be open any time the computer is running. You should add ports to the exceptions list only when it is not possible to add a program to the exceptions list.
- You should configure scope options for any exceptions that you enable.

# Help: Edit or delete a port exception

Updated: November 6, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To edit or delete a port exception**

1. Open Windows Firewall.

2. Click the **Exceptions** tab, and then click the port exception that you want to edit or delete.

   If you want to delete the port exception, click **Delete**, and then click **OK**.

   If you want to edit the port exception, click **Edit**, make changes to the port exception settings, and then click **OK**.

If you want to remove all your program and port exceptions, you can restore your firewall to the default settings. Restoring the default settings deletes all the Windows Firewall settings that you made since Windows was installed. This may cause some programs to stop working. For more information, see Help: Restore Windows Firewall default settings.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- Adding a port to the exceptions list can lessen the security of your computer because the port will be open any time the computer is running. You should add ports to the exceptions list only when it is not possible to add a program to the exceptions list.

- You should configure scope options for any exceptions that you enable.

# Help: Add a program to the Windows Firewall exceptions list

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a program to the Windows Firewall exceptions list**

1. Open Windows Firewall.

2. Click the **Exceptions** tab, and then click **Add program**.

   If the program that you want to add to the exceptions list appears in **Programs**, click the program, and then click **OK**.

   If the program that you want to add to the exceptions list does not appear in **Programs**, click **Browse**, and then do the following:

   - In the **Browse** dialog box, find the executable (.exe) file or command (.com) file for the program that you want to add to the exceptions list, click **Open**, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- You should configure scope options for any exceptions that you enable.

# Help: Edit or delete a program exception

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To edit or delete a program exception**

1. Open Windows Firewall.

2. Click the **Exceptions** tab, and then click the program exception that you want to edit or delete.

   If you want to delete the program exception, click **Delete**, and then click **Yes**.

   If you want to edit the program exception, click **Edit**, make the changes you want to the program exception settings, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. # Help: Add a system service to the Windows Firewall exceptions list

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a system service to the Windows Firewall exceptions list**

1. Open Windows Firewall, and then click the **Advanced** tab.

2. In **Network Connection Settings**, click the connection that the system service uses to communicate, and click **Settings**.

   If the system service that you want to add to the exceptions list appears in **Services**, select the check box for the system service, and click **OK**.

   If the system service that you want to add to the exceptions list does not appear in **Services**, click **Add**, and in the **Service Settings** dialog box, do the following:

   a. In **Description of service**, type a display name for the system service. The display name appears in the exceptions list.

   b. In **Name or IP address of the computer hosting this service on your network**, type the name or IP address of the local computer.

   c. In **External port number for this service**, type the port number that receives unsolicited traffic for this system service. Usually, this is the same as the IP address of the local computer.

   d. In **Internal port number for this service**, type the port number to which the local computer should forward (or translate) incoming traffic.

   e. Click either **TCP** or **UDP**, depending on the type of traffic your internal and external ports handle, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- You should configure scope options for any exceptions that you enable.

# Help: Edit or delete a system service exception

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To edit or delete a system service exception**

1. Open Windows Firewall, and click the **Advanced** tab.

2. In **Network Connection Settings**, click the connection that the system service uses to communicate, and then click **Settings**.

3. Click the system service that you want to edit or delete.

   If you want to delete the system service exception, click **Delete**, and then click **OK**.

   If you want to edit the system service exception, click **Edit**, make changes to the system service exception settings, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- You should configure scope options for any exceptions that you enable.

- You cannot change the name of a system service exception by clicking **Edit**. To rename a system service exception, delete the exception and create a new exception with the new name.

# Help: Enable or disable the Remote Desktop exception

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable the Remote Desktop exception**

1. Open Windows Firewall.

2. Click the **Exceptions** tab.

   To enable the Remote Desktop exception, in **Programs and Services**, select the **Remote Desktop** check box, and click **OK**.

   To disable the Remote Desktop exception, in **Programs and Services**, clear the **Remote Desktop** check box, and click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- The Remote Desktop exception allows unsolicited incoming traffic through TCP port 3389.

- Disabling the Remote Desktop exception can prevent other computers from using Remote Desktop Connection to connect to your computer.

- You should configure scope options for any exceptions that you enable.

# Help: Enable or disable the File and Printer Sharing exception

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable the File and Printer Sharing exception**

1. Open Windows Firewall.

2. Click the **Exceptions** tab.

   To enable the File and Printer Sharing exception, in **Programs and Services**, select the **File and Printer Sharing** check box, and click **OK**.

   To disable the File and Printer Sharing exception, in **Programs and Services**, clear the **File and Printer Sharing** check box, and click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- The File and Printer Sharing exception allows unsolicited incoming traffic through TCP ports 139 and 445, and UDP ports 137 and 138.

- Enabling the File and Printer Sharing exception allows incoming Internet Control Message Protocol (ICMP) echo traffic, which enables computers to ping your computer. To block incoming ICMP echo traffic, you must edit the File and Printer Sharing exception so that TCP port 445 is disabled.

- Editing or disabling the File and Printer Sharing exception can prevent other computers from accessing your shared folders, files, and printers. Be sure to test for the impact these changes might have on file and printer sharing functionality.

- You should configure scope options for any exceptions that you enable.

- Enabling the File and Printer Sharing exception will allow other computers to reach your computer with the **ping** command.

# Help: Enable or disable the UPnP Framework exception

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable the UPnP Framework exception**

1. Open Windows Firewall.

2. Click the **Exceptions** tab.

   To enable the UPnP Framework exception, in **Programs and Services**, select the **UPnP Framework** check box, and click **OK**.

   To disable the UPnP Framework exception, in **Programs and Services**, clear the **UPnP Framework** check box, and click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- The UPnP Framework exception allows unsolicited incoming traffic through TCP port 2869 and UDP port 1900.

- You might not want to disable or edit the UPnP Framework exception if your computer uses Internet Connection Sharing to provide other computers access to the Internet. Editing or disabling the UPnP Framework exception can prevent computers and devices from detecting and using the shared Internet connection. Be sure to test for the impact these changes might have on Internet Connection Sharing functionality.

- You should configure scope options for any exceptions that you enable.

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable the remote administration exception**

- To enable the remote administration exception, type the following at the command prompt, and press ENTER:

  **netsh firewall set service remoteadmin enable**

- To disable the remote administration exception, type the following at the command prompt, and press ENTER:

  **netsh firewall set service remoteadmin disable**

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.
- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.
- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- You cannot use Windows Firewall in Control Panel to configure the remote administration exception.
- The remote administration exception allows unsolicited incoming traffic through TCP ports 135 and 445 and through ports that are dynamically assigned by the RPC endpoint mapper. The remote administration exception also allows Svchost.exe and Lsass.exe to receive unsolicited incoming traffic.
- You should enable the remote administration exception only if your remote administrative tools require remote procedure calls (RPC) and Distributed Component Object Model (DCOM). Malicious users often attempt to attack networks and computers using RPC and DCOM. It is recommended that you contact the manufacturer of your remote administration tool to determine if it requires RPC and DCOM communication. If it does not, do not enable the remote administration exception.
- You should configure scope options for any exceptions that you enable.
- Enabling the remote administration exception will allow other computers to reach your computer with the **ping** command.

# Help: Change the scope of a Windows Firewall exception

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the scope of a Windows Firewall exception**

1. Open Windows Firewall, and click the **Exceptions** tab.

2. In **Programs and Services**, click the exception that you want to configure, and click **Edit**.

3. Click **Change scope**, and do one of the following:

   If you want to enable the exception for all computers, click **Any computer (including those on the Internet)**, and then click **OK**.

   If you want to enable the exception for computers that can be reached directly from your local subnet, click **My network (subnet) only**, and then click **OK**.

   If you want to enable the exception for specific IP addresses or IP address ranges, click **Custom list**, enter the specific IP addresses or IP address ranges, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- The **My network (subnet) only** and **Custom list** scope options do not necessarily increase your security. Malicious users can circumvent these scope restrictions by spoofing an IP address that appears to be directly reachable or is part of the custom list.

- When you use the **My network (subnet) only** scope option, Windows Firewall does not perform any IP configuration

testing or subnet mask interpretation to determine whether the traffic is coming from a computer that is a neighbor on a locally attached subnet. Instead, Windows Firewall determines whether the traffic is originating from an address that can be reached directly based on routes in the IP version 4 (IPv4) routing table. If it is, this traffic is considered to match the **My network (subnet) only** scope.

# Help: Configure ICMP exceptions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure ICMP exceptions**

1. Open Windows Firewall, and click the **Advanced** tab.
2. In **ICMP**, click **Settings**.
3. In the **ICMP Settings** dialog box, select the check box for each ICMP setting that the computer should respond to, or clear the check box for each ICMP setting that the computer should not respond to, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.
- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.
- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.
- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.
- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.
- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.
- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- You can also configure ICMP exceptions on a per-connection basis.
- If you clear the **Allow incoming echo request** check box to prevent your computer from responding to ping traffic, you might also have to configure the remote administration exception and the File and Printer Sharing exception so that incoming traffic is not allowed on TCP port 445. These exceptions open TCP port 445, which allows incoming echo request traffic.
- You can enable other computers to reach your computer with the **ping** command by selecting the **Allow incoming echo request** check box.
- You should configure scope options for any exceptions that you enable.

# Help: Enable or disable Windows Firewall notifications

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable Windows Firewall notifications**

1. Open Windows Firewall.

2. Click the **Exceptions** tab.

   To enable notifications, select the **Display a notification when Windows Firewall blocks a program** check box, and click **OK**.

   To disable notifications, clear the **Display a notification when Windows Firewall blocks a program** check box, and click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.

- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.

- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.

- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.

- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.

- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- Windows Firewall cannot display notifications if you select the **Don't allow exceptions** check box in Windows Firewall in Control Panel or if you enable the **Do not allow exceptions** policy setting in the Group Policy Object Editor. There are no Windows Firewall settings that allow you to override this behavior.

- Windows Firewall does not display notifications for programs that rely on the Winsock driver to dynamically bind to a UDP port. If a program uses this method (sometimes referred to as wildcard binds) to bind to a UDP port, you might be able to use the **netstat** command and other troubleshooting tools to determine which UDP port is being used.

- Windows Firewall does not display notifications for system services or programs that run when there is no user logged on to the computer. Most system services run this way, as do many server programs. However, Windows Firewall does

write an event (Event ID 861) to the security event log for any system service or program that attempts to listen on a port, no matter if a notification is displayed.

# Help: Determine which profile Windows Firewall is using

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To determine which profile Windows Firewall is using**

- Type the following at the command prompt, and press ENTER:

  **netsh firewall show currentprofile**

## Notes

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- Windows Firewall settings can be configured in two profiles: the domain profile, which is used when a computer is connected to a network in which the computer's domain account resides; and the standard profile, which is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network.

# Help: Enable auditing of Windows Firewall events

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable auditing of Windows Firewall events**

1. Open the Group Policy Object Editor snap-in to edit the Group Policy object (GPO) that is used to manage Group Policy settings in your organization.

2. Open **Windows Settings**, open **Security Settings**, open **Local Policies**, and then click **Audit Policy**.

3. Double-click **Audit process tracking**, select the **Success** and **Failure** check boxes, and then click **OK**.

4. Double-click **Audit policy change**, select the **Success** and **Failure** check boxes, and then click **OK**.

## Notes

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- You can determine when a system service listens on a port by enabling auditing and viewing security event log entries.

- You must enable auditing for Windows Firewall events to appear in the security event log.

# Help: Change the name and location of the Windows Firewall log file

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the name and location of the Windows Firewall log file**

1. Open Windows Firewall, and click the **Advanced** tab.
2. In **Security Logging**, click **Settings**.
3. Click **Save As**, and navigate to the location where you want to save the log file.
4. In **File name**, type the new log file name, or leave it blank to accept the default name of pfirewall.log.
5. Click **Save**, and then click **OK**.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.
- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.
- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.
- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.
- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.
- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

# Help: Change the size of the Windows Firewall log file

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the size of the Windows Firewall log file**

1. Open Windows Firewall, and click the **Advanced** tab.
2. In **Security Logging**, click **Settings**.
3. In **Size limit (KB)**, enter the maximum size of the log file, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To start Windows Firewall, click **Start**, point to **Control Panel**, and then click **Windows Firewall**.
- You can also use the **netsh** command with the **firewall** context to perform this procedure and configure other Windows Firewall settings.
- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.
- If a Windows Firewall setting appears dimmed in the graphical user interface, and on the **General** tab, you see **For your security, some settings are controlled by Group Policy**, the setting might be managed by Group Policy. If all Windows Firewall settings appear dimmed, and on the **General** tab, you see **You must be a computer administrator to change these settings**, you do not have administrative rights to configure Windows Firewall.
- On Windows Server 2003, Windows Firewall is turned off by default and the Windows Firewall/Internet Connection Sharing service is disabled by default. You might have to start the Windows Firewall/Internet Connection Sharing service if you try to perform this procedure and you have never started Windows Firewall.
- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- The default size of the Windows Firewall log file is 4,096 kilobytes (KB) and the maximum size is 32,767 KB.
- When the firewall log reaches the size that you set in **Size limit (KB)**, the log file is renamed and a new log file is created.

# Help: Configure Windows Firewall for IPSec Bypass and Multicast Traffic

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure Windows Firewall for IPSec and Multicast Traffic**

- Help: Allow IPSec traffic to bypass Windows Firewall
- Help: Block unicast responses to a computer's outgoing multicast traffic

# Help: Allow IPSec traffic to bypass Windows Firewall

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To allow IPSec traffic to bypass Windows Firewall**

1. Open the Group Policy Object Editor snap-in to edit the Group Policy object (GPO) that is used to manage Windows Firewall settings in your organization.

2. Open **Computer Configuration**, open **Administrative Templates**, open **Network**, open **Network Connections**, and then click **Windows Firewall**.

3. In the details pane, double-click **Windows Firewall: Allow authenticated IPSec bypass**.

4. In the **Windows Firewall: Allow authenticated IPSec bypass properties** dialog box, on the **Settings** tab, click **Enabled**.

5. In **Define IPSec peers to be exempted from firewall policy**, type the Security Descriptor Definition Language (SDDL) string that corresponds to the group accounts for the computers to which this policy applies, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- This procedure allows unsolicited incoming messages from specified systems that authenticate using IPSec.

- You cannot use Windows Firewall in Control Panel or the **netsh firewall** command to perform this procedure.

- The format of the SDDL string for a single group is:

  O:DAG:DAD:(A;;RCGW;;;SID)

  Where SID is the Security Identifier (SID) of a group account.

- You can use the Getsid.exe tool to obtain the SID of a group account. Getsid.exe is typically used to compare the SIDs of two accounts on different domain controllers, but you can also use it to obtain the SID of a specified user or group account. For more information about Getsid.exe, see the Windows Server 2003 Resource Kit Tools Web site.

- If you have more than one group, then the syntax for the SDDL string is:

  O:DAG:DAD:(A;;RCGW;;;SID1) (A;;RCGW;;;SID2) (A;;RCGW;;;SID3)...

- If you enable the **Windows Firewall: Allow authenticated IPSec bypass** policy setting, and then later disable the policy setting or change it to **Not Configured**, Windows Firewall deletes the SDDL string.

**Concepts**
Help: Administering Windows Firewall with Group Policy

# Help: Block unicast responses to a computer's outgoing multicast traffic

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To block unicast responses to a computer's outgoing multicast traffic**

- Type the following at the command prompt, and press ENTER:

  **netsh firewall set multicastbroadcastresponse disable**

## Notes

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- You can also use Group Policy settings to perform this procedure and configure other Windows Firewall settings.
- You can configure Windows Firewall settings in the standard profile or the domain profile. The domain profile is used when a computer is connected to a network in which the computer's domain account resides. The standard profile is used when a computer is connected to a network in which the computer's domain account does not reside, such as a public network or the Internet. Make sure Windows Firewall is using the correct profile when you perform this procedure.
- You cannot use Windows Firewall in Control Panel to perform this procedure.
- If you perform this procedure, and this computer sends multicast or broadcast messages to other computers, Windows Firewall blocks the unicast responses sent by those other computers.
- By default, when this computer sends a multicast or broadcast message to other computers, Windows Firewall waits as long as three seconds for unicast responses from the other computers and then blocks all later responses.

**To prevent administrators or users from running Windows Firewall**

1. Open the Group Policy Object Editor snap-in to edit the Group Policy object (GPO) that is used to manage Windows Firewall settings in your organization.

2. Open **Computer Configuration**, open **Administrative Templates**, open **Network**, open **Network Connections**, open **Windows Firewall**, and then open either **Domain Profile** or **Standard Profile**, depending on which profile you want to configure.

3. In the details pane, double-click **Windows Firewall: Protect all network connections**.

4. In the **Windows Firewall: Protect all network connections properties** dialog box, on the **Settings** tab, click **Disabled**, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- You cannot use Windows Firewall in Control Panel or the **netsh firewall** command to perform this procedure.

- Group Policy settings must be refreshed before they take effect.

# Managing Remote Connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing remote connections**
This section covers:

- Routing and Remote Access
- Connection Manager Administration Kit
- Connection Point Services
- Virtual Private Networks
- Internet Authentication Service

# Routing and Remote Access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing and Remote Access**

The Routing and Remote Access service in the Microsoft® Windows Server 2003 family provides:

- Multiprotocol LAN-to-LAN, LAN-to-WAN, virtual private network (VPN), and network address translation (NAT) routing services. For more information, see Routing.

- Dial-up and VPN remote access services. For more information, see Remote Access.

# Routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing**

Routing and Remote Access provides multiprotocol LAN-to-LAN, LAN-to-WAN, virtual private network (VPN), and network address translation (NAT) routing services. Routing and Remote Access is intended for use by system administrators who are already familiar with routing protocols and services, and routable protocols such as TCP/IP and AppleTalk.

- Before configuring the server running Routing and Remote Access to act as a router, see Checklist: Installing and configuring the router.
- To find features that have been moved or changed in the Microsoft® Windows Server 2003 family, see New ways to do familiar Routing tasks.
- For tips about using routing, see Routing best practices.
- For help with specific tasks, see Routing How To....
- For general background information, see Routing Concepts.
- For problem-solving instructions, see Troubleshooting routing.

# Checklist: Installing and configuring the router

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing and configuring the router**

| Step | Reference |
|---|---|
| Review key concepts. | Routing Overview |
| Verify the compatibility of all hardware to be installed in the server running Routing and Remote Access. | Support resources |
| Install the hardware. | Manufacturer's documentation |
| For a new network, decide which protocols and routing features of Routing and Remote Access you want to use. For an existing network, determine which protocols and routing features of Routing and Remote Access you need to enable. | Routing Overview and documentation about your network |
| Install and configure the protocols. | Network communications |
| Enable and configure the Routing and Remote Access service. | Enable the Routing and Remote Access service |
| (Optional) Design and deploy static IP routing. | Setting Up a Static Routed IP Internetwork |
| (Optional) Design and deploy the RIP-for-IP routing protocol. | Setting Up a RIP-for-IP Routed Internetwork |
| (Optional) Design and deploy the OSPF routing protocol. This feature is not available on the Itanium-based versions of the Windows operating systems. | Setting Up an OSPF Routed Internetwork |
| (Optional) Add and configure the DHCP Relay Agent. | Configure the DHCP Relay Agent |
| (Optional) Configure IP multicast support. | Configure IP Multicast Support |
| (Optional) Design and deploy network address translation. | Setting Up Network Address Translation |
| (Optional) Configure the appropriate IP packet filters. | Manage Packet Filters |
| (Optional) Design and deploy demand-dial routing. | Setting Up Demand-Dial Routing |

# New ways to do familiar Routing tasks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New ways to do familiar tasks**

The following table lists common tasks for configuring the routing features of Routing and Remote Access. The user interface for performing these tasks is different in this version of Windows from the way it was in Windows NT version 4.0 or Windows NT version 4.0 with the Routing and Remote Access Service (RRAS). The user interface for the Windows 2000 version of Routing and Remote Access differs slightly from that for the Windows Server 2003 family, but the steps for most common tasks have not changed.

Please choose your upgrade path:

- Windows NT 4.0 to a product in the Windows Server 2003 family
- Windows NT 4.0 with RRAS to a product in the Windows Server 2003 family

**Windows NT 4.0 to a product in the Windows Server 2003 family**

| If you want to | In Windows NT 4.0 use | In this version of Windows use |
|---|---|---|
| Install, configure, and remove routing protocols | **Services** tab of **Network** in Control Panel | Open Routing and Remote Access. For more information, see Manage Routing Protocols and Routing How To.... |
| View the IP routing table | The **route print** command at a Windows NT command prompt. This displays the IP Forwarding table, the actual table that is used to forward IP traffic. | Open Routing and Remote Access. The routing table displayed in Routing and Remote Access displays the table based on updates from routing protocols, dial-on demand connections, and static routes. The table maintained in Routing and Remote Access is used to update the IP Forwarding table. You can view the IP Forwarding table directly by using the **route print** command at the command prompt. For more information, see View routing tables. |

**Windows NT 4.0 with RRAS to a product in the Windows Server 2003 family**

| If you want to | In Windows NT 4.0 with RRAS use | In this version of Windows use |
|---|---|---|
| Install, configure, and remove routing protocols | Routing and RAS Admin | Open Routing and Remote Access. For more information, see Manage Routing Protocols and Routing How To.... |
| View the IP routing table | Routing and RAS Admin | Open Routing and Remote Access. For more information, see View routing tables. |

# Routing best practices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Best practices**
For best practice information about design, security, and deployment for the server running Routing and Remote Access, see the following:

- Security information for routing
- Setting Up a Static Routed IP Internetwork
- Setting Up a RIP-for-IP Routed Internetwork
- Setting Up an OSPF Routed Internetwork
- Setting Up Network Address Translation
- Setting Up Demand-Dial Routing
- Deploying Router-to-Router VPNs

**Note**

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Routing How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

This section provides instructions for installing and configuring the routing components of Routing and Remote Access.

- Enable the Routing and Remote Access service
- Enable LAN and WAN routing
- Manage Routing Interfaces
- Manage Devices and Ports
- Manage Routing Protocols
- Manage Static Routes
- Manage Routers
- Manage Packet Filters
- Configure RIP for IP
- Configure OSPF
- Configure NAT/Basic Firewall
- Enable ICMP router discovery
- Configure the DHCP Relay Agent
- Configure IP Multicast Support
- Enable AppleTalk routing
- Connect Your Internal Network to the Internet
- Gather Troubleshooting Information

**Note**

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Enable the Routing and Remote Access service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable the Routing and Remote Access service**

1. If this server is a member of an Active Directory domain and you are not a domain administrator, instruct your domain administrator to add the computer account of this server to the **RAS and IAS Servers** security group in the domain of which this server is a member. The domain administrator can add the computer account to the **RAS and IAS Servers** security group by using Active Directory Users and Computers or with the **netsh ras add registeredserver** command. If this server is using local authentication or is authenticating against a RADIUS server, skip this step.

2. Open Routing and Remote Access.

3. By default, the local computer is listed as a server.

   To add another server, in the console tree, right-click **Server Status**, and then click **Add Server**.

   In the **Add Server** dialog box, click the applicable option, and then click **OK**.

4. In the console tree, right-click the server you want to enable, and then click **Configure and Enable Routing and Remote Access**.

5. Follow the instructions in the Routing and Remote Access Server Setup Wizard.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable LAN and WAN routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable LAN and WAN routing**

1. Open Routing and Remote Access.
2. Right-click the server name for which you want to enable routing, and then click **Properties**.
3. On the **General** tab, select the **Router** check box, and then do one of the following:
   - For LAN routing, click **Local area network (LAN) routing only**.
   - For LAN and WAN routing, click **LAN and demand-dial routing**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Routing Overview

# Manage Routing Interfaces

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage routing interfaces**

- Add a routing interface
- Add a demand-dial interface
- Configure demand-dial filters
- Configure dial-out hours
- Configure the calling router for certificate-based EAP
- Configure the answering router for certificate-based EAP
- Configure a pre-shared key for a demand-dial routing interface
- Delete an Interface

# Add a routing interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a routing interface**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. Right-click **General**, and then click **New Interface**.
4. In **Interfaces**, click the interface you want to add, and then click **OK**.
5. If applicable, complete any configuration dialog boxes for the interface.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a demand-dial interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a demand-dial interface**

1. Open Routing and Remote Access.
2. In the console tree, click **Network Interfaces**.

   **Where?**

   - Routing and Remote Access/*server name*/Network Interfaces

3. Right-click **Network Interfaces**, and then click **New Demand-dial Interface**.
4. Follow the instructions in the Demand-Dial Interface wizard.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

# Configure demand-dial filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure demand-dial filters**

1. Open Routing and Remote Access.
2. In the console tree, click **Network Interfaces**.

   **Where?**

   - Routing and Remote Access/*server name*/Network Interfaces

3. In the details pane, right-click the demand-dial interface you want to configure, and then click **Set IP Demand-dial filters**.
4. In the **Set Demand-Dial Filters** dialog box, do one or more of the following:

   - To add a demand-dial filter, click **New**, fill in the required information for the filter, and then click **OK**.
   - To modify the settings for a demand-dial filter, click the filter, click **Edit**, edit the filter, and then click OK.
   - To delete a configured demand-dial filter, click the filter, and then click **Delete**.

5. After adding or editing a filter, in the **Set Demand-dial Filters** dialog box, click the filter, and in **Initiate connection**, click the appropriate action for the filter.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Configure dial-out hours

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure dial-out hours**

1. Open Routing and Remote Access.
2. In the console tree, click **Network Interfaces**.

   **Where?**

   - Routing and Remote Access/*server name*/Network Interfaces

3. In the details pane, right-click the demand-dial interface you want to configure, and then click **Dial-out Hours**.
4. In the **Dial-out Hours** dialog box, select the appropriate day and time boxes to either permit or deny dial-out access, click either **Permitted** or **Denied**, and then click **OK**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Configure the calling router for certificate-based EAP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the calling router for certificate-based EAP**

1. Open Routing and Remote Access.
2. In the console tree, click **Network Interfaces**.

   **Where?**

   - Routing and Remote Access/*server name*/Network Interfaces

3. In the details pane, right-click the appropriate demand-dial interface, and then click **Properties**.
4. On the **Security** tab, click **Advanced (custom settings)**, and then click **Settings**.
5. Under **Logon security**, click **Use Extensible Authentication Protocol (EAP)**, click **Smart card or other certificate (TLS) (encryption enabled)**, and then click **Properties**.
6. In the **Smart Card or Other Certificate (TLS) Properties** dialog box, click **Use a certificate on this computer**.
7. To enable validation of the server certificate, select the **Validate server certificate** check box, select the **Connect to these servers** check box, and then type the DNS domain name of the answering router preceded by a period.
8. In **Trusted Root Certification Authorities**, click the root certification authority of the answering router, and then click **OK**.
9. Click **OK** to save changes to the security configuration, and then click **OK** again to save changes to the demand-dial interface.
10. In the details pane, right-click the demand-dial interface, and then click **Set credentials**.
11. In **User name on certificate**, click the user certificate for this demand-dial connection, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- If the root certification authority for the answering router does not appear, the root certification authority certificate for the answering router may be in the personal store rather than trusted root certification authorities store.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure the answering router for certificate-based EAP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the answering router for certificate-based EAP**

1. Open Routing and Remote Access.
2. Right-click the name of the remote access router, and then click **Properties**.
3. On the **Security** tab, click **Authentication Methods**.
4. In the **Authentication Methods** dialog box, select the **Extensible authentication protocol (EAP)** check box, click **OK**, and then click **OK** again.
5. In the console tree, double-click the router name, and then click **Remote Access Policies**.
6. In the details pane, right-click the remote access policy that will be used by your certificate-based routers, click **Properties**, and then click **Edit Profile**.
7. On the **Authentication** tab, select the **Extensible Authentication Protocol** check box, click **Smart card or other certificate (TLS)**, and then click **Configure**.
8. In the **Smart Card or Other Certificate (TLS) Properties** dialog box, select the machine certificate you want to use, and then click **OK**.
9. Click **OK** to save the settings of the profile, and then click **OK** again to save the settings of the policy.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Configure a pre-shared key for a demand-dial routing interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure a pre-shared key for a demand-dial routing interface**

1. Open Routing and Remote Access.
2. Click **Network Interfaces**.

   **Where?**

   - Routing and Remote Access/*server name*/Network Interfaces

3. Right-click the interface you want to configure, and click **Properties**.
4. On the **Security** tab, click **IPSec Settings**.
5. Select the **Use pre-shared key for authentication** check box, and type the pre-shared key in **Key**.
6. Click **OK** twice.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- A pre-shared key can be any non-null string of any combination of up to 255 characters. Use care when typing the pre-shared key because any differences between the pre-shared key configured on the client and the pre-shared key configured on the server will prevent connections from being made.
- If the VPN type of the demand-dial routing interface you want to configure is not set to **L2TP IPSec VPN** or **Automatic**, the **IPSec Settings** button is not available.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**Manage devices and ports**

- Enable routing on ports
- Add PPTP or L2TP ports

# Enable routing on ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable routing on ports**

1. Open Routing and Remote Access.
2. In the console tree, click **Ports**.

   **Where?**

   - Routing and Remote Access/*server name*/Ports

3. Right-click **Ports**, and then click **Properties**.
4. On the **Devices** tab, click the device you want to configure, and then click **Configure**.
5. In the **Configure Device** dialog box, select the connection options you want to enable for the device, and then click **OK**.
6. Click **Apply**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Add PPTP or L2TP ports

# Add PPTP or L2TP ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add PPTP or L2TP ports**

1. Open Routing and Remote Access.
2. In the console tree, click **Ports**.

   **Where?**

   - Routing and Remote Access/*server name*/Ports

3. Right-click **Ports**, and then click **Properties**.
4. In the **Ports Properties** dialog box, click either **WAN Miniport (PPTP)** or **WAN Miniport (L2TP)**, and then click **Configure**.
5. In **Maximum ports**, type the number of ports, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.
- You cannot set the number of PPTP ports to 0. To disable PPTP, clear the **Remote access connections (inbound only)** and **Demand-dial routing connections (inbound and outbound)** check boxes.
- When you increase the number of ports for **WAN Miniport (PPTP)** or **WAN Miniport (L2TP)** from less than 1000 ports to greater than 1000 ports, you must restart the computer to apply the change.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Routing Protocols

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage routing protocols**

- Add an IP routing protocol
- Delete an IP routing protocol
- Change preference levels

# Add an IP routing protocol

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add an IP routing protocol**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. Right-click **General**, and then click **New Routing Protocol**.
4. In **Routing protocols**, click the protocol you want to add, and then click **OK**.
5. If applicable, complete any configuration dialog boxes for the protocol.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete an IP routing protocol**

1. Open Routing and Remote Access.
2. In the console tree, click an **IP routing protocol**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/*IP routing protocol*

3. Right-click the IP routing protocol you want to delete, and then click **Delete**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Change preference levels

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change preference levels**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. Right-click **General**, and then click **Properties**.
4. On the **Preference Levels** tab, click a route source, and then click either **Move Up** or **Move Down** to change the preference level of the protocol.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Manage Static Routes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage static routes**

- Add a static route
- Delete a static route
- Add a default static IP route
- Perform Auto-Static Updates

# Add a static route

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a static route**

1. Open Routing and Remote Access.
2. In the console tree, right-click **Static Routes**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/Static Routes

3. Click **New Static Route**.
4. In the **Static Route** dialog box, enter the interface, destination, network mask, gateway, and metric. If this is a demand-dial interface, **Gateway** is unavailable. You can also select the **Use this route to initiate demand-dial connections** check box to initiate a demand-dial connection for traffic that matches the route.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Delete a static route

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete a static route**

1. Open Routing and Remote Access.
2. In the console tree, click **Static Routes**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/Static Routes

3. In the details pane, right-click the static route you want to delete, and then click **Delete**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Add a default static IP route

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a default static IP route**

1. Open Routing and Remote Access.
2. In the console tree, right-click **Static Routes**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/Static Routes

3. Click **New Static Route**.
4. In **Interface**, click the interface you want to use for the default route.
5. In **Destination**, type **0.0.0.0**.
6. In **Network mask**, type **0.0.0.0**.
7. In **Gateway**, do one of the following:

   - If the interface is a demand-dial interface, **Gateway** is unavailable. Select the **Use this route to initiate demand-dial connections** check box to initiate a demand-dial connection for traffic matching the route.
   - If the interface for this route is a LAN connection, such as Ethernet or token ring, type the IP address of the router interface that is on the same network segment as the LAN interface.

8. In **Metric**, type **1**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Perform Auto-Static Updates

# Perform Auto-Static Updates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Perform auto-static updates**

- Perform manual auto-static updates
- Perform scheduled auto-static updates

# Perform manual auto-static updates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To perform manual auto-static updates**

1. Open Routing and Remote Access.

2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, right-click the demand-dial interface you want to update, and then click **Update Routes**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

- When an auto-static update is performed, the existing auto-static routes for the interface are deleted before the update is requested from the other router. If there is no response to the request, then the router cannot replace the routes it has deleted. This may lead to a loss of connectivity to remote networks.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Perform scheduled auto-static updates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To perform scheduled auto-static updates**

1. Create a batch file that contains the **netsh** commands you need to perform an auto-static update.

2. Open Task Scheduler, double-click **Add Scheduled Task**, and then follow the instructions in the Scheduled Task wizard to schedule the batch file to run.

## Notes

- To open Task Scheduler, click **Start**, click **Control Panel**, and then double-click **Scheduled Tasks**.

- When an auto-static update is performed, the existing auto-static routes for the interface are deleted before the update is requested from the other router. If there is no response to the request, then the router cannot replace the routes it has deleted. This may lead to a loss of connectivity to remote networks.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Routers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage routers**

- Administer a remote router
- View routing tables
- Reset the Routing and Remote Access service

# Administer a remote router

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To administer a remote router**

1. Open Routing and Remote Access.
2. In the console tree, right-click **Server Status**, and then click **Add Server**.
3. In the **Add Server** dialog box, do one of the following:
   - Click **The following computer**, and type the computer name or IP address of the server.
   - Click **All routing and remote access servers in the domain**, and then type the domain containing the server you want to administer. Click **OK**, and then select the server.
   - Click **Browse Active Directory**, click **Next**, and in the **Find Routers or Remote Access Servers** dialog box, select the check boxes next to the types of servers that you want to search for. Click **OK**, and then select the server.
4. Once the remote server appears as an item in the console tree, you can administer it.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- You can administer a server running Routing and Remote Access by using Terminal Services.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View routing tables

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view routing tables**

1. Open Routing and Remote Access.
2. In the console tree, right-click **Static Routes**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/Static Routes

3. Click **Show IP Routing Table**.

- The following table shows the detail views that are available in Routing and Remote Access by right-clicking the component.

| Component | Views |
|---|---|
| IP Routing/General | TCP/IP information |
| | Multicast forwarding table |
| | Multicast statistics |
| IP Routing/General/Interface | TCP/IP information |
| | Address translations |
| | IP addresses |
| | IP routing table |
| | TCP connections |
| | UDP listener ports |
| IP Routing/Static Routes | IP routing table |
| IP Routing/OSPF | Areas |
| | Link state database |
| | Neighbors |
| | Virtual interfaces |
| IP Routing/RIP | Neighbors |
| IP Routing/NAT/Basic Firewall | DHCP Allocator information |
| | DNS Proxy information |
| IP Routing/NAT/Basic Firewall/Interface | Mappings |
| IP Routing/IGMP | Group table |

| | |
|---|---|
| IP Routing/IGMP/Interface | Interface group table |

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Reset the Routing and Remote Access service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To reset the Routing and Remote Access service**

1. Open Routing and Remote Access.
2. Right-click the computer name for which you want to reset the Routing and Remote Access service, and then click **Disable Routing and Remote Access**.
3. Right-click the computer name for which you want to reset the Routing and Remote Access service, and then click **Configure and Enable Routing and Remote Access**.
4. Follow the instructions in the Routing and Remote Access Server Setup wizard.
5. When prompted to start the Routing and Remote Access service, click **Yes**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This procedure resets the current configuration back to the default values based on your selection of options in the Routing and Remote Access wizard. This includes removing all IP routing protocols and their configurations.
- Resetting the Routing and Remote Access service does not reset your remote access policies.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add local host filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add local host filters**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, right-click the interface on which you want to set the filter, and then click **Properties**.
4. On the **General** tab, click **Inbound Filters**.
5. In the **Inbound Filters** dialog box, click **New**, and create a set of five input filters.
6. In the **Inbound Filters** dialog box, click **Drop all packets except those that meet the criteria below**, and then click **OK**.

The five filters are described in the following table.

| Filter | Example |
|---|---|
| Accept packets sent directly to your computer. | Your router is configured with an IP address of 10.1.1.1 and a subnet mask of 255.255.0.0. To allow packets with a destination of your router, add a filter with a **Destination IP address** of 10.1.1.1, a **Destination Subnet mask** of 255.255.255.255, and select **Any** as the type of protocol. |
| Accept packets broadcast to the local subnet. | The second filter enables you to receive packets that are going to the 10.1.0.0 subnetted network. Add a filter with a **Destination IP address** of 10.1.255.255, a **Destination Subnet mask** of 255.255.255.255, and select **Any** as the type of protocol. |
| Accept packets broadcast to all subnets of a class-based network. | Set this filter to allow packets going to all subnets of the network 10.0.0.0. Add a filter with a **Destination IP address** of 10.255.255.255, a **Destination Subnet mask** of 255.255.255.255, and select **Any** as the type of protocol. |
| Accept packets sent to the limited broadcast (the all-1s address) | Add a filter with a **Destination IP address** of 255.255.255.255, a **Destination Subnet mask** of 255.255.255.255, and select **Any** as the type of protocol. |
| Accept all IP multicast packets | Add a filter with a **Destination IP address** of 224.0.0.0, a **Destination Subnet mask** of 240.0.0.0, and select **Any** as the type of protocol. |

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add PPTP Filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Add PPTP filters**

- Select the PPTP interface
- Set PPTP input filters
- Set PPTP output filters

# Select the PPTP interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To select the PPTP interface**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, click the interface on which you want to enable PPTP filtering, scroll to the **IP Address** column, and write down the IP address assigned to the interface.
4. Right-click the interface, and then click **Properties**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- All six filters work together to complete PPTP filtering. The PPTP filtering is not secure unless all six filters are set correctly.
- If the six filters are the only filters configured, then the only traffic that is allowed in and out of the interface is PPTP traffic to and from the PPTP server and PPTP client on the computer running Routing and Remote Access.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set PPTP input filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set PPTP input filters**

To set PPTP input filters, you must configure up to three input filters and select the appropriate filter action.

**To add the first input filter**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, right-click the interface on which you want to add a filter, and then click **Properties**.
4. On the **General** tab, click **Inbound Filters**.
5. In the **Inbound Filters** dialog box, click **New**.
6. In the **Add IP Filter** dialog box, select the **Destination network** check box.
7. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.
8. In **Protocol**, click **Other**.
9. In **Protocol number**, type **47**, and then click **OK**.

**To add the second input filter**

1. In the **Inbound Filters** dialog box, click **New**.
2. In the **Add IP Filter** dialog box, select the **Destination network** check box.
3. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.
4. In **Protocol**, click **TCP**.
5. In **Source port**, type **0**.
6. In **Destination port**, type **1723**, and then click **OK**.

**To add the third input filter (optional)**

If the PPTP server computer is also used as a PPTP client, you need to configure an additional filter.

1. In the **Inbound Filters** dialog box, click **New**.
2. In the **Add IP Filter** dialog box, select the **Destination network** check box.
3. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.

4. In **Protocol**, click **TCP [established]**.

5. In **Source port**, type **1723**.

6. In **Destination port**, type **0**, and then click **OK**.

**To select the filter action for the input filters**

- In the **Inbound Filters** dialog box, click **Drop all packets except those that meet the criteria below**, and then click **OK**.

## Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set PPTP output filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set PPTP output filters**

To set PPTP output filters, you must configure up to three output filters and select the appropriate filter action.

**To add the first output filter**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, right-click the interface on which you want to add a filter, and then click **Properties**.
4. On the **General** tab, click **Outbound Filters**.
5. In the **Outbound Filters** dialog box, click **New**.
6. In the **Add IP Filter** dialog box, select the **Source network** check box.
7. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.
8. In **Protocol**, click **Other**.
9. In the **Protocol** box, type **47**, and then click **OK**.

**To add the second output filter**

1. In the **Outbound Filters** dialog box, click **New**.
2. In the **Add IP Filter** dialog box, select the **Source network** check box.
3. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.
4. In **Protocol**, click **TCP**.
5. In **Source port**, type **1723**.
6. In **Destination port**, type **0**, and then click **OK**.

**To add the third output filter (optional)**

If the PPTP server computer is also used as a PPTP client, you need to configure an additional filter.

1. In the **Outbound Filters** dialog box, click **New**.
2. In the **Add IP Filter** dialog box, select the **Source network** check box.
3. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.

4. In **Protocol**, click **TCP**.

5. In **Source port**, type **0**.

6. In **Destination port**, type **1723**, and then click **OK**.

**To select the filter action for the output filters**

- In the **Outbound Filters** dialog box, click **Drop all packets except those that meet the criteria below**, and then click **OK**.

## Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Add L2TP over IPSec Filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Add L2TP over IPSec filters**

- Select the L2TP over IPSec interface
- Set L2TP over IPSec input filters
- Set L2TP over IPSec output filters

# Select the L2TP over IPSec interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To select the L2TP over IPSec interface**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, click the interface on which you want to enable L2TP over IPSec filtering, scroll to the **IP Address** column, and write down the IP address assigned to the interface.
4. Right-click the interface, and then click **Properties**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- All four L2TP over IPSec input and output filters work together to complete L2TP over IPSec filtering. The L2TP over IPSec filtering is not secure unless all four filters are set correctly.
- If the four L2TP over IPSec filters are the only filters that are configured, then the only traffic that is allowed in and out of the interface is L2TP over IPSec traffic to and from the L2TP server and L2TP client on the computer running Routing and Remote Access.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set L2TP over IPSec input filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set L2TP over IPSec input filters**

To set L2TP over IPSec input filters, you must configure the filters and select the appropriate filter action.

**To add the first L2TP over IPSec input filter**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, right-click the interface on which you want to add a filter, and then click **Properties**.
4. On the **General** tab, click **Inbound Filters**.
5. In the **Inbound Filters** dialog box, click **New**.
6. In the **Add IP Filter** dialog box, select the **Destination network** check box.
7. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.
8. In **Protocol**, click **UDP**.
9. In **Source port**, type **0**.
10. In **Destination port**, type **500**, and then click **OK**.

**To add the second L2TP over IPSec input filter**

1. On the **General** tab, click **Inbound Filters**.
2. In the **Inbound Filters** dialog box, click **New**.
3. In the **Add IP Filter** dialog box, select the **Destination network** check box.
4. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.
5. In **Protocol**, click **UDP**.
6. In **Source port**, type **0**.
7. In **Destination port**, type **1701**, and then click **OK**.

**To add the third L2TP over IPSec input filter**

1. On the **General** tab, click **Inbound Filters**.

2. In the **Inbound Filters** dialog box, click **New**.

3. In the **Add IP Filter** dialog box, select the **Destination network** check box.

4. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.

5. In **Protocol**, click **UDP**.

6. In **Source port**, type **0**.

7. In **Destination port**, type **4500**, and then click **OK**.

#### To select the filter action for the input filter

- In the **Inbound Filters** dialog box, click **Drop all packets except those that meet the criteria below**, and then click **OK**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Set L2TP over IPSec output filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set L2TP over IPSec output filters**

To set L2TP over IPSec output filters, you must configure the filters and select the appropriate filter action.

**To add the first L2TP over IPSec output filter**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, right-click the interface on which you want to add a filter, and then click **Properties**.
4. On the **General** tab, click **Outbound Filters**.
5. In the **Outbound Filters** dialog box, click **New**.
6. In the **Add IP Filter** dialog box, select the **Source network** check box.
7. In **IP Address**, type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.
8. In **Protocol**, click **UDP**.
9. In **Source port**, type **500**.
10. In **Destination port**, type **0**, and then click **OK**.

**To add the second L2TP over IPSec output filter**

1. On the **General** tab, click **Outbound Filters**.
2. In the **Outbound Filters** dialog box, click **New**.
3. In the **Add IP Filter** dialog box, select the **Source network** check box.
4. In **IP Address** type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.
5. In **Protocol**, click **UDP**.
6. In **Source port**, type **1701**.
7. In **Destination port**, type **0**, and then click **OK**.

**To add the third L2TP over IPSec output filter**

1. On the **General** tab, click **Outbound Filters**.

2. In the **Outbound Filters** dialog box, click **New**.

3. In the **Add IP Filter** dialog box, select the **Source network** check box.

4. In **IP Address** type the IP address of the interface, and in **Subnet mask**, type **255.255.255.255**.

5. In **Protocol**, click **UDP**.

6. In **Source port**, type **4500**.

7. In **Destination port**, type **0**, and then click **OK**.

#### To select the filter action for the output filter

- In the **Outbound Filters** dialog box, click **Drop all packets except those that meet the criteria below**, and then click **OK**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Configure RIP for IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure RIP for IP**

- Configure RIP version 2
- Enable authentication
- Enable auto-static update mode
- Add route filters
- Add peer filters
- Add a unicast neighbor
- Enable silent RIP
- Configure Advanced RIP Settings

# Configure RIP version 2

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure RIP version 2**

1. Open Routing and Remote Access.
2. In the console tree, click **RIP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/RIP

3. In the details pane, right-click the interface you want to configure for RIP version 2, and then click **Properties**.
4. On the **General** tab, in **Outgoing packet protocol**, do one of the following:

   - If there are RIP version 1 routers on the same network as this interface, click **RIP version 2 broadcast**.
   - If there are only RIP version 2 routers on the same network as this interface, or if the interface is a demand-dial interface, click **RIP version 2 multicast**.

5. On the **General** tab, in **Incoming packet protocol**, do one of the following:

   - If there are RIP version 1 routers on the same network as this interface, click **RIP version 1 and 2**.
   - If there are only RIP version 2 routers on the same network as this interface, or if the interface is a demand-dial interface, click **RIP version 2 only**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable authentication**

1. Open Routing and Remote Access.
2. In the console tree, click **RIP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/RIP

3. In the details pane, right-click the interface on which you want to set authentication, and then click **Properties**.
4. On the **General** tab, select the **Activate authentication** check box, and in **Password**, type a password.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- Authentication is used only for RIP version 2.
- All RIP version 2 routers on a network must use matching passwords or the routers cannot process each other's route announcements.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable auto-static update mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable auto-static update mode**

1. Open Routing and Remote Access.
2. In the console tree, click **RIP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/RIP

3. In the details pane, right-click the interface on which you want to set auto-static update mode, and then click **Properties**.
4. On the **General** tab, in **Operation mode**, click **Auto-static update mode**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Add route filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add route filters**

1. Open Routing and Remote Access.
2. In the console tree, click **RIP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/RIP

3. In the details pane, right-click the interface on which you want to set route filters, and then click **Properties**.
4. On the **Security** tab, in **Action**, do one of the following:

   - If you want filters to be applied to incoming RIP-for-IP announcement packets, click **For incoming routes**.
   - If you want filters to be applied to outgoing RIP-for-IP announcement packets, click **For outgoing routes**.

5. Do one of the following:

   - To include all routes, click **Accept all routes**.
   - To specify a range of addresses to accept or exclude, click **Accept all routes in the ranges listed** or **Ignore all routes in the ranges listed**, type in the range, and click **Add**.

6. After you set route filters, click **OK**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add peer filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add peer filters**

1. Open Routing and Remote Access.
2. In the console tree, click **RIP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/RIP

3. Right-click **RIP**, and then click **Properties**.
4. On the **Security** tab, do one of the following:

   - To process all announcements from all routers, click **Accept announcements from all routers**.
   - To process announcements only from specific routers, click **Accept announcements from listed routers only**.
   - To discard all announcements from specific routers, click **Ignore announcements from listed routers**.

5. If you have selected **Accept announcements from listed routers only** or **Ignore announcements from listed routers**, in **Router IP address**, type the IP address of the router, and then click **Add**. You must add each router individually.
6. Click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- The action you select applies to all the peer routers; you cannot set the action per router.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a unicast neighbor

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a unicast neighbor**

1. Open Routing and Remote Access.
2. In the console tree, click **RIP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/RIP

3. In the details pane, right-click the interface on which you want to set unicast neighbors, and then click **Properties**.
4. On the **Neighbors** tab, do one of the following:

   - To disable the use of neighboring routers, click **Use broadcast or multicast only**.
   - To use neighboring routers in addition to broadcast or multicast, click **Use neighbors in addition to broadcast or multicast**.
   - To use neighboring routers instead of broadcast or multicast, click **Use neighbors instead of broadcast or multicast**.

5. If you chose to use neighbors, in the **IP address** box, type the IP address of the unicast neighbor, and then click **Add**. You must add each neighbor separately.
6. Click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- The option you select applies to all of the unicast neighbors.

**Information about functional differences**

# Enable silent RIP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable silent RIP**

1. Open Routing and Remote Access.
2. In the console tree, click **RIP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/RIP

3. In the details pane, right-click the interface on which you want to set silent RIP mode, and then click **Properties**.
4. On the **General** tab, in **Outgoing packet protocol**, click **Silent RIP**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Advanced RIP Settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure advanced RIP settings**

- Set timers for periodic update mode
- Set split-horizon processing
- Set poison-reverse processing

# Set timers for periodic update mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set timers for periodic update mode**

1. Open Routing and Remote Access.
2. In the console tree, click **RIP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/RIP

3. In the details pane, right-click the interface on which you want to set timer values, and then click **Properties**.
4. On the **Advanced** tab, in **Periodic announcement interval (seconds)**, **Time before routes expire (seconds)**, and **Time before route is removed (seconds)**, type the appropriate time values in seconds.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Configure OSPF

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure OSPF**

- Add the OSPF routing protocol
- Configure OSPF Global Settings
- Configure OSPF Interface Settings

## Notes

- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.

# Add the OSPF routing protocol

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add the OSPF routing protocol**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. Right-click **General**, and then click **New Routing Protocol**.
4. In the **New Routing Protocol** dialog box, click **Open Shortest Path First (OSPF)**, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Add an interface to OSPF

# Configure OSPF Global Settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure OSPF global settings**

- Create an OSPF area
- Configure ranges for an OSPF area
- Configure an ASBR
- Add a virtual interface

## Notes

- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.

# Create an OSPF area

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create an OSPF area**

1. Open Routing and Remote Access.
2. In the console tree, click **OSPF**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/OSPF

3. Right-click **OSPF**, and then click **Properties**.
4. On the **Areas** tab, click **Add**.
5. On the **General** tab, in **Area ID**, type the dotted decimal number that identifies the area.
6. To use a plaintext password, verify that the **Enable plaintext password** check box is selected.
7. To mark the area as a stub, select the **Stub area** check box.
8. In **Stub metric**, click the arrows to set the stub metric.
9. To import routes of other areas into the stub area, select the **Import summary advertisements** check box.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.
- You cannot configure the backbone area (area ID 0.0.0.0) as a stub area, and you cannot configure virtual links through stub areas.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure ranges for an OSPF area

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure ranges for an OSPF area**

1. Open Routing and Remote Access.
2. In the console tree, click **OSPF**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/OSPF

3. Right-click **OSPF**, and then click **Properties**.
4. On the **Areas** tab, click **Add**.
5. On the **Ranges** tab, in **Destination**, type the IP network ID for the range.
6. In **Network mask**, type the associated mask for the range, and then click **Add**.
7. To delete a range, click the range you want to delete, and then click **Remove**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Configure an ASBR

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure an ASBR**

1. Open Routing and Remote Access.
2. In the console tree, click **OSPF**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/OSPF

3. Right-click **OSPF**, and then click **Properties**.
4. On the **General** tab, click **Enable autonomous system boundary router**.
5. To configure external route sources, do the following:

   a. On the **External Routing** tab, click either **Accept routes from all route sources except those selected** or **Ignore routes from all route sources except those selected**.

   b. Select or clear the appropriate check boxes next to the route sources.

6. To configure external route filters, do the following:

   a. On the **External Routing** tab, click **Route Filters**.

   b. In **Destination** and in **Network mask**, type the route you want to filter, and then click **Add**.

   c. Repeat the preceding step for all the routes you want to filter.

   d. Click either **Ignore listed routes** or **Accept listed routes** depending on the appropriate filtering action, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a virtual interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a virtual interface**

1. Open Routing and Remote Access.
2. In the console tree, click **OSPF**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/OSPF

3. Right-click **OSPF**, and then click **Properties**.
4. On the **Virtual Interfaces** tab, click **Add**.
5. In **Transit area ID**, click the transit area over which you are connecting the virtual link.
6. In **Virtual neighbor router ID**, type the OSPF router ID of the router at the other endpoint of the virtual link.
7. In **Transit delay (seconds)**, click the arrows to set the transit delay in seconds.
8. In **Retransmit interval (seconds)**, click the arrows to set the retransmit interval in seconds.
9. In **Hello interval (seconds)**, click the arrows to set the hello interval in seconds.
10. In **Dead interval (seconds)**, click the arrows to set the dead interval in seconds.
11. If the backbone area is configured to have a password, in **Plaintext password**, type a password.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.
- To configure a virtual link, each virtual link neighbor must add and configure a virtual interface.
- The hello interval, dead interval, and password must match between the virtual link neighbors.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure OSPF Interface Settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure OSPF interface settings**

- Add an interface to OSPF
- Configure an OSPF interface
- Set a password on an OSPF interface
- Configure the hello and dead intervals
- Add an OSPF neighbor

## Notes

- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.

# Add an interface to OSPF

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add an interface to OSPF**

1. Open Routing and Remote Access.
2. In the console tree, click **OSPF**.

   **Where?**

   - Routing and Remote Access\server name\IP Routing\OSPF

3. Right-click **OSPF**, and then click **New Interface**.
4. In **Interfaces**, click the interface you want to add, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**

Configure an OSPF interface

# Configure an OSPF interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure an OSPF interface**

1. Open Routing and Remote Access.
2. In the console tree, click **OSPF**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/OSPF

3. In the details pane, right-click the interface you want to configure, and then click **Properties**.
4. On the **General** tab, select the **Enable OSPF for this address** check box.
5. In **Area ID**, click the ID of the area to which the interface belongs.
6. In **Router priority**, click the arrows to set the priority of the router over the interface.
7. In **Cost**, click the scroll arrows to set the cost of sending a packet over the interface.
8. If the area to which the interface belongs is enabled for passwords, in **Password**, type a password.
9. Under **Network type**, click the type of OSPF interface.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.
- If the interface has multiple IP addresses configured on it, then the **General** tab displays an **IP Address** box. You need to configure OSPF settings for each IP address on the interface.
- A router priority of **0** means that the router cannot become an OSPF-designated router.
- A larger cost means the interface is not used as much as other interfaces with a lower cost.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure the hello and dead intervals

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the hello and dead intervals**

1. Open Routing and Remote Access.
2. In the console tree, click **OSPF**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/OSPF

3. In the details pane, right-click the interface you want to configure, and then click **Properties**.
4. On the **Advanced** tab, in **Hello interval (seconds)**, type the number of seconds between transmissions of hello packets by the router on the interface.
5. In **Dead interval (seconds)**, type the number of seconds before a silent remote router is declared down.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.
- The dead interval should be a multiple of the hello interval (commonly 4).
- The hello and dead intervals must be the same for all routers attached to a common network.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Set a password on an OSPF interface

# Add an OSPF neighbor

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add an OSPF neighbor**

1. Open Routing and Remote Access.
2. In the console tree, click **OSPF**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/OSPF

3. In the details pane, right-click the interface you want to configure, and then click **Properties**.
4. On the **NBMA Neighbors** tab, in **Neighbor IP address**, type the IP interface address (not the router ID) of a router that is attached to the nonbroadcast network.
5. In **Router priority**, click the arrows to set the priority for the neighbor, and then click **Add**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.
- You need to repeat the preceding steps for all the routers that are attached to the nonbroadcast network.
- The priority determines the neighbor's eligibility to become a designated router. When an interface to a nonbroadcast network comes up, the router sends hello packets only to those neighbors eligible to become a designated router, until the identity of the designated router is discovered.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure NAT/Basic Firewall

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure NAT/Basic Firewall**

- Add network address translation
- Add and configure an interface for network address translation
- Enable network address translation addressing
- Enable network address translation name resolution
- Configure interface IP address ranges
- Configure Basic Firewall for a public interface
- Configure services and ports
- Allow or deny ICMP messages

# Add network address translation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add network address translation**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. Right-click **General**, and then click **New Routing Protocol**.
4. In the **Select Routing Protocol** dialog box, click **NAT/Basic Firewall**, and then click **OK**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

# Add and configure an interface for network address translation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add and configure an interface for network address translation**

1. Open Routing and Remote Access.
2. In the console tree, click **NAT/Basic Firewall**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/NAT/Basic Firewall

3. Right-click **NAT/Basic Firewall**, and then click **New Interface**.
4. In **Interfaces**, click the interface you want to add, and then click **OK**.
5. Do one of the following:

   - If this interface connects to the Internet, on the **NAT/Basic Firewall** tab, click **Public interface connected to the Internet** and select the **Enable NAT on this interface** check box. If you want the public interface to be protected by dynamic packet filters, select the **Enable a basic firewall on this interface** check box.
   - If this interface connects to the small office or home network, on the **NAT/Basic Firewall** tab, click **Private interface connected to private network**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- You can enable Basic Firewall without NAT for a public interface by clicking **Basic Firewall only**.
- For a dial-up connection to the Internet, select the demand-dial interface that is configured to connect to your Internet service provider (ISP).
- For a permanent connection to the Internet, select the permanent interface that is connected to your ISP.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable network address translation addressing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable network address translation addressing**

1. Open Routing and Remote Access.
2. In the console tree, click **NAT/Basic Firewall**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/NAT/Basic Firewall

3. Right-click **NAT/Basic Firewall**, and then click **Properties**.
4. On the **Address Assignment** tab, select the **Automatically assign IP addresses by using the DHCP allocator** check box.
5. (Optional) To allocate to DHCP clients on the private network, in **IP address** and **Mask**, configure the range of IP addresses.
6. (Optional) To exclude addresses from allocation to DHCP clients on the private network, click **Exclude**, click **Add**, and then configure the addresses.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Enable network address translation name resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable network address translation name resolution**

1. Open Routing and Remote Access.
2. In the console tree, click **NAT/Basic Firewall**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/NAT/Basic Firewall

3. Right-click **NAT/Basic Firewall**, and then click **Properties**.
4. For host name resolution to a DNS server, on the **Name Resolution** tab, select the **Clients using Domain Name System (DNS)** check box.
5. If you want the connection to the Internet to be initiated when a host on the private network sends a DNS name query to the Network Address Translation (NAT) computer, select the **Connect to the public network when a name needs to be resolved** check box, and then click the name of the appropriate demand-dial interface in **Demand-dial interface**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Configure interface IP address ranges

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure interface IP address ranges**

1. Open Routing and Remote Access.
2. In the console tree, click **NAT/Basic Firewall**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/NAT/Basic Firewall

3. In the details pane, right-click the interface you want to configure, and then click **Properties**.
4. On the **Address Pool** tab, click **Add**, and do one of the following:

   - If you are using a range of IP addresses that can be expressed with an IP address and a subnet mask, in **Start address**, type the starting IP address, and in **Mask**, type the subnet mask.
   - If you are using a range of IP addresses that cannot be expressed with an IP address and a subnet mask, in **Start address**, type the starting IP address, and in **End address**, type the ending IP address.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- If you have multiple address ranges, you can use **Add** to add each one separately.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Basic Firewall for a public interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure Basic Firewall**

1. Open Routing and Remote Access.
2. In the console tree, click **NAT/Basic Firewall**.

   **Where?**

   - Routing and Remote Access/*ServerName*/IP Routing/NAT/Basic Firewall

3. In the details pane, right-click the interface you want to configure, and then click **Properties**.
4. On the **NAT/Basic Firewall** tab, do one of the following:

   - Click **Public interface connected to the Internet**, and select the **Enable a basic firewall on this interface** check box.
   - Click **Basic firewall only**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- You cannot enable Internet Connection Firewall (ICF) or Windows Firewall on a server running Routing and Remote Access.
- You can allow or prevent certain types of network traffic from reaching your network by configuring additional static packet filters. You can also accept or deny certain types of Internet Control Message Protocol (ICMP) messages, traffic required for particular services, or traffic that travels through particular ports.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure services and ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure services and ports**

1. Open Routing and Remote Access.
2. In the console tree, click **NAT/Basic Firewall**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/NAT/Basic Firewall

3. In the details pane, right-click the interface you want to configure, and then click **Properties**.
4. On the **Services and Ports** tab, do one of the following:

   - If the port is associated with a common network service, review the list in **Services**, select the service, review the settings displayed, and click **OK**.
   - If the port is not associated with a common network service, or if that service is not listed under **Services**, click **Add**, provide a name for the service and the settings required for the incoming and outgoing ports, and click **OK**.
   - If you want to disable a port that is associated with a common network service, review the list in **Services**, and clear the appropriate check box.
   - If you want to disable a previously added port, review the list in **Services**, and the clear the appropriate check box for the service that you added.
   - If you want to remove a previously added port, review the list in **Services**, select the service that you added, and click **Delete**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Allow or deny ICMP messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To allow or deny ICMP messages**

1. Open Routing and Remote Access.
2. In the console tree, click **NAT/Basic Firewall**.

   **Where?**

   - Routing and Remote Access/*ServerName*/IP Routing/NAT/Basic Firewall

3. In the details pane, right-click the interface you want to configure, and then click **Properties**.
4. Click the ICMP tab, and in **Allow the following**, do the following:

   - To allow a type of ICMP message to reach your network, select the appropriate check box.
   - To prevent a type of ICMP message from reaching your network, clear the appropriate check box.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- To display a description of a message type, click the message type. The description appears under Description.

# Enable ICMP router discovery

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable ICMP router discovery**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, right-click the interface you want to enable, and then click **Properties**.
4. On the **General** tab, select the **Enable router discovery advertisements** check box.
5. In **Advertisement lifetime (minutes)**, type or select the time after which a router is considered down after hearing its last router advertisement.
6. In **Minimum time (minutes)**, type or select the minimum rate at which the router periodically sends ICMP router advertisements.
7. In **Maximum time (minutes)**, type or select the maximum rate at which the router periodically sends ICMP router advertisements.

   Based on the values of minimum time and maximum time, the router sends periodic ICMP router advertisements between the minimum and maximum times.

8. In **Level of preference**, type or select the level of preference for this router to be a default gateway for hosts.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Configure the DHCP Relay Agent

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure the DHCP Relay Agent**

- Add the DHCP Relay Agent
- Configure global DHCP Relay Agent properties
- Enable the DHCP Relay Agent on a router interface

# Add the DHCP Relay Agent

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add the DHCP Relay Agent**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. Right-click **General**, and then click **New Routing Protocol**.
4. In the **Select Routing Protocol** dialog box, click **DHCP Relay Agent**, and then click **OK**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Configure global DHCP Relay Agent properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure global DHCP Relay Agent properties**

1. Open Routing and Remote Access.
2. In the console tree, click **DHCP Relay Agent**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/DHCP Relay Agent

3. Right-click **DHCP Relay Agent**, and then click **Properties**.
4. On the **General** tab, in **Server address**, type the IP address of your DHCP server, and then click **Add**.
5. Repeat step 4 for each DHCP server you need to add, and then click **OK**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Enable the DHCP Relay Agent on a router interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable the DHCP Relay Agent on a router interface**

1. Open Routing and Remote Access.
2. In the console tree, click **DHCP Relay Agent**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/DHCP Relay Agent

3. Right-click **DHCP Relay Agent**, and then click **New Interface**.
4. Click the interface you want to add, and then click **OK**.
5. In the **DHCP Relay Properties** dialog box, on the **General** tab, verify that the **Relay DHCP packets** check box is selected.
6. If needed, in **Hop-count threshold** and **Boot threshold (seconds)**, click the arrows to modify the thresholds.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Configure IP Multicast Support

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure IP multicast support**

- Configure the IGMP Routing Protocol
- Configure multicast scopes
- Configure multicast boundaries
- Configure multicast heartbeat

# Configure the IGMP Routing Protocol

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure the IGMP routing protocol**

- Add the IGMP routing protocol
- Enable IGMP router and IGMP proxy mode
- Configure IGMP router settings

# Add the IGMP routing protocol

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add the IGMP routing protocol**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. Right-click **General**, and then click **New Routing Protocol**.
4. In the **Select Routing Protocol** dialog box, click **IGMP Router and Proxy**, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- By default, IGMP protocol version 3 is selected. To change the IGMP protocol version, select a different version when configuring a new interface for IGMP, or change the version an interface uses by right-clicking the interface and selecting **Properties**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable IGMP router and IGMP proxy mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable IGMP router and IGMP proxy mode**

1. Open Routing and Remote Access.
2. In the console tree, click **IGMP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/IGMP

3. Right-click **IGMP**, and then click **New Interface**.
4. In **Interfaces**, click the interface you want to enable, and then click **OK**.
5. In the **General** dialog box, verify that the **Enable IGMP** check box is selected.
6. Under **Mode**, do one of the following:

   - To enable IGMP router mode, click **IGMP router**.
   - To enable IGMP proxy mode, click **IGMP proxy**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- You can only enable IGMP proxy mode on a single interface.
- By default, IGMP protocol version 3 is selected. To change the IGMP protocol version, select a different version when configuring a new interface for IGMP, or change the version an interface uses by right-clicking the interface and selecting **Properties**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure IGMP router settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure IGMP router settings**

1. Open Routing and Remote Access.
2. In the console tree, click **IGMP**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/IGMP

3. In the details pane, right-click the interface you want to configure, and then click **Properties**.
4. Click the **Router** tab, and then configure the appropriate settings.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- Typically, you do not need to modify the default IGMP router settings. You should only modify these settings after you have made a careful analysis of your network.
- Items on the **Router** tab are available only if IGMP router mode is enabled on the selected interface.
- By default, IGMP protocol version 3 is selected. To change the IGMP protocol version, select a different version when configuring a new interface for IGMP, or change the version an interface uses by right-clicking the interface and selecting **Properties**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure multicast scopes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure multicast scopes**

1. Open Routing and Remote Access.
2. In the console tree, right-click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. Click **Properties**.
4. On the **Multicast Scopes** tab, click **Add**.
5. In the **Add Scoped Boundary** dialog box, do the following:

   - In **Scope name**, type the name of the multicast scope.
   - In **IP address**, type the base IP address of the range.
   - In **Mask**, type the mask of the range.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- You can also edit or remove an existing multicast scope by clicking **Edit** or **Remove** on the **Multicast Scopes** tab.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure multicast boundaries

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure multicast boundaries**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, right-click the interface on which you want to configure multicast boundaries, and then click **Properties**.
4. On the **Multicast Boundaries** tab, do the following:

   - To add a scope to the list of multicast scope boundaries, in **Scope**, click a configured scope, and then click **Add**.
   - To remove a scope from the list of multicast scope boundaries, in **Scoped boundaries**, click the scope, and then click **Remove**.
   - To enable TTL scoping, select the **Activate TTL boundary** check box, and in **TTL value**, click the arrows to set a TTL value.
   - To set a rate limit, in **Rate limit (KBps)**, type the rate in kilobytes per second.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Enable AppleTalk routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable AppleTalk routing**

1. Open Routing and Remote Access.
2. In the console tree, right-click **AppleTalk Routing**.

   **Where?**

   - Routing and Remote Access*server name*\AppleTalk Routing

3. Click **Enable AppleTalk Routing**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect Your Internal Network to the Internet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connect your internal network to the Internet**

- Connect to the Internet by using an ISDN device
- Connect to the Internet by using a modem
- Connect to the Internet by using a T1 line
- Connect to the Internet by using Frame Relay
- Connect to the Internet by using PPPoE

# Connect to the Internet by using an ISDN device

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to the Internet by using an ISDN device**

1. Install the ISDN hardware in your computer.
2. On your desktop, right-click **My Computer**, click **Properties**, and on the **Hardware** tab, click **Add Hardware Wizard**.
3. After the ISDN adapter is added and the server is restarted, verify that the ISDN adapter appears as a port under **Ports** in Routing and Remote Access.
4. To configure the ISDN port, right-click **Ports**, and then click **Properties**.
5. In the **Port Properties** dialog box, select the ISDN device you want to configure, click **Configure**, select the **Demand-dial routing connections (inbound and outbound)** check box, and then click **OK**.
6. To create a demand-dial interface and configure it to use the ISDN device to dial in to the ISP, right-click **Network Interfaces**, and then click **New Demand-dial interface**.
7. Add a default route that uses the newly created demand-dial interface.

### Note

- A default route has a **Destination** of 0.0.0.0, a **Network mask** of 0.0.0.0, and a **Metric** of 1. Because the dial-up connection to the ISP is a point-to-point link, the **Gateway** IP address is not configurable.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to the Internet by using a modem

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to the Internet by using a modem**

1. Install the modem hardware on your computer.
2. Add the modem to your computer. In Control Panel, double-click **Phone and Modem Options**.
3. If you are prompted to provide location information, do so and then click **OK**.
4. On the **Modems** tab, click **Add**. Follow the steps in the Add Hardware Wizard.
5. After the modem is added, verify that the modem appears as a port under **Ports** in Routing and Remote Access.
6. To configure the modem port, right-click **Ports**, and then click **Properties**.
7. In the **Port Properties** dialog box, select the modem you want to configure, click **Configure**, select the **Demand-dial routing connections (inbound and outbound)** check box, and then click **OK**.
8. To create a demand-dial interface and configure it to use the modem to dial in to the ISP, right-click **Network Interfaces**, and then click **New Demand-dial interface**.
9. Add a default network route that uses the newly created demand-dial interface.

### Note

- A default network route has a **Destination** of 0.0.0.0, a **Network mask** of 0.0.0.0, and a **Metric** of 1. Because the dial-up connection to the ISP is a point-to-point link, the **Gateway** IP address is not configurable.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to the Internet by using a T1 line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to the Internet by using a T1 line**

1. Install the T1 adapter in your computer.
2. On your desktop, right-click **My Computer**, click **Properties**, and on the **Hardware** tab, click **Add Hardware Wizard**.
3. Configure the T1 adapter with the IP address allocated by your ISP.
4. After the T1 adapter is added and the server is restarted, verify that the T1 adapter appears as a network adapter under **Network Interfaces** in Routing and Remote Access.
5. Add a default network route that uses the T1 interface.

### Note

- A default network route has a **Destination** of 0.0.0.0, a **Network mask** of 0.0.0.0, and a **Metric** of 1. Because the T1 connection to the ISP is a point-to-point link, the **Gateway** IP address is not configurable.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to the Internet by using Frame Relay

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to the Internet by using Frame Relay**

1. Install the Frame Relay adapter in your computer.
2. On your desktop, right-click **My Computer**, click **Properties**, and on the **Hardware** tab, click **Add Hardware Wizard**. Follow the prompts to configure the Frame Relay adapter.
3. After the Frame Relay adapter is added and the server restarted, verify that the Frame Relay adapter appears as a routing interface under **Network Interfaces** in Routing and Remote Access.
4. Add a default network route that uses the Frame Relay adapter.

### Note

- A default network route has a **Destination** of 0.0.0.0, **Network mask** of 0.0.0.0, and **Metric** of 1. Because the Frame Relay connection to the ISP is a point-to-point link, the **Gateway** IP address is not configurable.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to the Internet by using PPPoE

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to the Internet by using PPPoE**

1. Open Routing and Remote Access.
2. In the console tree, click **Ports**.

   **Where?**

   - Routing and Remote Access/*ServerName*/Ports

3. Verify that the PPPoE adapter appears as a port.
4. In the console tree, right-click Network Interfaces, click **New Demand-dial Interface**, and follow the steps of the Demand Dial Interface wizard.
5. In **Connection Type**, click **Connect using PPP over Ethernet (PPPoE)**.
6. Complete the wizard.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- The PPPoE adapter should appear as a port by default.
- Any interface you create using the Demand-Dial Interface Wizard appears under **Network Interfaces**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Gather Troubleshooting Information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Gather troubleshooting information**

- Determine the status of the Routing and Remote Access service
- Check the state of an interface
- Verify that OSPF is enabled
- Determine whether the router is receiving routes
- View RIP neighbors
- View OSPF neighbors
- Log details for a routing protocol
- Gather Demand-Dial Troubleshooting Information

**Note**

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Determine the status of the Routing and Remote Access service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To determine the status of the Routing and Remote Access service**

1. Open Computer Management.
2. In the console tree, click **Services**.

   **Where?**

   - Computer Management/Services and Applications/Services

3. In the details pane, for **Routing and Remote Access**, verify that the **Status** column is **Started**.
4. If the service is not started, right-click **Routing and Remote Access**, and then click **Start**.
5. If the router does not start, check the system event log for error messages.

**Note**

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Check the state of an interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To check the state of an interface**

1. Open Routing and Remote Access.
2. In the console tree, click **General**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/General

3. In the details pane, click the interface you want to check, and then verify the values under the **Administrative Status** and **Operational Status** columns.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Verify that OSPF is enabled

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To verify that OSPF is enabled**

1. Open Routing and Remote Access.
2. In the console tree, click **OSPF**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/OSPF

3. In the details pane, right-click the OSPF interface you want to verify, and then click **Properties**.
4. On the **General** tab, verify that the **Enable OSPF for this address** check box is selected.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.

# Determine whether the router is receiving routes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To determine whether the router is receiving routes**

1. Open Routing and Remote Access.
2. In the console tree, right-click **Static Routes**.

   **Where?**

   - Routing and Remote Access/*server name*/IP Routing/Static Routes

3. Click **Show IP routing table**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Log details for a routing protocol

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To log details for a routing protocol**

1. Open Routing and Remote Access.
2. In the console tree, right-click the routing protocol for which you want to log details, and click **Properties**.

   **Where?**

   - Routing and Remote Access/*ServerName*/IP Routing/*RoutingProtocol*

3. Click the level of detail you want to log for this routing protocol, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- You can choose what level of detail to log for any protocol that appears under the IP Routing node in Routing and Remote Access.

**Information about functional differences**

# Gather Demand-Dial Troubleshooting Information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Gather demand-dial troubleshooting information**

- Check the unreachability reason
- Check the credentials being used by the calling router
- Check the authentication provider being used by the answering router
- Check the status of the port on the answering router
- Check the status of the demand-dial interface
- Check the static route for a demand-dial interface

# Check the unreachability reason

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To check the unreachability reason**

1. Open Routing and Remote Access.
2. In the console tree, click **Network Interfaces**.

   **Where?**

   - Routing and Remote Access/*server name*/Network Interfaces

3. In the details pane, right-click the demand-dial interface you want to check, and then click **Unreachability reason**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Check the static route for a demand-dial interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To check the static route for a demand-dial interface**

1. Open Routing and Remote Access.
2. In the console tree, click **Static Routes**.

   **Where?**

   - Routing and Remote Access/*ServerName*/IP Routing/Static Routes

3. In the **Interface** column, find the name of the demand-dial interface for which you want to check the static route.
4. Verify that the destination IP address, the network mask, and the gateway IP address (if any) are correct for the router to which you want to connect.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Routing Overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing overview**
Routing and Remote Access is a full-featured software router and an open platform for routing and internetworking. It offers routing services to businesses in local area network (LAN) and wide area network (WAN) environments or over the Internet by using secure virtual private network (VPN) connections.

An advantage of the Routing and Remote Access service is integration with the Microsoft® Windows Server 2003 family. The Routing and Remote Access service delivers many cost-saving features and works with a wide variety of hardware platforms and hundreds of network adapters. The Routing and Remote Access service is extensible with application programming interfaces (APIs) that developers can use to create custom networking solutions and that new vendors can use to participate in the growing business of open internetworking.

**Note**

- A computer running a member of the Windows Server 2003 family and the Routing and Remote Access service that provides LAN and WAN routing services is hereafter referred to as a server running Routing and Remote Access.

The server running Routing and Remote Access is intended for use by system administrators who are already familiar with routing protocols and routing services. Through Routing and Remote Access, administrators can view and manage both routers and remote access servers on their networks. For security information about enabling the routing features of Routing and Remote Access, see Security information for routing.

Routing and Remote Access includes the following features:

- Multiprotocol unicast routing for Internet Protocol (IP) and AppleTalk. For more information, see Unicast routing overview.
- Industry-standard unicast IP routing protocols:
  - Open Shortest Path First (OSPF) This feature is not available on the Itanium-based versions of the Windows operating systems. This content is not available in this preliminary release.
  - Routing Information Protocol (RIP) versions 1 and 2

  For more information, see Unicast routing overview.
- IP multicast services (Internet Group Management Protocol (IGMP) router mode and IGMP proxy mode) to enable the forwarding of IP multicast traffic. For more information, see Multicast Forwarding and Routing Overview.
- The Routing And Remote Access Server Setup Wizard, which includes a set of common server configurations to help meet your network needs. For more information, see Common server configurations for remote access servers.
- Support for multiple network interfaces. For more information, see Network interfaces.
- IP network address translation (NAT) services to simplify the connection of small office or home office (SOHO) networks to the Internet. For more information, see Internet Connection Sharing and network address translation.
- A simple packet filtering service that can be enabled for any public interface, even one that is also configured for network address translation. For more information, see Basic Firewall.
- Static IP packet filtering for security and performance. For more information, see Packet filtering.
- Demand-dial routing over dial-up WAN links. For more information, see Demand-dial routing.

- Virtual private network (VPN) support with the Point-to-Point Tunneling Protocol (PPTP) and the Layer Two Tunneling Protocol (L2TP) over Internet Protocol security (IPSec), referred to as L2TP/IPSec. For more information, see Routing over VPN connections.

- Industry standard support for a Dynamic Host Configuration Protocol (DHCP) Relay Agent for IP. For more information, see DHCP Relay Agent.

- Industry standard support for router advertisement by using Internet Control Message Protocol (ICMP) router discovery. For more information, see ICMP router discovery.

- A graphical user interface for remote monitoring and configuration. For more information, see Administration and management tools.

- A command-line interface for running scripts and automating configuration and remote monitoring. For more information, see Administration and management tools.

- Support for Windows power management capabilities. For more information, see Power management support.

- Simple Network Management Protocol (SNMP) management capabilities with support for popular management information bases (MIBs). For more information, see SNMP support.

- Extensive support for media, including Ethernet, token ring, Fiber Distributed Data Interface (FDDI), asynchronous transfer mode (ATM), Integrated Services Digital Network (ISDN), T-Carrier, Frame Relay, xDSL, cable modems, X.25, and analog modems.

- APIs for routing protocols, administration, and the user interface to enable value-added development.

# Unicast routing overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Unicast routing overview**

Unicast routing is the forwarding of traffic destined to a single location on an internetwork from a source host to a destination host by using routers. An internetwork is at least two networks that are connected by routers. A router is a network layer intermediate system that is used to connect networks together based on a common network layer protocol such as TCP/IP. A network is a portion of the networking infrastructure (encompassing repeaters, hubs, and bridges/Layer 2 switches) that is bounded by routers and is associated with the same network layer address known as a network address or network ID.

A typical router is connected to two or more networks over LAN or WAN media. Computers on a network can send packets to computers on other networks by forwarding the packets to the router. The router examines the packet and uses the destination network address in the packet header to decide which interface to use to forward the packet. Through routing protocols (OSPF, RIP, and others), a router learns network information (such as network addresses) from neighboring routers, and then propagates this information to routers on other networks to enable connectivity between all computers on all networks.

The server running Routing and Remote Access can route IP and AppleTalk traffic.

**IP routing**

The IP network protocol is part of a suite of Internet protocols known as Transmission Control Protocol/Internet Protocol (TCP/IP). IP is used to communicate across any set of interconnected IP networks. IP routers are either static routers (routes are established by an administrator and do not change until the administrator changes them) or dynamic routers (routes are updated dynamically by using routing protocols).

IP routing is the forwarding of IP traffic from a source host to a destination host through IP routers. At each router, the next hop is determined by matching the destination IP address within the packet with the best route in the routing table.

Routing and Remote Access includes support for two IP unicast routing protocols:

- Routing Information Protocol (RIP) for IP
- Open Shortest Path First (OSPF) This feature is not available on the Itanium-based versions of the Windows operating systems. This content is not available in this preliminary release.

Routing and Remote Access is not limited to supporting just RIP for IP and OSPF. The server running Routing and Remote Access is an extensible platform; other vendors can create additional IP routing protocols, such as Interior Gateway Routing Protocol (IGRP) and Border Gateway Protocol (BGP).

For more information about the IP unicast routing protocols supported by Routing and Remote Access, see RIP for IP and OSPF.

**AppleTalk routing**

AppleTalk is used primarily in Apple Macintosh environments.

Routing and Remote Access includes support for the Routing Table Maintenance Protocol (RTMP) routing protocol.

# Multicast Forwarding and Routing Overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multicast forwarding and routing overview**
Unicasting is the sending of network traffic to a specific endpoint. Multicasting is the sending of network traffic to a group of endpoints. Only those members in the group of endpoints that are listening for the multicast traffic (the multicast group) process the multicast traffic. All other nodes ignore the multicast traffic.

You can use multicast traffic to:

- Discover resources on the internetwork.
- Support datacasting applications such as file distribution or database synchronization.
- Support multicasting multimedia applications such as digitized audio and video.

Multicast forwarding is the intelligent forwarding of multicast traffic. Multicast routing is the propagation of multicast group listening information. Routing and Remote Access supports multicast forwarding and limited multicast routing.

This section covers:

- Multicast forwarding overview
- Multicast routing overview

For more detailed information about multicasting, see Understanding Multicasting.

# Multicast forwarding overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multicast forwarding overview**
With multicast forwarding, a router forwards multicast traffic to networks where other multicast devices are listening. Multicast forwarding prevents the forwarding of multicast traffic to networks where there are no nodes listening.

For multicast forwarding to work across an internetwork, nodes and routers must be multicast-capable.

**Multicast-capable nodes**
A multicast-capable node must be able to:

- Send and receive multicast packets.
- Register the multicast addresses being listened to by the node with local routers, so that multicast packets can be forwarded to the network of the node.

All computers running a member of the Microsoft® Windows Server 2003 family are IP multicast-capable and can both send and receive IP multicast traffic. IP multicasting applications that send multicast traffic must construct IP packets with the appropriate IP multicast address as the destination IP address. IP multicasting applications that receive multicast traffic must inform the TCP/IP protocol that they are listening for all traffic to a specified IP multicast address.

IP nodes use the Internet Group Management Protocol (IGMP) to register their interest in receiving IP multicast traffic from IP routers. IP nodes that use IGMP send out an IGMP Membership Report message to notify their local routers that they are listening on a specific IP multicast address.

**Multicast-capable routers**
A multicast-capable router must be able to:

- Listen for all multicast traffic on all attached networks. Upon receiving multicast traffic, forward the multicast packet to attached networks where nodes are listening or where downstream routers have nodes that are listening.

  In the Windows Server 2003 family, the ability to listen for all multicast traffic and forward multicast packets is provided by the TCP/IP protocol. The TCP/IP protocol uses a multicast forwarding table to make decisions on where to forward incoming multicast traffic.

- Listen for IGMP Membership Report messages and update the TCP/IP multicast forwarding table.

  In the Windows Server 2003 family, the ability to listen for IGMP Membership Report messages and update the TCP/IP multicast forwarding table is provided by the IGMP routing protocol on an interface operating in IGMP router mode.

- Use a multicast routing protocol to propagate multicast group listening information to other multicast-capable routers.

  Routing and Remote Access does not provide any multicast routing protocols. However, the Routing and Remote Access service is an extensible platform and can support multicast routing protocols.

**Note**

- The IGMP routing protocol component provided with Routing and Remote Access is not a multicast routing protocol. The maintenance of entries in the IP multicast forwarding table is a function of IGMP.

**The IGMP routing protocol component**
Maintaining entries in the TCP/IP multicast forwarding table is implemented through the IGMP routing protocol component, a component that is added as an IP routing protocol by using Routing and Remote Access. Once the IGMP routing protocol component is added, router interfaces are added to IGMP. You can configure each interface added to the IGMP routing protocol component in one of two operating modes:

1. IGMP router mode

2. IGMP proxy mode

**IGMP router mode**
In the Windows Server 2003 family, the ability to listen for IGMP Membership Report packets and track group membership is provided by an interface running in IGMP router mode. You must enable IGMP router mode on the interfaces where listening multicast hosts are located.

For more information about the IGMP router mode, see Multicast forwarding.

**IGMP proxy mode**
An interface running in IGMP proxy mode acts as a proxy multicast host that sends IGMP Membership Report messages on one interface for IGMP Membership Report messages received on all other interfaces running in IGMP router mode. The upstream router attached to the network of the IGMP proxy mode interface receives the IGMP proxy mode Membership Report packets and adds them to its own multicast tables. In this way, the upstream router knows to forward multicast packets to the network segment of the IGMP proxy mode interface for multicast groups that were registered by hosts attached to network segments of the IGMP proxy mode router.

When the upstream router forwards multicast traffic to the IGMP proxy mode interface network, it is forwarded to the appropriate hosts on the IGMP router mode interface networks by the TCP/IP protocol.

All nonlocal multicast traffic received on all interfaces running IGMP router mode is forwarded using the IGMP proxy mode interface. The upstream router that receives the forwarded multicast traffic can elect to forward the multicast traffic or discard it. Using IGMP proxy mode, multicast sources on networks attached to the server running Routing and Remote Access can send multicast traffic to multicast hosts attached to upstream multicast routers.

IGMP proxy mode is designed to pass IGMP Membership Report messages from a single router intranet to a multicast-capable portion of the Internet. The multicast-capable portion of the Internet is known as the Internet multicast backbone, or MBone. With IGMP proxy mode enabled on the Internet interface, hosts on the single router intranet can receive multicast traffic from multicast sources on the Internet and send multicast traffic to hosts on the Internet.

For more information about using IGMP proxy mode interfaces, see Multicast routing.

# Multicast routing overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multicast routing overview**

With multicast routing, multicast-capable routers communicate multicast group membership information to each other so that intelligent multicast forwarding decisions are made across the internetwork. Multicast routers use multicast routing protocols to communicate multicast group information with each other.

Examples of multicast routing protocols include Distance Vector Multicast Routing Protocol (DVMRP), Multicast Extensions to OSPF (MOSPF), Protocol Independent Multicast-Sparse Mode (PIM-SM), and Protocol Independent Multicast-Dense Mode (PIM-DM). The Windows Server 2003 family does not include any multicast routing protocols. However, Routing and Remote Access is an extensible platform; other vendors can create multicast routing protocols.

**Note**

- Open Shortest Path First (OSPF) is not available on Microsoft® Windows® XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Security information for routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security information for routing**

Before you enable the routing functions of Routing and Remote Access, you should carefully review your network infrastructure so that you can configure Routing and Remote Access to best meet your needs for security and functionality. Security for Routing and Remote Access can be considered in three parts: securing the server running Routing and Remote Access, securing the network traffic between the server and its clients, and using secure authentication methods.

Unless your server running Routing and Remote Access is functioning only as a router, you should also consider security for your remote access solution. For more information, see Security information for remote access.

In addition to understanding the security implications of enabling Routing and Remote Access on your network, you should also practice general server security, as described in Security. For example, you should use only servers that are running Microsoft® Windows® 2000 or a member of the Microsoft® Windows Server 2003 family, if possible. You will decrease your network security if you use servers that are running Routing and Remote Access on the same network as servers that are running Microsoft Windows NT® 4.0 and either Remote Access Service (RAS) or Routing and Remote Access Service (RRAS). For more information, see Domain and forest functionality and Member server in a domain.

Before you configure and enable the routing features of Routing and Remote Access, you should consider the following:

- **Who can enable, configure, and disable Routing and Remote Access**. You must be a member of the Administrators group to use the Routing and Remote Access snap-in, either on its own or within the Microsoft Management Console (MMC). Similarly, you must be a member of the Administrators group to run most of the **netsh routing** commands from the command line. You should restrict the membership of the Administrators group to the minimum number of users necessary to administer the server. For more information, see Default local groups and Default groups.

- **How to open Routing and Remote Access**. As a security best practice, you should consider using the **runas** command to open Routing and Remote Access rather than logging on with administrative credentials. For more information about why you might not want to log on with administrative credentials, see Why you should not run your computer as an administrator. To open Routing and Remote Access when you are not logged on as a member of the Administrators group, type the following at the command prompt:

  **runas /user:**[*Domain/*]*UserName***"mmc %windir%\system32\rrasmgmt.msc"**

  The user name that you provide must correspond to the Administrator account or an account that is a member of the Administrators group, and you must provide the password for the account when prompted. For more information, see Runas.

- **Which routing components your network requires**. You should document how your network is designed, what routing components it requires, and how those components are configured. This information can help you maintain your network and identify potential areas requiring special concern or improvement.

- **Whether you can simplify your network topology**. Simpler networks are easier to maintain, and they provide fewer attack points. Simplifying your network might include:

  - **Minimizing the number of network interfaces**. Although most servers running Routing and Remote Access are multihomed computers, you should configure as few network interfaces as possible. If possible, you should not configure the server running Routing and Remote Access with more than one public interface. For more information, see Network interfaces.

  - **Minimizing the number of routes**. You should use as few demand-dial and static routes as possible. For more information, see Demand-dial routing and Static routing design considerations.

  - **Minimizing the number of routing protocols in use**. You should track what routing protocols are enabled and how they are configured, and then you should configure and enable as few routing protocols as possible. For

example, unless your network requires AppleTalk, you should not enable AppleTalk routing on the server running Routing and Remote Access.

- **Which tunneling protocols to use**. If you are configuring a router-to-router virtual private network (VPN), you should consider using Layer Two Tunneling Protocol (L2TP) instead of Point-to-Point Tunneling Protocol (PPTP). For more information, see VPN Router-to-Router tunneling protocols and Security information for remote access.

- **Whether to use packet filters, firewalls, and other network traffic protection**. You should restrict routing network traffic to the minimum level that your network requires. You should also consider using IP filters in your default remote access policy to ensure that inbound network traffic comes from authorized remote access clients.

    - In Routing and Remote Access, you can configure static packet filters on network interfaces and enable Basic Firewall on public interfaces. You can use these security features alone or in conjunction with other software, such as Internet Authentication Service (IAS). For more information, see Basic Firewall, Packet filtering, and Internet Authentication Service.

    - You cannot configure Routing and Remote Access if Internet Connection Firewall (ICF) or Windows Firewall is enabled. Before you configure Routing and Remote Access, you must disable Internet Connection Firewall or Windows Firewall. For more information about Windows Firewall, see Help: Windows Firewall.

- **What level of logging to use**. You should consider how much information you want to log for each routing protocol. Routing and Remote Access has several logging options. Additionally, you can use features in IAS for more detail and centralized accounting and auditing. For more information, see Logging and Internet Authentication Service.

# Common server configurations for remote access servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Common configurations for remote access servers**

When you run the Routing and Remote Access Server Setup Wizard, the wizard prompts you to choose the configuration path that most closely resembles the remote access solution that you want to deploy. If none of the wizard configuration paths meets your needs exactly, you can further configure your server after the wizard finishes, or you can choose the custom configuration path. However, if you choose the custom configuration path, you must manually configure all elements of Routing and Remote Access. The most common remote access solutions include dial-up connections, virtual private network (VPN) connections, and secure connections between two private networks.

**Remote access (dial-up)**

If you choose this path, the server running Routing and Remote Access is configured to allow remote access clients to connect to the private network by dialing into a modem bank or other dial-up equipment. To configure this type of server in the wizard, click **Remote Access**, select the **Dial-up** check box, and follow the steps. After the wizard finishes, you can configure additional options. For example, you can configure how the server answers the call, how the server verifies which remote access clients have permission to connect to the private network, and whether the server routes network traffic between remote access clients and the private network. For more information about dial-up connections, see Dial-Up Networking and Setting Up Dial-Up Remote Access.

**Remote access (VPN)**

If you choose this path, the server running Routing and Remote Access is configured to allow remote access clients to connect to the private network across the Internet. To configure this type of server in the wizard, click **Remote Access**, select the **VPN** check box, and follow the steps. After the wizard finishes, you can configure additional options. For example, you can configure how the server verifies which VPN clients have permission to connect to the private network and whether the server routes network traffic between VPN clients and the private network. For more information about VPNs, see Deploying VPNs for Remote Access and Common configuration for the VPN server.

**Network address translation (NAT)**

If you choose this path, the server running Routing and Remote Access is configured to share an Internet connection with

computers on the private network and to translate traffic between its public address and the private network. Computers on the Internet will not be able to determine the IP addresses of computers on the private network. To configure this type of server in the wizard, click **Network address translation (NAT)**, and follow the steps. After the wizard finishes, you can configure additional options. For example, you can configure packet filters and choose what services to allow on the public interface. For more information about NAT, see Setting Up Network Address Translation and Translated Connection to the Internet.

**VPN and NAT**

If you choose this path, the server running Routing and Remote Access is configured to provide NAT for the private network and to accept VPN connections. Computers on the Internet will not be able to determine the IP addresses of computers on the private network. However, VPN clients will be able to connect to computers on the private network as if they were physically attached to the same network. To configure this type of server in the wizard, click **Virtual Private Network (VPN) access and NAT**, and follow the steps. For more information about NAT and VPN, see New features for virtual private networks and Network address translation design considerations.

**Secure connection between two private networks**

If you choose this path, two servers running Routing and Remote Access are configured to send private data securely across the Internet. You must choose this path when you run the Routing and Remote Access Server Setup Wizard on each server. The connection between the two servers can be persistent (always on) or on demand (demand-dial). To configure this type of server in the wizard, click **Secure connection between two private networks**, and follow the steps. After the wizard finishes, you can configure each server with additional options. For example, you can configure what routing protocols each server accepts and how each server routes traffic between the two networks. For more information about connections between two networks, see Deploying Router-to-Router VPNs, Branch Office over the Internet, and Dial-Up Branch Office Network.

# Network interfaces

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network interfaces**
Network interfaces enable any server running Routing and Remote Access to communicate with other computers over private or public networks. Network interfaces have two aspects that relate to Routing and Remote Access: the physical hardware, such as a network adapter, and the network interface configuration.

**Physical hardware**
Network interface hardware, commonly called network adapters, can be any adapter that plugs into the system bus of a computer and allows that computer to connect to a network. Most servers running Routing and Remote Access have at least two network adapters. This is required if the server running Routing and Remote Access is acting as a router between two network segments. A server that has two or more network adapters connecting to separate networks is called multihomed.

**Important**

- Because multihomed servers are accessible from more than one network, they have more security requirements than a server that is connected to a single network. Each network interface must be configured correctly in order to protect the server and the private networks to which the server connects. For more information, see Security information for routing and Security information for remote access.

The server running Routing and Remote Access usually detects all network adapters automatically when the Routing and Remote Access Server Setup Wizard is run. If you install an additional network adapter after the wizard has been run, you can add and configure the interface using Routing and Remote Access. For more information, see Add a routing interface.

**Network interface configuration**
In Routing and Remote Access, network interfaces fall into the following categories:

- **Private interface**. A private interface is a network adapter that is physically connected to a private network. Most private networks are configured with a private network IP address range, and the private interface is also configured with a private address. Because a private network is, in theory, composed of known users and computers, you generally have fewer security considerations for a private interface than for a public interface. For more information, see Internet private addresses.

- **Public interface**. A public interface is a network adapter that is physically connected to a public network, such as the Internet. The public interface is configured with a public IP address. You can configure a public interface to perform network address translation (NAT). Because a public interface is theoretically accessible by anyone on the public network, security considerations are generally higher for a public interface than for a private interface.

- **Demand-dial interface**. Demand-dial interfaces connect specific routers on either public or private networks. A demand-dial interface can be either on-demand (activated only when needed) or persistent (always connected). For more information, see Demand-dial routing.

In addition to configuring each network interface as a public, private, or demand-dial interface, you can configure packet filters, addresses, and other options for network interfaces. Some options for public interfaces, such as Basic Firewall, are not available for private interfaces. For more information about the kind of configuration you might want to consider and example implementations, see Routing Scenarios and Remote Access Scenarios.

# Internet Connection Sharing and network address translation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Connection Sharing and network address translation**
To connect a small office or home office (SOHO) network to the Internet, you can use one of two methods:

1. Routed connection

   For a routed connection, the server running Routing and Remote Access acts as an IP router that forwards packets between SOHO hosts and Internet hosts. While conceptually simple, a routed connection requires knowledge of IP address and routing configuration for SOHO hosts and the server running Routing and Remote Access. However, routed connections allow all IP traffic between SOHO hosts and Internet hosts. For more information, see SOHO Network to the Internet.

2. Translated connection

   For a translated connection, the server running Routing and Remote Access acts as an network address translator: an IP router that translates addresses for packets being forwarded between SOHO hosts and Internet hosts. This is called network address translation, or NAT. Translated connections that use a server running Routing and Remote Access require less knowledge of IP addressing and routing and provide a simplified configuration for SOHO hosts. However, translated connections might not allow all IP traffic between SOHO hosts and Internet hosts.

You can configure a translated connection to the Internet by using one of the following methods.

- You can use the Internet Connection Sharing feature of Network Connections. Internet Connection Sharing and Network Bridge are not included in Windows Server 2003, Web Edition; Windows Server 2003, Datacenter Edition; and the Itanium-based versions of the original release of the Windows Server 2003 operating systems.

- You can use the Network Address Translation (NAT) routing protocol provided with the Routing and Remote Access snap-in on servers running Windows Server 2003 and Routing and Remote Access.

Both Internet Connection Sharing and NAT provide translation, addressing, and name resolution services to SOHO hosts.

Internet Connection Sharing is designed to provide a single step of configuration (a single check box) in order to provide a translated connection to the Internet for all of the computers on the SOHO network. However, once enabled, Internet Connection Sharing does not allow further configuration beyond the configuration of services and ports on the SOHO network. For example, Internet Connection Sharing is designed for a single IP address obtained from an Internet service provider (ISP) and does not allow you to change the range of IP addresses allocated to SOHO hosts. For more information, see Connecting to the Internet in a home or small office network.

The NAT routing protocol component is designed to provide maximum flexibility in the configuration of the server running Routing and Remote Access to provide a translated connection to Internet. The NAT routing protocol component requires more configuration steps; however, each step of the configuration is customizable. Most of the configuration can be accomplished using the Routing and Remote Access server Setup Wizard. The NAT routing protocol component allows for ranges of IP addresses from an ISP and the configuration of the range of IP addresses allocated to SOHO hosts. For more information, see Understanding Network Address Translation.

The following table summarizes the features and capabilities of Internet Connection Sharing and the NAT routing protocol component.

| **Internet Connection Sharing** | **Network address translation** |
|---|---|
| Single check box configuration | Manual configuration |
| Single public IP address | Multiple public IP addresses |

| | |
|---|---|
| Fixed address range for SOHO hosts | Configurable address range for SOHO hosts |
| Single SOHO interface | Multiple SOHO interfaces |

**Notes**

- Internet Connection Sharing is a feature designed to connect SOHO networks to the Internet. The NAT routing protocol component is designed to connect small to medium business networks to the Internet. Neither Internet Connection Sharing nor the NAT routing protocol component is designed to:
    - Directly connect SOHO networks.
    - Connect networks within an intranet.
    - Directly connect branch office networks to a corporate network.
    - Connect branch office networks to a corporate network over the Internet.

# Basic Firewall

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Securing your network with Basic Firewall**
You can use Basic Firewall to help secure your network from unsolicited public network traffic, such as traffic sent from the Internet. People who send such traffic might be trying to access your network without your permission. You can enable Basic Firewall for any public interface, including one that also provides network address translation (NAT) for your network.

**How Basic Firewall works**
Basic Firewall is a stateful firewall, which combines dynamic packet filtering of network traffic with a set of static packet filters. Basic Firewall monitors traffic that travels through the interface for which Basic Firewall is enabled.

If the interface is configured for private network traffic only, Basic Firewall will route traffic among the computers on the private network only. Basic Firewall will route traffic between a private network and virtual private network (VPN) client computers. However, computers that are part of a private network will not be able to detect computers outside of the private network, and computers that are not part of the private network will not be able to detect computers that belong to the private network.

If the interface is configured for private network traffic and to provide NAT, each packet's source and destination addresses are recorded in a table. All traffic from the public network is compared to the entries in the table. Traffic from the public network can reach the private network only if the table contains an entry that shows that the communication exchange originated from within the private network. In this way, Basic Firewall prevents unsolicited traffic from a public network (such as the Internet) from reaching a private network.

For more information about packet filters and how they work, see Packet filtering. For information on configuring Basic Firewall, see Configure Basic Firewall for a public interface.

**Considerations when using Basic Firewall**
You do not need to use Basic Firewall if your network has other firewall software installed. Basic Firewall can provide protection only for public interfaces. You cannot enable Basic Firewall on a private interface. You must configure each instance of Basic Firewall individually to work correctly with all services and ports on that interface. For more information, see Network interfaces.

You can configure exceptions for certain types of traffic if Basic Firewall blocks traffic that your network should receive. For example, some programs, such as e-mail programs, might behave differently if Basic Firewall is enabled. For information on configuring exceptions, see Configure services and ports, Packet filtering, and Allow or deny ICMP messages.

You can further protect your private network by configuring static packet filters on private interfaces. Unlike Basic Firewall, static packet filters can be configured on private interfaces.

You can configure Basic Firewall when you configure and enable Routing and Remote Access or after Routing and Remote Access has been enabled. You cannot enable Internet Connection Firewall or Windows Firewall if Routing and Remote Access is configured and enabled. You cannot configure and enable Routing and Remote Access if Internet Connection Firewall or Windows Firewall is enabled. For more information about Windows Firewall, see Help: Windows Firewall.

**Basic Firewall logging and settings**
By default, Basic Firewall does not log an event when it discards unsolicited network traffic. Notifications of discarded traffic can be sent frequently enough to be a distraction to the network administrator. You can enable logging if you want to be notified when Basic Firewall discards traffic. For example, the default configuration of Basic Firewall does not allow echo requests sent from the Internet to reach a private network. If you enable logging and you do not allow echo requests to reach your network, the echo request fails, and a log entry that notes the failed attempt is generated. For more information, see Configure logging and Log details for a routing protocol.

# Packet filtering

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Packet filtering**
Routing and Remote Access supports IP packet filtering, which specifies what type of traffic is allowed into and out of the router. The packet filtering feature is based on exceptions. You can set packet filters per interface and configure them to do one of the following:

- Pass through all traffic except packets prohibited by filters.
- Discard all traffic except packets allowed by filters.

For more information about packet filtering, see Manage Packet Filters.

For detailed information about IP packet filtering, including examples of filtering configurations and fragmentation filtering, see "Part One: Routing" at the Microsoft® Windows® Resource Kits Web site.

**Protocols and Ports for Packet Filtering**
The following table details some of the common ports and protocols that you might want to allow, depending on your remote access configuration. Not all ports listed here might be required for your remote access server. For example, if you are allowing only Layer Two Tunneling Protocol (L2TP), you would not configure a filter for Point-to-Point Tunneling Protocol (PPTP). Similarly, this table might not contain all of the ports that your specific network needs.

**Ports Used for Protocols**

| Protocol | Port | Used For |
|---|---|---|
| TCP | 25 | Simple Mail Transfer Protocol (SMTP) |
| TCP | 67 | Dynamic Host Control Protocol (DHCP) (if the remote access server uses an external DHCP server) |
| TCP | 80 | World Wide Web (HyperText Transfer Protocol (HTTP)) |
| TCP | 110 | Post Office Protocol, version 3 (POP3) |
| TCP | 1701 | L2TP |
| TCP | 1723 | PPTP |
| TCP | 7250 | Network Access Quarantine Control (Remote Access Quarantine Client (RQC) messages from client computers) |
| UDP | 53 | Domain Name Service (DNS) (for name resolution of external Web sites) |
| UDP | 67 | DHCP (if the remote access server uses an external DHCP server) |
| UDP | 500 | Internet Protocol Security (IPSec) |
| UDP | 1701 | L2TP |
| UDP | 1723 | PPTP |
| UDP | 4500 | IPSec with network address translation (NAT) |
| | 47 | Generic Routing Encapsulation (GRE) |
| | 50 | Encapsulating Security Payload (ESP) (for firewalls that use NAT traversal [NAT-T]) |

**Note**

- To support Windows Update, you must allow TCP traffic to travel inbound and outbound on port 80 and UDP traffic to

travel inbound and outbound on port 53. Depending on your network configuration, you might have to configure these filters on your remote access server, on your firewall, or both.

# Demand-dial routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Demand-dial routing**

Routing and Remote Access also includes support for demand-dial routing (also known as dial-on-demand routing). By using a demand-dial interface, the router can initiate a connection to a remote site when the packet to be routed is received by the router. The connection becomes active only when data is sent to the remote site. When no data has been sent over the link for a specified amount of time, the link is disconnected. By making a demand-dial connection, you can use existing dial-up telephone lines instead of leased lines for low-traffic situations. Demand-dial routing can significantly reduce your connection costs.

Routing and Remote Access also includes support for demand-dial filters and dial-out hours.

You can use demand-dial filters to specify what types of traffic are allowed to create the connection. Demand-dial filters are separate from IP packet filters, which you configure to specify what traffic is allowed into and out of an interface once the connection is made. For more information about configuring demand-dial filters, see Configure demand-dial filters.

You can set dial-out hours to specify the hours that a router is allowed to dial out to make demand-dial connections. For more information about configuring dial-out hours, see Configure dial-out hours.

You can configure when the router accepts incoming connections through remote access policies. For more information, see Introduction to remote access policies.

For more information about demand-dial routing and an example, see Understanding Demand-Dial Routing.

# Routing over VPN connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing over VPN connections**

Conventional routing occurs between routers over either LAN-based shared access technologies, such as Ethernet or token ring, or WAN-based point-to-point technologies, such as T1 or Frame Relay. With conventional WAN technologies, IP packets are forwarded between two routers over a physical or logical point-to-point connection. This connection is dedicated to the customer across a private data network that is provided by the WAN service provider.

With the advent of the Internet, you can now route packets between routers that are connected to the Internet across a virtual connection that emulates the properties of a dedicated, private, point-to-point connection. This type of connection is known as a *router-to-router virtual private network (VPN)* connection. With router-to-router VPN connections, you can replace expensive long-haul WAN links with short-haul WAN links to your local Internet service provider (ISP).

To emulate a private, point-to-point connection, a packet that is forwarded between routers is encapsulated, or wrapped, with an additional header that provides routing information that is needed to reach the endpoint. The endpoints of the connection are the routers. The portion of the virtual private networking connection in which your data is encapsulated is called the tunnel.

For secure VPN connections, the data portion of your packets is encrypted. Intercepted packets are undecipherable without the encryption keys. The portion of the virtual private networking connection in which your data is encrypted is called the *virtual private network (VPN) connection*. In router-to-router VPN connections, the tunnel and the VPN connection are the same.

For general information about VPN technology, see Virtual Private Networks.

For more information about router-to-router VPNs, see Understanding Router-to-Router VPNs.

For information about designing and deploying a router-to-router VPN connection, see Deploying Router-to-Router VPNs.

For an example of a router-to-router VPN connection, see Branch Office over the Internet.

**Note**

- On Microsoft® Windows Server™ 2003, Web Edition, and Microsoft Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

# DHCP Relay Agent

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP Relay Agent**
The DHCP Relay Agent component is a Bootstrap Protocol (BOOTP) relay agent that relays Dynamic Host Configuration Protocol (DHCP) messages between DHCP clients and DHCP servers on different IP networks. The DHCP Relay Agent is compliant with RFC 1542, "Clarifications and Extensions for the Bootstrap Protocol." For each IP network segment that contains DHCP clients, either a DHCP server or a computer acting as a DHCP Relay Agent is required.

For information about installing and configuring the DHCP Relay Agent component, see Configure the DHCP Relay Agent.

### Notes

- You cannot use the DHCP Relay Agent component on a computer running the DHCP service, the network address translation (NAT) routing protocol component with automatic addressing enabled, or Internet Connection Sharing (ICS).

- Internet Connection Sharing and Network Bridge are not included in Windows Server 2003, Web Edition; Windows Server 2003, Datacenter Edition; and the Itanium-based versions of the original release of the Windows Server 2003 operating systems.

# ICMP router discovery

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ICMP router discovery**

To configure IP hosts with the IP addresses of local routers and provide a way for hosts to sense routers that are down, you can use Internet Control Message Protocol (ICMP) messages for router solicitation and advertisement (as described in RFC 1256, "ICMP Router Discovery Messages"):

- Router solicitations are sent by hosts to discover routers on their networks.
- Router advertisements are sent by routers in response to a router solicitation and periodically to notify hosts on the network that the router is still available.

The Microsoft® Windows Server 2003 family implementation of the TCP/IP protocol supports ICMP router solicitations and the receipt of ICMP router advertisements, but they are disabled by default. Routing and Remote Access supports ICMP router advertisements. For more information about enabling ICMP router solicitation, see Enable ICMP router discovery.

# Administration and management tools

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administration and management tools**

Routing and Remote Access includes the following routing administration and management tools:

- Routing and Remote Access

  The primary administration and management tool for configuring routing is Routing and Remote Access (available in the Administrative Tools folder in Control Panel).

  With Routing and Remote Access, you can:

  - Configure and enable, disable, start, and stop the Routing and Remote Access service.
  - Manage local and remote routers.
  - Configure routing behavior and routing protocols.
  - Configure demand-dial routing behavior.
  - Configure remote access policies.
  - Monitor active connections.
  - Configure local logging behavior.

  Members of the Administrators group can use Routing and Remote Access. If the computer is a member of a domain, members of the Domain Administrators group can use Routing and Remote Access.

- The Netsh command-line utility

  You can use the Netsh command-line utility to locally configure routing from the command prompt. The Netsh utility can use script files to automate configuration tasks.

  For more information about the Netsh utility, see The Netsh Command-Line Utility.

**Notes**

- You cannot use a server running a member of the Microsoft® Windows Server 2003 family to administer servers running Microsoft Windows NT® 4.0 and Remote Access Service (RAS) or to administer servers running Windows NT 4.0 and Routing and Remote Access Service (RRAS). For more information, see Administration tools in mixed environments.

- You cannot remotely configure AppleTalk routing properties with Routing and Remote Access.

# Power management support

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Power management support**

Power management support for Routing and Remote Access is listed in the following table. The first column indicates the configuration of the server running Routing and Remote Access, the second column indicates whether the computer goes into sleep mode based on an Advanced Configuration and Power Interface (ACPI) or Advanced Power Management (APM)-initiated sleep mode request, and the last column indicates whether the computer goes into sleep mode based on a user-initiated sleep mode request.

| Configuration of the server running Routing and Remote Access | ACPI/APM-initiated sleep mode | User-initiated sleep mode |
|---|---|---|
| LAN and WAN router | No | Yes |
| LAN only router | No | No |
| Router with an active VPN connection | No | Yes |
| Router with active network address translation | No | Yes |
| Remote access server | No | Yes |
| Remote access server with an active dial-up connection | No | Yes |
| Remote access server with an active VPN connection | No | Yes |

**Note**

- If there are active connections when a user-initiated sleep mode request is made, you are not informed. The active connections are terminated.

# SNMP support

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SNMP support**

If you want the Routing and Remote Access service to participate in a Simple Network Management Protocol (SNMP) environment as an SNMP agent, you need to install the SNMP service. For more information, see Install the SNMP service.

Routing and Remote Access supports the following management information bases (MIBs):

- Internet MIB II

  Objects in the Internet MIB II are documented in RFC 1213, "Management Information Base for Network Management of TCP/IP-based internets: MIB-II."

- IP Forwarding Table MIB

  Objects in the IP Forwarding Table MIB are documented in RFC 1354, "IP Forwarding Table MIB."

- Microsoft RIP Version 2 for Internet Protocol MIB

- Wellfleet-Series7-MIB for OSPF. Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

- Microsoft BOOTP for Internet Protocol MIB

- Internet Group Management Protocol MIB

  Objects in the Internet Group Management Protocol MIB are documented in RFC 2933, "Internet Group Management Protocol MIB."

For more information about the SNMP service, see SNMP.

# Understanding Routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding routing**

The routing services included with Windows NT Server 4.0, MultiProtocol Routing (MPR) version 1.0, provided a limited set of LAN-based routing services suitable for smaller organizations and branch offices. In June 1996, Microsoft offered the Routing and Remote Access Service as a free download component from the Microsoft Web site. The Routing and Remote Access Service for Windows NT 4.0, also known as RRAS, integrated routing and remote access services, extended the internetworking and routing capabilities available in MPR 1.0, and enabled routing over WANs and dial-up links. Windows 2000 offered Routing and Remote Access, a new service distinct from RRAS, that included expanded dial-in and VPN networking capabilities. The version of Routing and Remote Access included with the Windows Server 2003 family extends the capabilities of the Windows 2000 Routing and Remote Access service with simplified configuration for demand-dial routing, dynamic as well as static packet filtering, IPSec translation over network address translation (NAT) interfaces, and many other features.

This section covers:

- Understanding Unicast Routing
- Understanding Multicasting
- Understanding Network Address Translation
- Understanding Demand-Dial Routing
- Understanding Router-to-Router VPNs

# Understanding Unicast Routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding unicast routing**
Unicast routing, the forwarding of traffic to a specific destination address, is facilitated by knowing where traffic can be delivered in the internetwork. At each hop in the path from the source to the destination, a routing decision is made.

This section covers:

- Routing tables
- Routing Configurations
- IP Routing Protocols
- Routing interfaces, devices, and ports

# Routing tables

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing tables**

The routing decision is aided by knowing which network addresses (or network IDs) are available in the internetwork. This knowledge is obtained from a database called the routing table. The routing table is a series of entries called routes that contain information on where the network IDs of the internetwork are located. The routing table is not exclusive to a router. Hosts (non-routers) may also have a routing table that is used to determine the optimal route.

**Types of routing table entries**

Each entry in the routing table is considered a route and is one of the following types:

- Network route

  A network route provides a route to a specific network ID in the internetwork.

- Host route

  A host route provides a route to an internetwork address (network ID and node ID). Host routes are typically used to create custom routes to specific hosts to control or optimize network traffic.

- Default route

  A default route is used when no other routes in the routing table are found. For example, if a router or host cannot find a network route or host route for the destination, the default route is used. The default route simplifies the configuration of hosts. Rather than configuring hosts with routes for all the network IDs in the internetwork, a single default route is used to forward all packets with a destination network or internetwork address that was not found in the routing table.

**Routing table structure**

The following illustration shows the structure of the routing table.

Each entry in the routing table consists of the following information fields:

- Network ID

  The network ID or an internetwork address for a host route. On IP routers, there is an additional subnet mask field that determines the IP network ID from a destination IP address.

- Forwarding address

  The address to which the packet is forwarded. The forwarding address is a hardware address or an internetwork address. For networks to which the host or router is directly attached, the forwarding address field may be the address of the interface that is attached to the network.

- Interface

  The network interface that is used when packets are forwarded to the network ID. This is a port number or other type of

logical identifier.

- Metric

  A measurement of the preference of a route. Typically, the lowest metric is the most preferred route. If multiple routes exist to a given destination network, the route with the lowest metric is used. Some routing algorithms only store a single route to any network ID in the routing table, even when multiple routes exist. In this case, the metric is used by the router to determine which route to store in the routing table.

**Note**

- The preceding list is intended to be a representative list of fields in the routing tables used by routers. Actual fields in the routing tables for different routable protocols may vary.

# Routing Configurations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing configurations**
You can use routers in many different topologies and network configurations. When you add a server running Routing and Remote Access configured as a router to your network, you must select:

- The protocols to be routed (IP or AppleTalk) by the router.
- Routing protocols (RIP or OSPF) for each protocol to be routed.
- LAN or WAN media (network adapters, modems, or other dial-up equipment).

This section describes three typical routing scenarios:

- A simple routing scenario
- A multiple-router scenario
- A demand-dial routing scenario

For more detailed routing configurations, see Routing Scenarios.

**Note**

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# A simple routing scenario

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**A simple routing scenario**

The following illustration shows a simple network configuration with a server running Routing and Remote Access that connects two LAN segments (Networks A and B). In this configuration, routing protocols are not necessary because the router is connected to all the networks to which it needs to route packets.

# A multiple-router scenario

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**A multiple-router scenario**

The following illustration shows a more complex router configuration.

In this configuration, there are three networks (Networks A, B, and C) and two routers (Routers 1 and 2). Router 1 is on Networks A and B, and Router 2 is on Networks B and C. Router 1 must notify Router 2 that Network A can be reached through Router 1, and Router 2 must notify Router 1 that Network C can be reached through Router 2. This information is automatically communicated through the use of routing protocols, such as RIP or OSPF. When a user on Network A wants to communicate with a user on Network C, the user's computer on Network A forwards the packet to Router 1. Router 1 then forwards the packet to Router 2. Router 2 then forwards the packet to the user's computer on Network C.

Without the use of routing protocols, a network administrator has to enter static routes into the routing tables of Router 1 and Router 2. While static routes work, they do not scale well to larger internetworks or recover from changes in the internetwork topology.

**Note**

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# A demand-dial routing scenario

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**A demand-dial routing scenario**

The following illustration shows a router configuration that uses demand-dialing.

Networks A and B are geographically separated and, for the amount of traffic that is transferred between the networks, a leased WAN link is not economical. Router 1 and Router 2 can connect over an analog phone line by using modems on both ends (or another type of connectivity, such as ISDN). When a computer on Network A initiates communication with a computer on Network B, Router 1 establishes a phone connection with Router 2. The modem connection is maintained as long as there are packets going back and forth. When the connection is idle, Router 1 hangs up to reduce connection costs.

For a detailed explanation of what happens during a demand-dial connection, see Understanding Demand-Dial Routing.

# IP Routing Protocols

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP routing protocols**
In dynamic IP routing environments, IP routing information is propagated by using IP routing protocols. The two most common IP routing protocols that are used on intranets are Routing Information Protocol (RIP) and Open Shortest Path First (OSPF).

You can run multiple routing protocols on the same intranet. In this case, you must configure which routing protocol is the most preferred source of learned routes by configuring preference levels. The preferred routing protocol is the source of the route that is added to the routing table, regardless of the metric of the learned route. For example, if the metric of an OSPF learned route is 5 and the metric of the corresponding RIP learned route is 3 and OSPF is the preferred routing protocol, then the OSPF route is added to the IP routing table and the RIP route is ignored. For more information, see Change preference levels.

This section provides information about:

- RIP for IP
- OSPF

**Notes**

- If you are using multiple IP routing protocols, configure only a single routing protocol per interface.
- OSPF is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# RIP for IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**RIP for IP**

The Routing Information Protocol (RIP) is designed for exchanging routing information within a small to medium-size internetwork.

The biggest advantage of RIP is that it is extremely simple to configure and deploy. The biggest disadvantage of RIP is its inability to scale to large or very large internetworks. The maximum hop count used by RIP routers is 15. Networks that are 16 hops or more away are considered unreachable. As internetworks grow larger in size, the periodic announcements by each RIP router can cause excessive traffic. Another disadvantage of RIP is its high recovery time. When the internetwork topology changes, it may take several minutes before the RIP routers reconfigure themselves to the new internetwork topology. While the internetwork reconfigures itself, routing loops may form that result in lost or undeliverable data.

Initially, the routing table for each router includes only the networks that are physically connected. A RIP router periodically sends announcements that contain its routing table entries to inform other local RIP routers of the networks it can reach. RIP version 1 uses IP broadcast packets for its announcements. RIP version 2 uses multicast or broadcast packets for its announcements.

RIP routers can also communicate routing information through triggered updates. Triggered updates occur when the network topology changes and updated routing information is sent that reflects those changes. With triggered updates, the update is sent immediately rather than waiting for the next periodic announcement. For example, when a router detects a link or router failure, it updates its own routing table and sends updated routes. Each router that receives the triggered update modifies its own routing table and propagates the change.

Routing and Remote Access supports RIP versions 1 and 2. RIP version 2 supports multicast announcements, simple password authentication, and more flexibility in subnetted and Classless InterDomain Routing (CIDR) environments.

The Windows Server 2003 family implementation of RIP has the following features:

- Selection of which RIP version to run on each interface for incoming and outgoing packets.
- Split-horizon, poison-reverse, and triggered-update algorithms that are used to avoid routing loops and speed recovery of the internetwork when topology changes occur.
- Route filters for choosing which networks to announce or accept.
- Peer filters for choosing which router's announcements are accepted.
- Configurable announcement and route aging timers.
- Simple password authentication support.
- The ability to disable subnet summarization.

For information about designing and deploying a RIP-for-IP internetwork, see Setting Up a RIP-for-IP Routed Internetwork.

For detailed information about the operation of RIP for IP, see "Unicast IP Routing" at the Microsoft Windows Resource Kits Web site.

**Note**

- If you are using multiple IP routing protocols, configure only a single routing protocol per interface.

# OSPF

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**OSPF**

Open Shortest Path First (OSPF) is designed for exchanging routing information within a large or very large internetwork. This feature is not available on the Itanium-based versions of the Windows operating systems. This content is not available in this preliminary release.

The biggest advantage of OSPF is that it is efficient; OSPF requires very little network overhead even in very large internetworks. The biggest disadvantage of OSPF is its complexity; OSPF requires proper planning and is more difficult to configure and administer.

OSPF uses a Shortest Path First (SPF) algorithm to compute routes in the routing table. The SPF algorithm computes the shortest (least cost) path between the router and all the networks of the internetwork. SPF-calculated routes are always loop-free.

Instead of exchanging routing table entries like RIP routers, OSPF routers maintain a map of the internetwork that is updated after any change to the network topology. This map, called the link state database, is synchronized between all the OSPF routers and is used to compute the routes in the routing table. Neighboring OSPF routers form an adjacency, which is a logical relationship between routers to synchronize the link state database.

Changes to internetwork topology are efficiently flooded across the entire internetwork to ensure that the link state database on each router is synchronized and accurate at all times. Upon receiving changes to the link state database, the routing table is recalculated.

As the size of the link state database increases, memory requirements and route computation times increase. To address this scaling problem, OSPF divides the internetwork into areas (collections of contiguous networks) that are connected to each other through a backbone area. Each router only keeps a link state database for those areas that are connected to the router. Area border routers (ABRs) connect the backbone area to other areas.

To further reduce the amount of routing information flooded into areas, OSPF allows the use of stub areas. A stub area can contain a single entry and exit point (a single ABR), or multiple ABRs when any of the ABRS can be used to reach external route destinations.

The following illustration shows a diagram of an OSPF internetwork.

OSPF has the following advantages over RIP:

- OSPF-calculated routes are always loop-free.
- OSPF can scale to large or very large internetworks.
- Reconfiguration for network topology changes is faster.

The implementation of OSPF in Routing and Remote Access has the following features:

- Route filters for controlling interaction with other routing protocols.
- Dynamic reconfiguration of all OSPF settings.

- Coexistence with RIP.
- Dynamic addition and deletion of interfaces.

For information about designing and deploying an OSPF internetwork, see Setting Up an OSPF Routed Internetwork.

For detailed information about the operation of OSPF, see "Unicast IP Routing" at the Microsoft Windows Resource Kits Web site.

**Notes**

- Routing and Remote Access does not support the use of OSPF in a demand-dial configuration that uses nonpermanent, dial-up links.
- If you are using multiple IP routing protocols, configure only a single routing protocol per interface.

# Routing interfaces, devices, and ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing interfaces, devices, and ports**
Routing and Remote Access views the installed networking equipment as a series of routing interfaces, devices, and ports.

- A routing interface is a physical or logical interface over which unicast or multicast packets are forwarded.
- A device represents hardware or software that creates physical or logical point-to-point connections.
- A port is a communication channel that supports a single point-to-point connection.

**Routing interface**
The server running Routing and Remote Access uses a routing interface to forward unicast IP or AppleTalk packets and multicast IP packets. There are two types of routing interfaces:

- LAN interfaces

  A LAN interface is a physical interface that typically represents a local area connection that uses local area networking technology such as Ethernet or token ring. A LAN interface reflects an installed network adapter. An installed WAN adapter is sometimes represented as a LAN interface. For example, some Frame Relay adapters create a separate logical LAN interface for each configured virtual circuit. LAN interfaces are always active and typically do not require an authentication process to become active.

- Demand-dial interfaces

  A demand-dial interface is a logical interface that represents a point-to-point connection. The point-to-point connection is based on either a physical connection, such as two routers connected over an analog phone line that uses modems, or a logical connection, such as two routers connected over a virtual private network connection that uses the Internet. Demand-dial connections are either on-demand (the point-to-point connection is only established when needed) or persistent (the point-to-point connection is established and then remains in a connected state). Demand-dial interfaces typically require an authentication process to become connected. The equipment needed by a demand-dial interface is a port on a device.

You can view the installed and configured routing interfaces by clicking **Network Interfaces** in Routing and Remote Access.

**Device**
A device is the hardware or software that provide ports that demand-dial and remote access connections use to establish point-to-point connections. Devices can be physical, such as a modem, or virtual, such as virtual private network (VPN) protocols. Devices can support a single port, such as a modem, or multiple ports, such as modem bank hardware that can terminate 64 different incoming analog phone calls. An example of a virtual multiport device is the Point-to-Point Tunneling Protocol (PPTP) or Layer Two Tunneling Protocol (L2TP). Each of these tunneling protocols supports multiple VPN connections.

You can view the installed devices by viewing the properties of **Ports** in Routing and Remote Access.

**Port**
A port is a channel of a device that supports a single point-to-point connection. For single-port devices such as modems, the device and the port are indistinguishable. For multiport devices, the port is the subdivision of the device over which a separate point-to-point communication is possible. For example, Primary Rate Interface (PRI) ISDN adapters support two separate channels called B channels. The ISDN adapter is a device. Each B channel is a port because a separate point-to-point connection occurs over each B channel.

You can view the installed ports by clicking **Ports** in Routing and Remote Access.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider

using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Understanding Multicasting

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding multicasting**
Multicasting is useful for the point-to-multipoint delivery of information on an internetwork. You can use three mechanisms for point-to-multipoint delivery:

1. Send the information to each endpoint individually by using unicast addresses. The disadvantages of this method are the duplication of network traffic and the overhead of maintaining a list of unicast endpoints.

2. Send the information in a single packet by using a broadcast address. The advantages of this method are the use of a single packet and no overhead for keeping lists of recipients. The disadvantages are the use of broadcast packets (which disturbs all nodes on the network) and the fact that broadcasts are not forwarded by routers. A broadcast packet reaches everyone on a network, but not everyone on the internetwork.

3. Send the information in a single packet by using a multicast address. The advantages of this method are the use of a single packet and no overhead for keeping lists of recipients. Unlike broadcast packets, multicast traffic does not disturb those nodes who are not listening for it. Routers can be multicast-capable and forward the multicast packet to all networks where there is at least one node listening.

Multicasting is the best choice for point-to-multipoint delivery.

This section covers:

- Multicast forwarding
- Multicast routing
- Multicast boundaries and heartbeat

# Multicast forwarding

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multicast forwarding**
Multicast forwarding, the intelligent forwarding of multicast traffic, is provided by the TCP/IP protocol and the IGMP routing protocol component for interfaces running in IGMP router mode, on a server running Routing and Remote Access.

The TCP/IP protocol performs the following multicast forwarding functions:

- Receives and processes all multicast traffic

  The Windows Server 2003 family implementation of the TCP/IP protocol receives and processes all multicast traffic on interfaces that are configured for IGMP router mode. All IP multicast traffic is either forwarded to a process running on the router or intelligently forwarded to network segments that contain either multicast group members or routers connected to downstream network segments that contain multicast group members.

- Forwards multicast packets to appropriate interfaces

  Upon receipt of a multicast packet, Routing and Remote Access consults a multicast forwarding table to decide whether to forward the packet to any of its other attached interfaces.

Interfaces running in IGMP router mode perform the following multicast forwarding functions:

- Places the network adapter in multicast-promiscuous mode

  IGMP router mode sets the network adapter to multicast-promiscuous mode. In multicast-promiscuous mode, all multicast packets received by the network adapter are passed to the networking layers for processing. Not all network adapters are capable of multicast-promiscuous mode.

- Tracks multicast group membership

  The IGMP router mode interface listens for IGMP Membership Report messages on locally attached networks and compiles a list of multicast accounting information as a series of {receiver network, multicast group} pairs. The receiver network is the IP network ID of a network segment containing a listening node. The multicast group is the specific multicast address that is registered by a listening node. The multicast-capable router does not track the IP addresses of the hosts that are listening, only the IP network ID where at least one host is listening.

  To ensure that hosts are still listening on their registered multicast addresses, the IGMP router periodically queries each network. The response to the query is an IGMP Membership Report message. If there are multiple IGMP routers on a single network, one IGMP router is elected the querier and performs all periodic queries.

- Updates to the TCP/IP multicast forwarding table

  Based on the current state of listening hosts on IGMP router mode interfaces, the TCP/IP multicast forwarding table is updated with the appropriate entries.

# Multicast routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multicast routing**
Multicast routing, the propagation of multicast listening information, is provided by multicast routing protocols such as Distance Vector Multicast Routing Protocol (DVMRP). The Windows Server 2003 family does not provide any multicast routing protocols. However, you can use the IGMP routing protocol and IGMP router mode and IGMP proxy mode to provide multicast forwarding in a single router intranet or when connecting a single router intranet to the Internet.

**Single-router intranets**
For an intranet that connects multiple networks by using a single router, you can enable IGMP router mode on all router interfaces to provide multicast forwarding support between multicast sources and multicast listening hosts on any network.

For more information, see Add the IGMP routing protocol and Enable IGMP router and IGMP proxy mode.

**Single-router intranets and the Internet**
If the server running Routing and Remote Access is attached to the MBone (the multicast-capable portion of the Internet) through an Internet service provider (ISP), you can use IGMP proxy mode to send and receive multicast traffic to and from the Internet.

In the following illustration, IGMP proxy mode is enabled on the Internet interface and IGMP router mode is enabled on the intranet interface. Multicast hosts register themselves locally and the IGMP proxy mode interface registers their memberships to the multicast-capable router at the ISP. Multicast traffic from the Internet is forwarded to the ISP router. The ISP router forwards the multicast traffic to the server running Routing and Remote Access, which then forwards the traffic to listening hosts on your intranet.

When multicast traffic is sent by an intranet host, it is forwarded over the IGMP proxy mode interface to the ISP router. The ISP router then forwards it to the appropriate downstream router. In this way, Internet hosts can receive multicast traffic sent by intranet hosts.

For more information, see Add the IGMP routing protocol and Enable IGMP router and IGMP proxy mode.

### Note

- The IGMP routing protocol that uses IGMP router mode and IGMP proxy mode is not the equivalent of a multicast routing protocol. A multicast routing protocol is required for multicast forwarding and routing support in a multiple-router intranet. You may configure the IGMP router mode and IGMP proxy mode interfaces to provide multicast forwarding support in multiple-router intranets. However, it is not recommended or supported.

# Multicast boundaries and heartbeat

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multicast boundaries and heartbeat**
The Windows Server 2003 family also provides multicast boundary and multicast heartbeat support.

**Multicast boundaries**
Multicast boundaries are administrative barriers to the forwarding of IP multicast traffic. Without boundaries, an IP multicast router forwards all appropriate IP multicast traffic. You can create multicast boundaries by specifying a range of IP addresses, known as a multicast scope, or by the value of the Time to Live (TTL) field in the IP header.

**Scope-based boundaries**
Scope-based boundaries prevent the forwarding of IP multicast traffic with a specified group IP address or range of IP addresses.

**TTL-based boundaries**
TTL-based boundaries prevent the forwarding of IP multicast traffic with a TTL less than a specified value. TTL-based boundaries apply to all multicast packets regardless of the multicast group. TTL-based boundaries are less effective than scope-based boundaries.

For more information, see Configure multicast boundaries.

**Multicast heartbeat**
Multicast heartbeat is the ability of the server running Routing and Remote Access to listen for a regular multicast notification to a specified group address to verify that IP multicast connectivity is available on the network. If the heartbeat is not received within a configured amount of time, the server running Routing and Remote Access sets a flag on the configured interface. The status of this flag can be polled by a program to provide notification that the multicast heartbeat is no longer present. For more information, see "IP Multicast Support" at the Microsoft Windows Resource Kits Web site.

For more information, see Configure multicast heartbeat.

# Understanding Network Address Translation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding network address translation**
With network address translation (NAT), you can configure your home network or small office network to share a single connection to the Internet. NAT consists of the following components:

- **Translation component**

  The server running Routing and Remote Access on which NAT is enabled translates the IP addresses and TCP/UDP port numbers of packets that are forwarded between the private network and the Internet.

- **Addressing component**

  The network address translation computer provides IP address configuration information to the other computers on the home network. The addressing component is a simplified DHCP server that allocates an IP address, a subnet mask, a default gateway, and the IP address of a DNS server. You must configure computers on the home network as DHCP clients in order to receive the IP configuration automatically. The default TCP/IP configuration for computers running any member of the Windows Server 2003 family, Windows XP, Windows 2000, Windows NT, Windows Millennium Edition, Windows 98, or Windows 95 is as a DHCP client.

- **Name-resolution component**

  The network address translation computer becomes the DNS server for the other computers on the home network. When name resolution requests are received by the network address translation computer, it forwards the name-resolution requests to the Internet-based DNS server for which it is configured and returns the responses to the home network computer.

For more information about network address translation, see:

- Internet private addresses

- A NAT example

For more information about configuring NAT, see Setting Up Network Address Translation.

For an example of using NAT, see SOHO Network to the Internet.

**Note**

- Because NAT includes addressing and name resolution components that provide DHCP and DNS services for hosts on the private network, you cannot run:

  - The DHCP service or the DHCP Relay Agent if NAT addressing is enabled.

  - The DNS service if NAT TCP/IP networking name resolution is enabled.

# Internet private addresses

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet private addresses**

To communicate on the Internet, you must use addresses that have been allocated by the Internet Assigned Numbers Authority (IANA). Addresses allocated by IANA can receive traffic from Internet locations and are known as public addresses. A typical small business or home office is allocated a public address (or addresses) from its Internet service provider (ISP), who has received a range of public addresses.

To allow multiple computers in the small office or home office to communicate on the Internet, each computer must have its own public address. This requirement places great stress on the available pool of public addresses.

To relieve this stress, IANA has provided for an address reuse scheme by reserving network IDs for private internetworks. The private network IDs include:

- 10.0.0.0 with the subnet mask 255.0.0.0
- 172.16.0.0 with the subnet mask 255.240.0.0
- 192.168.0.0 with the subnet mask 255.255.0.0

For more information about portions of the IP address space that are reserved for private intranets, see RFC 1918, "Address Allocation for Private Internets." All addresses in these ranges are known as private addresses.

Private addresses cannot receive traffic from Internet locations. Therefore, if an intranet is using private addresses and communicating with Internet locations, the private address must be translated to a public address. A network address translator is placed between an intranet that uses private addresses and the Internet, which uses public addresses. Outgoing packets from the intranet have their private addresses translated by network address translation (NAT) into public addresses. Incoming packets from the Internet have their public addresses translated by NAT into private addresses. For more information, see A NAT example.

For more information about configuring NAT for the home office and small business, see SOHO Network to the Internet.

# A NAT example

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**A NAT example**

If a small business is using the 192.168.0.0 network ID for its intranet and has been granted the public address of *w1.x1.y1.z1* by its Internet service provider (ISP), then network address translation (NAT) maps all private addresses on 192.168.0.0 to the IP address of *w1.x1.y1.z1*. If multiple private addresses are mapped to a single public address, NAT uses dynamically chosen TCP and UDP ports to distinguish one intranet location from another.

**Note**

- The use of *w1.x1.y1.z1* and *w2.x2.y2.z2* is intended to represent valid public IP addresses as allocated by the Internet Assigned Numbers Authority (IANA) or an ISP.

The following illustration shows an example of using NAT to transparently connect an intranet to the Internet.

If a private user at 192.168.0.10 uses a Web browser to connect to the Web server at *w2.x2.y2.z2*, the user's computer creates an IP packet with the following information:

- Destination IP address: *w2.x2.y2.z2*
- Source IP address: 192.168.0.10
- Destination port: TCP port 80
- Source port: TCP port 5000

This IP packet is then forwarded to the NAT protocol, which translates the addresses of the outgoing packet to the following:

- Destination IP address: *w2.x2.y2.z2*
- Source IP address: *w1.x1.y1.z1*
- Destination port: TCP port 80
- Source port: TCP port 1025

The NAT protocol keeps the mapping of {192.168.0.10, TCP 1025} to {*w1.x1.y1.z1*, TCP 5000} in a table.

The translated IP packet is sent over the Internet. The response is sent back and received by the NAT protocol. When received, the packet contains the following public address information:

- Destination IP address: *w1.x1.y1.z1*

- Source IP address: *w2.x2.y2.z2*
- Destination port: TCP port 1025
- Source port: TCP port 80

The NAT protocol checks its translation table and maps the public addresses to private addresses and forwards the packet to the computer at 192.168.0.10. The forwarded packet contains the following address information:

- Destination IP address: 192.168.0.10
- Source IP address: *w2.x2.y2.z2*
- Destination port: TCP port 5000
- Source port: TCP port 80

For outgoing packets from the NAT protocol, the source IP address (a private address) is mapped to the ISP allocated address (a public address), and the TCP/UDP port numbers are mapped to a different TCP/UDP port number.

For incoming packets to the NAT protocol, the destination IP address (a public address) is mapped to the original intranet address (a private address), and the TCP/UDP port numbers are mapped back to their original TCP/UDP port numbers.

**Note**

- Packets that contain the IP address only in the IP header are properly translated by NAT. Packets that contain the IP address within the IP payload may not be properly translated by NAT.

# Understanding Demand-Dial Routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding demand-dial routing**

While the concept of demand-dial routing is fairly simple, configuration of demand-dial routing is relatively complex. This complexity is due to the following factors:

- **Connection endpoint addressing**

  The connection must be made over public data networks, such as the analog phone system. The endpoint of the connection must be identified by a phone number or other endpoint identifier.

- **Authentication and authorization of the caller**

  Anyone calling the server running Routing and Remote Access must be authenticated and authorized. Authentication is based on the caller's set of credentials that are passed during the connection establishment process. The credentials that are passed must correspond to a user account. Authorization is granted based on the dial-in permission of the user account and remote access policies. For more information, see Introduction to remote access policies.

- **Differentiation between remote access clients and routers**

  Both routing and remote access services coexist on the same server running Routing and Remote Access. Both remote access clients and routers can call the same phone number. The server running Routing and Remote Access that answers the call must be able to distinguish a remote access client from a router that is calling to create a demand-dial connection. To differentiate a remote access client from a demand-dial router, the user name in the authentication credentials sent by the calling router must exactly match the name of a demand-dial interface on the answering router. Otherwise, the incoming connection is assumed to be a remote access connection.

- **Configuration of both ends of the connection**

  Both ends of the connection must be configured even if only one end of the connection is initiating a demand-dial connection. Configuring only one side of the connection means that packets are successfully routed only in one direction. Normal communication requires that information travel in both directions.

- **Configuration of static routes**

  You should not use dynamic routing protocols over temporary dial-up demand-dial connections. Therefore, routes for network IDs that are available across the demand-dial interface must be added to the routing table as static routes. You can accomplish this manually or by using auto-static updates.

For more information, see:

- Demand-dial routing example
- The demand-dial connection process
- Demand-dial routing updates
- Unnumbered connections
- One-way initiated demand-dial connections

For information about designing and deploying demand-dial routing, see Setting Up Demand-Dial Routing.

# Demand-dial routing example

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Demand-dial routing example**

This section gives an example of the complexity (and elegance) of demand-dial routing. The following illustration shows the configuration between two offices that want to use demand-dial IP routing.

The Seattle office has a server running Routing and Remote Access that acts as a remote access server and demand-dial router. All computers in the Seattle office are connected to the 172.16.1.0 network (subnet mask 255.255.255.0). The Seattle router (hereafter referred to as Router 1) has a modem connected to its COM1 port and the phone number of the modem is 555-0111.

The New York office has a server running Routing and Remote Access that acts as a remote access server and demand-dial router. All computers in the New York office are connected to the 172.16.2.0 network (subnet mask 255.255.255.0). The New York router (hereafter referred to as Router 2) has a modem connected to its COM2 port and the phone number of the modem is 555-0122.

The user on the computer with the IP address of 172.16.1.10 needs to be able to connect to the user on the computer with the IP address of 172.16.2.20 and vice versa.

### Note

- To configure demand-dial routing, use the Demand-dial Interface wizard, and do not skip the **Add a Static Route** dialog box. For more information about adding a demand-dial interface, see Add a demand-dial interface.

**Configuring Router 1**

The configuration for demand-dial routing on Router 1 consists of the following three steps:

1. Create a demand-dial interface.
2. Create a static route.
3. Create an account that Router 2 uses when calling Router 1.

**Creating a demand-dial interface**

By using Routing and Remote Access with the Demand-dial Interface wizard, the administrator at Router 1 creates a demand-dial interface called DD_NewYork with the following configuration:

- Equipment: Modem on COM1
- Phone number: 555-0122
- Protocols: TCP/IP
- Authentication credentials: DD_Seattle with a password

**Creating a static route**

By using Routing and Remote Access, the Demand-dial Interface wizard will already have the name and destination of the static route with the following configuration:

- Interface: DD_NewYork
- Destination: 172.16.2.0
- Network mask: 255.255.255.0
- Metric: 1

**Note**

- Because the demand-dial connection is a point-to-point connection, the gateway IP address is not configurable.

**Creating an account with dial-in permissions**

By using Active Directory Users and Computers or Local Users and Groups, the administrator at Router 1 creates a user account with the following settings:

- Account name: DD_NewYork with a password.
- Account settings: Clear the **User must change password at next logon** check box and select the **Password never expires** check box.

The DD_NewYork account is granted dial-in permissions either through the dial-in properties of the user account or through remote access policies. For more information, see Introduction to remote access policies.

**Configuring Router 2**

The configuration for demand-dial routing on Router 2 consists of the following three steps:

1. Create a demand-dial interface.
2. Create a static route.
3. Create an account that Router 1 uses when calling Router 2.

**Creating a demand-dial interface**

By using Routing and Remote Access, the administrator at Router 2 creates a demand-dial interface called DD_Seattle with the following configuration:

- Equipment: Modem on COM2
- Phone number: 555-0111
- Protocols: TCP/IP
- Authentication credentials: DD_NewYork with a password

**Creating a static route**

By using Routing and Remote Access, the Demand-dial Interface wizard will already have the name and destination of the static route with the following configuration:

- Interface: DD_Seattle
- Destination: 172.16.1.0
- Network mask: 255.255.255.0
- Metric: 1

### Note

- Because the demand-dial connection is a point-to-point connection, the gateway IP address is not configurable.

**Creating an account with dial-in permissions**

By using Active Directory Users and Computers or Local Users and Groups, the administrator at Router 2 creates a user account with the following settings:

- Account name: DD_Seattle with a password.
- Account settings: Clear the **User must change password at next logon** check box and select the **Password never expires** check box.

The DD_Seattle account is granted dial-in permissions either through the dial-in properties of the user account or through remote access policies. For more information, see Introduction to remote access policies.

**The resulting configuration**

The following illustration shows the demand-dial routing configuration in terms of the demand-dial interfaces, static routes, and user accounts for the routers for the Seattle and New York offices.

### Note

- In order for two-way initiated demand-dial routing to work properly, authentication credentials (such as user account name) for the demand-dial interface must be created on both servers running Routing and Remote Access. This example shows a proper configuration and is summarized in the following table.

| Router | Demand-dial interface name | User account name |
|---|---|---|
| Router 1 | DD_NewYork | DD_Seattle |
| Router 2 | DD_Seattle | DD_NewYork |

For more information about how the demand-dial connection process works for this example configuration, see The demand-dial connection process.

# The demand-dial connection process

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The demand-dial connection process**

When the user at 172.16.1.10 tries to connect to a resource at 172.16.2.20, the following events occur:

1. Packets from 172.16.1.10 destined for 172.16.2.20 are forwarded to Router 1.
2. Router 1 receives the packet from 172.16.1.10 and checks its routing table. A route to 172.16.2.20 is found that uses the DD_NewYork interface.
3. Router 1 checks the state of the DD_NewYork interface and finds it is in a disconnected state.
4. Router 1 retrieves the configuration of the DD_NewYork demand-dial interface.
5. Based on the DD_NewYork configuration, Router 1 uses the modem on COM1 to dial the number 555-0122.
6. Router 2 answers the incoming call.
7. Router 2 requests authentication credentials from the incoming caller.
8. Router 1 sends the user name DD_Seattle with its associated password.
9. Upon receipt of the authentication credentials, Router 2 checks the user name and password against the security features of the Windows Server 2003 family and verifies that Router 1 has dial-in permission through the dial-in properties of the DD_Seattle user account and the configured remote access policies.
10. Router 2 must now determine whether the incoming caller is a dial-up networking client or a router that is creating a demand-dial connection. Router 2 looks in its list of demand-dial interfaces to find one that matches the user name sent by Router 1 as part of the authentication credentials. Router 2 finds a demand-dial interface DD_Seattle that matches the user name credential.
11. Router 2 changes the state of the DD_Seattle demand-dial interface to a connected state.
12. Router 1 forwards the packet from the computer at 172.16.1.10 across the demand-dial connection to Router 2.
13. Router 2 receives the packet and forwards it to the computer at 172.16.2.20.
14. The response to the connection request by the computer at 172.16.1.10 is forwarded to Router 2 by the computer at 172.16.2.20.
15. Router 2 receives the packet destined for 172.16.1.10 and checks its routing table. A route to 172.16.1.10 is found by using the DD_Seattle interface.
16. Router 2 checks the state of the DD_Seattle interface and finds it is in a connected state.
17. Router 2 forwards the packet to Router 1.
18. Router 1 forwards the packet to the computer at 172.16.1.10.

If the user name credential does not match the name of an appropriate demand-dial interface, the calling entity is identified as a remote access client, which can result in routing problems.

For example, if Router 1 uses DialUpRouter1 as its user name credential, then Router 1 is identified as a remote access client rather than a router (assuming DialUpRouter1 is a valid account with dial-in permissions). Packets are routed from the user at 172.16.1.10 to the user at 172.16.2.20 as described in the preceding process.

However, response packets from 172.16.2.20 to 172.16.1.10 are forwarded to Router 2 which, upon inspecting its routing table, determines that the interface to use is DD_Seattle. DD_Seattle is in a disconnected state. Based on the configuration for DD_Seattle, COM2 is to be used. However, COM2 is currently being used for a remote access client (Router 2). Router 2 then tries to locate another modem that is not being used. If found, Router 2 dials Router 1 and forwards the packet after the connection has been established. If another modem cannot be found, the response packets from 172.16.2.20 to 172.16.1.10 are dropped.

# Demand-dial routing updates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Demand-dial routing updates**

While demand-dial routing can save connection costs, typical routing protocols rely on a periodic advertising process to communicate routing information. For example, RIP for IP advertises the contents of its routing table every 30 seconds on all interfaces. This behavior is not a problem for permanently connected LAN or WAN lines. For usage-sensitive dial-up WAN lines, this type of periodic behavior could cause the router to call another router every 30 seconds, which may result in an undesirable phone bill. Therefore, you should not run routing protocols across temporary dial-up WAN lines.

If you do not use routing protocols to update the routing tables, then you must enter the routes as static routes. The static routes that correspond to the network IDs available across the interface are entered manually or automatically. The automatic entering of static routes for demand-dial interfaces is known as auto-static updates and is supported by the server running Routing and Remote Access. Auto-static updates are supported when you use RIP for IP, but not OSPF.

When instructed, a demand-dial interface that is configured for auto-static updates sends a request across an active connection to request all of the routes of the router on the other side of the connection. In response to the request, all of the routes of the requested router are automatically entered as static routes in the routing table of the requesting router. The static routes are persistent; they are kept in the routing table even if the interface becomes disconnected or the router is restarted. An auto-static update is a one-time, one-way exchange of routing information.

You can automate and schedule auto-static updates by executing the update as a scheduled task. For more information, see Scheduling auto-static updates.

**Notes**

- The "auto" in auto-static refers to the automatic adding of the requested routes as static routes in the routing table. The sending of the request for routes is performed through an explicit action: either through Routing and Remote Access or the Netsh utility while the demand-dial interface is in a connected state. Auto-static updates are not automatically performed every time a demand-dial connection is made.

- When an auto-static update is requested, the existing auto-static routes are deleted before the update is requested from other routers. If there is no response to the request, then the router cannot replace the routes it has deleted. This may lead to a loss of connectivity to remote networks.

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Unnumbered connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Unnumbered connections**

Demand-dial connections use the Point-to-Point Protocol (PPP) during the connection establishment process. For a TCP/IP-based connection, TCP/IP connection settings are negotiated. An important element of a TCP/IP-based PPP connection is the allocation of an IP address.

When a call is initiated between demand-dial routers (either servers running Routing and Remote Access or servers running Windows NT 4.0 Routing and Remote Access Service (RRAS)), the calling router requests an IP address from the answering router. Additionally, the answering router requests an IP address from the calling router. If both routers have an IP address to give each other, the logical interface on the PPP connection for each router is assigned an IP address from the other router. This is known as a numbered connection.

Windows NT 4.0 RRAS demand-dial connections require a numbered connection. If either the calling or the answering router does not have an IP address to assign to the other router, the connection establishment process fails. In order for both routers to assign IP addresses to each other, you must configure both routers for the proper IP address assignment behavior through the properties of RRAS. A common configuration problem with RRAS is that the default configuration for IP address assignment is to obtain an IP address through DHCP, and no DHCP server is available on the network. Because no IP address is allocated to the other router, the connection establishment process fails.

This configuration issue is no longer a problem with the Routing and Remote Access service for two reasons:

1. Use of Automatic Private IP Addressing (APIPA) addresses

   In Routing and Remote Access, the default IP address assignment configuration is still to obtain an IP address from a DHCP server. However, if a DHCP server is not available, APIPA addresses in the range from 169.254.0.1 through 169.254.255.254 are used. Therefore, the default configuration does not prevent two routers from establishing a numbered connection. For more information about APIPA, see New features for TCP/IP.

2. Support for unnumbered connections

   By default, demand-dial connections do not require a numbered connection. The calling and answering routers still request an IP address from each other during the connection establishment process. But if one of the routers rejects the request, both routers continue with the connection establishment process. The logical interface on the point-to-point connection does not have an assigned IP address. This is known as an unnumbered connection.

When you use an unnumbered connection, on the router that requests an IP address but is rejected, a warning is logged in the system event log with the following characteristics:

- Source: RemoteAccess
- Event ID: 20165
- Message text: A connection has been established on port [number] using interface [name of demand-dial interface], but no IP address was obtained.

On the router from which an IP address is requested but is not given, a warning is logged in the system event log with the following characteristics:

- Source: RemoteAccess
- Event ID: 20166
- Message text: A connection has been established on port [number] using interface [name of demand-dial interface], but the remote side got no IP address.

With unnumbered connections, servers running Routing and Remote Access can connect to other routers that do not assign an IP address during the connection establishment process. For example, some Internet service providers (ISPs) prefer to use an unnumbered connection to conserve IP addresses.

**Important**

- The routing protocols provided with Routing and Remote Access cannot operate over unnumbered connections. If you use unnumbered connections, you must employ static routing. This limitation is not an issue when you are using a server running Routing and Remote Access to connect to the Internet and you configure a default static IP route, rather than run a routing protocol.

# One-way initiated demand-dial connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**One-way initiated demand-dial connections**
If a demand-dial connection is always initiated by one router, a one-way initiated demand-dial connection, then you can simplify the configuration of the answering router by configuring static routes on the user account of the calling router.

Using the example scenario described in Demand-dial routing example, the Seattle router (Router 1) always calls the New York router (Router 2).

**Configuring Router 1**
The configuration of Router 1 is the same as described in Demand-dial routing example.

**Configuring Router 2**
The configuration for demand-dial routing on Router 2 consists of just two steps:

1. Create a user account that Router 1 uses when calling Router 2.

2. Configure static routes on the user account used by Router 1 for the network IDs of the Seattle office.

**Creating a user account with dial-in permissions**
By using Active Directory Users and Computers or Local Users and Groups, the administrator at Router 2 creates a user account with the following settings:

- Account name: DD_Seattle with a password.

- Account settings: Clear the **User must change password at next logon** check box and select the **Password never expires** check box.

The DD_Seattle account is granted dial-in permissions either through the dial-in properties of the user account or through remote access policies. For more information, see Introduction to remote access policies.

**Configuring the user account with static routes**
By using Active Directory Users and Computers or Local Users and Groups, the administrator at Router 2 obtains dial-in properties on the DD_Seattle user account and then adds the static routes of the Seattle office.

For more information, see Configure static routes for a dial-in user.

For this example, the network administrator adds the following route:

- Destination: 172.16.1.0

- Network mask: 255.255.255.0

- Hops: 1

**Note**

- You can only add static routes to the dial-in properties of a user account on a server running Routing and Remote Access acting as stand-alone router (not a member of a domain) or a server running Routing and Remote Access that is a member of a Windows 2000 native or a Windows Server 2003 domain.

**Connection process for a one-way initiated demand-dial connection**
When the user at 172.16.1.10 tries to connect to a resource at 172.16.2.20, the following events occur:

1. Packets from 172.16.1.10 destined for 172.16.2.20 are forwarded to Router 1.

2. Router 1 receives the packet from 172.16.1.10 and checks its routing table. A route to 172.16.2.20 is found by using the DD_NewYork interface.

3. Router 1 checks the state of the DD_NewYork interface and finds it is in a disconnected state.

4. Router 1 retrieves the configuration of the DD_NewYork demand-dial interface.

5. Based on the DD_NewYork configuration, Router 1 uses the modem on COM1 to dial the number 555-0122.

6. Router 2 answers the incoming call.

7. Router 2 requests authentication credentials from the incoming caller.

8. Router 1 sends the user name DD_Seattle with its associated password.

9. Upon receipt of the authentication credentials, Router 2 checks the user name and password against the security features of the Windows Server 2003 family and verifies that Router 1 has dial-in permission through the dial-in properties of the DD_Seattle user account and the configured remote access policies.

10. Router 2 retrieves the static route (172.16.1.0 with the subnet mask of 255.255.255.0) that is configured on the DD_Seattle user account and creates a corresponding static route in its routing table. If Router 2 is configured with routing protocols, Router 2 uses routing protocols to communicate with neighboring routers so that the route to the Seattle network is propagated to all of the routers in the New York office.

11. Router 2 must now determine whether the incoming caller is a dial-up networking client or a router creating a demand-dial connection. Router 2 looks in its list of demand-dial interfaces and does not find one called DD_Seattle. Therefore, Router 2 considers the connection to the Seattle office to be a remote access connection.

12. Router 1 forwards the packet from the computer at 172.16.1.10 across the demand-dial connection to Router 2.

13. Router 2 receives the packet and forwards it to the computer at 172.16.2.20.

14. The response to the connection request by the computer at 172.16.1.10 is forwarded to Router 2 by the computer at 172.16.2.20.

15. Router 2 receives the packet destined for 172.16.1.10 and checks its routing table. A route to 172.16.1.10 is found by using the connection to Router 1.

16. Router 2 forwards the packet to Router 1.

17. Router 1 forwards the packet to the computer at 172.16.1.10.

**Note**

- When the connection is made, the static routes on the user account of the calling router are added to the routing table of the answering router. If routing protocols are used to propagate the new static route, then there is a delay between the time the connection is made and the time when all of the routers on the intranet of the answering router are aware of the new route. Therefore, hosts on the intranet of the calling router may experience a delay between the time that the connection is made and the time when they begin to receive traffic back from hosts on the intranet of the answering router.

# Understanding Router-to-Router VPNs

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding router-to-router VPNs**

This section covers:

- Components of a router-to-router VPN connection
- VPN Router-to-Router tunneling protocols
- A dial-up router-to-router VPN connection

# Components of a router-to-router VPN connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Components of a router-to-router VPN connection**

A router-to-router VPN connection includes the following components:

- **Virtual private network (VPN) clients**

  The VPN client is the router that initiates the VPN connection, also known as the calling router. For router-to-router VPN connections, you can configure servers running Routing and Remote Access (available in both Windows 2000 and the Windows Server 2003 family) and computers running Windows NT Server 4.0 and the Routing and Remote Access Service (RRAS) as VPN clients.

- **VPN servers**

  The VPN server is the router that accepts the connection from the calling router, also known as the answering router. For router-to-router VPN connections, you can configure both servers running Routing and Remote Access and computers running Windows NT Server 4.0 and RRAS as VPN servers. On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

- **LAN and remote access protocols**

  LAN protocols are used to transport information. Remote access protocols are used to negotiate connections and provide framing for LAN protocol data. Routing and Remote Access supports the routing of TCP/IP LAN protocol packets by using the PPP remote access protocol across a router-to router VPN connection.

- **Tunneling protocols**

  Tunneling protocols are used by VPN clients and VPN servers to manage tunnels and send tunneled data. Routing and Remote Access includes support for the Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP) tunneling protocols. Windows NT Server 4.0 with RRAS only includes the PPTP tunneling protocol.

- **WAN options**

  VPN servers are typically connected to the Internet by using permanent WAN connections such as T1 or Frame Relay. VPN clients are connected to the Internet by using permanent WAN connections or by dialing in to a local Internet service provider (ISP) that uses standard telephone lines or ISDN. Once connected to the Internet, the VPN client can connect to the VPN server.

- **Demand-dial interfaces**

  The VPN client (the calling router) must have a demand-dial interface configured for:

  - The host name or IP address of the interface of the VPN server on the Internet.
  - A PPTP port (for a PPTP-based VPN connection) or an L2TP port (for an L2TP-based connection).
  - The user account credentials (user name, domain, password) for a user account that can be validated by the VPN server.
  - For an L2TP/IPSec-based connection, a valid certificate that can be validated by the VPN server.

The VPN server (the answering router) must have a demand-dial interface with the same name as the user account that is used by the VPN client (the calling router) in order for the incoming connection to be recognized and accepted as a demand-dial connection.

- **User accounts**

  A user account must be created for the calling router. This account can be created automatically when you run the Routing and Remote Access with the Routing and Remote Access Server Setup Wizard. This account must have dial-in permissions either through the dial-in properties of the user account or through remote access policies. For more information, see Introduction to remote access policies.

- **Static routes or routing protocols**

  In order for each router to forward packets across the router-to-router VPN connection, each router must contain the appropriate routes in the routing tables. Routes are added to the routing tables of both routers either as static routes or by enabling a routing protocol to operate across a persistent router-to-router VPN connection.

- **Security options**

  Because the router-to-router VPN connection is validated by the server running Routing and Remote Access, you can utilize all of the security features of the Windows Server 2003 family, including domain security, data encryption, Remote Authentication Dial-In User Service (RADIUS), smart cards, and callback. For more information, see Remote Access Security.

The following illustration shows the components of a router-to-router VPN connection.

# VPN Router-to-Router tunneling protocols

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tunneling protocols**

Routing and Remote Access provides two tunneling protocols for creating router-to-router VPN connections:

- Point-to-Point Tunneling Protocol (PPTP)
- Layer Two Tunneling Protocol (L2TP)

### Note

- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

**PPTP**

PPTP is a VPN tunneling protocol. PPTP is an extension of the Point-to-Point Protocol (PPP) and leverages the authentication, compression, and encryption mechanisms of PPP.

PPTP is installed with TCP/IP. By default, Routing and Remote Access is configured for five PPTP ports. To increase the number of PPTP ports, see Add PPTP or L2TP ports. You can enable PPTP ports for inbound remote access and demand-dial routing connections by using the Routing and Remote Access Server Setup Wizard. To enable PPTP ports for routing after the wizard is run, see Enable routing on ports.

Two primary services of virtual private networking are encapsulation and encryption.

**Encapsulation**

A PPP frame containing an IP datagram is wrapped with a Generic Routing Encapsulation (GRE) header and an IP header. In the IP header is the source and destination IP address that correspond to the VPN client and VPN server.

The following illustration shows PPTP encapsulation for a PPP frame.

**Encryption**

The PPP frame is encrypted with Microsoft Point-to-Point Encryption (MPPE) by using encryption keys generated from the MS-CHAP or EAP-TLS authentication process. Virtual private networking clients must use either the MS-CHAP or EAP-TLS authentication protocol in order to encrypt PPP payloads. PPTP does not provide encryption services. PPTP encapsulates a previously encrypted PPP frame.

### Note

- It is possible to have a nonencrypted PPTP connection where the PPP payload is sent in plaintext. However, a nonencrypted PPTP connection is not recommended for virtual private network connections over the Internet because communications of this type are not secure.

**L2TP**

L2TP is an industry-standard Internet tunnelling protocol that provides encapsulation for sending PPP frames across packet-oriented media. Like PPTP, L2TP leverages the authentication and compression mechanisms of PPP. Unlike PPTP, L2TP does not utilize Microsoft Point-to-Point Encryption (MPPE) to encrypt PPP frames. L2TP relies on Internet Protocol security (IPSec)

for encryption services.

The result is that L2TP-based virtual private networking connections are a combination of L2TP and IPSec. Both L2TP and IPSec must be supported by both routers. For more information about IPSec, see Internet Protocol Security Overview. L2TP is described in RFC 2661.

L2TP is installed with TCP/IP. By default, Routing and Remote Access is configured for five L2TP ports. To increase the number of L2TP ports, see Add PPTP or L2TP ports. You can enable L2TP ports for inbound remote access and demand-dial routing connections by using the Routing and Remote Access Server Setup Wizard. To enable L2TP ports for routing after the wizard is run, see Enable routing on ports.

Two primary services of virtual private networking are encapsulation and encryption.

**Encapsulation**
Encapsulation for L2TP over IPSec packets consists of two layers of encapsulation.

1. L2TP encapsulation

   A PPP frame containing an IP datagram is wrapped with an L2TP header and a UDP header.

2. IPSec encapsulation

   The resulting L2TP message is then wrapped with an IPSec Encapsulating Security Payload (ESP) header and trailer, an IPSec Authentication trailer that provides message integrity and authentication, and a final IP header. In the IP header is the source and destination IP address that correspond to the VPN client and VPN server.

The following illustration shows L2TP and IPSec encapsulation for a PPP frame.

**Encryption**
The L2TP message is encrypted with DES and 3DES encryption algorithms by using encryption keys generated from the IPSec authentication process.

### Note

- It is possible to have a non-IPSec-based (nonencrypted) L2TP connection where the PPP payload is sent in plaintext. However, a nonencrypted L2TP connection is not recommended for virtual private network connections over the Internet because communications of this type are not secure.

# A dial-up router-to-router VPN connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**A dial-up router-to-router VPN connection**

A router-to-router VPN connection is typically used to connect remote offices together when both routers are connected to the Internet through permanent WAN links, such as T1 or Frame Relay. In this configuration, the VPN connection is always available. However, when a permanent WAN link is not possible or practical, you can configure a dial-up router-to-router VPN connection.

The following illustration shows a dial-up router-to-router VPN connection.

A dial-up router-to-router VPN connection consists of two demand-dial interfaces and two static routes that are configured on the VPN client (the calling router):

1. A demand-dial interface to dial in to a local Internet service provider (ISP).
2. A demand-dial interface for the router-to-router VPN connection.
3. A static host route to dynamically connect to the Internet.
4. A static route to reach the locations of the corporate office.

A dial-up router-to-router VPN connection is automatically established when you route traffic to a specific location. For example, in a branch office configuration, when a packet is received to be routed to the corporate office, the branch office router uses a dial-up link to connect to a local Internet service provider (ISP) and then creates a router-to-router VPN connection with the corporate office router located on the Internet.

**Note**

- This discussion assumes that the corporate office router (the answering router) is connected to the Internet by using a permanent WAN link. It is possible to have both routers connected to the Internet by using a dial-up WAN link. However, this is only feasible if the ISP supports demand-dialing routing to customers; the ISP calls the customer router when an IP datagram is to be delivered to the customer. Demand-dial routing to customers is not widely supported by ISPs.

To configure a dial-up router-to-router VPN connection at the branch office router, do the following:

1. Create a demand-dial interface for the Internet connection that is configured for the appropriate equipment (a modem or ISDN device), the phone number of the local ISP, and the user name and password to gain Internet access.
2. Create a demand-dial interface for the VPN connection with the corporate office router that is configured for a VPN port (a PPTP or L2TP port), the IP address of the interface on the Internet for the corporate office router, and a user name and password that can be verified by the VPN server. The user name must match the name of a demand-dial interface on the corporate office router.
3. Create a static host route to the corporate office router that uses the ISP demand-dial interface.
4. Create a static route (or routes) for the IP network IDs of the corporate intranet that uses the VPN demand-dial interface.

To configure the corporate office router, do the following:

1. Create a demand-dial interface for the VPN connection with the branch office that is configured for a VPN device (a PPTP or L2TP port). The demand-dial interface must have the same name as the user name in the authentication credential that is used by the branch office router to create the VPN connection.

2. Create a static route (or routes) for the IP network IDs of the branch office that uses the VPN demand-dial interface.

The router-to-router VPN connection is automatically initiated by the branch office router through the following process:

1. Packets sent to a corporate hub network location from a computer in the branch office are forwarded to the branch office router.

2. The branch office router checks its routing table and finds a route to the corporate intranet network ID, which uses the VPN demand-dial interface.

3. The branch office router checks the state of the VPN demand-dial interface and finds it is in a disconnected state.

4. The branch office router retrieves the configuration of the VPN demand-dial interface.

5. Based on the VPN demand-dial interface configuration, the branch office router attempts to initialize a router-to-router VPN connection at the IP address of the corporate office router on the Internet.

6. To establish a VPN, either a TCP (by using PPTP) or UDP (by using L2TP/IPSec) packet must be sent to corporate office router that acts as the VPN server. The VPN establishment packet is created.

7. To forward the VPN establishment packet to the corporate office router, the branch office router checks its routing table and finds the host route that is using the ISP demand-dial interface.

8. The branch office router checks the state of the ISP demand-dial interface and finds it is in a disconnected state.

9. The branch office router retrieves the configuration of the ISP demand-dial interface.

10. Based on the ISP demand-dial interface configuration, the branch office router uses its modem to dial and establish a connection with its local ISP.

11. Once the ISP connection is made, the VPN establishment packet is sent to the corporate office router.

12. A router-to-router VPN connection is negotiated between the branch office router and the corporate office router. As part of the negotiation, the branch office router sends authentication credentials that are verified by the corporate office router.

13. The corporate office router checks its demand-dial interfaces and finds one that matches the user name sent during authentication and changes the interface to a connected state.

14. The branch office router forwards the routed packet across the VPN and the corporate office router forwards the packet to the appropriate intranet location.

15. When the intranet location responds to the packet sent to it by the user in the branch office, the packet is forwarded to the corporate office router.

16. The corporate office router checks its routing table and finds a route to the branch office network that uses the VPN demand-dial interface.

17. The corporate office router checks the state of the VPN demand-dial interface and finds it is in a connected state.

18. The response packet is forwarded across the Internet by using the VPN connection.

19. The response packet is received by the branch office router and is forwarded to the original user.

# Using Routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using routing**

This section covers:

- Installing the router
- Managing routing from the command line
- Deploying Routing
- Routing Scenarios

# Installing the router

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing the router**
To install and configure the server running Routing and Remote Access as a router, you must be logged on as a member of the local Administrators group.

**Hardware requirements**
Before you configure Routing and Remote Access as a router, all hardware needs to be installed and working. Depending on your network and requirements, you might need the following hardware:

- A LAN or WAN adapter with a WHQL signed driver.
- One or more compatible modems and an available COM port.
- A multiport adapter for acceptable performance with multiple remote connections.
- An X.25 smart card (if you are using an X.25 network).
- An ISDN adapter (if you are using an ISDN line).

To verify the compatibility of all hardware in a computer running Routing and Remote Access, see Support resources.

**Installation**
When you install the Windows Server 2003 family, the routing component is automatically installed. However, the Routing and Remote Access service is installed in a disabled state. For more information, see Enable the Routing and Remote Access service.

# Managing routing from the command line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing routing from the command line**

In addition to using Routing and Remote Access, you can use command-line utilities to manage routing for users, computers, or services. By combining command-line utilities within a batch file, you can simplify and automate complicated daily, weekly, or monthly tasks on one or more servers.

For example, you can use the Pathping command to diagnose network latency or loss problems. The **pathping** command sends Internet Control Message Protocol (ICMP) Echo Request messages to each router between a source and a destination over a period of time. Results based on the packets returned from each router are then computed and displayed. The Tracert command can be used to determine and display a path to a destination IP address that you want to reach. Used for diagnostic purposes only, the Ping command verifies IP-level connectivity to another TCP/IP computer. You can use Netsh overview to perform more advanced management tasks, such as scripting.

For more information about managing routing with command-line utilities, see Routing Tools and Utilities. For information about other command-line utilities, see Command-line reference A-Z.

# Deploying Routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying routing**
This section covers:

- Setting Up a Static Routed IP Internetwork
- Setting Up a RIP-for-IP Routed Internetwork
- Setting Up an OSPF Routed Internetwork
- Setting Up Network Address Translation
- Setting Up Demand-Dial Routing
- Deploying Router-to-Router VPNs

**Note**

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Setting Up a Static Routed IP Internetwork

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up a static routed IP internetwork**
A static routed IP internetwork does not use routing protocols such as RIP for IP or OSPF to communicate routing information between routers. All of the routing information is stored in a static routing table on each router. You need to ensure that each router has the appropriate routes in its routing table so that traffic can be exchanged between any two endpoints on the IP internetwork.

This section covers:

- The static routed environment
- Static routing design considerations
- Static routing security
- Deploying static routing

**Note**

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# The static routed environment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The static routed environment**

A static routed IP environment is best suited to a small, single-path, static IP internetwork:

- A small internetwork is defined as 2 to 10 networks.
- Single-path means that there is only a single path for packets to travel between any two endpoints on the internetwork.
- Static means that the topology of the internetwork does not change over time.

Candidates for a static routed environment include:

- A small business.
- A home office IP internetwork.
- A branch office with a single network.

  Rather than running a routing protocol across a typically low-bandwidth WAN link, a single default route at the branch office router ensures that all traffic not destined for a computer on the branch office network is routed to the main office.

The disadvantages of static routing are:

- No fault tolerance

  If a router or link goes down, static routers do not sense the fault and inform other routers of the fault. While this is a concern on large, corporate internetworks, a small office (with two routers and three networks based on LAN links) does not go down often enough to justify deploying a multipath topology and a routing protocol.

- Administrative overhead

  If a new network is added or removed from the internetwork, routes to the new network must be manually added or removed. If a new router is added, it must be properly configured for the routes of the internetwork.

# Static routing design considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Static routing design considerations**
To prevent problems, you should consider the following design issues before you implement static routing.

**Peripheral router configuration**
To simplify configuration, you can configure peripheral routers with a default route that points to the neighboring router. A peripheral router is a router attached to multiple networks, only one of which has a neighboring router.

**Default routes and routing loops**
It is recommended that you do not configure two neighboring routers with default routes that are pointing to each other. A default route passes all traffic that is not on a directly connected network to the configured router. Two routers that have default routes pointing to each other may produce routing loops for traffic with an unreachable destination.

**Demand-dial environments**
You can implement static routing across demand-dial links in one of two ways:

- Default route

  You can configure a default route on the branch office router that uses the demand-dial interface. The advantage of a default route is that a single route only needs to be added once. The disadvantage of a default route is that any traffic, including traffic for unreachable destinations, that is not on the branch office network causes the branch office router to call the main office.

- Auto-static routes

  Auto-static routes are static routes that are automatically added to the routing table for a router after routes are requested across a demand-dial connection by using the RIP-for-IP routing protocol. The advantage of auto-static routes is that unreachable destinations do not cause the router to call the main office. The disadvantage of auto-static routes is that they must be periodically updated to reflect the networks that are reachable at the main office. If a new network is added to the main office and the branch office has not performed an auto-static update, all destinations on the new main office network are unreachable from the branch office.

# Static routing security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Static routing security**

To prevent the intentional or unintentional modification of static routes on the routers, you should:

- Employ physical security so that the routers cannot be accessed by users.
- Assign administrator rights only to those users who will be running Routing and Remote Access.

# Deploying static routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying static routing**

If static routing is appropriate for your IP internetwork, you can perform the following steps to deploy static routing:

1. Draw a map of the topology of your IP internetwork that shows the separate networks and the placement of routers and hosts (nonrouter computers that run TCP/IP).

2. For each IP network (a cabling system bounded by one or more routers), assign a unique IP network ID (also known as an IP network address).

3. Assign IP addresses to each router interface. It is a common industry practice to assign the first IP addresses of a given IP network to router interfaces. For example, for an IP network ID of 192.168.100.0 with a subnet mask of 255.255.255.0, the router interface is assigned the IP address of 192.168.100.1.

4. For peripheral routers, configure a default route on the interface that has a neighboring router. The use of default routes on peripheral routers is optional.

5. For each nonperipheral router, compile a list of routes that need to be added as static routes to the routing table for that router. Each route consists of a destination network ID, a subnet mask, a gateway (or forwarding) IP address, a metric (number of router hops to reach the network), and the interface to be used to reach the network.

6. For nonperipheral routers, add the static routes compiled in step 5 to each router. You can add static routes by using Routing and Remote Access.

7. When your configuration is complete, use the **ping** and **tracert** commands to test connectivity between host computers so that all routing paths are checked. For more information about the **ping** and **tracert** commands, see Using the ping command and Using the tracert command.

For information about troubleshooting static routing, see Common routing problems and Understanding the IP routing table.

# Setting Up a RIP-for-IP Routed Internetwork

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up a RIP-for-IP routed internetwork**

A RIP-for-IP routed internetwork uses the RIP-for-IP routing protocol to dynamically communicate routing information between routers. Deployed properly, a RIP-for-IP environment automatically adds and removes routes as networks are added and removed from the internetwork. You need to ensure that each router is properly configured so that the RIP-based route announcements are sent and received by all RIP routers on the internetwork.

This section covers:

- The RIP-for-IP environment
- RIP-for-IP design considerations
- RIP-for-IP security
- Deploying RIP for IP

# The RIP-for-IP environment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The RIP-for-IP environment**

A RIP-for-IP routed environment is best suited to a small-to-medium-sized, multipath, dynamic IP internetwork:

- A small-to-medium-sized internetwork is defined as 10 to 50 networks.
- Multipath means that there are multiple paths for packets to travel between any two endpoints on the internetwork.
- Dynamic means that the topology of the internetwork changes over time because networks are added and removed and links occasionally go down and come back up.

Candidates for a RIP-for-IP routed environment include:

- A medium-sized business.
- A large branch office or satellite office with multiple networks.

# RIP-for-IP design considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**RIP-for-IP design considerations**
To prevent problems, you should consider the following design issues before you implement RIP for IP.

**Decreased diameter of 14 routers**
The maximum diameter of RIP internetworks is 15 routers. The diameter is a measure of the size of an internetwork in terms of hops or other metrics. However, the server running Routing and Remote Access considers all non-RIP learned routes to be at a fixed hop count of 2. Static routes, even static routes for directly connected networks, are considered non-RIP learned routes. When a server running Routing and Remote Access acting as a RIP router advertises its directly connected networks, it advertises them at a hop count of 2 even though there is only one physical router to cross. Therefore, a RIP-based internetwork that uses servers running Routing and Remote Access have a maximum physical diameter of 14 routers.

**RIP costs**
RIP uses the hop count as a metric to determine the best route. Using the number of routers to cross as the basis for selecting the best route may lead to undesired routing behavior. For example, if two sites were connected together by using a T1 link and a lower-speed satellite link as a backup, both links are considered the same metric. When the router is given a choice between two routes of the same lowest metric (hop count), the router is free to choose between them.

If the router chooses the satellite link, then the slower backup link is used rather than the higher bandwidth link. To prevent the satellite link from being chosen, you can assign a custom cost to the satellite interface. For example, if you assign a cost of 2 to the satellite interface (rather than the default of 1), then the best route is always the T1 link. If the T1 link goes down, the satellite link is chosen as the next best route.

If you are using custom costs to indicate link speed, delay, or reliability factors, ensure that the accumulated costs (hop counts) between any two endpoints on the internetwork do not exceed 15.

**Mixed RIP version 1 and RIP version 2 environments**
For maximum flexibility, you should use RIP version 2 in your RIP-for-IP internetwork. If there are routers in your internetwork that do not support RIP version 2, you can use a mixed environment of RIP v1 and RIP v2. However, RIP v1 does not support classless interdomain routing (CIDR) or variable-length subnet masks (VLSM) implementations. If you have support for CIDR and VLSM in one part of your internetwork but not another, you may experience routing problems.

If a network is using a mixture of RIP v1 and RIP v2 routers, then you must configure the interfaces of the server running Routing and Remote Access to advertise by using either RIP v1 broadcasts or RIP v2 broadcasts and accept either RIP v1 or RIP v2 announcements.

**RIP version 2 authentication**
If you use RIP version 2 simple password authentication, then you must configure all of the RIP v2 interfaces on the same network with the same case-sensitive password. You can use the same password for all the networks of your internetwork or you can vary the password for each network.

**RIP version 2 across demand-dial links**
If you use RIP to perform auto-static updates across demand-dial links, then you must configure each demand-dial interface to use RIP v2 multicast announcements and to accept RIP v2 announcements. Otherwise, the RIP request for routes sent by the requesting router is not responded to by the router on the other side of the demand-dial link.

**RIP over Frame Relay**
Since RIP is primarily a broadcast and multicast-based protocol, you need a special configuration for proper RIP operation over a nonbroadcast technology such as Frame Relay. How RIP is configured for Frame Relay depends on how the Frame Relay virtual circuits appear as network interfaces on servers running Routing and Remote Access. Either the Frame Relay adapter appears as a single adapter for all the virtual circuits (single adapter model), or each virtual circuit appears as a separate adapter (multiple adapter model).

**Single-adapter model**
With the single adapter model, also known as the nonbroadcast multiple access (NBMA) model, the network of the Frame Relay service provider (also known as the Frame Relay cloud) is treated as an IP network and the endpoints are assigned IP addresses from a designated IP network ID. To ensure that RIP traffic is received by all of the appropriate endpoints on the cloud, you must configure the Frame Relay interface to unicast its RIP announcements to all of the appropriate endpoints. You

do this by configuring RIP neighbors. For more information about configuring RIP neighbors, see Add a unicast neighbor.

Also, in a spoke and hub Frame Relay topology, the Frame Relay interface for the hub router must have split-horizon processing disabled. Otherwise, the spoke routers never receive each other's routes. For more information, see Set split-horizon processing.

**Multiple-adapter model**

With the multiple adapter model, each Frame Relay virtual circuit appears as a point-to-point link with its own network ID, and the endpoints are assigned IP addresses from a designated IP network ID. Because each virtual circuit is its own point-to-point connection, you can either broadcast (assuming both endpoints are on the same IP network ID) or multicast RIP announcements.

### Note

- The preceding discussion also applies to other nonbroadcast technologies such as X.25 and ATM.

**Silent RIP hosts**

A silent RIP host (a nonrouter) processes received RIP announcements but does not make RIP announcements. The processed RIP announcements are used to build the routing table for the host. You do not need to configure silent RIP hosts with a default gateway. Silent RIP is commonly used in UNIX environments. If there are silent RIP hosts on a network, you must determine which version of RIP they support. If the silent RIP hosts only support RIP v1, then you must use RIP v1 on the network for that host.

# RIP-for-IP security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**RIP-for-IP security**

In addition to the security steps listed in Static routing security, you can enhance RIP-for-IP security through:

- RIP version 2 authentication
- Peer security
- Route filters
- Neighbors

**RIP version 2 authentication**

To prevent the corruption of RIP routes by an unauthorized RIP router in a RIP version 2 environment, you can configure RIP v2 router interfaces to use simple password authentication. Received RIP announcements that do not match the configured password are discarded. Note that the password is sent in plaintext. Any user with a network sniffer, such as Microsoft Network Monitor, can capture the RIP v2 announcements and view the password. For more information, see Enable authentication.

**Peer security**

You can configure each RIP router with a list of routers (by IP address) from which RIP announcements are accepted. By default, RIP announcements from all sources are accepted. By configuring a list of RIP peers, RIP announcements from unauthorized RIP routers are discarded. For more information about configuring peer security, see Add peer filters.

**Route filters**

You can configure route filters on each RIP interface so that the only routes considered for addition to the routing table are those that reflect reachable network IDs within the internetwork. For example, if an organization is using subnets of the private network ID 10.0.0.0, route filtering can be used so that the RIP routers discard all routes except those within the 10.0.0.0 network ID. For more information about configuring RIP route filters, see Add route filters.

**Neighbors**

By default, RIP either broadcasts (RIP version 1 or RIP version 2) or multicasts (RIP v2 only) announcements. To prevent RIP traffic from being received by any node except neighboring RIP routers, the server running Routing and Remote Access can unicast RIP announcements. While originally intended for use by nonbroadcast multiaccess (NBMA) network technologies such as Frame Relay, the configuration of RIP neighbors ensures that RIP announcements are directed to neighboring RIP routers. For more information about configuring RIP neighbors, see Add a unicast neighbor.

### Note

- When you configure RIP routers to unicast to neighboring RIP routers, the ability of silent RIP hosts to receive RIP traffic is impaired. Therefore, you need to either add the silent RIP hosts as neighbors or configure the server running Routing and Remote Access to broadcast or multicast (in addition to unicasting to RIP neighbors).

# Deploying RIP for IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying RIP for IP**

While basic RIP version 1 functionality is easy to configure and deploy, RIP version 2 and advanced RIP capabilities, such as peer security and route filtering, require additional configuration and testing. To make troubleshooting and problem isolation easier, it is recommended that you deploy your RIP-based internetwork in the following stages:

1. Set up basic RIP and make sure it is working.

2. Add advanced capabilities one at a time, testing after each feature is added.

**Deploying RIP**

To deploy RIP, you can perform the following steps:

1. Draw a map of the topology of your IP internetwork that shows the separate networks and the placement of routers and hosts (nonrouter computers running TCP/IP).

2. For each IP network (a cabling system bounded by one or more routers), assign a unique IP network ID (also known as an IP network address).

3. Assign IP addresses to each router interface. It is a common industry practice to assign the first IP addresses of an IP network to router interfaces. For example, for an IP network ID of 192.168.100.0 with a subnet mask of 255.255.255.0, the router interface is assigned an IP address of 192.168.100.1.

4. For each router interface, designate whether that interface will be configured for RIP v1 or RIP v2. If an interface is configured for RIP v2, designate whether the RIP v2 announcements will be broadcast or multicast.

5. By using Routing and Remote Access, add the RIP routing protocol and configure the appropriate interfaces for RIP v1 or RIP v2 for each server running Routing and Remote Access.

6. When your configuration is complete, allow a few minutes for the routers to update each other's routing tables and then test the internetwork.

For more information, see Configure RIP for IP.

**Testing a RIP internetwork**

To test your RIP internetwork, you can perform the following steps:

1. To verify that a server running Routing and Remote Access is receiving RIP announcements from all of its neighboring RIP routers, view the RIP neighbors for the router. For more information about viewing RIP neighbors, see View RIP neighbors.

2. For each RIP router, view the IP routing table and verify that all of the routes that should be learned from RIP are present. For more information about viewing the IP routing table, see View routing tables.

3. Use the **ping** and **tracert** commands to test connectivity between host computers so that all routing paths are checked. For more information about the **ping** and **tracert** commands, see Using the ping command and Using the tracert command.

For information about troubleshooting RIP for IP, see Troubleshooting RIP for IP.

# Setting Up an OSPF Routed Internetwork

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up an OSPF routed internetwork**

An Open Shortest Path First (OSPF) routed internetwork uses the OSPF routing protocol to dynamically communicate routing information between routers. Deployed properly, an OSPF environment automatically adds and removes routes as networks are added and removed from the internetwork. You need to ensure that each router is properly configured so that the OSPF-based route advertisements are propagated to OSPF routers on the internetwork. This feature is not available on the Itanium-based versions of the Windows operating systems. This content is not available in this preliminary release.

This section covers:

- The OSPF environment
- OSPF design considerations
- OSPF security
- Deploying OSPF
- Deploying a single-area OSPF internetwork

# The OSPF environment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The OSPF environment**

An Open Shortest Path First (OSPF) routed environment is best suited to a large-to-very-large, multipath, dynamic IP internetwork.

- A large-to-very-large internetwork contains more than 50 networks.
- Multipath means that there are multiple paths for packets to travel between any two endpoints on the internetwork.
- Dynamic means that the topology of the internetwork changes over time because networks are added and removed and links occasionally go down and come back up.

Candidates for an OSPF routed environment include:

- A corporate or institutional campus.
- A worldwide corporate or institutional internetwork.

**Notes**

- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.

# OSPF design considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**OSPF design considerations**
To prevent problems, you should consider the following design issues before you implement Open Shortest Path First (OSPF). This feature is not available on the Itanium-based versions of the Windows operating systems. This content is not available in this preliminary release.

**OSPF design**
There are three levels of OSPF design:

- Autonomous system design
- Area design
- Network design

To aid in configuration and to prevent problems, you should consider the following elements for each level of OSPF design.

**Autonomous system design**
The following guidelines are recommended when designing an OSPF autonomous system:

- Subdivide the OSPF autonomous system into areas that can be summarized.
- If possible, subdivide your IP address space into a network/area/subnet/host hierarchy.
- Make the backbone area a single high-bandwidth network.
- Create stub areas whenever possible.
- Avoid virtual links whenever possible.

**Area design**
The following guidelines are recommended when designing each OSPF area:

- Ensure that all areas are assigned network IDs that can be expressed as a small number of summary routes.
- If an area can be summarized with a single route, make the area ID the single route being advertised.
- Ensure that multiple area border routers (ABRs) for the same area are summarizing the same routes.
- Ensure that there are no back doors between areas and that all inter-area traffic crosses the backbone area.
- Keep areas under 100 networks.

**Network design**
The following guidelines are recommended when designing each network:

- Assign router priorities so that the least busy routers are the designated router and backup designated router.
- Designate link costs to reflect bit rate, delay, or reliability characteristics.
- Assign a password.

**OSPF over Frame Relay**
Although OSPF packets are typically multicast, OSPF was designed to operate over a nonbroadcast technology such as Frame Relay. How OSPF is configured for Frame Relay depends on how the Frame Relay virtual circuits appear as network interfaces on the server running Routing and Remote Access. Either the Frame Relay adapter appears as a single adapter for all the virtual circuits (single adapter model) or each virtual circuit appears as a separate adapter (multiple adapter model).

**Single-adapter model**
With the single adapter model, also known as the nonbroadcast multiple access (NBMA) model, the network for the Frame Relay service provider (also known as the Frame Relay cloud) is treated as an IP network and the endpoints on the cloud are assigned IP addresses from a designated IP network ID. To ensure that OSPF traffic is received by all of the appropriate endpoints on the cloud, you must configure the Frame Relay interface to unicast its OSPF announcements to all of the appropriate endpoints. For the server running Routing and Remote Access, this is done by designating the interface as a nonbroadcast multiple access (NBMA) network and adding OSPF neighbors. To add OSPF neighbors, see Add an OSPF neighbor.

Also, in a spoke and hub Frame Relay topology, the Frame Relay interface for the hub router must have a router priority set to 1 or greater and the Frame Relay interfaces for the spoke routers must have a router priority set to 0. Otherwise, the hub router, which is the only router that can communicate with all of the spoke routers, cannot become the designated router and adjacencies cannot form across the Frame Relay network.

**Multiple-adapter model**
With the multiple adapter model, each Frame Relay virtual circuit appears as a point-to-point link with its own network ID, and the endpoints are assigned IP addresses from a designated IP network ID. Since each virtual circuit is its own point-to-point connection, you can configure the interface for the point-to-point network type.

### Note

- The preceding discussion also applies to other NBMA technologies such as X.25 and ATM.

**Using virtual links**
An OSPF routed internetwork can be subdivided into areas, which are collections of contiguous networks. All areas are connected together through a common area called the backbone area. A router that connects an area to the backbone area is called an area border router (ABR). Normally, ABRs have a physical connection to the backbone area. When it is not possible or practical to have an ABR of an area physically connected to the backbone area, you can use a virtual link to connect the ABR to the backbone.

A virtual link is a logical point-to-point connection between an ABR of an area and an ABR that is physically connected to the backbone area. For example, a virtual link is configured between the ABR of Area 2 and the ABR of Area 1. The ABR of Area 1 is physically connected to the backbone area. Area 1 is known as the transit area, the area across which the virtual link is created in order to logically connect Area 2 to the backbone.

To create a virtual link, both routers, called virtual link neighbors, are configured with the transit area, the router ID of the virtual link neighbor, matching hello and dead intervals, and a matching password.

For more information, see Add a virtual interface.

To troubleshoot a virtual link, see Troubleshooting OSPF.

**External routes and ASBRs**
The set of OSPF routers in an organization defines an OSPF autonomous system (AS). By default, only OSPF routes corresponding to directly connected network segments are propagated within the AS. An external route is any route that is not within the OSPF AS. External routes can come from many sources:

- Other routing protocols such as RIP for IP (v1 and v2).
- Static routes.
- Routes set on the router through SNMP.

External routes are propagated throughout the OSPF AS through one or more autonomous system boundary routers (ASBRs). An ASBR advertises external routes within the OSPF AS. For example, if you need to advertise the static routes of a server running Routing and Remote Access, you need to enable that router as an ASBR.

For more information, see Configure an ASBR.

**External route filters**
By default, OSPF routers acting as ASBRs import and advertise all external routes. You may want to filter out external routes to keep the ASBR from advertising improper routes. External routes can be filtered on the ASBR by:

- External route source

  You can configure the ASBR to accept or ignore the routes of certain external sources such as routing protocols (RIP v2) or other sources (static routes or SNMP).

- Individual route

  You can configure the ASBR to accept or discard specific routes by configuring one or multiple {Destination, Network mask} pairs.

**OSPF on a remote access server**
If you configure a server running Routing and Remote Access using OSPF to also act as a remote access server and the static IP address pool address ranges are for a separate subnet, in order to properly advertise the route that represents all remote access clients:

1. Enable the server running Routing and Remote Access as an autonomous system boundary router (ASBR).

2. Configure OSPF route filters to **Accept listed routes** and then add the routes that correspond to the address ranges of your static IP address pool.

For more information, see Configure an ASBR.

**OSPF on an answering demand-dial router**
If you configure a server running Routing and Remote Access by using OSPF to act as the answering router in a one-way initiated connection, in order to properly advertise the routes that represent the network segments of your calling routers:

1. Enable the answering router as an autonomous system boundary router (ASBR).

2. If the answering router is also configured with static IP address pool address ranges that are for a separate subnet, add the routes that correspond to the static routes on the user accounts being used by the calling routers.

For more information, see Configure an ASBR.

For more information about using static routes for one-way initiated demand-dial connections, see One-way initiated demand-dial connections.

# OSPF security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**OSPF security**

In addition to the security steps listed in Static routing security, you can enhance Open Shortest Path First (OSPF) security through:

- Authentication
- External route filters on ASBRs

**Authentication**

By default, OSPF interfaces on the server running Routing and Remote Access are configured to send the simple password of "12345678" in their OSPF Hello messages. The simple password helps prevent the corruption of OSPF data from an unauthorized OSPF router on a network. The password is sent in plaintext. Any user with a network sniffer, such as Microsoft Network Monitor, can capture the OSPF Hello messages and view the password.

**External route filters on ASBRs**

To prevent the propagation of invalid routes into the OSPF autonomous system (AS) from external sources such as RIP or static routes, you can configure autonomous system boundary routers (ASBRs) with route filters. You can configure ASBR route filters so that any route that matches a configured list is discarded, or any route that does not match a configured list is discarded.

For more information, see Configure an ASBR.

### Notes

- You can only use external route filters to filter routes from non-OSPF sources. There is no capability to filter OSPF routes within the OSPF autonomous system.
- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.

# Deploying OSPF

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying OSPF**

Deploying Open Shortest Path First (OSPF) requires careful planning and configuration at three levels:

- The autonomous system
- The area
- The network

**Planning the autonomous system**

For the OSPF autonomous system (AS), you need to:

1. Subdivide the OSPF AS into areas that can be easily summarized by using summary routes.
2. Designate the backbone area.
3. Assign area IDs.
4. Identify virtual links.
5. Identify area border routers (ABRs).
6. Identify stub areas.
7. Identify autonomous system boundary routers (ASBRs).

**Planning each area**

For each router, you need to:

1. Add the areas to which the router is connected.
2. If the area is a stub area, enable the area as a stub area.
3. If the router is an ABR, optionally configure the ranges that summarize the IP networks within the area.
4. If the router is an ABR that uses a virtual link, add the virtual interface.
5. If the router is an ASBR, enable ASBR and configure optional external route filters.

**Planning each network**

For each IP address for each router interface that uses OSPF, you need to:

1. Add the interface to the OSPF routing protocol.
2. Enable OSPF on the interface.
3. Configure the interface for the appropriate area ID.
4. Configure the interface for the appropriate router priority.

5. Configure the interface for the appropriate link cost.

6. Configure the interface for the appropriate password.

7. Configure the interface for the appropriate network type.

8. If the interface is a single-adapter Frame Relay (or X.25 or ATM) interface, configure the nonbroadcast multiple access (NBMA) neighbors.

For more information, see Configure OSPF.

**Testing OSPF**

To test your OSPF internetwork, you can perform the following steps:

1. To verify that a server running Routing and Remote Access is receiving OSPF announcements from all of its adjacent OSPF routers, view the OSPF neighbors for the router. For more information, see View OSPF neighbors.

2. For each router, view the IP routing table and verify that all of the routes that should be learned from OSPF are present. For more information, see View routing tables.

3. Use the **ping** and **tracert** commands to test connectivity between host computers so that all routing paths are checked. For more information about the **ping** and **tracert** commands, see Using the ping command and Using the tracert command.

For information about troubleshooting OSPF, see Troubleshooting OSPF.

### Notes

- This feature is not available on the Itanium-based versions of the Windows operating systems.

- This content is not available in this preliminary release.

# Deploying a single-area OSPF internetwork

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying a single-area OSPF internetwork**
While Open Shortest Path First (OSPF) is a routing protocol designed to scale to very large internetworks, the planning and implementation of a large scale OSPF internetwork is complex and time-consuming. However, you do not need a large or very large internetwork to take advantage of the advanced features of OSPF.

In the Windows Server 2003 family implementation of OSPF, the default values of global and interface settings make it very easy to create a single-area OSPF internetwork with minimal configuration. The single area is the backbone area (0.0.0.0).

**OSPF default global settings**
The OSPF default global settings are as follows:

- The router identification is set to the IP address of the first IP binding at the time of the installation of the OSPF routing protocol.
- The router is not configured as an OSPF autonomous system boundary router.
- A single area, the backbone area, is configured and enabled for a plaintext password. It is not configured as a stub area and there are no address ranges.
- There are no configured virtual interfaces, and external routes are not filtered.

For a single-area OSPF internetwork, no changes to the OSPF default global settings are required.

**OSPF default interface settings**
The OSPF default interface settings for LAN interfaces are as follows:

- By default, OSPF is *not* enabled to run over the interface.
- The area ID is set to the backbone area (0.0.0.0).
- The router priority is set to 1. With multiple OSPF routers on the same network with the same router priority, the OSPF designated router and backup designated router are elected based on the router with the highest router ID.
- The cost is set to 2.
- The password is set to 12345678.
- The network type is set to broadcast for LAN interfaces.
- There are no configured neighbors.
- The hello interval is set to 10 seconds.
- The dead interval is set to 40 seconds.

For a single-area OSPF internetwork, the only required change to the OSPF default interface settings is to enable OSPF to run over the interface.

**Deploying OSPF**
To deploy an OSPF single-area internetwork that consists of LAN interfaces, perform the following steps on each server running Routing and Remote Access:

1. Enable the Routing and Remote Access service. For more information, see Enable the Routing and Remote Access service.

2. Add the OSPF routing protocol. For more information, see Add the OSPF routing protocol.

3. Add the routing interfaces of the router to the OSPF routing protocol, enabling OSPF for each interface. For more information, see Add an interface to OSPF.

**Testing OSPF**

To test your single-area OSPF internetwork, you can perform the following steps:

1. To verify that a server running Routing and Remote Access is receiving OSPF announcements from all of its adjacent OSPF routers, view the OSPF neighbors for the router. For more information, see View OSPF neighbors.

2. For each router, view the IP routing table and verify that all of the routes that should be learned from OSPF are present. For more information, see View routing tables.

3. Use the **ping** and **tracert** commands to test connectivity between host computers so that all routing paths are checked. For more information about the **ping** and **tracert** commands, see Using the ping command and Using the tracert command.

For information about troubleshooting OSPF, see Troubleshooting OSPF.

### Notes

- This feature is not available on the Itanium-based versions of the Windows operating systems.

- This content is not available in this preliminary release.

# Setting Up Network Address Translation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up network address translation**

This section covers:

- Network address translation design considerations
- Deploying network address translation

# Network address translation design considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network address translation design considerations**
To prevent problems, you should consider the following design issues before you implement network address translation.

**Private network addressing**
You should use the following IP addresses from the Internet Assigned Numbers Authority (IANA) private IP network IDs: 10.0.0.0 with a subnet mask of 255.0.0.0, 172.16.0.0 with a subnet mask of 255.240.0.0, and 192.168.0.0 with a subnet mask of 255.255.0.0. By default, network address translation uses the private network ID 192.168.0.0 with the subnet mask of 255.255.255.0 for the private network.

For more information, see Enable network address translation addressing.

If you are using public IP addresses that have not been allocated by IANA or your ISP, then you may be using the IP network ID of another organization on the Internet. This is known as illegal or overlapping IP addressing. If you are using overlapping public addresses, then you cannot reach the Internet resources of the overlapping addresses. For example, if you use 1.0.0.0 with the subnet mask of 255.0.0.0, then you cannot reach any Internet resources of the organization that is using the 1.0.0.0 network.

You can also exclude specific IP addresses from the configured range. Excluded addresses are not allocated to private network hosts.

**Single or multiple public addresses**
If you are using a single public IP address allocated by your ISP, no other IP address configuration is necessary. If you are using multiple IP addresses allocated by your ISP, then you must configure the network address translation (NAT) interface with your range of public IP addresses. For the range of IP addresses given to you by your ISP, you must determine whether the range of public IP addresses can be expressed by using an IP address and a mask.

If you are allocated a number of addresses that is a power of 2 (2, 4, 8, 16, and so on), you might be able to express the range by using a single IP address and mask. For example, if you are given the four public IP addresses 206.73.118.212, 206.73.118.213, 206.73.118.214, and 206.73.118.215 by your ISP, then you can express these four addresses as 206.73.118.212 with a mask of 255.255.255.252.

If your IP addresses are not expressible as an IP address and a subnet mask, you can enter them as a range or series of ranges by indicating the starting and ending IP addresses.

For more information, see Configure interface IP address ranges.

**Allowing inbound connections**
Normal NAT usage from a home or small business allows outbound connections from the private network to the public network. Some programs that run from the private network create connections to Internet resources. The return traffic from the Internet can be translated because the connection was initiated from the private network.

To allow Internet users to access resources on your private network, you must do the following:

- Configure a static IP address configuration on the resource server including IP address (from the range of IP addresses allocated by the NAT computer), subnet mask (from the range of IP addresses allocated by the NAT computer), default gateway (the private IP address of the NAT computer), and DNS server (the private IP address of the NAT computer).
- Exclude the IP address being used by the resource computer from the range of IP addresses being allocated by the NAT computer.
- Configure a special port. A special port is a static mapping of a public address and port number to a private address and port number. A special port maps an inbound connection from an Internet user to a specific address on your private network. By using a special port, you can create a Web server on your private network that is accessible from the Internet.

For more information, see Configure services and ports.

**Configuring applications and services**

You may need to configure applications and services to work properly across the Internet. For example, if users on your small office or home office (SOHO) network want to play the game Asheron's Call with other users on the Internet, network address translation must be configured for Asheron's Call.

For more information, see Configure services and ports.

**VPN connections from a translated SOHO network**

To access a private intranet using a virtual private network (VPN) connection from a translated SOHO network, you can use the Point-to-Point Tunneling Protocol (PPTP) and create a VPN connection from a host on the SOHO network to the VPN server of the private intranet on the Internet.

The Windows Server 2003 family allows L2TP/IPSec VPN connections to work with NAT. For more information, see Virtual Private Networks.

# Deploying network address translation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying network address translation**

To deploy network address translation for a small office or home office network, you need to configure:

- The network address translation computer.
- Other computers on the small office or home network.

**Configuring the network address translation computer**

To configure the network address translation (NAT) computer, you can complete the following steps:

1. Install and enable the Routing and Remote Access service.

   In the Routing and Remote Access Server Setup Wizard, choose **Network address translation (NAT)**. After the wizard is finished, all of the configuration for NAT is complete. You do not need to complete steps 2 through 8.

   If you have already enabled the Routing and Remote Access service, then complete steps 2 through 8 as needed.

   For information about installing and enabling the Routing and Remote Access service, see Enable the Routing and Remote Access service.

2. Configure the IP address of the private network interface.

   For the IP address of the LAN adapter that connects to the home network, you need to configure the following:

   - IP address: 192.168.0.1
   - Subnet mask: 255.255.255.0
   - No default gateway

   **Note**

   - The IP address in the preceding configuration for the home network interface is based on the default address range of 192.168.0.0 with a subnet mask of 255.255.255.0, which is configured for the addressing component of network address translation. If you change this default address range, you should change the IP address of the private interface for the network address translation computer to be the first IP address in the configured range. Using the first IP address in the range is a recommended practice, not a requirement of the network address translation components.

3. Enable routing on your dial-up port.

   If your connection to the Internet is a permanent connection that appears as a LAN interface (such as DDS, T-Carrier, Frame Relay, permanent ISDN, xDSL, or cable modem) or if you are connecting your server running Routing and Remote Access to another router before the connection to the Internet, and the LAN interface is configured with an IP address, subnet mask, and default gateway either statically or through DHCP, skip to step 6.

   For information about enabling routing on your dial-up port, see Enable routing on ports.

4. Create a demand-dial interface to connect to your Internet service provider.

You need to create a demand-dial interface that is enabled for IP routing and uses your dial-up equipment and the credentials that you use to dial your Internet service provider (ISP). For more information about creating demand-dial interfaces, see Add a demand-dial interface.

5. Create a default static route that uses the Internet interface.

   For a default static route, you need to select the demand-dial interface (for dial-up connections) or LAN interface (for permanent or intermediate router connections) that is used to connect to the Internet. The destination is 0.0.0.0 and the network mask is 0.0.0.0. For a demand-dial interface, the gateway IP address is not configurable.

   For more information about configuring a default static route, see Add a default static IP route.

6. Add the network address translation (NAT) routing protocol.

   For information about adding the network address translation (NAT) IP routing protocol, see Add network address translation.

7. Add your Internet and home network interfaces to the NAT routing protocol.

   For information about adding interfaces to the NAT IP routing protocol, see Add and configure an interface for network address translation.

8. Enable NAT addressing and name resolution.

   For information about enabling network address translation addressing, see Enable network address translation addressing.

   For information about enabling network address translation name resolution, see Enable network address translation name resolution.

   **Note**

   - The NAT addressing feature only assigns addresses from a single range that corresponds to a single subnet. If multiple home network LAN interfaces are added to the NAT routing protocol, a single subnet configuration (where all LAN interfaces are connected to the same network) is assumed. If the LAN interfaces correspond to different networks, connectivity between clients on different networks who receive addresses from the NAT computer may not be possible.

**Configuring other computers on the small office or home network**

You need to configure the TCP/IP protocol on the other computers on the small office or home network to obtain an IP address automatically, and then restart them. When the computers on the home network receive their IP address configuration from the network address translation computer, they are configured with:

- IP address (from the address range of 192.168.0.0 with a subnet mask of 255.255.255.0).
- Subnet mask (255.255.255.0).
- Default gateway (the IP address of a directly reachable IP router on the small office or home network).
- DNS server (the IP address of the interface for the NAT computer on the small office or home network).

**Advanced NAT settings**

To configure advanced NAT settings, you can do the following:

- If you have been given a range of IP addresses from your ISP, configure the range of IP addresses on your Internet interface.

- If there are services running on the private network that need to be accessed by users from the Internet, add a special port that maps the public IP address and port number to a private IP address and port number.

For more information, see Configure NAT/Basic Firewall.

For information about troubleshooting network address translation, see Troubleshooting network address translation.

# Setting Up Demand-Dial Routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up demand-dial routing**

This section covers:

- Demand-dial routing design considerations
- Demand-dial routing security
- Deploying demand-dial routing
- Deploying certificate-based authentication for demand-dial routing

# Demand-dial routing design considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Demand-dial routing design considerations**
To prevent problems, you should consider the following design issues before you implement demand-dial routing.

**On-demand or persistent connections**
You must decide whether your demand-dial connections will be on-demand or persistent:

- On-demand demand-dial connections are used when the cost of using the communications link is time-sensitive. For example, long distance analog phone calls are charged on a per-minute basis. With on-demand connections, the connection is made when traffic is forwarded, and the connection is terminated when the link is not used. You can configure idle disconnect behavior for the answering router by setting an idle disconnect through the profile properties of the remote access policy that is used for the demand-dial connection. You can configure idle disconnect behavior for the calling router on the **Options** tab on the properties of the demand-dial interface.

- Persistent demand-dial connections use a dial-up link but can be left in a connected state 24 hours a day without incurring additional usage charges. Examples of persistent demand-dial connections include local calls that use analog phone lines and flat-rate ISDN.

**One-way or two-way initiated connections**
You must decide whether your demand-dial connections will be initiated by one router or by both routers:

- With one-way initiated connections, one router is always the answering router and one router is always the calling router. The answering router accepts the connection and the calling router initiates the connection. One-way initiated connections are well suited to an on-demand spoke and hub topology where the branch office router is the only router that initiates the connection. One-way initiated connections require the following:

    - The answering router is configured as a LAN and demand-dial router.

    - A user account is added for the authentication credentials of the calling router that is accessed and validated by the answering router.

    - A demand-dial interface is configured at the answering router with the same name as the user account that is used by the calling router. The demand-dial interface is not used to dial out; therefore it is not configured with the phone number of the calling router or with valid user credentials.

  For an alternate configuration that does not require a demand-dial interface on the answering router, see One-way initiated demand-dial connections.

- With two-way initiated connections, either router can be the answering router or the calling router depending on who is initiating the connection. Both routers must be configured to initiate and accept a demand-dial connection. You can use two-way initiated connections when traffic from either router can create the demand-dial connection. Two-way initiated demand-dial connections require the following:

    - Both routers are configured as LAN and demand-dial routers.

    - User accounts are added for both routers so that the authentication credentials of the calling router are accessed and validated by the answering router.

    - Demand-dial interfaces, with the same name as the user account that is used by the calling router, are fully configured at both routers, including the phone number of the answering router and user account credentials to authenticate the calling router.

**Restricting the initiation of an on-demand connection**
To prevent the calling router from making unnecessary on-demand dial-up connections, which may result in excessive phone charges, you can restrict the calling router from making connections in two ways:

- Demand-dial filtering

  You can use demand-dial filtering to configure either the types of IP traffic that do not cause a connection to be made or the types of IP traffic that cause a connection to be made. For more information, see Configure demand-dial filters.

- Dial-out hours

  You can use dial-out hours to configure the hours that a calling router is either permitted or denied to make a demand-dial connection. For more information, see Configure dial-out hours.

**IP packet filters and demand-dial filters**
Demand-dial filters are applied before the connection is made. IP packet filters are applied after the connection is made. To prevent the demand-dial connection from being established for traffic that is discarded by the IP packet filters:

- If you have configured a set of output IP packet filters with the **Receive all packets except those that meet the criteria listed below** option, then configure the same set of filters as demand-dial filters with **Initiate connection** set to **For all traffic except**.

- If you have configured a set of output IP packet filters with the **Drop all packets except those that meet the criteria listed below** option, then configure the same set of filters as demand-dial filters with **Initiate connection** set to **Only for the following traffic**.

**Routing**
Both routers on a demand-dial connection must have the appropriate routes in their routing tables to forward traffic across the connection. Additionally, routes in the routers of the intranets of both demand-dial routers must be present that support the two-way forwarding of traffic between any two destinations. Routes can be static or dynamic.

Static routing is recommended for on-demand connections. You can add static routes to the routing table either manually or through an auto-static update. For more information, see Add a static route or Demand-dial routing updates.

Dynamic routing is recommended for persistent connections by adding the demand-dial interface to an IP routing protocol.

**Creating a remote access policy for demand-dial connections**
By using remote access policies, you can create a policy that requires demand-dial connections to use a specific authentication method and encryption strength.

For example, you can create a user group account called Demand-Dial Routers whose members are the user accounts that are used by calling routers when a demand-dial connection is created. Then, you create a policy with one condition: the **Windows-Group** is set to **Demand-Dial Routers**. Finally, you configure the profile for the policy to select a specific authentication method and encryption strength.

For more information, see Introduction to remote access policies.

**User accounts for demand-dial connections**
When you create a user account by using the Demand-Dial Interface wizard, the remote access permission is set to **Allow access** even though for a new account in a Windows 2000 or Windows Server 2003 domain or a stand-alone router, the default remote access permission for newly created accounts is set to **Control access through Remote Access Policy**. This behavior may cause some confusion if you are using the access-by-policy administrative model. In the access-by-policy administrative model, the remote access permission of all user accounts is set to **Control access through Remote Access Policy** and the remote access permission of individual policies are set to either **Grant remote access permission** or **Deny remote access permission**. For more information, see Remote Access Policies Examples.

When the user account is created, it is created with the current default password settings and policies set for your domain. Verify that the user accounts that are used by calling routers have the following settings on the **General** tab on the properties of the user account:

- The **User must change password at next logon** check box is cleared.

If the check box is selected, then you must manually clear this setting. Accounts created with the Demand-Dial Interface wizard automatically have this check box cleared. If you do not clear this setting, then a demand-dial router cannot connect by using this account. When the calling router sends its credentials, the calling router is prompted to change the password. Because the initiation of a demand-dial connection is not an interactive process involving a user, the calling router is unable to change the password and aborts the connection attempt.

- The **Password never expires** check box is selected.

  Because the demand-dial connection process is not interactive, if the password expires, the calling router is prompted to change the expired password and the connection attempt is ended.

# Demand-dial routing security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Demand-dial routing security**
Security is less of a concern for demand-dial connections than for router-to-router VPN connections because data is not traveling across a public network like the Internet. However, data may be intercepted as it travels through the infrastructure of your telecommunications provider.

In addition to the security steps listed in Static routing security, you can enhance demand-dial routing security through:

- Strong authentication
- Data encryption

**Strong authentication**
For authentication, use the strongest authentication scheme that is possible for your demand-dial configuration. The strongest authentication scheme is the use of EAP-TLS with certificates. For more information, see Deploying certificate-based authentication for demand-dial routing.

Otherwise, use MS-CHAP v2 authentication and enforce the use of strong passwords on your network. For more information, see Enable authentication protocols.

**Data encryption**
For encryption, you can use either link encryption or end-to-end encryption:

- Link encryption encrypts the data only on the link between the two routers. You can use 128-bit Microsoft Point-to-Point Encryption (MPPE). 40-bit MPPE can be used for compatibility with older versions of Microsoft operating systems. You must use MPPE in conjunction with either MS-CHAP or EAP-TLS authentication.
- End-to-end encryption encrypts the data between the source host and its final destination. You can use Internet Protocol security (IPSec) to encrypt data from the source host to the destination host across the demand-dial link.

  For more information, see Internet Protocol Security (IPSec).

To require encryption, clear the **No encryption** option and select the appropriate encryption strengths on the **Encryption** tab of the remote access policy profile that is used by your calling routers. For more information, see Configure encryption.

# Deploying demand-dial routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying demand-dial routing**

In order to create a two-way, initiated demand-dial routing connection from a branch office router to a corporate office router, you must perform the following:

1. Configure the corporate office router to initiate and receive demand-dial connections with the branch office router.
2. Configure the branch office router to initiate and receive demand-dial connections with the corporate office router.
3. Initiate the demand-dial connection from either the branch office router or the corporate office router.

### Notes

- This deployment assumes a demand-dial connection between a branch office router and a corporate office router. You can also apply this deployment to the demand-dial connections between two corporate offices.
- For maximum flexibility, the demand-dial connection is a two-way initiated connection that is initiated by either the branch office router or the corporate office router.

The following illustration shows elements of Routing and Remote Access that provide demand-dial routed connections.

**Configuring the corporate office router**

If you want your corporate office router to support two-way initiated demand-dial connections, complete the following steps:

- Configure the connection to the corporate office intranet.
- Configure the LAN and WAN router.
- Configure ports to allow demand-dial connections.
- Configure demand-dial interfaces.
- Configure static routes.
- Configure remote access policies.

**Configuring the connection to the intranet**

The connection to the intranet is a LAN adapter that is installed in the computer. You need to verify that the LAN adapter is compatible with your operating system. For more information, see Support resources.

You need to configure the following TCP/IP settings on the LAN adapter:

- IP address and subnet mask assigned from the network administrator.
- IP addresses of the corporate DNS and WINS servers.

Because the corporate office router will act as a router between the corporate office and the branch office, it must be configured with either static routes or with routing protocols so that all of the destinations on the corporate network are reachable from the corporate office router.

**Configuring the LAN and demand-dial router**

You can enable LAN and demand-dial routing by installing the Routing and Remote Access service and using the Routing and Remote Access Server Setup Wizard. For more information, see Enable the Routing and Remote Access service.

If you have already run the Routing and Remote Access Server Setup Wizard but did not choose the routing options, you can configure LAN and demand-dial routing through the properties of the router in Routing and Remote Access. For more information, see View properties of the remote access server.

To allow demand-dial connections, you need to either run the Routing and Remote Access Server Setup Wizard and choose the routing options, or configure the following settings manually:

- **General**

  Verify that the **Router** check box and **LAN and demand-dial routing** are selected for the server running Routing and Remote Access.

- **Security**

  - **Authentication Methods**

    Select the authentication methods that are supported by the router to authenticate the credentials of demand-dial routers. For servers running Routing and Remote Access configured as demand-dial routers, select either MS-CHAP v2 or EAP (if smart cards or machine certificates are available) authentication.

  - **Authentication Provider**

    You can verify the credentials of demand-dial routers by using the security features of the Windows Server 2003 family or a RADIUS server. If RADIUS is selected, you need to configure RADIUS server settings for your RADIUS server or RADIUS proxy.

  - **Accounting Provider**

    You can record demand-dial router activity for analysis or accounting purposes by selecting and configuring an accounting provider.

- **IP**

  Click **Static address pool** and configure the ranges of IP addresses that are dynamically allocated to demand-dial routers.

- **PPP**

  Select the **Link control protocol (LCP) extensions** check box.

  Select the **Software compression** check box.

**Configuring demand-dial interfaces**

For each branch office router, you can create a demand-dial interface by using the Demand-Dial Interface wizard. In the wizard, enter the following:

- **Interface name**

The name of the interface that represents the connection to the branch office and that has the same name as the user account used by the branch office router. For example, for a router in the New York branch office, enter **NewYorkRouter**.

- **Connection type**

  Click **Connect using a modem, ISDN adapter, or other physical device**.

- **Select a device**

  Click the device being used to create the connection.

- **Phone number or address**

  Because the corporate router can also initiate a demand-dial connection, the phone number of the branch office router is required.

- **Protocols and security**

  Select the protocols to route and the **Add a user account so a remote router can dial in** check boxes.

- **Dial-in credentials**

  Type the domain and password for the account that will be used to authenticate the branch office router. The Demand-Dial Interface wizard automatically creates the account and sets its remote access permission to **Allow access**. The name of the account is the same as the name of the demand-dial interface. For example, for the New York branch office router, the name of the account is **NewYorkRouter**.

- **Dial-out credentials**

  Because the corporate router can also initiate a demand-dial connection, the name, domain, and password are required. The user credentials that you enter are used to authenticate the corporate office router when it initiates a connection with the branch office router. For example, for the corporate office router, the name of the account is **CorpHub**.

**Configuring static routes**

You need to add static routes so that traffic to the branch office is forwarded by using the appropriate demand-dial interface. For each route of each branch office, configure the interface, destination, network mask, and metric. For interface, you need to select the demand-dial interface that corresponds to the branch office.

For example, the route that corresponds to the New York branch office is 192.168.25.0 with a subnet mask of 255.255.255.0. This route becomes the static route with the following configuration:

- Interface: NewYorkRouter
- Destination: 192.168.25.0
- Network mask: 255.255.255.0
- Metric: 1

**Note**

- Because the demand-dial connection is a point-to-point connection, the gateway IP address is not configurable.

For more information, see Add a static route.

**Configuring remote access policies**
By using the Demand-Dial Interface wizard, the dial-in properties of user accounts that are used by branch office routers are already configured to allow remote access.

If you want to grant remote access to the demand-dial-based branch office routers based on group membership, do the following:

1. For a stand-alone router, use Local Users and Groups and set dial-in properties to **Allow access** for all users.

2. For a router in a domain, use Active Directory Users and Computers and set dial-in properties to **Control access through Remote Access Policy** for all users.

3. Create a user group whose members can create demand-dial connections with the corporate office router. For example, create a user group named BranchOfficeRouters.

4. Add the appropriate user accounts that correspond to the accounts that are used by the branch office routers to the group.

5. Delete the default remote access policies.

6. Create a new remote access policy with the following properties:

    - Set **Policy name** to **Demand-dial connection if member of BranchOfficeRouters** (example).

    - Set the **Windows-Groups** attribute to **BranchOfficeRouters** (example).

    - Set the **NAS-Port-Type** condition to all except **Virtual (VPN)**.

The default settings for encryption on the **Encryption** tab on the properties of a remote access policy profile are to allow no encryption and all levels of encryption strength. To require encryption for demand-dial connections, clear the **No Encryption** option and select the encryption strength you want to use.

For more information, see Configure encryption.

**Configuring the branch office router**
If you want your branch office router to support two-way initiated demand-dial connections, complete the following steps:

- Configure the connection to the branch office intranet.

- Configure the LAN and WAN router.

- Configure ports to allow demand-dial connections.

- Configure a demand-dial interface.

- Configure static routes.

- Configure remote access policies.

**Configuring the connection to the branch office intranet**
The connection to the branch office network is a LAN adapter installed in the computer. To verify whether the LAN adapter is compatible with your operating system, see Support resources.

You need to configure the following TCP/IP settings on the LAN adapter:

- IP address and subnet mask assigned from the network administrator.

- IP addresses of the branch office DNS and WINS servers.

Because the branch office router will act as a router between the corporate office and the branch office, it must be configured with either static routes or with routing protocols so that all of the destinations on the branch office network are reachable from the branch office router.

**Configuring the LAN and demand-dial router**

You can enable the LAN and demand-dial router by installing the Routing and Remote Access service and using the Routing and Remote Access Server Setup Wizard. For more information, see Enable the Routing and Remote Access service.

If you have already run the Routing and Remote Access Server Setup Wizard but did not choose the routing options, you can configure LAN and demand-dial routing through the properties on the router in Routing and Remote Access. For more information, see View properties of the remote access server.

To allow demand-dial connections, you need to either run the Routing and Remote Access Server Setup Wizard and choose the routing options, or configure the following settings manually:

- **General**

  Verify that the **Router** check box and **LAN and demand-dial routing** are selected.

- **Security**

  - **Authentication Methods**

    Select the authentication methods that are supported by the router to authenticate the credentials of demand-dial routers. For servers running Routing and Remote Access configured to act as demand-dial routers, select either MS-CHAP v2 or EAP (if smart cards or machine certificates are available) authentication.

  - **Authentication Provider**

    You can verify the credentials of demand-dial routers by using the security features of the Windows Server 2003 family or a RADIUS server. If RADIUS is selected, you need to configure RADIUS server settings for your RADIUS server or RADIUS proxy.

  - **Accounting Provider**

    You can record demand-dial router activity for analysis or accounting purposes by selecting and configuring an accounting provider.

- **IP**

  Click **Static address pool** and configure the ranges of IP addresses that are dynamically allocated to demand-dial routers.

- **PPP**

  Select the **Link control protocol (LCP) extensions** check box.

  Select the **Software compression** check box.

**Configuring a demand-dial interface**

You can create a demand-dial interface by using the Demand-Dial Interface wizard. In the wizard, enter the following:

- **Interface name**

  The name of the interface is the name of the user account configured on the corporate server running Routing and Remote Access and used by the branch office router to connect to the corporate network. For example, enter **CorpHub**.

- **Connection type**

Click **Connect using a modem, ISDN adapter, or other physical device**.

- **Select a device**

  Click the device being used to create the connection.

- **Phone number or address**

  Because the branch office router can also initiate a demand-dial connection, the phone number of the corporate office router is required.

- **Protocols and security**

  Select the protocols to route and the **Add a user account so a remote router can dial in** check boxes.

- **Dial-in credentials**

  Type the domain and password for the account that will be used to authenticate the corporate office router. The Demand-Dial Interface wizard automatically creates the account and sets its remote access permission to **Allow access**. The name of the account is the same as the name of the demand-dial interface. For example, for the corporate office router, the name of the account is **CorpHub**.

- **Dial-out credentials**

  Because the branch office router can also initiate a demand-dial connection, the name, domain, and password are required. The user credentials that you enter are used to authenticate the branch office router when it initiates a connection with the corporate office router. For example, for the branch office router in the New York branch office, the name of the account is **NewYorkRouter**.

**Note**

- In order for two-way initiated demand-dial routing to work properly, the user name of the calling router must match the name of a demand-dial interface on both sides of the connection. The following table shows an example.

| Router | Demand-dial interface name | User account name |
|---|---|---|
| Corporate office router | NewYorkRouter | CorpHub |
| Branch office router | CorpHub | NewYorkRouter |

**Configuring static routes**

You need to add static routes so that traffic to the corporate office is forwarded by using the appropriate demand-dial interface. For each route of the corporate office, configure the interface, destination, network mask, and metric. For interface, you need to select the demand-dial interface that corresponds to the corporate office previously created.

For example, the route that corresponds to the corporate office is 10.0.0.0 with a subnet mask of 255.0.0.0. To configure this route as a static route, set the following:

- Interface: CorpHub
- Destination: 10.0.0.0
- Network mask: 255.0.0.0
- Metric: 1

**Note**

- Because the demand-dial connection is a point-to-point connection, the gateway IP address is not configurable.

For more information, see Add a static route.

**Configuring remote access policies**
By using the Demand-Dial Interface wizard, the dial-in properties of user accounts that are used by corporate office routers are already configured to allow remote access.

If you want to grant remote access to the demand-dial-based corporate office routers based on group membership, do the following:

1. For a stand-alone router, use Local Users and Groups and set dial-in properties to **Allow access** for all users.

2. For a router in a domain, use Active Directory Users and Computers and set dial-in properties to **Control access through Remote Access Policy** for all users.

3. Create a user group whose members can create demand-dial connections with the branch office router. For example, create a user group named DemandDialRouters.

4. Add the appropriate user accounts that correspond to the accounts that are used by the corporate office router or other branch office routers to the group.

5. Delete the default remote access policies.

6. Create a new remote access policy with the following properties:

    - Set **Policy name** to **Demand-dial connection if member of DemandDialRouters** (example).

    - Set the **Windows-Groups** attribute to **DemandDialRouters** (example).

    - Set the **NAS-Port-Type** condition to all except **Virtual (VPN)**.

The default settings for encryption on the **Encryption** tab on the properties of a remote access policy profile are to allow no encryption and all levels of encryption strength. To require encryption for demand-dial connections, clear the **No Encryption** option and select the encryption strength you want to use.

For more information, see Configure encryption.

**Initiating the demand-dial connection**
To connect the branch office router to the corporate office router, do one of the following:

- From the branch office router

  In Routing and Remote Access, right-click the demand-dial interface that connects to the corporate office (in this example, the CorpHub demand-dial interface), and then click **Connect**.

- From the corporate office router

  In Routing and Remote Access, right-click the demand-dial interface that connects to the branch office (in this example, the NewYorkRouter demand-dial interface), and then click **Connect**.

For information about troubleshooting demand-dial routing, see Troubleshooting demand-dial routing.

# Deploying certificate-based authentication for demand-dial routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying certificate-based authentication for demand-dial routing**

The use of certificates for authentication of calling routers is the strongest form of authentication in the Windows Server 2003 family. For certificate-based authentication of demand-dial connections, you must use the Extensible Authentication Protocol (EAP) with the **Smart card or other certificate (TLS)** EAP type, also known as EAP-Transport Level Security (EAP-TLS). EAP-TLS requires the use of user certificates for the calling router and machine certificates (also known as computer certificates) for the answering router.

The deployment of certificate-based authentication for demand-dial routing typically occurs in the following situations:

- Business partner demand-dial connection
- Branch office demand-dial connection

# Business partner demand-dial connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Business partner demand-dial connection**
To use certificates for a two-way initiated, mutually authenticated, demand-dial configuration between two business partners (in this example, Company A and Company B), you must perform the following:

- Configure the calling and answering routers for demand-dial routing.
- Install computer certificates on the calling router and answering router computers.
- Configure the domain for Web-based certificate enrollment.
- At Company A, create a user account for the Company B router and export a certificate for the user account.
- At Company B, create a user account for the Company A router and export a certificate for the user account.
- At Company A, import the certificate from Company B.
- Configure the Company A router to support certificate-based authentication as a calling router and as an answering router.
- At Company B, import the certificate from Company A.
- Configure the Company B router to support certificate-based authentication as a calling router and as an answering router.

**Configuring the calling and answering routers for demand-dial routing**
Configure the Routing and Remote Access calling and answering routers as described in Deploying demand-dial routing for dial-in demand-dial routing or Router-to-router VPN Deployment for VPN demand-dial routing.

**Installing computer certificates on the calling router and answering router computers**
To use EAP-TLS, a computer certificate (also known as a machine certificate) must be installed on the authenticating server and the remote access client. In order to install a computer certificate, a certification authority must be present to issue certificates. Once the certification authority is configured, you can install a certificate in three different ways:

- By configuring the automatic enrollment, or autoenrollment, of computer certificates to computers in a Windows Server 2003 domain.
- By using the Certificates snap-in to obtain a computer certificate.
- By using your browser to connect to the CA Web enrollment pages to install a certificate on the local computer or to a floppy disk for installation on another computer, such as non-domain member computers that cannot obtain a certificate through autoenrollment.

Based on the certificate policies in your organization, you only need to perform one of these allocations.

For more information, see Network access authentication and certificates.

To configure a certification authority and install the computer certificate, perform the following steps:

1. Install the Certificate Services component as an enterprise root certification authority (CA). This step is only necessary if you do not already have an enterprise root CA.

    a. If necessary, promote the computer that will be a CA to a domain controller (DC).

b. Install the Certificate Services component as an enterprise root CA. For more information, see Install an enterprise root certification authority.

2. Configure the CA to issue certificates that permit exportable keys. To do so, you must clone and rename the **router (offline request)** template, choose to make the keys exportable, and add the new template to the templates the CA can use to issue certificates. For more information, see To establish the certificate types that an enterprise certification authority can issue.

3. Do one of the following:

   - To auto-enroll computer certificates, configure the domain. For more information, see Configure automatic certificate allocation from an enterprise CA.

     To create a computer certificate for the calling or answering router that is a member of the domain for which auto-enrollment is configured (as well as other computers that are members of the domain), restart the computer or type **gpupdate /Target:Computer /Force** from the command prompt.

   - To manually enroll computer certificates, use the Certificates snap-in or the CA Web enrollment pages to install the CA root certificate. For more information, see Manage certificates for a computer and Request a certificate.

In order for the CA to issue certificates for the calling router, you must configure the domain for Web-based enrollment. For more information, see Set up certification authority Web enrollment support.

**Creating a user account and exporting its certificate for the Company B router**

To create a dial-in user account for the Company B router and export the user certificate of the user account, do the following:

1. Log on as a domain administrator.

2. Create a user account that the Company B router will use when it dials the Company A router. For more information, see Create a new user account.

3. Obtain a certificate that has an exportable key from the certification authority through Web-based enrollment. This certificate might be called **router (offline request)**, or have another name. For more information, see Install a router (offline request) certificate.

4. Export the exportable key certificate to a .cer file. For more information, see Export a certificate. Within the Certificates snap-in Export wizard, do not export the private key.

5. Map the newly created certificate (the .cer file) to the user account that was created for the Company B router. For more information, see Map a certificate to a user account.

6. Export the certificate to a .pfx file. For more information, see Export a certificate. Within the Certificates snap-in Export wizard, export the private key, select the **Delete the private key if the import is successful** check box, and click **Include all certificates in the certification path if possible**. Save this file to a floppy disk to send to the network administrator at Company B.

7. Send the floppy disk that contains the Company B dial-in account user certificate file to the network administrator at Company B.

**Creating a user account and exporting its certificate for the Company A router**

To create a dial-in user account for the Company A router and export the user certificate of the user account, do the following:

1. Log on as a domain administrator.

2. Create a user account that the Company A router will use when it dials the Company B router. For more information, see

Create a new user account.

3. Obtain a certificate that has exportable keys from the certification authority through Web-based enrollment. This certificate might be called **router (offline request)**, or it might have another name. For more information, see Install a router (offline request) certificate.

4. Export the certificate to a .cer file. For more information, see Export a certificate. Within the Certificates snap-in Export wizard, do not export the private key.

5. Map the newly created certificate (the .cer file) to the user account created for the Company A router. For more information, see Map a certificate to a user account.

6. Export the certificate to a .pfx file. For more information, see Export a certificate. Within the Certificates snap-in Export wizard, export the private key, select the **Delete the private key if the import is successful** check box, and click **Include all certificates in the certification path if possible**. Save this file to a floppy disk to send to the network administrator at Company A.

7. Send the floppy disk that contains the Company A dial-in account user certificate file to the network administrator at Company A.

**Importing the certificates from Company B**
Upon receipt at Company A of the floppy disk that contains the certificate file from Company B, on the Company A router, import the user certificate. For more information, see Import a certificate.

**Configuring the Company A router to support certificate-based authentication**
To configure the Company A router for certificate-based authentication as an answering router, see Configure the answering router for certificate-based EAP.

To configure the Company A router for certificate-based authentication as a calling router, see Configure the calling router for certificate-based EAP.

**Importing the certificates from Company A**
Upon receipt at Company B of the floppy disk that contains the certificate files from Company A, on the Company B router, import the user certificate. For more information, see Import a certificate.

**Configuring the Company B router to support certificate-based authentication**
To configure the Company B router for certificate-based authentication as an answering router, see Configure the answering router for certificate-based EAP.

To configure the Company B router for certificate-based authentication as a calling router, see Configure the calling router for certificate-based EAP.

# Branch office demand-dial connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Branch office demand-dial connection**
To use certificates for a two-way initiated, mutually authenticated, demand-dial configuration between two routers in the same organization (in this example, a branch office router and a corporate office router), you must perform the following:

- Configure the calling and answering routers for demand-dial routing.
- Install a computer certificate on the corporate office router.
- Configure the domain for Web-based certificate enrollment.
- Create user accounts and export certificates.
- Import the dial-out user certificate on the corporate office router.
- Configure the corporate office router to support certificate-based authentication as a calling router and as an answering router.
- Import the dial-in certificate on the branch office router.
- Configure the branch office router to support certificate-based authentication as a calling router.
- Connect to the corporate office and join the organization domain.

**Configuring the calling and answering routers for demand-dial routing**
Configure the calling and answering routers as described in Deploying demand-dial routing for dial-up demand-dial routing or Router-to-router VPN Deployment for VPN demand-dial routing.

**Installing a computer certificate on the corporate office router**
In order to configure EAP-TLS on the corporate office router, you must install a computer certificate (also known as a machine certificate). In order to install a computer certificate, a certification authority must be present to issue certificates. Once the certification authority is configured, you can install a certificate in three different ways:

- By configuring the automatic enrollment, or autoenrollment, of computer certificates to computers in a Windows Server 2003 domain.
- By using the Certificates snap-in to obtain a computer certificate.
- By using your browser to connect to the CA Web enrollment pages to install a certificate on the local computer or to a floppy disk for installation on another computer, such as non-domain member computers that cannot obtain a certificate through autoenrollment.

Based on the certificate policies in your organization, you only need to perform one of these allocations.

For more information, see Network access authentication and certificates.

To configure a certification authority and install the computer certificate, perform the following steps:

1. Install the Certificate Services component as an enterprise root certification authority. This step is only necessary if you do not already have an enterprise root certification authority (CA).
    a. If necessary, promote the computer that will be a CA to a domain controller (DC).
    b. Install the Certificate Services component as an enterprise root CA. For more information, see Install an enterprise root

certification authority.

2. Configure the CA to issue certificates with exportable keys. For more information, see To establish the certificate types that an enterprise certification authority can issue.

3. Do one of the following:

   - To auto-enroll computer certificates, configure the domain. For more information, see Configure automatic certificate allocation from an enterprise CA.

     To create a computer certificate for the calling or answering router that is a member of the domain for which autoenrollment has been configured (as well as other computers that are members of the domain), restart the computer or type **gpupdate /Target:***Computer***/Force** from the command prompt.

   - To manually enroll computer certificates, use the Certificates snap-in or the CA Web enrollment pages to install the CA root certificate. For more information, see Manage certificates for a computer and Request a certificate.

In order for the CA to issue certificates for the calling router, you must configure the domain for Web-based enrollment. For more information, see Set up certification authority Web enrollment support.

**Creating user accounts and exporting certificates**

To create dial-in and dial-out user accounts and export certificates, do the following:

1. Log on as a domain administrator.

2. Create a user account that the corporate office router will use when it dials the branch office router (the dial-out account). For more information, see Create a new user account.

3. Obtain a certificate that has exportable keys for the dial-out account from the certification authority through Web-based enrollment. This certificate might be called **router (offline request)**, or it might have another name. For more information, see Install a router (offline request) certificate.

4. Export the certificate for the dial-out account to a .cer file. For more information, see Export a certificate. Within the Certificates snap-in Export wizard, do not export the private key.

5. Map the newly created certificate (the .cer file) to the dial-out user account. For more information, see Map a certificate to a user account.

6. Export the certificate of the dial-out account to a .pfx file. For more information, see Export a certificate. Within the Certificates snap-in Export wizard, export the private key and click **Delete the private key if the import is successful** and select the option to **Include all certificates in the certification path if possible**.

7. Create a user account that the branch office router will use when it dials the corporate office router (the dial-in account). For more information, see Create a new user account.

8. Obtain a certificate that has exportable keys for the dial-in account from the certification authority through Web-based enrollment. This certificate might be called **router (offline request)**, or it might have another name. For more information, see Install a router (offline request) certificate.

9. Export the certificate for the dial-in account to a .cer file. For more information, see Export a certificate. Within the Certificates snap-in Export wizard, do not export the private key.

10. Map the newly created certificate (the .cer file) to the dial-in user account. For more information, see Map a certificate to a user account.

11. Export the certificate of the dial-in account to a .pfx file. For more information, see Export a certificate. Within the Certificates snap-in Export wizard, export the private key and click **Delete the private key if the import is successful**. Save this file to a floppy disk to send to the network administrator at the branch office.

12. Send the floppy disk that contains the dial-in account user certificate file to the network administrator at the branch office.

**Importing the dial-out certificate on the corporate office router**
On the corporate office router, import the user certificate for the dial-out account. For more information, see Import a certificate.

**Configuring the corporate office router to support certificate-based authentication**
To configure the corporate office router for certificate-based authentication as an answering router, see Configure the answering router for certificate-based EAP.

To configure the corporate office router for certificate-based authentication as a calling router, see Configure the calling router for certificate-based EAP.

**Importing the certificate on the branch office router**
Upon receipt at the branch office of the floppy disk that contains the certificate file from the corporate office, import the user certificate for the dial-in account. For more information, see Import a certificate.

**Configuring the branch office router to support certificate-based authentication**
To configure the branch office router for certificate-based authentication as a calling router, see Configure the calling router for certificate-based EAP.

**Connecting to the corporate office and joining the organization domain**
To connect to the corporate office and join the organization domain, do the following:

1. From the branch office, connect to the corporate office by right-clicking the demand-dial interface, and then clicking **Connect**.

2. Once connected, the branch office router joins the domain through the **Computer Name** tab (in the properties of My Computer).

3. After joining the domain, restart the branch office router.

4. After restarting the branch office router, connect to the corporate office router again.

5. Once connected, the branch office router receives domain policy and a computer certificate (if auto-enrollment of computer certificates is configured). If auto-enrollment of computer certificates is not configured, obtain a computer certificate through the Certificates snap-in. For more information, see Manage certificates for a computer and Request a certificate.

6. Once a computer certificate is obtained, configure the branch office router for certificate-based authentication as an answering router. For more information, see Configure the answering router for certificate-based EAP.

At this point, you can install a domain controller in the branch office by using the demand-dial connection to the corporate office. For more information on installing a domain controller, see Checklist: Installing a domain controller.

### Notes

- The ability of the branch office router to join the domain and the installation of a domain controller depends on DNS name resolution. Ensure that both the router and the domain controller computer are configured with the proper DNS server IP addresses.

- By default, an answering router checks the certificate revocation list when authenticating the calling router. Because the root CA computer is always reachable by the corporate office router, the certificate revocation list can always be checked. However, the root CA computer is not reachable by the branch office router until after the connection is made. If the root CA computer cannot be reached, then Active Directory is checked. In this case, the branch office router accesses its local domain controller for the revocation list. If the certificate revocation list is not published in Active Directory, then the branch office router acting as the answering router rejects the connection attempt. To prevent this problem, do one of the following:

    - Publish the certificate revocation list in Active Directory. For more information, see Schedule the publication of the certificate revocation list or Manually publish the certificate revocation list.

    - On the branch office router, set the following registry value to 1:

**HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RasMan\PPP\EAP\13\IgnoreRevocationOffline**

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

# Deploying Router-to-Router VPNs

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying router-to-router VPNs**

This section covers:

# Router-to-router VPN design considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Router-to-router VPN design considerations**
To prevent problems, you should consider the following design issues before you implement router-to-router VPN connections:

- PPTP-based or L2TP/IPSec connections
- Installing certificates
- On-demand or persistent connections
- Restricting the initiation of an on-demand connection
- One-way or two-way initiated connections
- Number of PPTP or L2TP ports needed
- Configuring firewall packet filters
- Routing
- Single hop across VPN connection
- Creating a remote access policy for router-to-router VPN connections

For more information, see Router-to-router VPN connection.

**PPTP-based or L2TP/IPSec connections**
A VPN server running Windows Server 2003 provides support for both Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP). When choosing between PPTP and L2TP/IPSec router-to-router VPN solutions, consider the following:

- PPTP can be used for router-to-router VPN connections for routers running Windows NT Server 4.0 with the Routing and Remote Access Service (RRAS), Windows 2000 Server, or Windows Server 2003 operating systems. PPTP does not require a public key infrastructure (PKI) to issue computer certificates. By using encryption, PPTP-based VPN connections provide data confidentiality--captured packets cannot be interpreted without the encryption key. PPTP-based VPN connections, however, do not provide data integrity (proof that the data was not modified in transit) or data origin authentication (proof that the data was sent by the authorized user).

- L2TP can be used only with routers running Windows 2000 Server or Windows Server 2003 operating systems. When both types of routers are used, a public key infrastructure (PKI) is required to issue computer certificates to all routers. Routers running Windows Server 2003 operating systems additionally support a single preshared key configured on the answering router and all calling routers. By using Internet Protocol Security (IPSec), L2TP/IPSec VPN connections provide data confidentiality, data integrity, and data origin authentication.

**Installing certificates**
To use certificate authentication for L2TP/IPSec router-to-router VPN connections, you must install computer certificates, also known as machine certificates, on both routers. For more information, see Computer certificates for L2TP/IPSec VPN connections and Network access authentication and certificates.

**On-demand or persistent connections**
You must decide whether your router-to-router VPN connections will be on-demand or persistent:

- On-demand demand-dial connections require that the answering router is permanently connected to the Internet. The calling router connects to the Internet by using a dial-up link such as an analog phone line or ISDN. You need to configure a single demand-dial interface at the answering router. You need to configure two demand-dial interfaces at the calling router: one to connect to a local Internet service provider (ISP) and one for the router-to-router VPN connection. Demand-dial router-to-router VPN connections also require an additional host route in the IP routing table of the calling router. For more information, see A dial-up router-to-router VPN connection.

- Persistent connections require that both routers are connected to the Internet by using permanent WAN connections. You only need to configure a single demand-dial interface at each router. Permanent connections can be initiated and left in a connected state 24 hours a day.

**Restricting the initiation of an on-demand connection**

To prevent the calling router from making unnecessary connections, you can restrict the calling router from making on-demand router-to-router VPN connections in two ways:

- Demand-dial filtering

  You can use demand-dial filtering to configure either the types of IP traffic that do not cause a demand-dial connection to be made or the types of IP traffic that cause a connection to be made. For more information, see Configure demand-dial filters.

- Dial-out hours

  You can use dial-out hours to configure the hours that a calling router is either permitted or denied to make a router-to-router VPN connection. For more information, see Configure dial-out hours.

**One-way or two-way initiated connections**

You must decide whether your router-to-router VPN connections will be initiated by one router or by both routers:

- With one-way initiated connections, one router is the VPN server and one router is the VPN client. The VPN server accepts the connection and the VPN client initiates the connection. One-way initiated connections are well suited to a permanent connection spoke-and-hub topology where the branch office router is the only router that initiates the connection. One-way initiated connections require that:

  - The VPN server (the answering router) is configured as a LAN and demand-dial router.

  - A user account is added for the authentication credentials of the calling router that is accessed and validated by the answering router.

  - A demand-dial interface is configured at the answering router with the same name as the user account that is used by the calling router. This demand-dial interface is not used to dial out, therefore it is not configured with the host name or IP address of the calling router or with valid user credentials.

  For more information, see One-way initiated demand-dial connections.

- With two-way initiated connections, either router can be the VPN server or the VPN client depending on who is initiating the connection. Both routers must be configured to initiate and accept a VPN connection. You can use two-way initiated connections when the router-to-router VPN connection is not up 24 hours a day and traffic from either router is used to create the on-demand connection. Two-way initiated router-to-router VPN connections require that:

  - Both routers are connected to the Internet by using a permanent WAN link.

  - Both routers are configured as LAN and demand-dial routers.

  - User accounts are added for both routers so that the authentication credentials for the calling router are accessed and validated by the answering router.

- Demand-dial interfaces, with the same name as the user account that is used by the calling router, must be fully configured at both routers, including settings for the host name or IP address of the answering router and user account credentials to authenticate the calling router.

**Configuring firewall packet filters**
If you have a firewall, you must configure packet filters on the firewall to allow traffic between the VPN router and the routers on the Internet. For more information, see VPN servers and firewall configuration.

**Routing**
Both routers on a router-to-router VPN connection must have the appropriate routes in their routing tables to forward traffic across the connection. Routes can be static or dynamic. You can add static routes to the routing table either manually or through an auto-static update. You can add dynamic routes to the routing table by adding the VPN connection demand-dial interface to a routing protocol. However, enabling a routing protocol on the VPN connection demand-dial interface is only recommended when the demand-dial interface is permanently connected.

### Note

- Unlike demand-dial routing by using direct links, you cannot use a default IP route for the VPN demand-dial interface to summarize all the routes of the corporate office. Because the branch office router is connected to the Internet, the default route must be used to summarize all the routes of the Internet and configured to use the interface that connects the router to the Internet.

**Single hop across VPN connection**
For the purposes of designing a routed infrastructure, you can consider the router-to-router VPN connection as a single hop regardless of how many routers are crossed when the encapsulated data is sent across the Internet.

**Creating a remote access policy for router-to-router VPN connections**
By using remote access policies, you can create a policy that requires router-to-router VPN connections to use a specific authentication method and encryption strength.

For example, you can create an Active Directory group called VPN Routers whose members are the user accounts that are used by calling routers when a router-to-router VPN connection is created. Then, you create a policy with two conditions on the policy: the **NAS-Port-Type** is set to **Virtual (VPN)** and the **Windows-Group** is set to **VPN Routers**. Finally, you configure the profile for the policy to select a specific authentication method and encryption strength.

You can also use the **Tunnel-Type** condition to create separate remote access policies for PPTP and L2TP connections. For example, to require a specific authentication method and encryption strength for PPTP connections, set the **Tunnel-Type** condition to **Point-to-Point Tunneling Protocol**.

# Router-to-router VPN security considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Router-to-router VPN security considerations**
In addition to the security steps listed in Static routing security, you can enhance router-to-router VPN security through:

- Strong authentication
- Data encryption
- PPTP or L2TP/IPSec packet filtering
- Firewall packet filtering

For more information, see Router-to-router VPN connection.

**Strong authentication**
For authentication, use the strongest authentication scheme that is possible for your router-to-router VPN configuration. The strongest authentication scheme is the use of EAP-TLS with certificates. For more information, see Deploying certificate-based authentication for demand-dial routing.

Otherwise, use MS-CHAP version 2 authentication and enforce the use of strong passwords on your network. For more information, see MS-CHAP version 2.

**Data encryption**
For encryption, you can use either link encryption or end-to-end encryption:

- Link encryption encrypts the data only on the link between the two routers. You can use 128-bit Microsoft Point-to-Point Encryption (MPPE) for high security with PPTP connections. Otherwise, you can use either 56-bit or 40-bit MPPE. 40-bit MPPE is used with older versions of Microsoft operating systems. MPPE is only used in conjunction with either MS-CHAP, MS-CHAP v2, or EAP-TLS authentication. L2TP/IPSec connections use DES or 3DES encryption.
- End-to-end encryption encrypts the data between the source host and its final destination. You can use IPSec to encrypt data from the source host to the destination host across the demand-dial link.

To specify encryption strength, select the appropriate encryption strengths on the **Encryption** tab of the remote access policy profile that is used by your calling routers. The **No Encryption** option is cleared by default; do not select this option or your network security is in jeopardy. For more information, see Security issues for VPN and Configure encryption.

**Packet filtering**
To secure the calling or answering corporate router from sending or receiving any traffic on its Internet interface except router-to-router VPN traffic, you need to ensure that PPTP or L2TP/IPSec input and output filters are configured on the router interface that corresponds to the connection to the Internet.

When you configure your VPN server using the Routing and Remote Access Server Setup Wizard, PPTP or L2TP/IPSec input and output filters are configured automatically. For more information about PPTP filters, see Add PPTP Filters. For more information about L2TP/IPSec filters, see Add L2TP over IPSec Filters.

Because IP routing is enabled on the Internet interface, if PPTP or L2TP/IPSec filters are not configured on the Internet interface, then any traffic received on the Internet interface is routed, which may forward unwanted Internet traffic to your intranet.

**Firewall packet filtering**
It is a common practice to provide protection to intranet hosts, such as a VPN server, from Internet hosts using a firewall. If you have a firewall, you must configure packet filters on the firewall to allow traffic between the VPN router and the routers on the Internet. For more information, see VPN servers and firewall configuration.

# Router-to-router VPN Deployment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Router-to-router VPN deployment**
This section covers:

- PPTP-based router-to-router VPN deployment
- L2TP-based router-to-router VPN deployment

# PPTP-based router-to-router VPN deployment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**PPTP-based router-to-router VPN deployment**

To create a PPTP-based router-to-router VPN connection to send private data across the Internet, you must perform the following:

1. Configure the router running a Windows Server 2003 operating system at the corporate office to receive PPTP connections from a branch office router.
2. Configure the router running a Windows Server 2003 operating system at the branch office to initiate a PPTP connection with the corporate office router.
3. Initiate the PPTP connection from the branch office router.

**Note**

- These steps assume that the PPTP-based router-to-router VPN connection is between a corporate office and a branch office. However, you can also apply these steps to the VPN connection between two corporate offices.

**Configuring the corporate office router**

If you want your router running a Windows Server 2003 operating system in the corporate to support multiple branch office PPTP connections, complete the following steps:

- Configure the connection to the Internet.
- Configure the connection to the intranet.
- Configure the corporate router.
- Configure demand-dial interfaces.
- Configure firewall packet filters.
- Configure remote access policies.

The following illustration shows the elements of a PPTP-based router-to-router VPN connection on a computer running a Windows Server 2003 operating system.

For more information, see Router-to-router VPN connection and Point-to-Point Tunneling Protocol.

**Note**

- To simplify configuration, the branch office router always initiates the PPTP connection.

**Configuring the connection to the Internet**
The connection to the Internet is a dedicated connection--a WAN adapter that is installed in the computer. The WAN adapter is typically a DDS, T1, Fractional T1, or Frame Relay adapter. You must contract with a local telephone company to run the appropriate physical wiring to your premises. You need to verify that the WAN adapter is compatible with products in the Windows Server 2003 family. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

The WAN adapter includes drivers that are installed in Windows Server 2003 operating systems so that the adapter appears as a network adapter.

You need to configure the following TCP/IP settings on the WAN adapter:

- IP address and subnet mask assigned from the InterNIC or an Internet service provider (ISP).
- Default gateway of the ISP router.

**Configuring the connection to the intranet**
The connection to the intranet is a LAN adapter that is installed in the computer. You need to verify that the LAN adapter is compatible with products in the Windows Server 2003 family. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

You need to configure the following TCP/IP settings on the LAN adapter:

- IP address and subnet mask assigned from the network administrator.
- DNS and WINS name servers of corporate intranet name servers.

Because the corporate router will route traffic between the corporate office and the branch office, you must configure the corporate router with either static routes or with routing protocols so that all of the destinations on the corporate network are reachable from the corporate router.

**Configuring the corporate router**
You need to enable the corporate router by installing the Routing and Remote Access service. For more information, see Enable the Routing and Remote Access service.

**Configuring demand-dial interfaces**
For each branch office router, you can create a demand-dial interface by using the Demand-Dial Interface Wizard. In the wizard, configure the following:

- **Interface Name**

  The name of the interface that represents the connection to the branch office. For example, for a router in the New York branch office, type **NewYorkRouter**.

- **Connection Type**

  Click **Connect using virtual private networking (VPN)**.

- **VPN Type**

  Click **Point-to-Point Tunneling Protocol (PPTP)**.

- **Destination Address**

  Because the corporate router will not initiate the VPN connection, no phone number or address is required.

- **Protocols and Security**

  Select the **Add a user account so a remote router can dial in** check box.

- **Configuring static routes**

  You need to add static routes so that traffic to the branch office is forwarded by using the appropriate demand-dial interface. For each route of each branch office, configure the interface, destination, network mask, and metric. For the interface, you need to select the demand-dial interface that corresponds to the branch office.

  For example, the route that corresponds to the New York branch office is 192.168.25.0 with a subnet mask of 255.255.255.0. This route becomes the static route with the following configuration:

  - Interface: NewYorkRouter
  - Destination: 192.168.25.0
  - Network mask: 255.255.255.0
  - Metric: 1

- **Dial-out Credentials**

  Because the corporate router will not initiate the VPN connection, type in any name, domain, and password.

- **Dial-in Credentials**

  Type the domain and password for the account that will be used to authenticate the branch office router. The Demand-Dial Interface Wizard automatically creates the account and sets its remote access permission to **Allow access**. The name of the account is the same as the name of the demand-dial interface. For example, for the New York branch office router, the name of the account is **NewYorkRouter**.

**Note**

- Because the PPTP connection is a point-to-point connection, the Gateway IP address is not configurable.

For more information, see Add a static route.

**Configuring firewall packet filters**
If you are using a firewall in the corporate office, you need to configure PPTP packet filters on your firewall to allow PPTP traffic between the branch office routers and the corporate office router. For more information, see VPN servers and firewall configuration.

**Configuring remote access policies**
By using the Demand-Dial Interface Wizard, the dial-in properties of user accounts that are used by branch office routers are already configured to allow remote access.

If you want to grant remote access to the PPTP-based branch office routers based on group membership, do the following:

1. For a stand-alone router that is not a member of a domain, use Local Users and Groups and set dial-in properties to **Allow access** for all users.

2. For a directory services-based router, use Active Directory Users and Computers and set dial-in properties to **Control access through Remote Access Policy** for all users.

3. Create an Active Directory group whose members can create virtual private networking connections with the VPN server. For example, BranchOfficeRouters.

4. Add the appropriate user accounts that correspond to the accounts that are used by the branch office routers to the Active Directory group.

5. Create a new remote access policy with the following properties:

    - Set **Policy name** to **VPN Access if member of BranchOfficeRouters** (example).
    - Set the **Windows-Groups** condition to **BranchOfficeRouters** (example).
    - Set the **NAS-Port-Type** condition to **Virtual (VPN)**.
    - Set the **Tunnel-Type** condition to **Point-to-Point Tunneling Protocol**.
    - Select the **Grant remote access permission** option.

6. If this computer is only used to provide router-to-router VPN connections, you need to delete the default remote access policies. Otherwise, move the default remote access policy so that it is evaluated last.

For encryption, the default setting allows no encryption and all levels of encryption strength. To require encryption, clear the **No Encryption** option and select the appropriate encryption strengths on the **Encryption** tab of the remote access policy profile that is used by your calling routers.

For more information, see Configure encryption.

**Configuring the branch office router**
If you want your router running a Windows Server 2003 operating system in the branch office to initiate a PPTP connection with the corporate office router, complete the following steps:

- Configure the connection to the Internet.
- Configure the connection to the branch office network.
- Configure a demand-dial interface.
- Configure static routes.
- Configure firewall packet filters.

### Note

- To simplify this configuration, the branch office router always initiates the PPTP connection.

**Configuring the connection to the Internet**
The connection to the Internet is a dedicated connection--a WAN adapter that is installed in the computer. The WAN adapter is typically a DDS, T1, Fractional T1, or Frame Relay adapter. You must contract with a local telephone company to run the appropriate physical wiring to your premises. You need to verify that the WAN adapter is compatible with the server operating systems. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

The WAN adapter includes drivers that are installed in Windows Server 2003 operating systems so that the adapter appears as a network adapter.

You need to configure the following TCP/IP settings on the WAN adapter:

- IP address and subnet mask assigned from the InterNIC or an Internet service provider (ISP).
- Default gateway of the ISP router.

**Configuring the connection to the branch office network**
The connection to the branch office network is a LAN adapter that is installed in the computer. You need to verify that the WAN

adapter is compatible with products in the Windows Server 2003 family. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

You need to configure the following TCP/IP settings on the LAN adapter:

- IP address and subnet mask assigned from the network administrator.
- DNS and WINS name servers of branch office name servers.

**Configuring a demand-dial interface**

You can create a demand-dial interface by using the Demand-Dial Interface Wizard. In the wizard, configure the following:

- **Interface Name**

  Type the name of the interface that represents the connection to the corporate office. For example, type **CorpOffice**.

- **Connection Type**

  Click **Connect using virtual private networking (VPN)**.

- **VPN Type**

  Click **Point-to-Point Tunneling Protocol (PPTP)**.

- **Destination Address**

  Type the IP address or host name that is assigned to the Internet interface of the router at the corporate office. If you enter a host name, verify that the host name resolves to the proper IP address.

- **Dial-out Credentials**

  Type the name, domain name, and password of the user account that corresponds to this branch office router. The credentials are the same as those entered in the **Dial-Out Credentials** page of the Demand-Dial Interface Wizard when the demand-dial interface for this branch office was created on the corporate router.

**Configuring static routes**

You need to add static routes so that traffic to the corporate office is forwarded by using the appropriate demand-dial interface. For each route of the corporate office, configure the interface, destination, network mask, and metric. For the interface, select the demand-dial interface that corresponds to the corporate office previously created.

For example, the route that corresponds to the corporate office is 10.0.00 with a subnet mask of 255.0.0.0. This route becomes a static route with the following configuration:

- Interface: CorpOffice
- Destination: 10.0.0.0
- Network mask: 255.0.0.0
- Metric: 1

**Note**

- Because the PPTP connection is a point-to-point connection, the Gateway IP address is not configurable.

For more information, see Add a static route.

**Configuring firewall packet filters**

If you are using a firewall in the branch office, you need to configure PPTP packet filters on your firewall to allow PPTP traffic between the corporate office router and the branch office router. For more information, see VPN servers and firewall configuration.

**Initiating the PPTP router-to-router VPN connection**

To test the branch office router to the corporate router, in Routing and Remote Access, right-click the demand-dial interface that connects to the corporate office, and then click **Connect**.

For information about troubleshooting a router-to-router VPN, see Troubleshooting router-to-router VPNs.

# L2TP-based router-to-router VPN deployment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**L2TP-based router-to-router VPN deployment**

To create an L2TP/IPSec router-to-router VPN connection to send private data across the Internet, you must perform the following:

1. Configure the router running a Windows Server 2003 operating system at the corporate office to receive L2TP connections from a branch office router.
2. Configure the router running a Windows Server 2003 operating system at the branch office to initiate an L2TP connection with the corporate office router.
3. Initiate the L2TP connection from the branch office router.

**Note**

- These steps assume that the L2TP/IPSec router-to-router VPN connection is between a corporate office and a branch office. However, you can also apply these steps to a VPN connection between two corporate offices.

**Configuring the corporate office router**

If you want your router running a Windows Server 2003 operating system in the corporate office to support multiple branch office L2TP connections, complete the following steps:

- Configure the connection to the Internet.
- Configure the connection to the intranet.
- Install a computer certificate.
- Configure the corporate router.
- Configure demand-dial interfaces.
- Configure firewall packet filters.
- Configure remote access policies.

The following illustration shows the elements of a L2TP/IPSec router-to-router VPN connection on a computer running a Windows Server 2003 operating system.

For more information, see Router-to-router VPN connection and Layer Two Tunneling Protocol.

**Note**

- To simplify this configuration, the branch office router always initiates the L2TP connection.

**Configuring the connection to the Internet**

The connection to the Internet is a dedicated connection--a WAN adapter that is installed in the computer. The WAN adapter is typically a DDS, T1, Fractional T1, or Frame Relay adapter. You must contract with a local telephone company to run the appropriate physical wiring to your premises. You need to verify that the WAN adapter is compatible with the Windows Server 2003 operating systems. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

The WAN adapter includes drivers that are installed in Windows Server 2003 operating systems so that the adapter appears as a network adapter.

You need to configure the following TCP/IP settings on the WAN adapter:

- IP address and subnet mask assigned from the InterNIC or an Internet service provider (ISP).
- Default gateway of the ISP router.

**Configuring the connection to the intranet**

The connection to the intranet is a LAN adapter that is installed in the computer. You need to verify that the LAN adapter is compatible with the Windows Server 2003 operating systems. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

You need to configure the following TCP/IP setting on the LAN adapter:

- IP address and subnet mask assigned from the network administrator.

If the corporate router is running applications, you need to configure the following TCP/IP setting on the LAN adapter:

- DNS and WINS name servers of corporate intranet name servers.

Because the corporate router will route traffic between the corporate office and the branch office, you must configure the corporate router with either static routes or with routing protocols so that all of the destinations on the corporate network are reachable from the corporate router.

**Installing a computer certificate**

Although you can use either computer certificates or a preshared key to provide authentication for IPSec security associations for an L2TP/IPSec connection, computer certificates are the recommended method. Therefore, you must install a computer certificate on the corporate router.

For more information about installing a computer certificate on the corporate router, see Computer certificates for L2TP/IPSec VPN connections and Network access authentication and certificates.

**Configuring the corporate router**

You need to enable the corporate router by installing the Routing and Remote Access service. For more information, see Enable the Routing and Remote Access service.

**Configuring demand-dial interfaces**

For each branch office router, you can create a demand-dial interface by using the Demand-Dial Interface Wizard. In the wizard, configure the following:

- **Interface Name**

  Type the name of the interface that represents the connection to the branch office. For example, for a router in the New York branch office, type **NewYorkRouter**.

- **Connection Type**

  Click **Connect using virtual private networking (VPN)**.

- **VPN Type**

  Click **Layer 2 Tunneling Protocol (L2TP)**.

- **Destination Address**

  Because the corporate router will not initiate the VPN connection, no address is required.

- **Protocols and Security**

  Select the protocols you want to route, and then select the **Add a user account so a remote router can dial in** check box.

- **Configuring static routes**

  You need to add static routes so that traffic to the branch office is forwarded by using the appropriate demand-dial interface. For each route of each branch office, configure the interface, destination, network mask, and metric. For the interface, you need to select the demand-dial interface that corresponds to the branch office.

  For example, the route that corresponds to the New York branch office is 192.168.25.0 with a subnet mask of 255.255.255.0. This route becomes the static route with the following configuration:

  - Interface: NewYorkRouter
  - Destination: 192.168.25.0
  - Network mask: 255.255.255.0
  - Metric: 1

- **Dial-out Credentials**

  Because the corporate router will not initiate the VPN connection, type in any name, domain, and password.

- **Dial-in Credentials**

  Type the domain and password for the account that will be used to authenticate the branch office router. The Demand-Dial Interface Wizard automatically creates the account and sets its remote access permission to **Allow access**. The name of the account is the same as the name of the demand-dial interface. For example, for the New York branch office router, the name of the account is **NewYorkRouter**.

**Note**

- Because the L2TP connection is a point-to-point connection, the Gateway IP address is not configurable.

For more information, see Add a static route.

**Configuring firewall packet filters**
If you are using a firewall in the corporate office, you need to configure L2TP/IPSec packet filters on your firewall to allow L2TP/IPSec traffic between branch office routers and the corporate office router. For more information, see VPN servers and firewall configuration.

**Configuring remote access policies**
By using the Demand-Dial Interface Wizard, the dial-in properties of user accounts that are used by branch office routers are already configured to allow remote access.

If you want to grant remote access to the L2TP/IPSec branch office routers based on group membership, do the following:

1. For a stand-alone router that is not a member of a domain, use Local Users and Groups and set dial-in properties to **Allow access** for all users.

2. For a directory services-based router, use Active Directory Users and Computers and set dial-in properties to **Control access through Remote Access Policy** for all users.

3. Create a Windows Server 2003 Active Directory group whose members can create virtual private networking connections with the VPN server. For example, BranchOfficeRouters.

4. Add the appropriate user accounts that corresponds to the accounts that are used by the branch office routers to the Active Directory group.

5. Create a new remote access policy with the following properties:

   - Set **Policy name** to **VPN Access if member of BranchOfficeRouters** (example).
   - Set the **Windows-Groups** condition to **BranchOfficeRouters** (example).
   - Set the **NAS-Port-Type** condition to **Virtual (VPN)**.
   - Set the **Tunnel-Type** condition to **Layer Two Tunneling Protocol**.
   - Select the **Grant remote access permission** option.

6. If this computer is only used to provide router-to-router VPN connections, you need to delete the default remote access policies. Otherwise, move the default remote access policy so that it is evaluated last.

For encryption, the default setting allows no encryption and all levels of encryption strength. To require encryption, clear the **No Encryption** option and select the appropriate encryption strengths on the **Encryption** tab of the remote access policy profile that is used by your calling routers.

For more information, see Configure encryption.

**Configuring the branch office router**

If you want your router running a Windows Server 2003 operating system in the branch office to initiate an L2TP connection with the corporate office router, complete the following steps:

- Configure the connection to the Internet.
- Configure the connection to the branch office network.
- Install a computer certificate.
- Configure a demand-dial interface.
- Configure static routes.
- Configure firewall packet filters.

**Note**

- To simplify configuration, the branch office router always initiates the L2TP connection.

**Configuring the connection to the Internet**

The connection to the Internet is a dedicated connection--a WAN adapter that is installed in the computer. The WAN adapter is

typically a DDS, T1, Fractional T1, or Frame Relay adapter. You must contract with a local telephone company to run the appropriate physical wiring to your premises. You need to verify that the WAN adapter is compatible with the Windows Server 2003 operating systems. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

The WAN adapter includes drivers that are installed in Windows Server 2003 operating systems so that the adapter appears as a network adapter.

You need to configure the following TCP/IP settings on the WAN adapter:

- IP address and subnet mask assigned from the InterNIC or an Internet service provider (ISP).
- Default gateway of the ISP router.

**Configuring the connection to the branch office network**

The connection to the branch office network is a LAN adapter that is installed in the computer. You need to verify that the LAN adapter is compatible with the Windows Server 2003 operating systems. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

You need to configure the following TCP/IP settings on the LAN adapter:

- IP address and subnet mask assigned from the network administrator.
- DNS and WINS name servers of branch office name servers.

Because the branch office router will act as a router between the corporate office and the branch office, you must configure the branch office router with either static routes or with routing protocols so that all of the destinations on the branch office network are reachable from the branch office router.

**Installing a computer certificate**

Because the corporate office router is using computer certificates to authenticate the IPSec security association for the L2TP/IPSec connection, you must install a computer certificate on the branch office router in order for an L2TP/IPSec connection to be successfully established.

For more information about installing a computer certificate on the branch office router, see Computer certificates for L2TP/IPSec VPN connections and Network access authentication and certificates.

**Configuring a demand-dial interface**

You can create a demand-dial interface by using the Demand-Dial Interface Wizard. In the wizard, configure the following:

- **Interface Name**

  Type the name of the interface that represents the connection to the corporate office. For example, type **CorpOffice**.

- **Connection Type**

  Click **Connect using virtual private networking (VPN)**.

- **VPN Type**

  Click **Layer 2 Tunneling Protocol (L2TP)**.

- **Destination Address**

  Type the IP address or host name that is assigned to the Internet interface of the router at the corporate office. If you enter a host name, verify that the host name resolves to the proper IP address.

- **Protocols and Security**

  Select the protocols you want to route.

- **Dial-out Credentials**

  Type the name, domain name, and password of the user account that corresponds to this branch office router. The credentials are the same as those entered in the **Dial-Out Credentials** page of the Demand-Dial Interface Wizard when the demand-dial interface for this branch office was created on the corporate router.

**Configuring static routes**
You need to add static routes so that traffic to the corporate office is forwarded by using the appropriate demand-dial interface. For each route of the corporate office, configure the interface, destination, network mask, and metric. For the interface, select the demand-dial interface that corresponds to the corporate office previously created.

For example, the route that corresponds to the corporate office is 10.0.00 with a subnet mask of 255.0.0.0. This route becomes a static route with the following configuration:

- Interface: CorpOffice
- Destination: 10.0.0.0
- Network mask: 255.0.0.0
- Metric: 1

### Note

- Because the L2TP connection is a point-to-point connection, the Gateway IP address is not configurable.

For more information, see Add a static route.

**Configuring firewall packet filters**
If you are using a firewall in the branch office, you need to configure L2TP/IPSec packet filters on your firewall to allow L2TP/IPSec traffic between the corporate office router and the branch office router. For more information, see VPN servers and firewall configuration.

**Initiating the L2TP router-to-router VPN connection**
To connect the branch office router to the corporate router, in Routing and Remote Access, right-click the demand-dial interface that connects to the corporate office, and then click **Connect**.

For information about troubleshooting a router-to-router VPN, see Troubleshooting router-to-router VPNs.

# Routing Scenarios

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing scenarios**
This section describes typical network configurations that use Routing and Remote Access. Each scenario reviews the configuration of network media, addresses, routing protocols, and other services. While your network configuration may be different than those described here, the basic concepts apply.

The network addresses in these scenarios use private address ranges as specified by RFC 1597, "Address Allocation for Private Internets." If your network is connected to the Internet, you can contact an Internet service provider (ISP) to receive network addresses acquired from the Internet Assigned Numbers Authority (IANA).

**Notes**

- A computer running a member of the Windows Server 2003 family and the Routing and Remote Access service that provides LAN and WAN routing services is hereafter referred to as a server running Routing and Remote Access, or in specific contexts, as the Windows Server 2003 family routing service.

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

The following routing scenarios are described:

- SOHO Network to the Internet
- Small Office Network
- Medium-Size Office Network
- Corporate Network
- Dial-Up Branch Office Network
- Branch Office over the Internet

# SOHO Network to the Internet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SOHO network to the Internet**

To connect a small office or home office (SOHO) network to the Internet, you can use one of two methods:

1. Routed connection

   For a routed connection, the server running Routing and Remote Access acts as an IP router that forwards packets between SOHO hosts and Internet hosts. For more information, see Routed Connection to the Internet.

2. Translated connection

   For a translated connection, server running Routing and Remote Access and NAT acts as a network address translator, an IP router that translates addresses for packets that are forwarded between SOHO hosts and Internet hosts. For more information, see Translated Connection to the Internet.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Routed Connection to the Internet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routed connection to the Internet**
This scenario describes a small office or home office (SOHO) network that connects to the Internet by using a routed connection.

A SOHO network has the following characteristics:

- One network segment.
- A single protocol: TCP/IP.
- Demand-dial or dedicated-link connections to the Internet service provider (ISP).

The following illustration shows an example of a SOHO network.

The server running Routing and Remote Access is configured with a network adapter for the media that is used in the home network (for example, Ethernet) and an ISDN adapter or an analog modem. You can use a leased line or other permanent connection technologies, such as xDSL and cable modems, but this scenario describes the more typical configuration that uses a dial-up link to a local ISP.

This section covers:

- Planning for a routed connection
- Configuring a routed connection
- Testing a routed connection

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Planning for a routed connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning for a routed connection**

While offering maximum flexibility in the types of traffic that can be sent and received, a routed connection requires more configuration. The server running Routing and Remote Access must be manually configured with an IP address configuration and, if DHCP is not being used, all the SOHO hosts must also be manually configured with an IP address configuration. If DHCP is being used, a DHCP server on the SOHO network must be configured with the proper scope and scope options. For more information about DHCP, see DHCP

For this scenario, an Internet service provider (ISP) supplies a range of IP addresses to use for the SOHO hosts and the IP address of a DNS server for host name resolution.

Routing protocols are not needed to propagate IP routing information on the SOHO network. The computers on the SOHO network are either manually configured with the default gateway IP address of the server running Routing and Remote Access or receive a default gateway IP address through DHCP. The server running Routing and Remote Access is not configured with a default gateway but with a default route. For an example of adding the default route on the server running Routing and Remote Access, see Add a default static IP route.

If the ISP is on the MBone, the multicast backbone of the Internet, it can forward IP multicast traffic from the Internet. To receive the multicast traffic, the interfaces on the server running Routing and Remote Access are configured for the IGMP router mode and IGMP proxy mode. For more information, see Configuring a routed connection.

A routed connection to the Internet means that communication can occur with any host on the Internet. It also means that the SOHO hosts are exposed to attackers on the Internet. To provide security, packet filters are configured on the server running Routing and Remote Access to prevent unwanted Internet traffic on the SOHO network. For more information, see Packet filtering.

Computers on the home network are configured to use any services provided by an ISP, such as Network News Transfer Protocol (NNTP) servers and mail servers.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Configuring a routed connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring a routed connection**
To configure a routed connection to the Internet for a small office or home office (SOHO) network, the following are configured:

- The server running Routing and Remote Access.
- Other computers on the SOHO network.

**Configuring the server running Routing and Remote Access to act as a router**
To configure the server running Routing and Remote Access to act as a router, the following steps are completed:

1. The TCP/IP protocol on the server running Routing and Remote Access for the SOHO network interface is configured with:

   - IP address (from the address range obtained from the ISP).
   - Subnet mask (from the address range obtained from the ISP).
   - DNS server (from the IP address received from the ISP).

   TCP/IP is configured through the properties of the TCP/IP protocol for the local area connection in Network Connections.

   **Note**

   - Do not configure a default gateway.

2. The Routing and Remote Access service is installed and enabled.

   For information on installing and enabling the Routing and Remote Access service, see Enable the Routing and Remote Access service.

3. Routing on the dial-up port is enabled.

   If the connection to the Internet is a permanent connection that appears as a LAN interface (such as DDS, T-Carrier, Frame Relay, permanent ISDN, xDSL, or cable modem), or if you are connecting your server running Routing and Remote Access to another router before the connection to the Internet, skip to step 5.

   For information about enabling routing on the dial-up port, see Enable routing on ports.

4. A demand-dial interface is created to connect to the ISP.

   A demand-dial interface is created that is enabled for IP routing and uses the dial-up equipment and credentials that are used to dial the ISP. For more information about creating demand-dial interfaces, see Add a demand-dial interface.

5. A default static route is created that uses the Internet interface.

   For a default static route, the demand-dial interface (for dial-up connections) or LAN interface (for permanent or intermediate router connections) that is used to connect to the Internet is selected. The destination is 0.0.0.0 and the network mask is 0.0.0.0. For a demand-dial interface, the gateway IP address is not configurable. For a LAN interface that

is a point-to-point connection to your ISP, the gateway address is 0.0.0.0.

For more information about configuring a default static route, see Add a default static IP route.

6. Multicast support is configured (optional).

   To add multicast support to the SOHO network:

   - The IGMP routing protocol is added. For more information, see Add the IGMP routing protocol.
   - IGMP router mode is enabled on the interface that is connected to the home network. For more information, see Enable IGMP router and IGMP proxy mode.
   - IGMP proxy mode is enabled on the interface that is connected to the ISP. For more information, see Enable IGMP router and IGMP proxy mode.

**Configuring other computers on the SOHO network**

The TCP/IP protocol on the SOHO hosts is configured with:

- IP address (from the address range obtained from the ISP).
- Subnet mask (from the address range obtained from the ISP).
- Default gateway (the IP address assigned to the SOHO server running Routing and Remote Access network adapter).
- DNS server (from the IP address received from the ISP).

TCP/IP is configured through the properties of the TCP/IP protocol for the local area connection in Network Connections.

### Notes

- The previous configuration of SOHO hosts assumes that TCP/IP is configured manually. To automatically configure TCP/IP for SOHO hosts, you must install and configure a DHCP server. For more information, see DHCP Overview.
- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Testing a routed connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Testing a routed connection**

From a computer in the home network, the **ping** command is used to ping a computer on the Internet and activate the demand-dial connection to the ISP. Once connected, the **ping** command is used again. If a reply is received, the packets are being routed correctly. For more information, see Using the ping command.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Translated Connection to the Internet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Translated connection to the Internet**
This scenario describes a small office or home office (SOHO) network that connects to the Internet by using a translated connection.

The network configuration is simplified through the use of the network address translation (NAT) routing protocol, which provides network address translation, addressing, and name resolution services for SOHO network computers.

A SOHO network has the following characteristics:

- One network segment.
- A single protocol: TCP/IP.
- Demand-dial or dedicated-link connections to the Internet service provider (ISP).

The following illustration shows an example of a SOHO network.

The server running Routing and Remote Access is configured with a network adapter for the media that is used in the home network (for example, Ethernet) and an ISDN adapter or an analog modem. You can use a leased line or other permanent connection technologies, such as xDSL and cable modems, but this scenario describes the more typical configuration that uses a dial-up link to a local ISP.

This section covers:

- Planning for a translated connection
- Configuring a translated connection
- Testing a translated connection

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Planning for a translated connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning for a translated connection**

For this scenario, the network address translation addressing component on the network address translation computer automatically assigns unique addresses from the Internet Assigned Numbers Authority (IANA) private network IP of 192.168.0.0 with a subnet mask of 255.255.255.0 to all the other computers on the home network.

Traditional routing protocols such as RIP and OSPF are not needed to propagate IP routing information on the home network. The computers on the home network receive the default gateway IP address of the network address translation computer. The network address translation computer must be configured with a default route. For an example of adding the default route on the server running Routing and Remote Access, see Add a default static IP route.

If the Internet service provider (ISP) is on the MBone, the multicast backbone of the Internet, it can forward IP multicast traffic from the Internet. To receive the multicast traffic, the interfaces on the server running Routing and Remote Access are configured for IGMP router mode or IGMP proxy mode. For more information, see Configuring a translated connection.

Computers on the home network are configured to use any services provided by an ISP, such as Network News Transfer Protocol (NNTP) servers and mail servers.

**Notes**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Configuring a translated connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring a translated connection**
To configure the server running Routing and Remote Access to connect a small office or home office (SOHO) network to the Internet with a translated connection by using the network address translation (NAT) routing protocol and a dial-up connection to an Internet service provider (ISP), the steps in Deploying network address translation are completed.

**Notes**

- This scenario assumes the use of the NAT routing protocol for the translated connection. You can simplify the configuration of a translated connection by using the Internet Connection Sharing feature of Network Connections. For more information about the differences between Internet Connection Sharing and NAT, see Internet Connection Sharing and network address translation. For information about Internet Connection Sharing, see Connecting to the Internet in a home or small office network.

- Internet Connection Sharing and Network Bridge are not included in Windows Server 2003, Web Edition; Windows Server 2003, Datacenter Edition; and the Itanium-based versions of the original release of the Windows Server 2003 operating systems.

For more information about setting up network address translation, see Setting Up Network Address Translation.

**Configuring multicast support (optional)**
To add multicast support to the home network:

- The IGMP routing protocol is added. For more information, see Add the IGMP routing protocol.

- IGMP router mode is enabled on the interface that is connected to the home network. For more information, see Enable IGMP router and IGMP proxy mode.

- IGMP proxy mode is enabled on the interface that is connected to the ISP. For more information, see Enable IGMP router and IGMP proxy mode.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Testing a translated connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Testing a translated connection**

From a computer in the small office or home office network, the **ping** command is used to ping a computer on the Internet and activate the demand-dial connection to the ISP. Once connected, the **ping** command is used again. If a reply is received, the packets are being routed correctly. For more information, see Using the ping command.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Small Office Network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Small office network**
A small office network has the following characteristics:

- Few network segments (for example, one segment on each floor or wing of a building).
- A closed network with no connections to or from another network such as the Internet.
- Support for the IP protocol.

The following illustration shows an example of a small office network.

In this small office network scenario, Routers 1 and 2 are configured with a network adapter for each medium that is used on Networks A, B, and C.

This section covers:

- Planning addresses for the small office network
- Routing protocols for the small office network
- Other services for the small office network
- Configuring the small office network
- Testing the small office network

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Planning addresses for the small office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning addresses for the small office network**
The following sections describe how IP addresses are assigned for this small office network scenario.

**IP addressing**
IP addresses are assigned based on the private network ID of 192.168.0.0 for each network segment that uses a subnet mask of 255.255.255.0. This provides for growth of up to 254 computers on each network segment.

The following table shows the assignment of IP addresses for this scenario.

**IP addresses for the small office network**

| Segment | IP address with a subnet mask | Range of host IDs |
|---|---|---|
| Network A | 192.168.1.0, 255.255.255.0 | 192.168.1.1-192.168.1.254 |
| Network B | 192.168.2.0, 255.255.255.0 | 192.168.2.1-192.168.2.254 |
| Network C | 192.168.3.0, 255.255.255.0 | 192.168.3.1-192.168.3.254 |

After planning the network for this small office, addresses are assigned (either manually or by using DHCP) in the ranges described in the preceding table for all other computers on Networks A, B, and C.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Routing protocols for the small office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing protocols for the small office network**
For the small office network, IP routing is implemented through the Routing Information Protocol (RIP) or through static routes.

**IP routing protocols**
In this scenario, configuring RIP for IP is easier than configuring static routes. For more information, see Configuring the small office network.

### Note

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Other services for the small office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Other services for the small office network**

For this scenario, the DHCP service is used to automatically configure IP addresses and other information on client computers. Because DHCP is used, the DHCP Relay Agent must be configured on the interface for Router 1 on Network A and on the interface for Router 2 on Network C. When the DHCP Relay Agent is used, DHCP client computers on Networks A and C can acquire addresses from the DHCP server on Network B. For information about setting up a DHCP server, see DHCP Overview.

### Notes

- You do not need to use the DHCP Relay Agent on a router if there is a DHCP server on each network segment.
- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Configuring the small office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring the small office network**
To configure the small office network in this scenario, the following steps are completed:

1. Network adapters are installed and configured.
2. The Routing and Remote Access service is installed.
3. Routing protocols are added to each router.
4. The DHCP relay agent is installed and configured.
5. A WINS or DNS name server is installed.

These steps are outlined in the following sections and are intended as general guidelines for setting up a small office routed IP network.

**Installing and configuring network adapters**
To install and configure network adapters, the following steps are performed:

1. Two network adapters are installed in every router.
2. The drivers for the network adapters are installed.
3. The TCP/IP protocol is installed.
4. IP addresses are configured on the network adapters.

The following table shows the IP addresses for this small office network scenario.

| Router | Network adapter connected to | IP address |
|---|---|---|
| Router 1 | Network A | 192.168.1.1 |
| | Network B | 192.168.2.1 |
| Router 2 | Network B | 192.168.2.2 |
| | Network C | 192.168.3.1 |

**Installing the Routing and Remote Access service**
For this small office network scenario, the Routing and Remote Access service is installed. For more information about installing the Routing and Remote Access service, see Enable the Routing and Remote Access service.

**Configuring RIP for dynamic IP routing**
To implement dynamic IP routing for this small office network, the RIP routing protocol is added and then both LAN interfaces are added to RIP. For more information, see Add an IP routing protocol and Add a routing interface.

**Installing and configuring the DHCP Relay Agent**
In this small office network scenario, for Router 1, the DHCP Relay Agent is enabled for the interface that is on Network A. For Router 2, the DHCP Relay Agent is enabled for the interface that is on Network C. The DHCP server is also configured so that the clients on all the networks can use DHCP.

For information about configuring the DHCP Relay Agent, see Configure the DHCP Relay Agent.

**Installing a WINS or DNS name server**

To access network resources by using NetBIOS or domain names, a WINS or DNS name server is installed. For more information, see WINS Overview and DNS Overview.

### Note

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Testing the small office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Testing the small office network**

For this scenario, the ability of the small office network to route packets is tested by answering the following questions:

1. Are the packets being routed correctly?

   From a computer on each network, the **ping** command is used to ping a computer on the other networks. If a reply is not received from a network, the packets are not being routed correctly. For more information, see Using the ping command.

2. Are the RIP packets being sent correctly?

   To ensure that RIP packets are sent correctly, the neighboring RIP routers are viewed from one RIP router. Neighboring RIP routers are routers connected to a common network. For information about viewing RIP neighbors, see View RIP neighbors.

3. Are all the networks being routed to?

   To ensure that all the networks are being routed to, the IP routing table is viewed from a router. For more information, see Understanding the IP routing table.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Medium-Size Office Network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Medium-size office network**

A medium-size office network has the following characteristics:

- Several LAN segments with a backbone (for example, one segment on each floor or wing of a building).
- Dial-up connections for users who connect from home or while traveling.
- Internet connections.

The following illustration shows an example of a medium-size office network.

A medium-size office network typically uses a few different types of network media. The different office segments can use 10-megabit-per-second (Mbps) Ethernet or token ring networks, but the backbone network that is used to connect to the different networks and host servers can use 100-Mbps Ethernet, Fiber Distributed Data Interface (FDDI), or other types of networks.

The following table shows the network media that is used in this medium-size office network scenario.

| Router | Role | Medium |
|---|---|---|
| Router 1 | Connects to Network A | One Ethernet (10 Mbps) or token ring adapter |
| | Connects to the backbone | One Ethernet (100 Mbps) or FDDI adapter |
| Router 2 | Connects to Network B | One Ethernet (10 Mbps) or token ring adapter |
| | Connects to the backbone | One Ethernet (100 Mbps) or FDDI adapter |
| Router 3 | Connects to Network C | One Ethernet (10 Mbps) or token ring adapter |
| | Connects to the backbone | One Ethernet (100 Mbps) or FDDI adapter |
| Router 4 | Connects to the backbone | One Ethernet (100 Mbps) or FDDI adapter |
| | Connects to dial-up networking clients | Modems and/or ISDN adapters |

This section covers:

- Planning addresses for the medium-size office network

- Routing protocols for the medium-size office network
- Other services for the medium-size office network
- Configuring the medium-size office network
- Testing the medium-size office network

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Planning addresses for the medium-size office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning addresses for the medium-size office network**
The following sections describe how IP addresses are assigned for this medium-size office network scenario.

**IP addressing**
Network IDs are assigned based on the private network ID of 192.168.0.0 for each network segment that uses a subnet mask of 255.255.255.0. This provides for growth of up to 254 computers on each network segment.

The following table shows the assignment of IP addresses for this scenario.

**IP addresses for the medium-size office network**

| Segment | IP network ID with mask | Range of host IDs |
|---|---|---|
| Backbone | 192.168.1.0, 255.255.255.0 | 192.168.1.1-192.168.1.254 |
| Network A | 192.168.2.0, 255.255.255.0 | 192.168.2.1-192.168.2.254 |
| Network B | 192.168.3.0, 255.255.255.0 | 192.168.3.1-192.168.3.254 |
| Network C | 192.168.4.0, 255.255.255.0 | 192.168.4.1-192.168.4.254 |

After planning the network for this medium-size office, addresses are assigned (either manually or by using DHCP) in the ranges described in the preceding table for all other computers on Networks A, B, C, and D.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Routing protocols for the medium-size office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing protocols for the medium-size office network**
The IP routing protocol for medium-size networks is Routing Information Protocol (RIP) version 2. In this scenario, RIP v2 is configured on Routers 1, 2, 3, and 4.

### Note

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Other services for the medium-size office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Other services for the medium-size office network**

For this scenario, the DHCP service is used to automatically configure IP addresses and other information on client computers. Because DHCP is used, the DHCP Relay Agent must be configured on Routers 1, 2, and 3. When the DHCP Relay Agent is used, client computers on Networks A, B, and C can acquire addresses from the DHCP server on the backbone. For information about setting up a DHCP server, see DHCP Overview.

### Notes

- You do not need to use the DHCP Relay Agent on a router if you have a DHCP server on each network segment.
- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Configuring the medium-size office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring the medium-size office network**

To configure the medium-size office network described in this scenario, the following steps are completed:

1. Network adapters are installed and configured.
2. The Routing and Remote Access service is installed.
3. RIP is configured.
4. Remote access devices are configured.
5. The DHCP Relay Agent is installed and configured.
6. A WINS or DNS name server is installed.

These steps are outlined in the following sections and are intended as general guidelines for setting up and testing a medium-size office routed IP network.

**Installing and configuring network adapters**

To install and configure network adapters, the following steps are performed:

1. Two network adapters are installed in every router.
2. The drivers are installed for the network adapters.
3. The TCP/IP protocol is installed.
4. IP addresses are configured on the network adapters.

The following table shows the IP addresses for this medium-size office network scenario.

| Router | Network adapter connected to | IP address |
|---|---|---|
| Router 1 | Backbone | 192.168.1.1 |
| | Network A | 192.168.2.1 |
| Router 2 | Backbone | 192.168.1.2 |
| | Network B | 192.168.3.1 |
| Router 3 | Backbone | 192.168.1.3 |
| | Network C | 192.168.4.1 |
| Router 4 | Backbone | 192.168.1.4 |

**Installing the Routing and Remote Access service**

For this medium-size office network scenario, the Routing and Remote Access service is installed and enabled as a LAN router on every router. For more information about installing the Routing and Remote Access service, see Enable the Routing and Remote Access service.

On Router 4, the Routing and Remote Access service is installed and enabled as a LAN router and as a remote access server.

An IP address pool is created with a starting address of 192.168.1.225 and an ending IP address of 192.168.1.254. This pool allows up to 29 simultaneously connected dial-up networking clients. IP addresses for interfaces on the backbone network must now be selected so that they are within the range 192.168.1.1 to 192.168.1.224.

For more information about creating IP address pools, see Create a static IP address pool.

**Configuring RIP**
On each router, the RIP protocol is configured. To configure RIP, the RIP routing protocol is added to IP, each interface is added to RIP, and then RIP version 2 is enabled on the RIP interface that is connected to the backbone. For more information, see Configure RIP version 2.

This scenario assumes that all the routers on the medium-size office network are servers running Routing and Remote Access that are configured for RIP version 2. If there are existing routers on the network that only support RIP version 1, then you must install and configure RIP version 1.

**Configuring remote access devices**
In this routing scenario, Router 4 is a remote access server for dial-up networking clients. On Router 4, remote access devices such as modems and ISDN adapters are installed. For more information, see Installing Dial-Up Equipment.

**Installing and configuring the DHCP Relay Agent**
To use DHCP on the network, the DHCP Relay Agent is installed on Routers 1, 2, and 3, the interfaces that are not on the backbone are configured to use the DHCP Relay Agent, and the DHCP server is configured for use by clients.

For information about configuring the DHCP Relay Agent, see Configure the DHCP Relay Agent.

**Installing a WINS or DNS name server**
To access network resources by using NetBIOS or domain names, a WINS or DNS name server is installed. For more information, see WINS Overview and DNS Overview.

## Note

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Testing the medium-size office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Testing the medium-size office network**

For this scenario, the ability of the medium-size office network to route packets is tested by answering the following questions:

1. Are the packets being routed correctly?

   From a computer on each network, the **ping** command is used to ping a computer on the other networks. If a reply is not received from a network, the packets are not being routed correctly. For more information, see Using the ping command.

2. Are the RIP packets being sent correctly?

   To ensure that RIP packets are sent correctly, the neighboring RIP routers are viewed from one RIP router. Neighboring RIP routers are routers connected to a common network. For information about viewing RIP neighbors, see View RIP neighbors.

3. Are all the networks being routed to?

   To ensure that all the networks are being routed to, the IP routing table is viewed from a router. For more information, see Understanding the IP routing table.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Corporate Network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Corporate network**

A typical corporate network has the following characteristics:

- Many LAN segments with a backbone (for example, one segment on each floor or wing of several buildings).
- More than one network protocol.
- Areas configured with Open Shortest Path First (OSPF).
- Dial-up connections for users who connect from home or while traveling.
- Leased-line connections to branch offices.
- Demand-dial connections to branch offices.
- Internet connections.

The following illustration shows an example of a corporate network.

A corporate network typically uses different types of network media. The different office segments can use 10-megabit-per-second (Mbps) Ethernet or token ring networks, but the backbone network that is used to connect to the different networks and host servers is usually made up of 100-Mbps Ethernet or Fiber Distributed Data Interface (FDDI). Connections to external networks (the Internet) are over leased lines or packet-switched services such as Frame Relay. Connections to branch offices are over either switched media (ISDN or analog modems), dedicated media (leased lines or Frame Relay), or the Internet.

You can also use a tunneling protocol to connect the branch offices to the corporate network over the Internet, as shown by Router 10 and Network G. For more information on this type of configuration, see Branch Office over the Internet.

This corporate network scenario depicts branch office connections that use switched, demand-dial links and dedicated links, as shown in the following table.

**Network media for the corporate network**

| Router | Role | Medium |
|---|---|---|
| Router 1 | Connects to the backbone | One Ethernet (100 Mbps) or FDDI adapter |
| | Connects to Network C | One Ethernet (10 Mbps) or token ring adapter |
| Router 2 | Connects to Network A | One Ethernet (10 Mbps) or token ring adapter |
| | Connects to Network C | One Ethernet (10 Mbps) or token ring adapter |
| Router 3 | Connects to Network B | One Ethernet (10 Mbps) or token ring adapter |
| | Connects Network C | One Ethernet (10 Mbps) or token ring adapter |
| Router 4 | Connects to the backbone | One Ethernet (100 Mbps) or FDDI adapter |
| | Connects to Network D | One Ethernet (10 Mbps) or token ring adapter |
| Router 5 | Connects to the backbone | One Ethernet (100 Mbps) or FDDI adapter |
| | Connects to Router 6 | One or more ISDN adapters and/or analog modems |
| | Connects to Router 7 | One Frame Relay adapter |
| Router 6 | Connects to Router 5 | One or more ISDN adapters and/or analog modems |
| | Connects to Network F | One Ethernet (10 Mbps) or token ring adapter |
| Router 7 | Connects to Router 5 | One Frame Relay adapter |
| | Connects to Network E | One Ethernet (10 Mbps) or token ring adapter |
| Router 8 | Connects to the backbone | One Ethernet (100 Mbps) or FDDI adapter |
| | Connects to dial-up networking clients | Analog modems and/or ISDN adapters |
| Router 9 | Connects to the backbone | One Ethernet (100 Mbps) or FDDI adapter |
| | Connects to the Internet | One leased line (56K/T1) or Frame Relay adapter |
| Router 10 | Connects to Network G | One Ethernet (100 Mbps) or FDDI adapter |
| | Connects to the Internet | One leased line (56K/T1) or Frame Relay adapter |

This section covers:

- Planning addresses for the corporate network
- Routing protocols for the corporate network
- Other services for the corporate network
- Configuring the corporate network
- Testing the corporate network

**Notes**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.
- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Planning addresses for the corporate network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning addresses for the corporate network**
The following sections describe how IP addresses are assigned for this corporate network scenario.

**IP addressing**
Network IDs are assigned based on the private network ID of 172.16.0.0 for each network segment that uses a subnet mask of 255.255.255.0. This provides for growth of up to 254 computers on each network segment.

The following table shows the assignment of IP addresses for this scenario.

**IP addresses for the corporate network**

| Segment | IP network ID with mask | Range of host IDs |
|---|---|---|
| Backbone | 172.16.1.0, 255.255.255.0 | 172.16.1.1-172.16.1.254 |
| Network A | 172.16.2.0, 255.255.255.0 | 172.16.2.1-172.16.2.254 |
| Network B | 172.16.3.0, 255.255.255.0 | 172.16.3.1-172.16.3.254 |
| Network C | 172.16.4.0, 255.255.255.0 | 172.16.4.1-172.16.4.254 |
| Network D | 172.16.5.0, 255.255.255.0 | 172.16.5.1-172.16.5.254 |
| Network E | 172.16.6.0, 255.255.255.0 | 172.16.6.1-172.16.6.254 |
| Network F | 172.16.128.0, 255.255.255.0 | 172.16.128.1-172.16.128.254 |
| Network G | 172.16.129.0, 255.255.255.0 | 172.16.129.1-172.16.129.254 |

After planning the network, addresses are assigned (either manually or by using DHCP) in the ranges described in the preceding table for all computers on the backbone and Networks A, B, C, D, E, F, and G.

If more than 254 addresses are needed on a segment, a new segment is configured rather than increasing the network address range. To provide for growth in the network, branch offices are assigned a 254-address range, even if there are not that many computers.

However, if a branch office has 10 to 15 people, the extra addresses in a 254-address range should not be wasted. Instead, variable-length subnets are used to divide the 254 addresses into multiple subnets of different lengths. Both the Routing Information Protocol (RIP) version 2 and the Open Shortest Path First (OSPF) protocols support variable-length subnets.

### Notes

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Routing protocols for the corporate network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing protocols for the corporate network**
The following section describes the use of OSPF as the IP routing protocol for this corporate network scenario.

**IP routing protocols**
Corporate networks typically use the OSPF protocol because it is efficient in large networks. For this corporate network scenario, OSPF is configured on all the servers running Routing and Remote Access within the corporate site. Different types of routes are used depending on the type of WAN connection. For a demand-dial link, you must use either static routes or auto-static routes that use RIP. For dedicated WAN links, you can use static routes, RIP, or OSPF.

For this scenario, Routers 5, 6, 7, 9, and 10 are also configured with either static routes or RIP version 2 on the interfaces that are not configured for OSPF. Static routes are preferable to using RIP version 2 when the link bandwidth is not adequate or when routing update traffic is considered an unnecessary overhead cost.

### Notes

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Other services for the corporate network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Other services for the corporate network**

For this scenario, the DHCP service is used for automatic configuration of IP addresses and other information on client computers. Because DHCP is used, the DHCP Relay Agent must be configured on the servers running Routing and Remote Access acting as Routers 1, 2, 3, 4, and 7. When the DHCP Relay Agent is used, client computers on Networks A, B, D, and G can acquire addresses from the DHCP server on the backbone. For information about setting up a DHCP server, see DHCP Overview.

**Notes**

- You do not need to use the DHCP Relay Agent on your router if you have a DHCP server on each network.
- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Configuring the corporate network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring the corporate network**

To configure the corporate network described in this scenario, the following steps are completed at each router, as shown in the following table.

These steps are intended as general guidelines for setting up and testing a corporate routed IP network.

**Individual configurations for each router in the corporate network**

| Router | Configuration step |
|---|---|
| Router 1 | 1. Two network adapters are installed and then the drivers for the network adapters are installed.<br><br>2. The address 172.16.1.1 is assigned to the network adapter that is connected to the backbone, and 172.16.4.1 is assigned to the network adapter that is connected to Network C.<br><br>3. The Routing and Remote Access service is installed and LAN routing is enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access. For more information, see Enable the Routing and Remote Access service.<br><br>4. The OSPF routing protocol is configured. For more information, see Configure OSPF.<br><br>The area 0.0.0.1 is added to the router. By default, the backbone area 0.0.0.0 is added to the router.<br><br>On the interface connected to the backbone, the area is configured as 0.0.0.0.<br><br>On the interface connected to Network C, the area is configured as 0.0.0.1 for Area 1.<br><br>Passwords are configured for each interface.<br><br>5. The DHCP Relay Agent is installed and configured on the interface on Network C. For more information, see Configure the DHCP Relay Agent. |

| | |
|---|---|
| Router 2 | 1. Two network adapters are installed and then the drivers are installed for the network adapters.<br><br>2. The address 172.16.4.3 is assigned to the network adapter that is connected to Network C, and 172.16.2.1 is assigned to the network adapter that is connected to Network A.<br><br>3. The Routing and Remote Access service is installed and LAN routing is enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.<br><br>4. The OSPF routing protocol is configured.<br><br>The area 0.0.0.1 is added to the router. The backbone area 0.0.0.0 is deleted, which was added to the router by default.<br><br>On the interface connected to Network A, the area is configured as 0.0.0.1 for Area 1.<br><br>On the interface connected to Network C, the area is configured as 0.0.0.1 for Area 1.<br><br>Passwords are configured for each interface.<br><br>5. The DHCP Relay Agent is installed and configured on the interface connected to Network A. |
| Router 3 | 1. Two network adapters are installed and then the drivers for the network adapters are installed.<br><br>2. The address 172.16.4.2 is assigned to the network adapter that is connected to Network C, and 172.16.3.1 is assigned to the network adapter that is connected to Network B.<br><br>3. The Routing and Remote Access service is installed and LAN routing is enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.<br><br>4. The OSPF routing protocol is configured.<br><br>The area 0.0.0.1 is added to the router. The DHCP Relay Agent is installed and configured on the interface connected to Network B. |

| | |
|---|---|
| Router 4 | 1. Two network adapters are installed and then the drivers for the network adapters are installed.<br><br>2. The address 172.16.1.2 is assigned to the network adapter that is connected to the backbone, and 172.16.5.1 is assigned to the network adapter that is connected to Network D.<br><br>3. The Routing and Remote Access service is installed and LAN routing is enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.<br><br>4. The OSPF routing protocol is configured.<br><br>The area 0.0.0.2 is added to the router. By default, the backbone area 0.0.0.0 is added to the router.<br><br>On the interface connected to the backbone, the area is configured as 0.0.0.0.<br><br>On the interface connected to Network D, the area is configured as 0.0.0.2 for Area 2.<br><br>Passwords are configured for each interface.<br><br>5. The DHCP Relay Agent is installed and configured on the interface connected to Network D. |
| Router 5 | 1. One network adapter, one Frame Relay card, and a modem, ISDN, or remote access device are installed and then the drivers are installed.<br><br>2. The address 172.16.1.3 is assigned to the network adapter that is connected to the backbone, and the address 172.16.7.1 is assigned to the Frame Relay adapter.<br><br>3. The Routing and Remote Access service is installed and LAN and demand-dial routing are enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.<br><br>4. A pool of addresses is assigned to the router with a starting address of 172.16.1.193 and an ending IP address of 172.16.1.194. For more information, see Create a static IP address pool.<br><br>5. The OSPF routing protocol is configured.<br><br>The router is configured as an autonomous system boundary router.<br><br>On the interface connected to the backbone, the area is configured as 0.0.0.0.<br><br>6. RIP for IP is enabled on the Frame Relay interface that connects to Router 7.<br><br>7. Static routes are configured on the interface that connects to Router 6. For more information, see Add a static route. |

| | |
|---|---|
| Router 6 | 1. One network adapter and one modem, ISDN, or remote access device are installed and then the drivers for the adapters are installed.<br><br>For more information about the configuration of Router 5 and Router 6 to support a demand-dial connection, see Dial-Up Branch Office Network.<br><br>2. The address 172.16.128.1 is assigned to the network adapter that is connected to Network F.<br><br>3. The Routing and Remote Access service is installed and LAN and WAN routing are enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.<br><br>4. A pool of addresses is assigned to the router with a starting address of 172.16.128.253 and an ending IP address of 172.16.128.254. For more information, see Create a static IP address pool.<br><br>5. Static routes are configured on the interface that connects to Router 5. For more information, see Add a static route. |
| Router 7 | 1. One network adapter and one Frame Relay adapter are installed and then the drivers for the adapters are installed.<br><br>2. The address 172.16.7.2 is assigned to the Frame Relay adapter that is connected to Router 5, and 172.16.6.1 is assigned to the network adapter that is connected to Network G.<br><br>3. The Routing and Remote Access service is installed and LAN routing is enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.<br><br>4. Static routes, or any routing protocol that is used on the branch office LAN, are configured.<br><br>5. RIP for IP is configured on the interface that connects to Router 5.<br><br>6. The DHCP Relay Agent is installed and configured on the interface connected to Network E. |
| Router 8 | 1. One network adapter is installed and then the drivers for the network adapter are installed.<br><br>2. The address 172.16.1.4 is assigned to the network adapter that is connected to the backbone.<br><br>3. The Routing and Remote Access service is installed and LAN routing and remote access are enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.<br><br>4. Remote access devices are installed.<br><br>5. A pool of addresses is assigned with a starting address of 172.16.1.192 and an ending IP address of 172.16.1.254. This pool defines a range of 62 IP addresses for dial-up networking clients.<br><br>6. The OSPF routing protocol is configured.<br><br>On the interface that is connected to the backbone, the area is configured as 0.0.0.0.<br><br>Passwords are configured for each interface. |

| | |
|---|---|
| Router 9 | 1. Two network adapters are installed and then the drivers for the network adapters are installed.<br><br>2. The address 172.16.1.5 is assigned to the network adapter that is connected to the backbone. The IP address (as allocated by the Internet service provider) is assigned to the interface that is connected to the Internet.<br><br>3. The Routing and Remote Access service is installed and LAN and WAN routing and remote access are enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.<br><br>4. A pool of addresses is assigned with a starting address of 172.16.1.65 and an ending IP address of 172.16.1.66.<br><br>5. The OSPF routing protocol is configured.<br><br>On the interface that is connected to the backbone, the area is configured as 0.0.0.0.<br><br>Passwords are configured for each interface. |
| Router 10 | 1. One network adapter and one modem, ISDN, or remote access device are installed and then the drivers for the adapters are installed.<br><br>2. The address 172.16.129.1 is assigned to the network adapter that is connected to Network F.<br><br>3. The Routing and Remote Access service is installed and LAN and WAN routing are enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.<br><br>4. A pool of addresses is assigned to the router with a starting address of 172.16.129.253 and an ending IP address of 172.16.129.254.<br><br>5. Static routes are configured on the interface that connects to Router 9.<br><br>For more information about the configuration of Router 9 and Router 10 to support a demand-dial PPTP connection over the Internet, see Branch Office over the Internet. |

**Installing a WINS or DNS name server**
To access network resources by using NetBIOS or domain names, a WINS or DNS name server is installed. For more information, see WINS Overview and DNS Overview.

### Notes

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Testing the corporate network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Testing the corporate network**

For this scenario, the ability of the corporate network to route packets is tested by answering the following questions:

1. Are the packets being routed correctly?

   From a computer on each network, the **ping** command is used to ping a computer on the other networks. If a reply is not received from a network, the packets are not being routed correctly. For more information, see Using the ping command.

2. Is OSPF working correctly?

   The status of OSPF is checked by viewing OSPF neighbors. For more information, see View OSPF neighbors. This feature is not available on the Itanium-based versions of the Windows operating systems. This content is not available in this preliminary release.

   For more information about troubleshooting OSPF, see Troubleshooting OSPF.

3. Are all the networks being routed to?

   To ensure that all the networks are being routed to, the IP routing table is viewed from a router. For more information, see Understanding the IP routing table.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Dial-Up Branch Office Network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dial-up branch office network**

The Corporate Network scenario depicted a network that included branch offices. This scenario describes the configuration of a network for a branch office that is connected through a dial-up link.

A typical branch office network has the following characteristics:

- One LAN segment.
- Demand-dial connections to the corporate office.

The following illustration shows an example of a dial-up branch office network.

In this scenario, the server running Routing and Remote Access must be configured with a network adapter for the media that is used in the branch office (for example, Ethernet) and an ISDN device or analog modem for connection to the corporate office.

For more information, see:

- Planning addresses for the branch office network
- Routing protocols for the branch office network
- Other services for the branch office network
- Configuring the branch office network
- Testing the branch office network

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Planning addresses for the branch office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning addresses for the branch office network**
For IP addressing, the branch office network segment is assigned a network range of 254 addresses to enable potential growth. In this scenario, the branch office network (Network F) uses the address of 172.16.128.0 for the network and 255.255.255.0 for the mask.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Routing protocols for the branch office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing protocols for the branch office network**
For this branch office scenario, static routes are used for IP routing.

**IP routing protocols**
It is not necessary to use IP routing protocols to propagate IP routing information to the branch office. Instead, static routes are configured on the server running Routing and Remote Access. For an example of adding a static route, see Configuring the branch office network.

If there are many static routes or static services to add, RIP is configured to use auto-static updates. Auto-static updates enable the router to automatically send a request for a list of routes from other routers. The list is then converted to static routes. For more information, see Perform Auto-Static Updates.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Other services for the branch office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Other services for the branch office network**

Using a long-haul analog phone line or an ISDN line unnecessarily can be expensive. To prevent a demand-dial connection from initiating except when information resources such as a Web site or file shares are accessed, DHCP and name servers are installed on the branch office network.

In this scenario, the DHCP service is used for automatic configuration of IP addresses and other information on client computers. Installing and configuring the DHCP Relay Agent on Router 6 may cause Router 6 to dial the corporate hub router every time a DHCP packet is sent by a computer in the branch office network. Therefore, a DHCP server is installed on the branch office network. For information about setting up a DHCP server, see DHCP Overview.

Name servers (WINS and DNS) are installed on the branch office network to enable local name resolution. The branch office name servers must be configured to replicate with the corporate name servers. For more information, see WINS Overview and DNS Overview.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Configuring the branch office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring the branch office network**
To configure the dial-up branch office network described in this scenario, the following steps are completed:

1. A network adapter is installed and configured.
2. The Routing and Remote Access service is installed.
3. An IP address pool is configured.
4. Remote access devices are installed and configured.
5. Demand-dial interfaces are created.
6. Dial-in accounts are created.
7. IP static routes are added.
8. A DHCP, WINS, or DNS name server is installed.

These steps are outlined in the following sections and are intended as general guidelines for setting up and testing a branch office network.

**Installing and configuring the network adapter**
To configure Router 5 and Router 6, the following steps are performed:

1. The network adapter is installed.
2. The driver for the network adapter is installed.
3. The IP address on the network adapter is configured through the properties of the TCP/IP protocol.

In this branch office network scenario, the IP addresses are assigned as follows:

- For Router 5, the IP address 172.16.1.3 is assigned to the network adapter that connects to the backbone.
- For Router 6, the IP address 172.16.128.1 is assigned to the network adapter that connects to the branch office network.

**Installing the Routing and Remote Access service**
For this branch office network scenario, the Routing and Remote Access service is installed and LAN and demand-dial routing are enabled. For more information, see Enable the Routing and Remote Access service. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access.

**Configuring an IP address pool**
In this scenario, the branch office router (Router 6) is configured with an IP address pool with a single range, as shown in the following table.

| Starting address of the range | Ending address of the range | Number of addresses in the range |
|---|---|---|
| 172.16.128.253 | 172.16.128.254 | 2 |

The corporate router (Router 5) is also configured with an IP address pool with a single range, as shown in the following table.

| Starting address of the range | Ending address of the range | Number of addresses in the range |
|---|---|---|
| 172.16.1.133 | 172.16.1.134 | 2 |

For information about configuring an IP address pool, see Create a static IP address pool.

**Installing and configuring dial-up devices**

For both Router 5 and Router 6, modem or ISDN devices are installed and configured. For more information, see Installing Dial-Up Equipment.

**Creating demand-dial interfaces**

On Router 6, a demand-dial interface is created by using the Demand-Dial Interface wizard with the following configuration:

- Name: CorpOffice
- Protocols to route: IP
- Modem or adapter: Installed modem or ISDN device
- Phone number: Phone number of Router 5
- Dial-out credentials: BranchOffice

On Router 5, a demand-dial interface is created by using the Demand-Dial Interface wizard with the following configuration:

- Name: BranchOffice
- Protocols to route: IP
- Modem or adapter: Installed modem or ISDN device
- Phone Number: Phone number of Router 6
- Dial-out credentials: CorpOffice

For more information about the Demand-Dial Interface wizard, see Add a demand-dial interface.

**Creating dial-in accounts**

For this branch office network scenario, the dial-in accounts are created as follows:

- On Router 6, the account CorpOffice is added and dial-in permissions are enabled.
- On Router 5, the account BranchOffice is added and dial-in permissions are enabled.

For information about creating dial-in accounts, see Configure dial-in user properties.

**Adding IP static routes**

For this branch office scenario, on the branch office router (Router 6), a static default route is added. The demand-dial interface that connects to the corporate network is used.

The following route specifies that if a packet is sent to a computer that is not on the branch office network, a demand-dial connection is made with the corporate office. Because the connection between the branch office and the corporate office is a point-to-point connection, the gateway IP address is not configurable.

| Interface | Destination | Network mask | Metric |
|---|---|---|---|
| CorpOffice | 0.0.0.0 | 0.0.0.0 | 2 |

For more information about configuring a static default route, see Add a default static IP route.

On the corporate router (Router 5), a static route is added in order to connect to the branch office. The following route specifies that all packets destined for the branch office network are sent over the demand-dial interface.

| Interface | Destination | Network mask | Metric |
|---|---|---|---|
| BranchOffice | 172.16.128.0 | 255.255.255.0 | 2 |

For information about adding static routes, see Add a static route.

The corporate router (Router 5) is configured as an autonomous system boundary router so that the static routes are advertised to other OSPF routers.

**Installing a DHCP, WINS, or DNS name server**

A DHCP server is installed on the branch office network so that the clients can receive IP addresses. For more information about DHCP, see DHCP Overview. To access network resources by using NetBIOS or domain names, a WINS or DNS name server is installed. For more information, see WINS Overview and DNS Overview.

### Notes

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Testing the branch office network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Testing the branch office network**

From a computer in the branch office, the **ping** command is used to ping a computer on the corporate network and activate the demand-dial connection with the corporate network router. Once connected, the **ping** command is used again. If a reply is received from that computer, the packets are being routed correctly.

For more information, see Using the ping command.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Branch Office over the Internet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Branch office over the Internet**
Branch offices can be connected through leased or dial-up lines to a corporate network. Using leased or dial-up lines across long distances can be expensive. Routing and Remote Access enables branch offices to connect to the corporate networks by using the Internet. In this scenario, a branch office has a dial-up connection to a local Internet service provider (ISP). The branch office router then makes a secure, encrypted tunnel by using the Point-to-Point Tunneling Protocol (PPTP) across the Internet to the corporate network. This network configuration can result in cost savings, because the dial-up line is local instead of long distance.

**Note**

- To establish the tunnel, the branch office router must know the IP address of the corporate network router.

The following illustration shows an example of a branch office that connects to the corporate network by using the Internet.

In this scenario, the server running Routing and Remote Access acting as a branch office router makes a demand-dial PPTP connection to the server running Routing and Remote Access on the corporate network.

The branch office router must be configured with a network adapter for the medium that is used in the branch office (for example, Ethernet) and an ISDN adapter or analog modem for connection to the ISP. You can use a leased line to connect to the ISP, but this scenario discusses only demand-dial connections. The corporate office router must be connected to the Internet by using a leased line.

This section covers:

- Planning addresses for the branch office over the Internet
- Routing protocols for the branch office over the Internet
- Other services for the branch office over the Internet
- Configuring the PPTP connection at the branch office
- Configuring the PPTP connection at the corporate office
- Testing the PPTP connection

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Planning addresses for the branch office over the Internet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning addresses for the branch office over the Internet**
To enable potential growth, a network range of 254 IP addresses is assigned to the branch office network segment. In this scenario, the branch office network segment (Network G) uses the address of 172.16.129.0 for the network and 255.255.255.0 for the mask.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Routing protocols for the branch office over the Internet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing protocols for the branch office over the Internet**
For this branch office scenario, because the connection between the branch office and the corporate office is not permanent, static routes are used for IP routing.

**IP routing protocols**
It is not necessary to use IP routing protocols to propagate IP routing information to the branch office. Instead, static routes are configured on the server running Routing and Remote Access. For an example of adding a static route, see Configuring the PPTP connection at the branch office.

If there are many static routes or static services to add, RIP is configured to use auto-static updates. Auto-static updates enable the router to automatically send a request for a list of routes from other routers. This list is then converted to static routes. Auto-static updates must be performed on both sides of the connection. For more information, see Perform Auto-Static Updates.

### Note

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Other services for the branch office over the Internet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Other services for the branch office over the Internet**
To maximize performance and minimize the amount of data that is sent over the connection, DHCP and name servers are installed on the branch office network. The branch office name servers are configured to replicate with the corporate name servers.

In this scenario, the DHCP service is used for automatic configuration of IP addresses and other information on client computers. A DHCP server is installed on the branch office network. For information about setting up a DHCP server, see DHCP Overview.

To access network resources by using NetBIOS or domain names, a WINS or DNS name server is installed. For more information, see WINS Overview and DNS Overview.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Configuring the PPTP connection at the branch office

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring the PPTP connection at the branch office**
To configure a PPTP connection to a corporate network at a branch office router, you must create a demand-dial interface for the ISP connection, a demand-dial interface for the PPTP connection to the corporate router, and a static route for each interface. For this scenario, the following steps are completed:

1. Network adapters are installed and configured.
2. An IP address pool is configured.
3. The Routing and Remote Access service is installed.
4. Remote access devices are installed and configured.
5. Demand-dial interfaces are created.
6. IP static routes are added.
7. PPTP filters are added.
8. Remote access policies are configured.

These steps are outlined in the following sections and are intended as general guidelines for setting up a branch office PPTP connection to a corporate network.

**Installing and configuring network adapters**
To install and configure network adapters, the following steps are performed:

1. On the server running Routing and Remote Access, one network adapter is installed.
2. The driver for the network adapter is installed.
3. The IP address on the network adapter is configured through the properties of the TCP/IP protocol.

For this scenario, the address 172.16.129.1 is assigned to the network adapter that is connected to the branch office network.

**Installing the Routing and Remote Access service**
For this branch office network scenario, the Routing and Remote Access service is installed and LAN and demand-dial routing are enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access. For more information, see Enable the Routing and Remote Access service.

**Configuring an IP address pool**
In this scenario, the branch office router (Router 10) is configured with an IP address pool with a single range, as shown in the following table.

| Starting address of the range | Ending address of the range | Number of addresses in the range |
|---|---|---|
| 172.16.129.253 | 172.16.129.254 | 2 |

For information about configuring an IP address pool, see Create a static IP address pool.

**Creating demand-dial interfaces**
Two demand-dial interfaces are created: one for the modem or remote access device and one for the PPTP VPN device.

A demand-dial interface for the ISP connection is created by using the Demand-Dial Interface wizard with the following configuration:

- Name: ISP
- Protocols to route: IP
- Modem or adapter: Installed modem or ISDN device
- Phone number: Phone number of local ISP
- Dial-out credentials: ISP user account

A demand-dial interface for the PPTP connection is created by using the Demand-Dial Interface wizard with the following configuration:

- Name: CorpPPTP
- Protocols to route: IP
- Modem or adapter: VPN1 device
- Phone number: *w.x.y.z* (IP address of the Internet interface for Router 9)
- Dial-out credentials: BranchOfficePPTP

For more information about the Demand-Dial Interface wizard, see Add a demand-dial interface.

**Note**

- The use of *w.x.y.z* is intended to represent a valid public IP address as allocated by the Internet Assigned Numbers Authority (IANA) or an ISP. For your configuration, substitute your allocated public address for *w.x.y.z*.

Routing and Remote Access now displays three interfaces that correspond to:

1. The network adapter that connects to the branch office.
2. The ISP connection.
3. The PPTP connection.

**Adding IP static routes**

The PPTP connection to the corporate network is made by adding two IP static routes: a route to the ISP and a route to the PPTP server.

To call the PPTP server, a static route is added with the characteristics shown in the following table. This route specifies that if a packet's destination is on the corporate network, the PPTP demand-dial interface is used.

| Interface | Destination | Network mask | Metric |
|---|---|---|---|
| CorpPPTP | 172.16.0.0 | 255.255.0.0 | 1 |

To call the ISP, another static route is added with the characteristics shown in the following table. This route specifies that if a PPTP connection is made to the corporate PPTP server, the ISP demand-dial interface is used.

| Interface | Destination | Network mask | Metric |
|---|---|---|---|

| | | | |
|---|---|---|---|
| ISP | *w.x.y.z* | 255.255.255.255 | 1 |

For more information about adding static routes, see Add a static route.

**Note**

- The use of *w.x.y.z* is intended to represent a valid public IP address as allocated by the Internet Assigned Numbers Authority (IANA) or an ISP. For your configuration, substitute your allocated public address for *w.x.y.z*.

This configuration enables the router that is sending packets to 172.16.0.0 (the corporate network) to first connect to the ISP and then connect to the corporate office PPTP server (Router 9). After the interfaces are added and the static routes or routing protocols are set up, a manual connection to the corporate network is not needed except during the testing process.

**Adding PPTP filters**

To prevent the branch office router from sending or receiving any traffic except the packets sent over the PPTP connection, PPTP filters are added to the ISP demand-dial interface. For information about adding PPTP filters, see Add PPTP Filters.

**Configuring remote access policies**

A new remote access policy is created with the following properties:

- **Policy name** is set to **PPTP Access for Branch Office Routers** (example).
- The **NAS-Port-Type** condition is set to **Virtual (VPN)**.
- The **Tunnel-Type** condition is set to **Point-to-Point Tunneling Protocol**.
- The **Grant remote access permission** option is selected.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Configuring the PPTP connection at the corporate office

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring the PPTP connection at the corporate office**
To route PPTP tunneled data to a branch office router, you must create a demand-dial interface for the PPTP connection to the branch office router and a static route. For this scenario, the following steps are completed:

1. Network adapters are installed and configured.
2. The Routing and Remote Access service is installed.
3. An IP address pool is configured.
4. A demand-dial interface is created.
5. A dial-in account is created.
6. An IP static route is added.
7. PPTP filters are added for security.
8. Remote access policies are configured.

These steps are outlined in the following sections and are intended as general guidelines for setting up a branch office PPTP connection to a corporate network.

**Installing and configuring network adapters**
To install and configure network adapters, the following steps are performed:

1. One network adapter is installed to connect to the backbone and one network adapter is installed to permanently connect to the Internet.
2. The drivers for the network adapters are installed.
3. The IP addresses on the network adapters are configured through the properties of the TCP/IP protocol.

In this network scenario, the IP addresses are configured as follows:

1. The IP address 172.16.1.5 is assigned to the network adapter that connects to the backbone.
2. The IP address *w.x.y.z* is assigned to the network adapter that connects to the Internet.

**Note**

- The use of *w.x.y.z* is intended to represent a valid public IP address as allocated by the Internet Assigned Numbers Authority (IANA) or an ISP. For your configuration, substitute your allocated public address for *w.x.y.z*.

**Installing the Routing and Remote Access service**
For this branch office network scenario, the Routing and Remote Access service is installed and LAN and WAN routing are enabled. To allow remote access clients to create remote access VPN connections to the corporate network, remote access is also enabled. The network adapters that are installed automatically appear as interfaces in Routing and Remote Access. For more information, see Enable the Routing and Remote Access service.

**Configuring an IP address pool**

In this scenario, the corporate router (Router 9) is configured with an IP address pool with a single range, as shown in the following table.

| Starting address of the range | Ending address of the range | Number of addresses in the range |
|---|---|---|
| 172.16.1.137 | 172.16.1.138 | 2 |

For information about configuring an IP address pool, see Create a static IP address pool.

**Creating a demand-dial interface**
A demand-dial interface is created by using the Demand-Dial Interface wizard with the following configuration:

- Name: BranchOfficePPTP
- Protocols to route: IP
- Modem or adapter: VPN1 device
- Phone number: <none>
- Dial-out credentials: <none>

For more information about the Demand-Dial Interface wizard, see Add a demand-dial interface.

Routing and Remote Access now displays three interfaces that correspond to:

1. The network adapter that is connected to the backbone.
2. The network adapter that is connected to the Internet.
3. The PPTP connection.

**Creating a dial-in account**
The account BranchOfficePPTP is added and dial-in permissions are enabled.

For more information, see Configure dial-in user properties.

**Adding an IP static route**
At the corporate router, a single IP static route is added so that traffic can be routed to the branch office network.

To route packets to the branch office, a static route is added with the characteristics shown in the following table. This route specifies that if a packet is to be delivered to the branch office network, the PPTP demand-dial interface is used.

| Interface | Destination | Network mask | Metric |
|---|---|---|---|
| BranchOfficePPTP | 172.16.129.0 | 255.255.255.0 | 1 |

For more information about adding static routes, see Add a static route.

**Adding PPTP filters**
In this scenario, Router 9 is also configured as a Microsoft Proxy Server. The Microsoft Proxy Server configuration settings are used to add PPTP filters to the Internet interface. For information about adding filters by using Microsoft Proxy Server, see the Microsoft Proxy Server documentation.

**Configuring remote access policies**
A new remote access policy is created with the following properties:

- **Policy name** is set to **PPTP Access for Corporate Office Router** (example).
- The **NAS-Port-Type** condition is set to **Virtual (VPN)**.

- The **Tunnel-Type** condition is set to **Point-to-Point Tunneling Protocol**.
- The **Grant remote access permission** option is selected.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Testing the PPTP connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Testing the PPTP connection**

From a computer on the branch office network, the **ping** command is used to ping a computer on the corporate network and activate the demand-dial PPTP connection. Once connected, the **ping** command is used again. If a reply is received from that computer, the packets are being routed correctly. For more information, see Using the ping command.

For this scenario, the status of both the ISP and PPTP connections is determined by checking each of the following conditions:

1. Is there a connection to the ISP?

   From the branch office server running Routing and Remote Access, the connection state of the ISP demand-dial interface is checked.

2. Is there a connection by PPTP to the corporate network?

   From the branch office server running Routing and Remote Access, a manual connection to the corporate office is made by using the PPTP demand-dial interface. Once connected, a computer is pinged on the corporate network.

For more information, see Troubleshooting demand-dial routing.

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Routing Tools and Utilities

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing tools and utilities**
This section covers:

- Administration tools in mixed environments
- Understanding the IP routing table
- Using the ping command
- Using the tracert command
- Using the pathping command
- Using the IP multicasting utilities
- Using event logging
- Using tracing
- The Netsh Command-Line Utility

# Administration tools in mixed environments

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administration tools in mixed environments**
A mixed environment contains a combination of at least two of the following: servers running Windows NT 4.0 with Remote Access Service (RAS), servers running Windows NT 4.0 with Routing and Remote Access Service (RRAS), servers running Windows 2000 and Routing and Remote Access, and servers running members of the Windows Server 2003 family and Routing and Remote Access.

The platforms use different administration tools, as follows:

- With Windows 2000 and the Windows Server 2003 family, you use Routing and Remote Access or the Netsh command-line utility.
- With servers running Windows NT 4.0 with RRAS, you use the Routing and RAS Admin administrative tool.
- With servers running Windows NT 4.0 with RAS, you use the Remote Access Admin administrative tool.

The following sections describe the capabilities and behavior of each of these administrative tools when they are used to administer a platform for which they were not designed.

**Using Routing and Remote Access to administer a server running Windows NT 4.0 with RRAS**
You can use Routing and Remote Access to administer a server acting as a router and running Windows NT 4.0 with RRAS. However, due to the differences in configuration and features, you cannot do the following:

- Configure the remote access properties. On Windows NT 4.0, you must configure these properties on the server running Windows NT 4.0 with RRAS through Network in Control Panel.
- Install or remove the Routing and Remote Access service.
- Run Telnet.
- Configure remote access policies.
- Configure logging.
- Configure dial-in hours.
- Configure demand-dial filters.
- Install IGMP or network address translation (NAT) routing protocols.
- Obtain multicast statistics.
- Configure TCP/IP or IPX settings.

### Notes

- IPX routing is not supported on servers running the Windows Server 2003 family version of Routing and Remote Access.
- The IPX/SPX protocol is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

**Using Routing and Remote Access to administer a server running Windows NT 4.0 with RAS**

You cannot use Routing and Remote Access to manage a server running Windows NT 4.0 with RAS. When you select a server running Windows NT 4.0 with RAS, the Remote Access Admin administrative tool is started.

**Using Netsh to administer a server running Windows NT 4.0 with RAS or a server running Windows NT 4.0 with RRAS**
You cannot use the Netsh command-line utility to manage a server running Windows NT 4.0 with RAS or a server acting as a router and running Windows NT 4.0 with RRAS.

**Using Routing and RAS Admin to administer a server running Routing and Remote Access**
You cannot use Routing and RAS Admin to manage the routing components of Routing and Remote Access. When you select a server running Routing and Remote Access configured as a router, the router is displayed. However, there are no routing nodes and you cannot configure the routing components.

**Using Routing and RAS Admin to administer a server running Windows NT 4.0 with RAS**
You cannot use Routing and RAS Admin to manage a server running Windows NT 4.0 with RAS. When you select a server running Windows NT 4.0 with RAS, the Remote Access Admin administrative tool is started.

**Using Remote Access Admin to administer a server running Windows NT 4.0 with RRAS or a server running Routing and Remote Access**
You cannot use Remote Access Admin to manage a server acting as a router and running Windows NT 4.0 with RRAS or the routing components of Routing and Remote Access. When you select a server acting as a router and running Windows NT 4.0 with RRAS or a server running Routing and Remote Access, Remote Access Admin displays the "Remote Access Service is not started on the selected server" message.

# Understanding the IP routing table

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding the IP routing table**

To troubleshoot routing problems, you must understand the routing table. Every computer that runs TCP/IP makes routing decisions that are determined by the IP routing table.

For information about displaying the IP routing table, see View routing tables.

The following illustration shows an example of a routing table.

RRAS-ROUTER1 - IP Routing Table

| Destination | Network mask | Gateway | Interface | Metric | Protocol |
|---|---|---|---|---|---|
| 10.57.76.0 | 255.255.255.0 | 10.57.76.1 | Local Area C... | 1 | Local |
| 10.57.76.1 | 255.255.255.255 | 127.0.0.1 | Loopback | 1 | Local |
| 10.255.255.255 | 255.255.255.255 | 10.57.76.1 | Local Area C... | 1 | Local |
| 127.0.0.0 | 255.0.0.0 | 127.0.0.1 | Loopback | 1 | Local |
| 127.0.0.1 | 255.255.255.255 | 127.0.0.1 | Loopback | 1 | Local |
| 192.168.45.0 | 255.255.255.0 | 192.168.45.1 | Local Area C... | 1 | Local |
| 192.168.45.1 | 255.255.255.255 | 127.0.0.1 | Loopback | 1 | Local |
| 224.0.0.0 | 224.0.0.0 | 192.168.45.1 | Local Area C... | 1 | Local |
| 224.0.0.0 | 224.0.0.0 | 10.57.76.1 | Local Area C... | 1 | Local |
| 255.255.255.255 | 255.255.255.255 | 192.168.45.1 | Local Area C... | 1 | Local |
| 255.255.255.255 | 255.255.255.255 | 10.57.76.1 | Local Area C... | 1 | Local |

The IP routing table contains information in the following columns:

- **Destination**

  The destination is the destination host, subnet address, network address, or default route. The destination for a default route is 0.0.0.0.

- **Network mask**

  The network mask is used in conjunction with the destination to determine when a route is used. For example, a host route has a mask of 255.255.255.255, a default route has a mask of 0.0.0.0, and a subnet or network route has a mask between these two extremes.

  A mask of 255.255.255.255 means that only an exact match of the destination uses this route. A mask of 0.0.0.0 means that any destination can use this route. When a mask is written in binary, a **1** is significant (must match) and a **0** is insignificant (does not need to match).

  For example, a destination of 172.16.8.0 has a network mask of 255.255.248.0. This network mask means that the first two octets must match exactly, the first five bits of the third octet must match (248=11111000) and the last octet does not matter. The third octet of 172.16.8.0 (that is, 8) equals **00001**000 in binary. Without changing the first 5 bits (the masked-off portion shown in **bold**), you can go up to 15, or **00001**111 in binary. So a route with a destination of 172.16.8.0 and a mask of 255.255.248.0 applies to all packets destined for 172.16.**8**.0 through 172.16.**15**.255.

- **Gateway**

  The gateway is the IP address of the next router where a packet needs to be sent. On a LAN link (such as Ethernet or token ring), the gateway must be directly reachable by this router by using the interface indicated in the **Interface** column. On a LAN link, both the gateway and interface determine how the traffic is being forwarded by the router. For a demand-dial interface, the gateway address is not configurable. On a point-to-point link, the interface determines how the traffic is being forwarded by the router.

- **Interface**

  The interface indicates the LAN or demand-dial interface that is to be used to reach the next router.

- **Metric**

The metric indicates the relative cost of using the route to reach the destination. A typical metric is hops, or the number of routers to cross to reach the destination. If there are multiple routes with the same destination, the route with the lowest metric is the best route.

- **Protocol**

  The protocol shows how the route was learned. If the **Protocol** column lists RIP, OSPF, or anything other than Local, then the router is receiving routes. Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Using the ping command

Updated: August 22, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using the ping command**

If you are having connectivity problems, you can use the **ping** command to check the destination IP address you want to reach and record the results. The **ping** command displays whether the destination responded and how long it took to receive a reply. If there is an error in the delivery to the destination, the **ping** command displays an error message.

You can use the **ping** command to:

- Ping your computer (by address, not host name) to determine that TCP/IP is functioning. (Pinging your computer does not verify that your network adapter is functioning.)
- Ping the local router to determine whether the router is running.
- Ping beyond your local router.

The following table shows some useful **ping** command options.

| Option | Use |
|---|---|
| **-n** *Count* | Determines the number of echo requests to send. The default is 4 requests. |
| **-w** *Timeout* | Enables you to adjust the time-out (in milliseconds). The default is 1,000 (a 1-second time-out). |
| **-l** *Size* | Enables you to adjust the size of the ping packet. The default size is 32 bytes. |
| **-f** | Sets the Do Not Fragment bit on the ping packet. By default, the ping packet allows fragmentation. |

The following example illustrates how to send two pings, each 1,450 bytes in size, to IP address 131.107.8.1:

```
C:\>ping -n 2 -l 1450 131.107.8.1
Pinging 131.107.8.1 with 1450 bytes of data:

Reply from 131.107.8.1: bytes=1450 time<10ms TTL=32
Reply from 131.107.8.1: bytes=1450 time<10ms TTL=32

Ping statistics for 131.107.8.1:
    Packets: Sent = 2, Received = 2, Lost = 0 (0% loss),
Approximate roundtrip times in milliseconds:
    Minimum = 0ms, Maximum =  10ms, Average =  2ms
```

By default, **ping** waits 4,000 milliseconds (4 seconds) for each response to be returned before displaying the "Request Timed Out" message. If the remote system being pinged is across a high-delay link, such as a satellite link, responses may take longer to be returned. You can use the **-w** (wait) option to specify a longer time-out.

For more information about other **ping** options, see Command-line utilities.

To check connectivity by using the **ping** command, at the command prompt, type **ping** and the IP address you want to reach.

A response of "Destination net unreachable" means there was no route to the destination. You need to check the routing table on the router listed in the "Reply from" address in the "Destination net unreachable" message. For more information about the routing table, see Understanding the IP routing table.

A response of "Request timed out" means that there was no response to the ping in the default time period (1 second). You can check for the following:

- A router is down.

  To check the routers in the path between the source and the destination, use the **tracert** command. For more information, see Using the tracert command.

- The destination host is down.

  Physically verify that the host is running or check connectivity through another protocol.

- There is no route back to your computer.

  If the host is running, you can check for a return route by viewing the default gateway and local routing table on the destination host.

- The latency of the response is more than one second.

  Use the **-w** option on the **ping** command to increase the time-out. For example, to allow responses within 5 seconds, use **ping -w 5000**.

# Using the tracert command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using the tracert command**

If you are having connectivity problems, you can use the **tracert** command to check the path to the destination IP address that you want to reach and record the results. The **tracert** command displays the series of IP routers that are used in delivering packets from your computer to the destination and how long it took on each hop. If the packets are unable to be delivered to the destination, the **tracert** command displays the last router that successfully forwarded your packets.

For more information about the **tracert** command, you can type **tracert -?** at a command prompt.

The most common use of **tracert** is as follows:

**tracert** *IP address* [**-d**]

This returns a list of the routers that are crossed to get to *IP address*. By using the **-d** option, the router path is displayed faster because **tracert** does not try to resolve the names of the routers in the path.

# Using the pathping command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using the pathping command**

The **pathping** command is a route tracing tool that combines features of the **ping** and **tracert** commands with additional information that neither of those tools provides. The **pathping** command sends packets to each router on the way to a final destination over a period of time, and then computes results based on the packets returned from each hop. Since the command shows the degree of packet loss at any given router or link, it is easy to determine which routers or links might be causing network problems. A number of switches are available, as shown in the following table.

| Switch | Name | Function |
|---|---|---|
| **-n** | Hostnames | Does not resolve addresses to host names. |
| **-h** | Maximum hops | Maximum number of hops to search for target. |
| **-g** | Host-list | Loose source route along host list. |
| **-p** | Period | Number of milliseconds to wait between pings. |
| **-q** | Num_queries | Number of queries per hop. |
| **-w** | Timeout | Waits this many milliseconds for each reply. |
| **-T** | Layer Two tag | Attaches a Layer Two priority tag (for example, for IEEE 802.1p) to the packets and sends it to each of the network devices in the path. This helps in identifying the network devices that do not have Layer Two priority configured properly. The -T switch is used to test for Quality of Service (QoS) connectivity. |
| **-R** | RSVP test | Checks to determine whether each router in the path supports the Resource Reservation Protocol (RSVP), which allows the host computer to reserve a certain amount of bandwidth for a data stream. |

The default number of hops is 30, and the default wait time before a time-out is 3 seconds. The default period is 250 milliseconds, and the default number of queries to each router along the path is 100.

The following is a typical **pathping** report. The compiled statistics that follow the hop list indicate packet loss at each individual router.

```
D:\>pathping -n microsoft

Tracing route to microsoft [157.54.1.196]
over a maximum of 30 hops:
  0  172.16.87.35
  1  172.16.87.218
  2  192.168.52.1
  3  192.168.80.1
  4  157.54.247.14
  5  157.54.1.196

Computing statistics for 125 seconds...
            Source to Here   This Node/Link
Hop  RTT    Lost/Sent = Pct  Lost/Sent = Pct  Address
  0                                           172.16.87.35
                                 0/ 100 =  0%   |
  1   41ms     0/ 100 =  0%     0/ 100 =  0%  172.16.87.218
                                13/ 100 = 13%   |
  2   22ms    16/ 100 = 16%     3/ 100 =  3%  192.168.52.1
                                 0/ 100 =  0%   |
  3   24ms    13/ 100 = 13%     0/ 100 =  0%  192.168.80.1
                                 0/ 100 =  0%   |
  4   21ms    14/ 100 = 14%     1/ 100 =  1%  157.54.247.14
                                 0/ 100 =  0%   |
```

```
  5   24ms    13/ 100 = 13%     0/ 100 =  0%  157.54.1.196

Trace complete.
```

When **pathping** is run, you first see the results for the route as it is tested for problems. This is the same path that is shown by the **tracert** command. The **pathping** command then displays a busy message for the next 125 seconds (this time varies by the hop count). During this time, **pathping** gathers information from all the routers previously listed and from the links between them. At the end of this period, it displays the test results.

The two rightmost columns--**This Node/Link Lost/Sent=Pct** and **Address**--contain the most useful information. The link between 172.16.87.218 (hop 1), and 192.168.52.1 (hop 2) is dropping 13 percent of the packets. All other links are working normally. The routers at hops 2 and 4 also drop packets addressed to them (as shown in the **This Node/Link** column), but this loss does not affect their forwarding path.

The loss rates displayed for the links (marked as a **|** in the rightmost column) indicate losses of packets being forwarded along the path. This loss indicates link congestion. The loss rates displayed for routers (indicated by their IP addresses in the rightmost column) indicate that those routers' CPUs might be overloaded. These congested routers might also be a factor in end-to-end problems, especially if packets are forwarded by software routers.

# Using the IP multicasting utilities

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using the IP multicasting utilities**

IP multicasting utilities in the Windows Server 2003 family consist of the following:

- The **mrinfo** command.
- Netsh support for multicast troubleshooting.
- Support for the **mtrace** command.

**The mrinfo command**

The Windows Server 2003 family includes the **mrinfo** command that displays the configuration of a multicast router. You can use the configuration information to aid in the troubleshooting of multicast forwarding and routing problems.

The **mrinfo** command queries a specified multicast router with an Internet Group Management Protocol (IGMP) message. The response to the query contains a version number, the list of interfaces and the neighbors on each interface, metrics, Time to Live (TTL) thresholds, and flags. The syntax of the **mrinfo** command is:

**mrinfo** [**-n**] [ **-i***address* ] [ **-r***retry_count* ] [ **-t***timeout_count* ] *multicast_router*

- The **-n** option displays IP addresses in numeric format.
- The **-i** option specifies the IP address of the interface from which you want to send the **mrinfo** query. By default, the interface from which to send the **mrinfo** query is determined by the IP routing table.
- The **-r** option specifies the neighbor query retry limit. The default value is 3.
- The **-t** option specifies how long in seconds **mrinfo** waits for a neighbor query reply. The default value is 4.

The following is an example of the **mrinfo** command:

```
C:\>mrinfo 10.1.0.1
10.1.0.1(test1.microsoft.com) [version 18.55,mtrace,snmp]:
10.1.0.1 -> 0.0.0.0 (local) [1/0/querier/leaf]
10.2.0.1 -> 10.2.0.2 (test2.microsoft.com) [1/0]
10.2.0.1 -> 10.2.0.3 (test3.microsoft.com) [1/0]
10.3.0.1 -> 0.0.0.0 (local) [1/0/querier/leaf]
```

In the above example, **mrinfo** is run against the multicast router at 10.1.0.1. The first line shows the multicast router configuration: version number (for servers running Routing and Remote Access, the version number reflects the build number of the operating system) and flags (mtrace and snmp supported).

Each additional line displays the interfaces on the multicast router and the neighbors on each interface. Interfaces 10.1.0.1 and 10.3.0.1 have no neighbors. Interface 10.2.0.1 has two neighbors, 10.2.0.2 and 10.2.0.3. For each line, **mrinfo** displays the interface and neighbor, the domain name for the neighbor, the multicast routing metric, the TTL threshold, and flags indicating its role on the network such as the IGMP querier of the network (querier) or whether it has no neighbors (leaf).

**Netsh support for multicast troubleshooting**

To view multicast tables and gather information to aid in the troubleshooting of multicast routing and forwarding problems, you can use the following **netsh** commands:

- **netsh routing ip show mfe**

  Displays the entries in the multicast forwarding table. This is equivalent to the Multicast Forwarding Table available in

Routing and Remote Access. To view the Multicast Forwarding Table from within Routing and Remote Access, under **IP Routing**, right-click **General**, and then click **Show Multicast forwarding table**.

- **netsh routing ip show mfestats**

  Displays packet statistics and input and output interface information for multicast forwarding entries in the multicast forwarding table. This is equivalent to the Multicast Statistics table available in Routing and Remote Access. To view the Multicast Statistics table from within Routing and Remote Access, under **IP Routing**, right-click **General**, and then click **Show Multicast statistics**.

- **netsh interface ip show joins**

  Displays the multicast groups locally joined on each interface.

**Support for the mtrace command**

Although the Windows Server 2003 family does not provide a version of the Mtrace multicasting utility, the server running Routing and Remote Access does respond to **mtrace** command queries from other Mtrace utilities.

# Using event logging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using event logging**

Routing and Remote Access logs routing events extensively in the system event log. You can use information in the event logs to troubleshoot routing processes.

Four levels of logging are available:

- Log errors only
- Log errors and warnings (the default)
- Log the maximum amount of information
- Disable event logging

For example, if an OSPF router is unable to establish an adjacency on an interface, you can:

1. Disable OSPF on the interface.
2. Change the level of logging for OSPF to log the maximum amount of information.
3. Enable OSPF on the interface.
4. Examine the system event log for information on the OSPF adjacency process.
5. Change the level of logging for OSPF to log error information only.

You can further troubleshoot the adjacency problem by analyzing the OSPF entries in the system event log.

Logging is available in the following dialog boxes:

- **General** tab of the properties of IP Routing\General
- **General** tab of the properties of IP Routing\Network Address Translation (NAT)
- **General** tab of the properties of IP Routing\RIP
- **General** tab of the properties of IP Routing\OSPF
- **General** tab of the properties of IP Routing\IGMP

**Notes**

- Logging consumes system resources and should be used sparingly to help identify network problems. After the event has been logged or the problem is identified, you should immediately reset logging to its default value (log errors and warnings).
- When logging the maximum amount of information, the logging information can be complex and very detailed. Some of this information is useful only to Microsoft Product Support Services engineers or to network administrators who are very experienced with Routing and Remote Access.
- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the

Windows Server 2003 family.

# Using tracing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using tracing**

The server running Routing and Remote Access has an extensive tracing capability that you can use to troubleshoot complex network problems. You can enable the components in the Windows Server 2003 family to log tracing information to files. You must enable the tracing function by changing settings in the registry under:

**HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing**

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

You enable tracing for each routing protocol by setting the registry values described later in this section. You can enable and disable tracing for routing protocols while the router is running. Each routing protocol is capable of tracing and appears as a subkey (such as **OSPF** and **RIPV2**) under the preceding registry key.

To enable tracing for each routing protocol, you can configure the following registry entries for each protocol key:

- **EnableFileTracing REG_DWORD 1**

  You can enable logging tracing information to a file by setting **EnableFileTracing** to **1**. The default value is **0**.

- **FileDirectory REG_EXPAND_SZ** *Path*

  You can change the default location of the tracing files by setting **FileDirectory** to the path you want. The file name for the log file is the name of the component for which tracing is enabled. By default, log files are placed in the *systemroot*\Tracing folder.

- **FileTracingMask REG_DWORD** *LevelOfTracingInformationLogged*

  **FileTracingMask** determines how much tracing information is logged to the file. The default value is **FFFF0000**.

- **MaxFileSize REG_DWORD** *SizeOfLogFile*

  You can change the size of the log file by setting different values for **MaxFileSize**. The default value is **10000** (64K).

**Notes**

- Tracing consumes system resources and should be used sparingly to help identify network problems. After the trace is captured or the problem is identified, you should immediately disable tracing. Do not leave tracing enabled on multiprocessor computers.

- The tracing information can be complex and very detailed. Most of the time this information is useful only to Microsoft Product Support Services engineers or to network administrators who are very experienced with Routing and Remote Access.

# The Netsh Command-Line Utility

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The Netsh command-line utility**
Netsh is a command-line and scripting utility for networking components for local or remote computers. The Netsh utility can also save a configuration script in a text file for archival purposes or for configuring other servers.

The Netsh utility is a shell that can support multiple components through the addition of Netsh helper DLLs. A Netsh helper DLL extends Netsh functionality by providing additional commands to monitor or configure a specific networking component. Each Netsh helper DLL provides a context, a group of commands for a specific networking component. Within each context, subcontexts can exist. For example, within the routing context, the subcontext **ip** exists to group IP routing commands together.

Netsh command-line options include the following:

- **-a** *AliasFile*

  Specifies that an alias file is used. An alias file contains a list of **netsh** commands and an aliased version so that you can use the aliased command line in place of the **netsh** command. You can use alias files to map commands that may be more familiar in other platforms to the appropriate **netsh** command.

- **-c** *Context*

  Specifies the context of the command that corresponds to an installed helper DLL.

- *Command*

  Specifies the **netsh** command to execute.

- **-f** *ScriptFile*

  Specifies that all of the **netsh** commands in the *ScriptFile* file are run.

- **-r** *RemoteMachine*

  Specifies that the **netsh** commands are run on a remote computer specified by either its name or IP address.

You can abbreviate commands to the shortest unambiguous string. For example, issuing the command **sh ip int** is equivalent to issuing **show ip interface**. **Netsh** commands can be either global or context-specific. Global commands can be issued in any context and are used for general Netsh utility functions. Context-specific commands vary according to the context. You can log commands issued to a log file to create an audit trail of a **netsh** command session.

The following table lists the **netsh** global commands.

| Command | Description |
|---|---|
| **..** | Moves up one context level. |
| **?** or **help** | Displays command-line Help. |
| **show version** | Displays the current version of Windows and the Netsh utility. |
| **show netdlls** | Displays the current version of installed Netsh helper DLLs. |
| **add helper** | Add a Netsh helper DLL. |
| **delete helper** | Removes a Netsh helper DLL. |

| | |
|---|---|
| **show helper** | Displays the installed Netsh helper DLLs. |
| **cmd** | Creates a command window. |
| **online** | Sets the current mode to online. |
| **offline** | Sets the current mode to offline. |
| **set mode** | Sets the current mode to online or offline. |
| **show mode** | Displays the current mode. |
| **flush** | Discards any changes in offline mode. |
| **commit** | Commits changes made in offline mode. |
| **set audit-logging** | Turns on or off the logging facility. |
| **show audit-logging** | Displays current audit logging settings. |
| **set loglevel** | Sets level of logging information. |
| **show loglevel** | Displays the level of logging information. |
| **set machine** | Configures the computer on which the **netsh** commands are executed. |
| **show machine** | Displays the computer on which the **netsh** commands are executed. |
| **exec** | Executes a script file containing **netsh** commands. |
| **quit** or **bye** or **exit** | Exits the Netsh utility. |
| **add alias** | Adds an alias to an existing command. |
| **delete alias** | Deletes an alias to an existing command. |
| **show alias** | Displays all defined aliases. |
| **dump** | Writes configuration to a text file. |
| **popd** | A scripting command that pops a context from the stack. |
| **pushd** | A scripting command that pushes the current context on the stack. |

The Netsh utility has the following command modes:

- Online

  In online mode, commands issued at a Netsh command prompt are executed immediately.

- Offline

  In offline mode, commands issued at a Netsh command prompt are accumulated and executed as a batch by issuing the **commit** global command. You can discard accumulated commands by issuing the **flush** global command.

- Script

  With either the **-f** command-line option or by issuing the **exec** global command at a Netsh command prompt, all the **netsh** commands in the specified file are executed.

To create a script of the current configuration, use the global **dump** command. The **dump** command outputs the current running configuration in terms of **netsh** commands. You can use the script created by this command to configure a new server or to reconfigure the existing server. If you are making extensive changes to the configuration of a component, it is

recommended that you begin the configuration session with the **dump** command, in case you need to restore the configuration prior to changes being made.

For more information on **netsh** commands for the Routing and Remote Access service, see:

- Interface commands
- IP routing commands
- Scheduling auto-static updates
- Netsh commands for remote access

# Interface commands

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Interface commands**

The following table lists the **netsh** commands that you can type at a command prompt to administer interface settings on a server running Routing and Remote Access. If there are multiple commands for a particular function, they are indicated by separating the individual commands with a slash (/).

When you type the command at the command prompt, precede each command with **netsh**. For the exact syntax of each command, type the command with the **?** option. For example, to receive command-line Help on the **netsh interface** command, type **netsh interface ?** at the command prompt.

| Command | Description |
|---|---|
| **interface set/show interface** | Enables, disables, connects, disconnects, and displays the configuration of demand-dial interfaces. |
| **interface set/show credentials** | Configures or displays the user name, password, and domain name on a demand-dial interface. |

# IP routing commands

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP routing commands**

The following table lists the **netsh** commands that you can type at a command prompt to administer IP settings on a server running Routing and Remote Access. If there are multiple commands for a particular function, they are indicated by separating the individual commands with a slash (/). For example, the command **routing ip set/show loglevel** is actually two separate commands: **routing ip set loglevel** and **routing ip show loglevel**.

When you type the command at the command prompt, precede each command with **netsh**. For the exact syntax of each command, type the command with the **?** option. For example, to receive command-line Help on the **netsh routing ip set interface** command, type **netsh routing ip set interface ?** at the command prompt.

| Command | Description |
|---|---|
| **routing ip add/delete/set/show interface** | Adds, deletes, configures, or displays general IP routing settings on a specified interface. |
| **routing ip add/delete/set/show filter** | Adds, deletes, configures, or displays IP packet filters on a specified interface. |
| **routing ip add/delete/show boundary** | Adds, deletes, or displays multicast boundary settings on a specified interface. |
| **routing ip add/delete/set/show rtmroute** | Adds, deletes, configures, or displays a non-persistent Route Table Manager route. |
| **routing ip add/delete/set/show persistentroute** | Adds, deletes, configures, or displays persistent routes. |
| **routing ip add/delete/set/show preferenceforprotocol** | Adds, deletes, configures, or displays the preference level for a routing protocol. |
| **routing ip add/delete/set/show scope** | Adds, deletes, or displays a multicast scope. |
| **routing ip set/show loglevel** | Configures or displays the global IP logging level. |
| **routing ip show helper** | Displays all Netsh utility subcontexts of IP. |
| **routing ip show protocol** | Displays all running IP routing protocols. |
| **routing ip show mfe** | Displays multicast forwarding entries. |
| **routing ip show mfestats** | Displays multicast forwarding entry statistics. |
| **routing ip show boundarystats** | Displays IP multicast boundaries. |
| **routing ip show rtmdestinations** | Displays destinations in the Route Table Manager routing table. |
| **routing ip show rtmroutes** | Displays routes in the Route Table Manager routing table. |

| | |
|---|---|
| **routing ip nat set/show global** | Configures or displays global network address translation (NAT) settings. |
| **routing ip nat add/delete/set/show interface** | Adds, deletes, configures, or displays network address translation (NAT) settings for a specified interface. |
| **routing ip nat add/delete addressrange** | Adds or deletes an address range to the NAT interface public address pool. |
| **routing ip nat add/delete addressmapping** | Adds or deletes a NAT address mapping. |
| **routing ip nat add/delete portmapping** | Adds or deletes a NAT port mapping. |
| **routing ip autodhcp set/show global** | Configures or displays global DHCP allocator parameters. |
| **routing ip autodhcp set/show interface** | Configures or displays DHCP allocator settings for a specified interface. |
| **routing ip autodhcp add/delete exclusion** | Adds or deletes an exclusion from the DHCP allocator range of addresses. |
| **routing ip dnsproxy set/show global** | Configures or displays global DNS proxy parameters. |
| **routing ip dnsproxy set/show interface** | Configures or displays DNS proxy parameters for a specified interface. |
| **routing ip igmp set/show global** | Configures or displays IGMP global settings. |
| **routing ip igmp add/delete/set/show interface** | Adds, deletes, configures, or displays IGMP on the specified interface. |
| **routing ip igmp show grouptable** | Displays the IGMP host groups table. |
| **routing ip igmp show ifstats** | Displays the IGMP statistics for each interface. |
| **routing ip igmp show iftable** | Displays the IGMP host groups for each interface. |
| **routing ip igmp show proxygrouptable** | Displays the IGMP group table for the IGMP proxy interface. |
| **routing ip igmp show rasgrouptable** | Displays the group table for internal interface used by the remote access server. |
| **routing ip ospf set/show global** | Configures or displays global OSPF settings. This feature is not available on the Itanium-based versions of the Windows operating systems. This content is not available in this preliminary release. |
| **routing ip ospf add/delete/set/show interface** | Adds, removes, configures, or displays OSPF on a specified interface. |
| **routing ip ospf add/delete/set/show area** | Adds, removes, configures, or displays an OSPF area. |

| | |
|---|---|
| **routing ip ospf add/delete/set/show virtif** | Adds, removes, configures, or displays an OSPF virtual interface. |
| **routing ip ospf add/delete/show neighbor** | Adds, removes, configures, or displays an OSPF neighbor. |
| **routing ip ospf add/delete/show protofilter** | Adds, removes, configures, or displays routing information sources for OSPF external routes. |
| **routing ip ospf add/delete/show routefilter** | Adds, removes, configures, or displays route filtering for OSPF external routes. |
| **routing ip ospf show areastats** | Displays OSPF area statistics. |
| **routing ip ospf show lsdb** | Displays the OSPF link state database. |
| **routing ip ospf show virtifstats** | Displays OSPF virtual link statistics. |
| **routing ip relay set global** | Configures DHCP Relay Agent global settings. |
| **routing ip relay add/delete/set interface** | Adds, removes, or configures DHCP Relay Agent settings on a specified interface. |
| **routing ip relay add/delete dhcpserver** | Adds or removes a DHCP server IP address to the list of DHCP server addresses. |
| **routing ip relay show ifbinding** | Displays IP address bindings for interfaces. |
| **routing ip relay show ifconfig** | Displays DHCP Relay Agent configuration for each interface. |
| **routing ip relay show ifstats** | Displays DHCP statistics for each interface. |
| **routing ip rip set/show global** | Configures or displays global RIP-for-IP settings. |
| **routing ip rip add/delete/set/show interface** | Adds, deletes, configures, or displays RIP-for-IP settings on a specified interface. |
| **routing ip rip add/delete peerfilter** | Adds or removes a RIP peer filter. |
| **routing ip rip add/delete acceptfilter** | Adds or removes a RIP route filter to the list of routes being accepted. |
| **routing ip rip add/delete announcefilter** | Adds or removes a RIP route filter to the list of routes being announced. |
| **routing ip rip add/delete/show neighbor** | Adds, removes, or displays a RIP neighbor. |
| **routing ip rip set/show flags** | Configures and displays advanced settings of RIP for IP on a specified interface. |

| | |
|---|---|
| **routing ip rip show globalstats** | Displays global RIP parameters. |
| **routing ip rip show ifbinding** | Displays IP address bindings for interfaces. |
| **routing ip rip show ifstats** | Displays RIP statistics for each interface. |

# Scheduling auto-static updates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Scheduling auto-static updates**

You can automate scheduled updates by using a combination of Netsh utility scripts and Task Scheduler. To perform an automated auto-static update by using Routing Information Protocol (RIP) for IP, use the following **netsh** commands:

**netsh interface set interface name=** *DemandDialInterfaceName* **connect=CONNECTED**

**netsh routing ip rip update** *DemandDialInterfaceName*

**netsh interface set interface name=** *DemandDialInterfaceName* **connect=DISCONNECTED**

For example, to automatically update the RIP-for-IP routes by using a demand-dial connection called CorpHub, you type the following **netsh** commands:

**netsh interface set interface name=CorpHub connect=CONNECTED**

**netsh routing ip rip update CorpHub**

**netsh interface set interface name=CorpHub connect=DISCONNECTED**

You can run these commands from a batch file or you can place them in a Netsh script file. For example, the script file Corphub.scp runs the following commands for CorpHub:

**interface set interface name=CorpHub connect=CONNECTED**

**routing ip rip update CorpHub**

**interface set interface name=CorpHub connect=DISCONNECTED**

To run the Corphub.scp script, type the following at a command prompt:

**netsh -f corphub.scp**

After the batch file or Netsh script file is created, you can execute the batch file or Netsh script on a scheduled basis by using Task Scheduler.

# Netsh commands for remote access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Netsh commands for remote access**

The following table lists the Netsh commands that you can type at a command prompt to administer a server running Routing and Remote Access. If there are multiple commands for a particular function, they are indicated by separating the individual commands with a slash (/). For example, the command **ras add/delete/show registeredserver** is actually three separate commands: **ras add registeredserver**, **ras delete registeredserver**, and **ras show registeredserver**.

When you type the command at the command prompt, precede each command with **netsh**. For the exact syntax of each command, type the command with the **?** option. For example, to receive command-line Help on the **netsh ras add registeredserver** command, type **netsh ras add registeredserver ?** at the command prompt.

| Command | Description |
|---|---|
| **ras add/delete/show registeredserver** | Configures or displays whether the specified remote access server computer is a member of the **RAS and IAS Servers** security group in the Active Directory directory service of the specified domain. |
| **ras show activeservers** | Displays current servers running Routing and Remote Access on your network. |
| **ras set/show authmode** | Configures or displays whether and when dial-in connections are authenticated. |
| **ras add/delete/show authtype** | Configures or displays the permitted authentication types. |
| **ras add/delete/show client** | Configures or displays currently connected remote access clients. |
| **ras add/delete/show link** | Configures or displays the configuration of software compression and link control protocol (LCP) extensions. |
| **ras add/delete/show multilink** | Configures or displays Multilink and Bandwidth Allocation Protocol (BAP) settings. |
| **ras set/show tracing** | Configures or displays tracing settings. |
| **ras set/show user** | Configures or displays remote access settings for user accounts. |
| **ras ip set access** | Configures whether IP traffic from remote access clients is forwarded to the networks to which the remote access server is connected. |
| **ras ip set addrassign** | Configures the method by which the remote access server assigns IP addresses to incoming connections. |
| **ras ip set addrreq** | Configures whether remote access clients or demand-dial routers can request their own IP addresses. |
| **ras ip show config** | Displays IP remote access configuration. |
| **ras ip set negotiation** | Configures whether IP is negotiated for remote access connections. |
| **ras ip delete pool** | Deletes the static IP address pool. |
| **ras ip add/delete range** | Adds or removes a range of addresses from the static IP address pool. |
| **ras appletalk set access** | Configures whether AppleTalk traffic from remote access clients is forwarded to the networks to which the remote access server is connected. |

| | |
|---|---|
| **ras appletalk show config** | Displays AppleTalk remote access configuration. |
| **ras appletalk set negotiation** | Configures whether AppleTalk is negotiated for remote access connections. |
| **ras aaaa set/show accounting** | Configures or displays the accounting provider. |
| **ras aaaa add/delete/set/show acctserver** | Configures or displays RADIUS accounting servers. |
| **ras aaaa set/show authentication** | Configures or displays the authentication provider. |
| **ras aaaa add/delete/set/show authserver** | Configures or displays RADIUS authentication servers. |

For more information about Netsh, see The Netsh Command-Line Utility.

# Troubleshooting routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting**
This section covers:

- Common routing problems
- Troubleshooting RIP for IP
- Troubleshooting OSPF
- Troubleshooting network address translation
- Troubleshooting the DHCP Relay Agent
- Troubleshooting IP multicast
- Troubleshooting demand-dial routing

**Note**

- Open Shortest Path First (OSPF) is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

# Common routing problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Common routing problems**

What problem are you having?

**The server running Routing and Remote Access is not properly forwarding traffic.**

**Cause:** The Routing and Remote Access service is not running.

**Solution:** Verify that the Routing and Remote Access service is running.

**See also:** Determine the status of the Routing and Remote Access service

**Cause:** Routing is not enabled.

**Solution:** Verify that routing is enabled.

**See also:** Enable LAN and WAN routing

**Cause:** IP routing is not enabled.

**Solution:** Verify that IP routing is enabled on the **IP** tab for the properties of the server.

**See also:** View properties of the remote access server

**Cause:** The router is not receiving routes from routing protocols.

**Solution:** Verify whether the router is receiving routes from routing protocols.

For example, in the IP routing table, the **Protocol** column shows how the route was learned. If the **Protocol** column lists RIP or OSPF (or anything other than Local), then the router is receiving routes.

**See also:** Determine whether the router is receiving routes; Understanding the IP routing table

**Cause:** The proper routing protocols are not enabled on the proper interfaces.

**Solution:** Verify that the proper routing protocols are enabled on the proper interfaces.

In Routing and Remote Access, you can click **IP Routing** to see what routing protocols are installed. You can then click a routing protocol to see what interfaces are using that routing protocol.

For an interface running OSPF, you must verify that OSPF is enabled on that interface. This feature is not available on the Itanium-based versions of the Windows operating systems. This content is not available in this preliminary release.

**See also:** Verify that OSPF is enabled

**Cause:** Your TCP/IP configuration is incorrect.

**Solution:** Verify your TCP/IP configuration by using the **ipconfig** command.

Unlike hosts, routers are typically configured with a static TCP/IP configuration rather than by using DHCP. Verify that you are using the correct subnet mask for your environment. To verify that you are using the correct subnet mask, you can use the **ping** command to try to ping hosts on your network segment and your neighboring routers.

**See also:** Using the ping command

**Cause:** Your default route configuration is incorrect.

**Solution:** Verify your default route configuration.

Unlike hosts, routers are not normally configured with a default gateway. Instead, a default route is used to forward all traffic with an unknown destination. If default routing is to be used on the router, a default route is either learned through routing protocols or configured on the router. If a default route is not being learned through routing protocols (for example, when you connect a network to the Internet), you should configure a static default route on the router.

For a statically configured default route, you need to check the configuration to make sure the route is using the correct interface. If the interface being used is a LAN interface, such as Ethernet or token ring, the **Gateway** IP address for the route must be a directly reachable IP address on the same network as the selected interface.

**See also:** Add a default static IP route

To reset Routing and Remote Access back to default values, see Reset the Routing and Remote Access service.

# Troubleshooting RIP for IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting RIP for IP**
What problem are you having?

- There are improper routes in a mixed RIP v1 and RIP v2 environment.
- Silent RIP hosts are not receiving routes.
- RIP routers are not receiving expected routes.
- Auto-static RIP updates are not working.
- Host or default routes are not being propagated.

**There are improper routes in a mixed RIP v1 and RIP v2 environment.**
**Cause:** RIP v2 routers are configured to multicast announcements. Multicast announcements are never received by RIP v1 routers.

**Solution:** On networks containing RIP v1 routers, verify that RIP v2 is configured to broadcast its announcements on networks that contain RIP v1 routers and verify that the RIP v2 router interfaces are configured to accept both RIP v1 and RIP v2 announcements.

**See also:** Configure RIP version 2

**Silent RIP hosts are not receiving routes.**
**Cause:** RIP v2 routers are configured to multicast announcements. Multicast announcements are never received by silent RIP hosts.

**Solution:** If there are silent RIP hosts on a network that are not receiving routes from the local RIP router, verify the version of RIP supported by the silent RIP hosts. For example, if the silent RIP hosts only support listening for broadcasted, RIP v1 announcements, you cannot use RIP v2 multicasting.

If you are using the RIP listener component, available on Microsoft Windows NT Workstation version 4.0, Service Pack 4, or the Windows 2000 RIP Listening Service, you must configure your RIP routers for RIP v1 or RIP v2 broadcasting.

**See also:** Configure RIP version 2

**RIP routers are not receiving expected routes.**
**Cause:** You are deploying variable length subnetting, disjointed subnets, or supernetting in a RIP v1 or mixed RIP v1 and RIP v2 environment.

**Solution:** Do not deploy variable length subnetting, disjointed subnets, or supernetting in a RIP v1 or mixed RIP v1 and RIP v2 environment.

**See also:** "Unicast IP Routing" at the Microsoft Windows Resource Kits Web site.

**Cause:** Your password is not matched for all the RIP v2 interfaces on a network segment.

**Solution:** If authentication is enabled, verify that all interfaces on the same network are using the same case-sensitive password.

**See also:** Enable authentication

**Cause:** RIP peer filtering is not configured correctly.

**Solution:** If RIP peer filtering is being used, verify that the correct IP addresses for the neighboring peer RIP routers are configured.

**See also:** Add peer filters

**Cause:** RIP route filtering is not configured correctly.

**Solution:** If RIP route filtering is being used, verify that the ranges of network IDs for your internetwork are included or are not being excluded.

**See also:** Add route filters

**Cause:** RIP neighbors are not configured correctly.

**Solution:** If RIP neighbors are configured, verify that the correct IP addresses are configured for the unicasted RIP announcements.

**See also:** Add a unicast neighbor

**Cause:** IP packet filtering is preventing the receiving (through input filters) or sending (through output filters) of RIP traffic.

**Solution:** Verify that IP packet filtering on the router interfaces is not preventing the receiving (through input filters) or sending (through output filters) of RIP traffic. RIP traffic uses User Datagram Protocol (UDP) port 520.

**See also:** Manage Packet Filters

**Cause:** TCP/IP filtering is preventing the receiving of RIP traffic.

**Solution:** Verify that TCP/IP filtering on the router interfaces is not preventing the receiving of RIP traffic. RIP traffic uses UDP port 520.

**See also:** Configure TCP/IP to use TCP/IP filtering

**Cause:** You are using auto-static RIP and you did not do an initial manual update.

**Solution:** When you use auto-static RIP on a demand-dial interface, the first time you make a connection, you must manually update routes.

You must also update routes manually on the router for the corresponding interface. The routes then appear in the IP routing table.

**See also:** Perform Auto-Static Updates; View routing tables

**Auto-static RIP updates are not working.**
**Cause:** The demand-dial interfaces are configured to broadcast announcements.

**Solution:** For dial-up demand-dial interfaces that use auto-static updates, configure the demand-dial interfaces to use RIP v2 multicast as the outgoing packet protocol. When a router calls another router, each router receives an IP address from the IP address pool of the other router, which is on a different subnet. Because broadcasted RIP messages are addressed to the subnet broadcast address, each router does not process the other router's broadcasted request for routes. Using multicasting, RIP requests and announcements are processed regardless of the subnet for the router interfaces.

**See also:** Configure RIP version 2

**Host or default routes are not being propagated.**
**Cause:** RIP by default is not configured to propagate host or default routes.

**Solution:** If host routes or default routes need to be propagated, change the default settings on the **Advanced** tab of the properties of a RIP interface.

# Troubleshooting OSPF

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting OSPF**
What problem are you having?

- OSPF adjacency is not forming.
- A virtual link is not forming.
- Lack of OSPF routes or existence of improper OSPF routes.

**OSPF adjacency is not forming.**
**Cause:** OSPF is not enabled on the interface.

**Solution:** Verify that OSPF is enabled on the interface on the network segment where an adjacency should form. By default, when you add an interface to the OSPF routing protocol, OSPF is disabled for the interface and must be manually enabled.

**See also:** Verify that OSPF is enabled

**Cause:** Adjacency should not form.

**Solution:** Verify that the two neighboring routers should form an adjacency. If the two routers are the only routers on the network, an adjacency should form. If there are more than two routers on the network, adjacencies only form with the designated router (DR) and backup designated router (BDR). If the two routers have already formed adjacencies with the DR and the BDR, they cannot form adjacencies with each other. In this case, the neighbor should appear as **2-way** under **Neighbor State** (in the **Neighbors** dialog box from IP Routing\General).

**See also:** View routing tables

**Cause:** No IP connectivity to a neighboring router.

**Solution:** Ping the neighboring router to ensure basic IP and network connectivity. You can use the **tracert** command to trace the route to the neighboring router. There should not be any routers between the neighboring routers.

**See also:** Using the ping command; Using the tracert command

**Cause:** Adjacency cannot form because of mismatched OSPF configuration.

**Solution:** Use OSPF logging to log errors and warnings to record information on why the adjacency is not forming.

**See also:** Using event logging

**Cause:** Mismatched authentication setting or mismatched passwords.

**Solution:** Verify that the areas are enabled for authentication and the OSPF interfaces are using the same password. Servers running Routing and Remote Access configured to act as OSPF routers have authentication enabled by default and the default password is 12345678. You need to change the authentication to match all neighboring OSPF routers on the same network. The password can vary per network.

**See also:** Create an OSPF area; Set a password on an OSPF interface

**Cause:** The neighboring routers are not configured for the same hello or dead interval.

**Solution:** Verify that the neighboring routers are configured for the same hello and dead intervals. By default the hello interval is 10 seconds and the dead interval is 40 seconds.

**See also:** Configure the hello and dead intervals

**Cause:** Mismatched stub area configuration on neighboring routers.

**Solution:** Verify that the routers agree as to whether the area to which the common network segment belongs is a stub area

or not.

**See also:** Create an OSPF area

**Cause:** Neighboring routers have mismatched Area IDs.

**Solution:** Verify that the interfaces of the neighboring routers are configured with the same Area ID.

**See also:** Create an OSPF area

**Cause:** Non-Broadcast Multiple Access (NBMA) interfaces are not configured with OSPF neighbors.

**Solution:** If the routers are on a NBMA network such as X.25 or Frame Relay that operate in single interface mode, their neighbors must be manually configured by using the unicast IP address of the neighbor or neighbors to which the OSPF packets need to be sent.

**See also:** Add an OSPF neighbor; OSPF design considerations

**Cause:** All router interfaces are set to a router priority of 0.

**Solution:** On broadcast networks (Ethernet, token ring, FDDI) or NBMA networks (X.25 and Frame Relay operating in single interface mode), verify that all routers do not have a router priority of 0. At least one router must have a router priority of 1 or greater so that it can become the DR for the network.

**See also:** Configure an OSPF interface

**Cause:** IP packet filtering is preventing the receiving (through input filters) or sending (through output filters) of OSPF traffic.

**Solution:** Verify that IP packet filtering on the router interfaces is not preventing the receiving (through input filters) or sending (through output filters) of OSPF traffic. OSPF traffic uses IP protocol number 89.

**See also:** Manage Packet Filters

**Cause:** TCP/IP filtering is preventing the receiving of OSPF traffic.

**Solution:** Verify that TCP/IP filtering on the router interfaces is not preventing the receiving of OSPF traffic. OSPF traffic uses IP protocol number 89.

**See also:** Configure TCP/IP to use TCP/IP filtering

**A virtual link is not forming.**
**Cause:** Mismatched configuration of password, hello interval, or dead interval.

**Solution:** Verify that the virtual link neighbor routers are configured for the same password, hello interval, and dead interval.

**See also:** Add a virtual interface

**Cause:** The router ID of the virtual link neighbor is configured incorrectly.

**Solution:** For each router, verify that the router ID of the virtual link neighbor is correctly configured. The router ID is found on the **General** tab on the properties of the OSPF routing protocol.

**See also:** Add a virtual interface

**Cause:** Virtual link neighbors are configured for the incorrect transit area ID.

**Solution:** Verify that both virtual link neighbors are configured for the same correct transit area ID.

**See also:** Add a virtual interface

**Cause:** The retransmit interval is not long enough.

**Solution:** For large internetworks with substantial round-trip delays across the transit area, verify that the retransmit interval is long enough.

**See also:** Add a virtual interface

**Lack of OSPF routes or existence of improper OSPF routes.**
**Cause:** Not receiving summarized routes.

**Solution:** If you are not receiving summarized OSPF routes for an area, verify that the area border routers (ABRs) for the area

are configured with the proper {Destination, Network mask} pairs summarizing that area's routes.

**See also:** Configure ranges for an OSPF area

**Cause:** You are receiving both individual and summarized OSPF routes for an area.

**Solution:** Verify that all the ABRs for the area are configured with the proper {Destination, Network mask} pairs summarizing that area's routes.

**See also:** Configure ranges for an OSPF area

**Cause:** You are not receiving external routes from the autonomous system boundary router (ASBR).

**Solution:** Verify that the source and route filtering that is configured on the ASBR is not too restrictive, preventing proper routes from being propagated to the OSPF autonomous system. External source and route filtering is configured on the **External Routing** tab on the properties of the OSPF routing protocol.

**See also:** Configure an ASBR

**Cause:** All ABRs are not connected to the backbone.

**Solution:** Verify that all ABRs are either physically connected to the backbone or logically connected to the backbone by using a virtual link. There should not be backdoor routers, which are routers that connect two areas without going through the backbone.

**Notes**

- This feature is not available on the Itanium-based versions of the Windows operating systems.
- This content is not available in this preliminary release.
- For more information, see "Unicast IP Routing" at the Microsoft Windows Resource Kits Web site.

# Troubleshooting network address translation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting network address translation**
What problem are you having?

- The network address translation (NAT) computer is not properly translating packets.
- Private network hosts are not receiving IP address configuration.
- Name resolution for private network hosts is not working.

**The network address translation (NAT) computer is not properly translating packets.**
**Cause:** NAT interfaces are not properly configured.

**Solution:** You must add both public (Internet) and private (small office or home office) interfaces to the NAT routing protocol.

You need to verify that the interface on the server running Routing and Remote Access that connects to the Internet is configured for translation. The **Public interface connected to the Internet** option on the **General** tab of the properties of the Internet interface should be selected.

You need to verify that the interfaces on the server running Routing and Remote Access that connects to the small office or home office are properly configured. The **Private interface connected to private network** option on the **General** tab of the properties of the home network interface should be selected.

**See also:** Add and configure an interface for network address translation

**Cause:** TCP/UDP port translation is not enabled.

**Solution:** If you have more private hosts than public IP addresses, you need to verify that the **Translate TCP/UDP headers (recommended)** check box on the **General** tab of the properties of the public interface is selected.

**Cause:** Your range of public addresses is not configured correctly.

**Solution:** If you have multiple public IP addresses, you need to verify that they are properly entered on the **Address Pool** tab of the properties of the Internet interface. If your address pool includes an IP address that was not allocated to you by your ISP, then inbound Internet traffic that is mapped to that IP address may be routed by the ISP to another location.

**See also:** Configure interface IP address ranges

**Cause:** The traffic being forwarded by the network address translation computer is not translatable.

**Solution:** If you have some programs that do not seem to work through the NAT computer, you can try running them from the NAT computer. If they work from the NAT computer and not from a computer on the private network, then the payload of the program may not be translatable.

**Cause:** Your range of private addresses is configured incorrectly.

**Solution:** You need to verify that the range of addresses configured on the **Addressing** tab of the properties of the NAT routing protocol corresponds to a private network (10.0.0.0 with a subnet mask of 255.0.0.0, 172.16.0.0 with a subnet mask of 255.240.0.0, 192.168.0.0 with a subnet mask of 255.255.0.0) or a subnet of a private network. The default range of addresses is 192.168.0.0 with a subnet mask of 255.255.255.0.

**See also:** Enable network address translation addressing

**Cause:** IP packet filtering is preventing the receiving or sending of IP traffic.

**Solution:** You need to verify that IP packet filtering on the private network and Internet interfaces is not preventing the receiving (input filters) or sending (output filters) of Internet-based traffic.

**See also:** Manage Packet Filters

**Private network hosts are not receiving IP address configuration.**
**Cause:** Network address translation addressing is not enabled on the private interface.

**Solution:** You need to verify that network address translation addressing is enabled on the interface that corresponds to your small office or home office network segment.

**See also:** Enable network address translation addressing

**Name resolution for private network hosts is not working.**
**Cause:** Network address translation name resolution is not enabled on the private interface.

**Solution:** You need to verify that network address translation name resolution is enabled on the interface that corresponds to your small office or home office network segment.

**See also:** Enable network address translation name resolution

**Cause:** The network address translation computer is not properly configured for name resolution.

**Solution:** If computers on the small office or home office network are not able to resolve names to IP addresses, then you can check the name resolution configuration of the network address translation computer by using the **ipconfig** command. There are two ways that you can configure name resolution when dialing an ISP:

- Statically assigned name servers

  You must manually configure the TCP/IP protocol with the IP address (or addresses) of the name servers provided by the ISP. If you have statically assigned name servers, you can use the **ipconfig** command at any time to get the IP addresses of your configured name servers.

- Dynamically assigned name servers

  Manual configuration is not required. The IP addresses of the name servers provided by the ISP are dynamically assigned whenever you dial the ISP. If you have dynamically assigned name servers, you must run the **ipconfig** command *after* a connection to the ISP has been made.

# Troubleshooting the DHCP Relay Agent

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting the DHCP Relay Agent**
What problem are you having?

- The DHCP Relay Agent is not providing relay services for DHCP clients on a network segment.

**The DHCP Relay Agent is not providing relay services for DHCP clients on a network segment.**
**Cause:** The interface on the server running Routing and Remote Access that connects to the network segment where the DHCP clients are located is not added to the DHCP Relay Agent IP routing protocol.

**Solution:** Verify that the interface on the server running Routing and Remote Access that connects to the network segment where the DHCP clients are located is added to the DHCP Relay Agent IP routing protocol.

**See also:** Enable the DHCP Relay Agent on a router interface

**Cause:** The **Relay DHCP packets** check box is not selected for the DHCP Relay Agent interface that is connected to the network segment where the DHCP clients are located.

**Solution:** Verify that the **Relay DHCP packets** check box is selected for the DHCP Relay Agent interface that is connected to the network segment where the DHCP clients are located.

**Cause:** The IP addresses of DHCP servers configured on the global properties of the DHCP Relay Agent are incorrect.

**Solution:** Verify that the IP addresses of DHCP servers configured on the global properties of the DHCP Relay Agent are the correct IP addresses for DHCP servers on your internetwork.

**See also:** Configure global DHCP Relay Agent properties

**Cause:** The correctly configured DHCP servers are not reachable.

**Solution:** From the router with the DHCP Relay Agent enabled, use the **ping** command to ping each of the DHCP servers that are configured in the global DHCP Relay Agent dialog box. If you cannot ping the DHCP servers from the DHCP Relay Agent router, troubleshoot the lack of connectivity between the DHCP Relay Agent router and the DHCP server or servers.

**See also:** Troubleshooting TCP/IP

**Cause:** IP packet filtering is preventing the receiving (through input filters) or sending (through output filters) of DHCP traffic.

**Solution:** Verify that IP packet filtering on the router interfaces is not preventing the receiving (through input filters) or sending (through output filters) of DHCP traffic. DHCP traffic uses the User Datagram Protocol (UDP) ports of 67 and 68.

**See also:** Manage Packet Filters

**Cause:** TCP/IP filtering is preventing the receiving of DHCP traffic.

**Solution:** Verify that TCP/IP filtering on the router interfaces is not preventing the receiving of DHCP traffic. DHCP traffic uses the UDP ports of 67 and 68.

**See also:** Configure TCP/IP to use TCP/IP filtering

# Troubleshooting IP multicast

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting IP multicast**
What problem are you having?

**The IGMP router does not work correctly.**

**Cause:** The network adapters that are installed may not support multicast promiscuous mode.

**Solution:** Multicast promiscuous mode is a special mode of the network adapter in which all multicasted traffic is passed up to the network operating system. Not all network adapters support multicast promiscuous mode. If a server running Windows Server 2003 fails to put the network adapter into multicast promiscuous mode during the initialization of the IGMP router component, then an event is logged in the System Event Log. The event has the following attributes:

- Source: IP Router Manager
- Event ID: 20157
- Message text: The interface [name of the interface] could not be enabled for multicast. IGMP router will not be activated over this interface.

**See also:** Using the IP multicasting utilities

# Troubleshooting demand-dial routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting demand-dial routing**
What problem are you having?

- On-demand connection is not made automatically.
- Unable to make a demand-dial connection.
- Unable to reach locations beyond the calling router or answering router.
- Auto-static updates are not working.

**On-demand connection is not made automatically.**
**Cause:** IP routing is not enabled.

**Solution:** Verify that IP routing is enabled on the **IP** tab on the properties of the server.

**See also:** View properties of the remote access server

**Cause:** Static routes are configured incorrectly.

**Solution:** Verify that the correct static routes exist and are configured with the appropriate demand-dial interface.

**See also:** Add a static route

**Cause:** A static route cannot initiate a demand-dial connection.

**Solution:** For the static routes that use a demand-dial interface, verify that the **Use this route to initiate demand-dial connections** check box is selected.

**See also:** Add a static route

**Cause:** The demand-dial interface is disabled.

**Solution:** Verify that the demand-dial interface is not in a disabled state. To enable, under **Network Interfaces**, right-click the demand-dial interface, and then click **Enable**.

**Cause:** Dial-out hours are preventing the connection from initiating.

**Solution:** Verify that the dial-out hours for the demand-dial interface on the calling router are not preventing the connection attempt.

**See also:** Configure dial-out hours

**Cause:** Demand-dial filters are preventing the connection from initiating.

**Solution:** Verify that the demand-dial filters for the demand-dial interface on the calling router are not preventing the connection attempt.

**See also:** Configure demand-dial filters

**Unable to make a demand-dial connection.**
**Cause:** The Routing and Remote Access service is not started on the calling router and the answering router.

**Solution:** Verify the state of the Routing and Remote Access service on the calling router and the answering router.

**See also:** Monitor the Routing and Remote Access service

**Cause:** The demand-dial interface is in an unreachable state.

**Solution:** Determine the unreachability reason. If a demand-dial connection fails, the demand-dial interface is in an

unreachable state. The Routing and Remote Access service records the reason why the connection failed through the unreachability reason. Based on the information in the unreachability reason, you can perform further troubleshooting.

**See also:** Check the unreachability reason

**Cause:** LAN and WAN routing is not enabled on the calling router and the answering router.

**Solution:** Enable **LAN and demand-dial routing** on the calling router and the answering router.

**See also:** Enable LAN and WAN routing

**Cause:** Demand-dial connections for the protocols being routed are not allowed.

**Solution:** Verify that IP-based remote access and demand-dial connections are allowed (on the **IP** tab on the properties of the server).

**See also:** View properties of the remote access server

**Cause:** Dial-up, PPTP, or L2TP ports are not enabled for inbound and outbound demand-dial routing connections.

**Solution:** Enable dial-up, PPTP, or L2TP ports for inbound and outbound demand-dial routing connections.

**See also:** Enable routing on ports

**Cause:** All of the ports on the calling or answering router are already being used by currently connected remote access clients or demand-dial routers.

**Solution:** Verify that not all of the ports are already being used by clicking **Ports** in Routing and Remote Access. For VPN connections, if necessary, change the number of PPTP or L2TP ports to allow more concurrent connections.

**See also:** Add PPTP or L2TP ports

**Cause:** For VPN connections, the tunneling protocol of the calling router is not supported by the answering router.

By default, VPN-based demand-dial interfaces use the **Automatic** server type option, which means that they try to establish a PPTP-based VPN connection first, and then they try an L2TP/IPSec VPN connection. If calling routers use either the **Point-to-Point Tunneling Protocol (PPTP) or Layer Two Tunneling Protocol (L2TP)** server type option, verify that the selected tunneling protocol is supported by the answering router.

By default, a server running Routing and Remote Access is a PPTP and L2TP-capable demand-dial router. To create a PPTP-only router, set the number of L2TP ports to zero. To create an L2TP-only router, set the number of PPTP ports to one.

**Solution:** Verify that the appropriate number of PPTP or L2TP ports is configured on the calling router and answering router.

**See also:** Add PPTP or L2TP ports

**Cause:** The calling router and the answering router in conjunction with a remote access policy are not configured to use at least one common authentication method.

**Solution:** Configure the calling router and the answering router in conjunction with a remote access policy to use at least one common authentication method.

**Cause:** The calling router and the answering router in conjunction with a remote access policy are not configured to use at least one common encryption strength.

**Solution:** Configure the calling router and the answering router in conjunction with a remote access policy to use at least one common encryption strength.

**See also:** Configure encryption

**Cause:** The account option on the **Account** tab on the properties of the user account of the calling router is configured to change the password at the next logon attempt.

**Solution:** Clear the **User must change password at next logon** check box on the **Account** tab on the properties of the user account of the calling router.

**Cause:** The password of the user account of the calling router has expired.

**Solution:** Reset the password and select the **Password never expires** check box on the **Account** tab on the properties of the user account of the calling router.

**Cause:** The demand-dial connection does not have the appropriate permissions through dial-in properties of the user account and remote access policies.

**Solution:** Verify that the demand-dial connection has the appropriate permissions through dial-in properties of the user account and remote access policies. If the answering router is configured to use Windows Authentication, the remote access policies stored on the answering router are used. If the answering router is configured to use RADIUS authentication and the RADIUS server being used is an Internet Authentication Service (IAS) server, then the remote access policies of the IAS server are used.

In order for the connection to be established, the settings of the connection attempt must:

- Match all of the conditions of at least one remote access policy.
- Be granted remote access permission through the local user account (set to **Allow access**) or through the domain user account (set to **Control access through Remote Access Policy**) and the remote access permission of the matching remote access policy (set to **Grant remote access permission**).
- Match all the settings of the profile.
- Match all the settings of the dial-in properties of the user account.

**See also:** Introduction to remote access policies; Accepting a connection attempt

**Cause:** The settings of the remote access policy profile are in conflict with properties of the answering router.

**Solution:** Verify that the settings of the remote access policy profile are not in conflict with properties of the answering router.

The properties of the remote access policy profile and the properties of the answering router both contain settings for:

- Multilink
- Bandwidth allocation protocol
- Authentication protocols

If the settings of the profile of the matching remote access policy are in conflict with the settings of the answering router, the connection attempt is rejected. For example, if the matching remote access policy profile specifies that the EAP-TLS authentication protocol must be used and EAP is not enabled on the answering router, the connection attempt is rejected.

**See also:** Enable authentication protocols; Configure authentication

**Cause:** The credentials of the calling router (user name, password, and domain name) are incorrect and cannot be validated by the answering router.

**Solution:** Verify that the credentials of the calling router (user name, password, and domain name) are correct and can be validated by the answering router.

**Cause:** There are not enough addresses in the static IP address pool.

**Solution:** If the answering router is configured with a static IP address pool, verify that there are enough addresses in the pool. If all of the addresses in the static pool have been allocated to connected remote access clients or demand-dial routers, the answering router is unable to allocate an IP address, and the connection attempt is rejected. Modify the static IP address pool if needed.

**See also:** Create a static IP address pool

**Cause:** The authentication provider of the answering router is improperly configured.

**Solution:** Verify the configuration of the authentication provider. You can configure the answering router to use either the security features of the Windows Server 2003 family or RADIUS to authenticate the credentials of the VPN client.

**See also:** Use RADIUS authentication

**Cause:** The answering router cannot access Active Directory.

**Solution:** For an answering router that is a member server of a domain that is configured for Windows Authentication, verify that:

- The **RAS and IAS Servers** security group exists. If not, then create the group and set the group type to **Security** and the group scope to **Domain local**.

- The **RAS and IAS Servers** security group has Read permission to the **RAS and IAS Servers Access Check** object.

- The computer account of the answering router computer is a member of the **RAS and IAS Servers** security group. You can use the **netsh ras show registeredserver** command to view the current registration. You can use the **netsh ras add registeredserver** command to register the server in a specified domain.

  If you add or remove the answering router computer to the **RAS and IAS Servers** security group, the change will not take effect immediately (due to the way that the Windows Server 2003 family caches Active Directory information). For the change to take effect immediately, you need to restart the answering router computer.

- The answering router has joined the domain.

**See also:** Create a new group; Verify permissions for the RAS and IAS security group; Netsh commands for remote access

**Cause:** An answering router running Windows NT 4.0 with the Routing and Remote Access Service (RRAS) cannot validate connection requests.

**Solution:** If calling routers are dialing in to an answering router running Windows NT 4.0 with RRAS that is a member of a domain, verify that the Everyone group is added to the Pre-Windows 2000 Compatible Access group with the **net localgroup "Pre-Windows 2000 Compatible Access"** command. If not, type **net localgroup "Pre-Windows 2000 Compatible Access" everyone /add** at the command prompt on a domain controller computer and then restart the domain controller computer.

**Cause:** The Fax Service is enabled and your modem does not support adaptive answer.

**Solution:** Verify that if the Fax Service and the Routing and Remote Access service are sharing the same modem, that the modem supports adaptive answer. If the modem does not support adaptive answer, you must disable the Fax Service on the modem to receive incoming demand-dial or remote access connections.

**Cause:** The calling router is not correctly configured for certificate-based demand-dial routing.

**Solution:** Verify that EAP is enabled as an authentication protocol. Verify that the correct certificate for the root certification authority certificate of the answering router is selected. Verify that the correct router (offline request) certificate is selected when configuring the credentials of the demand-dial interface.

**See also:** Configure the calling router for certificate-based EAP; Deploying certificate-based authentication for demand-dial routing

**Cause:** The answering router is not correctly configured for certificate-based demand-dial routing.

**Solution:** Verify that EAP is enabled as an authentication protocol. Verify that the correct computer certificate for the root certification authority of the answering router is selected.

**See also:** Configure the answering router for certificate-based EAP; Deploying certificate-based authentication for demand-dial routing

**Cause:** You are using MS-CHAP v1 and a user password over 14 characters long.

**Solution:** Either use a different authentication protocol such as MS-CHAP v2 or change your password so that it is 14 characters or less.

**See also:** MS-CHAP; Enable authentication protocols

**Unable to reach locations beyond the calling router or answering router.**
**Cause:** IP routing is not enabled.

**Solution:** Verify that IP routing is enabled (on the **IP** tab on the properties of the server).

**See also:** View properties of the remote access server

**Cause:** The appropriate demand-dial interface has not been added to the protocol being routed.

**Solution:** Add the appropriate demand-dial interface to the protocol being routed.

**See also:** Add a routing interface

**Cause:** There are no routes on both sides of the demand-dial connection that support the two-way exchange of traffic.

**Solution:** Unlike a remote access connection, a demand-dial connection does not automatically create a default route. You need to create routes on both sides of the demand-dial connection so that traffic can be routed to and from the other side of the demand-dial connection.

You can manually add static routes to the routing table, or you can add static routes through routing protocols. For persistent demand-dial connections, you can enable Open Shortest Path First (OSPF) or Routing Information Protocol (RIP) across the demand-dial connection. OSPF is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family. For on-demand demand-dial connections, you can automatically update routes through an auto-static RIP update.

**See also:** Add an IP routing protocol; Add a static route; Perform Auto-Static Updates

**Cause:** There are no routes on the calling router and answering router's intranet that support the forwarding of packets between hosts on the intranets.

**Solution:** Verify that there are routes in the intranet routers on the calling router and answering router's intranet so that all locations on both networks are reachable. You can add routes to the routers of each intranet through static routes or by enabling a routing protocol on the intranet interface of the calling and answering routers.

**See also:** Unicast routing overview; Deploying Routing

**Cause:** A two-way initiated, demand-dial connection is being interpreted by the answering router as a remote access connection.

**Solution:** In order for the answering router to determine that the incoming call is a router rather than remote access client, the user name of the credentials for the calling router must match the name of a demand-dial interface that is configured on the answering router.

If the incoming caller is a router, the port on which the call was received shows a status of **Active** and the corresponding demand-dial interface is in a **Connected** state. If the name of the user name credential for the calling router appears under **Remote Access Clients** in Routing and Remote Access, then the calling router has been interpreted by the answering router as a remote access client.

For two-way initiated connections, either router can be the calling router or the answering router. The user names and demand-dial interface names must be properly matched. For example, two-way initiated connections would work under the following configuration:

- Router 1 has a demand-dial interface called NEW-YORK which is configured to use SEATTLE as the user name when sending authentication credentials.

- Router 2 has a demand-dial interface called SEATTLE which is configured to use NEW-YORK as the user name when sending authentication credentials.

This example assumes that the SEATTLE user name can be validated by Router 2 and the NEW-YORK user name can be validated by Router 1.

**See also:** Demand-dial routing example; Check the status of the port on the answering router; Check the status of the demand-dial interface

**Cause:** Static routes on the user account of the calling router for a one-way initiated demand-dial connection are not configured correctly.

**Solution:** For a one-way initiated demand-dial connection, verify that the appropriate static routes are enabled on the user account of the calling router and that the answering router is configured with a routing protocol so that when a connection is made, the static routes of the user account of the calling router are advertised to neighboring routers.

**See also:** One-way initiated demand-dial connections; Configure static routes for a dial-in user

**Cause:** Packet filters on the demand-dial interfaces of the calling router or answering router are preventing the flow of traffic.

**Solution:** Verify that there are no IP packet filters on the demand-dial interfaces of the calling router or the answering router that prevent the sending or receiving of TCP/IP traffic.

You can configure each demand-dial interface with IP input and output filters to control the exact nature of TCP/IP traffic that is allowed into and out of the demand-dial interface.

**See also:** Manage Packet Filters

**Cause:** Packet filters on the remote access policy profile are preventing the flow of IP traffic.

**Solution:** Verify that there are no configured TCP/IP packet filters on the profile properties of the remote access policy being used by the demand-dial connection (or the RADIUS server if Internet Authentication Service is used) that are preventing the sending or receiving of TCP/IP traffic.

You can use remote access policies to configure TCP/IP input and output packet filters that control the exact nature of TCP/IP traffic allowed on the demand-dial connection.

**See also:** Configure IP options

**Auto-static updates are not working.**
**Cause:** For IP auto-static updates, each demand-dial interface is not configured for RIP v2 multicast.

**Solution:** Verify on both routers that the demand-dial interface is added to the RIP routing protocol, that its operation mode is set to **Auto-static update** mode, the outgoing packet protocol is **RIP version 2 multicast**, and that the incoming packet protocol is set to **RIP version 1 and 2**.

**See also:** Configure RIP version 2; Enable auto-static update mode

**Note**

- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

# Remote Access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access**
The remote access features of the Microsoft® Windows Server 2003 family enable remote or mobile workers who use dial-up communication links to access corporate networks as if they were directly connected. Remote access also provides virtual private network (VPN) services so that users can access corporate networks over the Internet.

- Before installing Routing and Remote Access, see Checklist: Installing and configuring the remote access server.
- To find features that have been moved in the Windows Server 2003 family, see New ways to do familiar Remote Access tasks.
- For tips about using remote access, see Best Remote Access practices.
- For help with specific tasks, see Remote Access How To....
- For general background information, see Remote Access Concepts.
- For problem-solving instructions, see Remote Access Troubleshooting.

# Checklist: Installing and configuring the remote access server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing and configuring the remote access server**

| Step | Reference |
|---|---|
| Review key concepts. | Remote Access Overview |
| Verify the compatibility of all hardware to be installed in the server running Routing and Remote Access. | Compatible Hardware and Software at Support resources |
| Install the hardware. | Manufacturer's documentation |
| Verify that the hardware is successfully installed. | Device Manager |
| Install and configure modems. | Checklist: Installing and configuring modems |
| Install and configure the protocols. | Network communications |
| Enable and configure the Routing and Remote Access service. | Enable the Routing and Remote Access service |
| Configure dial-in properties and remote access policies for dial-in permission, authentication, and encryption settings. | Introduction to remote access policies |
| (Optional) Configure the server running Routing and Remote Access as a RADIUS client to an IAS server for centralized remote access policy management. | Using RADIUS |

# New ways to do familiar Remote Access tasks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New ways to do familiar tasks**

The following table lists common tasks for configuring the remote access features of Routing and Remote Access. The user interface for performing these tasks is different in this version of Windows from the way it was in Windows NT version 4.0 or Windows NT version 4.0 with the Routing and Remote Access Service (RRAS). The user interface for the Windows 2000 version of Routing and Remote Access differs slightly from that for the Windows Server 2003 family, but the steps for most common tasks have not changed.

Please choose your upgrade path:

- Windows NT 4.0 to a product in the Windows Server 2003 family
- Windows NT 4.0 with RRAS to a product in the Windows Server 2003 family

**Windows NT 4.0 to a product in the Windows Server 2003 family**

| If you want to | In Windows NT 4.0 use | In this version of Windows use |
|---|---|---|
| Enable and configure remote access | **Services** tab of **Network** in Control Panel | Open Routing and Remote Access. For more information, see Enable the Routing and Remote Access service and Configure the Remote Access Server. |
| Configure authentication and encryption options | **Services** tab of **Network** in Control Panel | Open Routing and Remote Access. For more information, see Configure Remote Access Security. |
| Manage remote access servers and clients | Remote Access Admin | Open Routing and Remote Access. For more information, see Administer the Remote Access Server and Manage Remote Access Clients. |
| Grant remote access permission to user accounts | Remote Access Admin or User Manager for Domains | Open Computer Management or Active Directory Users and Computers. For more information, see Configure remote access permission for a user. |

**Windows NT 4.0 with RRAS to a product in the Windows Server 2003 family**

| If you want to | In Windows NT 4.0 with RRAS use | In this version of Windows use |
|---|---|---|
| Enable and configure remote access | **Services** tab of **Network** in Control Panel | Open Routing and Remote Access. For more information, see Enable the Routing and Remote Access service and Configure the Remote Access Server. |
| Configure authentication and encryption options | **Services** tab of **Network** in Control Panel | Open Routing and Remote Access. For more information, see Configure Remote Access Security. |
| Manage remote access servers and clients | Routing and RAS Admin | Open Routing and Remote Access. For more information, see Administer the Remote Access Server and Manage Remote Access Clients. |
| Grant remote access permission to user accounts | Remote Access Admin or User Manager for Domains | Open Computer Management or Active Directory Users and Computers. For more information, see Configure remote access permission for a user. |

# Best Remote Access practices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Best practices**

The following list provides best practices for implementing and configuring the remote access server and is based on recommendations from Microsoft Product Support Services:

- **Plan for security**

  When designing and implementing your remote access solution, be sure to plan for the most secure deployment possible. For more information, see Security information for remote access.

- **Use DHCP to obtain IP addresses**

  If you installed a DHCP server, configure the remote access server to use DHCP to obtain IP addresses for remote access clients. If you did not install a DHCP server, configure the remote access server with a static IP address pool, which is a subset of addresses from the subnet to which the remote access server is attached.

- **Use strong authentication**

  Use strong passwords more than 8 characters long that contain a mixture of uppercase and lowercase letters, numbers, and permitted punctuation. Do not use passwords based on names or words. Strong passwords are more resistant to a dictionary attack, where an attacker attempts to determine a password by sending a series of commonly used names and words.

  Although EAP-TLS works with registry-based certificates, for security reasons you should use EAP-TLS with smart cards only.

  If you are using MS-CHAP, use MS-CHAP version 2. You can obtain the latest MS-CHAP updates for Windows NT version 4.0, Windows 98, and Windows 95. For more information, see MS-CHAP version 2.

- **Avoid configuring different remote access policies for the same user**

  If a user dials in by using a multilink connection, all connections beyond the first connection are connected by using the remote access policy that matched the first connection.

# Remote Access How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

This section provides instructions for installing and configuring Routing and Remote Access to act as remote access server:

- Enable the Routing and Remote Access service
- Configure the Remote Access Server
- Configure Dial-up Equipment
- Configure Remote Access Security
- Configure dial-in user properties
- Administer the Remote Access Server

# Enable the Routing and Remote Access service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable the Routing and Remote Access service**

1. If this server is a member of an Active Directory domain and you are not a domain administrator, instruct your domain administrator to add the computer account of this server to the **RAS and IAS Servers** security group in the domain of which this server is a member. The domain administrator can add the computer account to the **RAS and IAS Servers** security group by using Active Directory Users and Computers or with the **netsh ras add registeredserver** command. If this server is using local authentication or is authenticating against a RADIUS server, skip this step.

2. Open Routing and Remote Access.

3. By default, the local computer is listed as a server.

   To add another server, in the console tree, right-click **Server Status**, and then click **Add Server**.

   In the **Add Server** dialog box, click the applicable option, and then click **OK**.

4. In the console tree, right-click the server you want to enable, and then click **Configure and Enable Routing and Remote Access**.

5. Follow the instructions in the Routing and Remote Access Server Setup Wizard.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure the Remote Access Server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure the remote access server**

- View properties of the remote access server
- Enable the remote access server
- Create a static IP address pool
- Configure AppleTalk remote access
- Enable Multilink
- Enable BAP and BACP
- Enable or disable broadcast name resolution
- Re-create the default remote access policy
- Configure Ports

# View properties of the remote access server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view properties of the remote access server**

1. Open Routing and Remote Access.
2. Right-click the server name for which you want to view properties, and then click **Properties**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable the remote access server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable the remote access server**

1. Open Routing and Remote Access.
2. Right-click the server name for which you want to enable remote access, and then click **Properties**.
3. On the **General** tab, select the **Remote access server** check box.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

# Create a static IP address pool

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a static IP address pool**

1. Open Routing and Remote Access.
2. Right-click the server name for which you want to create a static IP address pool, and then click **Properties**.
3. On the **IP** tab, click **Static address pool**, and then click **Add**.
4. In **Start IP address**, type a starting IP address, and then either type an ending IP address for the range in **End IP address** or type the number of IP addresses in the range in **Number of addresses**.
5. Click **OK**, and then repeat steps 3 and 4 for as many ranges as you need to add.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- If the static IP address pool consists of ranges of IP addresses that are for a separate subnet, then you need to either enable an IP routing protocol on the remote access server computer or add static IP routes consisting of the {IP Address, Mask} of each range to the routers of the intranet. If the routes are not added, then remote access clients cannot receive traffic from resources on the intranet.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure AppleTalk remote access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure AppleTalk remote access**

1. Open Routing and Remote Access.
2. Right-click the server name for which you want to configure AppleTalk remote access, and then click **Properties**.
3. On the **AppleTalk** tab, configure the AppleTalk remote access settings.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Enable Multilink

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable Multilink**

1. Open Routing and Remote Access.
2. Right-click the server name for which you want to enable Multilink, and then click **Properties**.
3. On the **PPP** tab, select the **Multilink connections** check box.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

# Enable BAP and BACP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable BAP and BACP**

1. Open Routing and Remote Access.
2. Right-click the server name for which you want to enable BAP and BACP, and then click **Properties**.
3. On the **PPP** tab, select the **Dynamic bandwidth control using BAP and BACP** check box.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Enable or disable broadcast name resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable broadcast name resolution**

1. Open Routing and Remote Access.
2. Right-click the name of the server on which you want to enable or disable broadcast name resolution, and then click **Properties**.
3. On the **IP** tab, select or clear the **Enable broadcast name resolution** check box, and click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- Broadcast name resolution is enabled by default.
- If you enable or disable broadcast name resolution, you must restart the Routing and Remote Access service on the server for which you enabled or disabled broadcast name resolution.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Re-create the default remote access policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To re-create the default remote access policy**

1. Open Routing and Remote Access.
2. In the console tree, right-click **Remote Access Policies**.

   **Where?**

   - Routing and Remote Access/*server name*/Remote Access Policies

3. Click **New Remote Access Policy**.
4. In the New Remote Access Policy wizard, do the following:

   - Choose **Set up a custom policy**.
   - In **Policy name**, type a default name, and then click **Next**.

     When the Routing and Remote Access service is installed, the default remote access policies are **Connections to Microsoft Routing and Remote Access server** and **Connections to other access servers**. However, you are not required to use these names.

   - On the Policy Conditions page, click **Add**, click **Day-and-Time-Restrictions**, click **Add**, and configure the attribute to permit all times on all days. Click **OK**, and then click **Next**.
   - On the Permissions page, click **Deny remote access permission**, and then click **Next**.
   - On the Profile page, click **Next**. Do not make changes to the profile for this policy.
   - Click **Finish**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- By following the steps in this procedure, you will re-create the policy conditions of the **Connections to other access servers** policy.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Add a remote access policy

# Configure Ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure ports**

- Configure ports for remote access
- Set the phone number on a port
- Add PPTP or L2TP ports

# Configure ports for remote access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure ports for remote access**

1. Open Routing and Remote Access.
2. In the console tree, right-click **Ports**.

   **Where?**

   - Routing and Remote Access/*server name*/Ports

3. Click **Properties**.
4. In the **Ports Properties** dialog box, click a device, and then click **Configure**.
5. In the **Configure Device** dialog box, do one or more of the following:

   - To enable remote access, select the **Remote access connections (inbound only)** check box.
   - To enable demand-dial routing, select the **Demand-dial routing connections (inbound and outbound)** check box.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set the phone number on a port

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the phone number on a port**

1. Open Routing and Remote Access.
2. In the console tree, click **Ports**.

   **Where?**

   - Routing and Remote Access/*server name*/Ports

3. Right-click **Ports**, and then click **Properties**.
4. In the **Ports Properties** dialog box, click the port that corresponds to the dial-up equipment, and then click **Configure**.
5. In **Phone number for this device**, type the phone number of the port, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- You also set the phone number on a port when you are using the **Restrict Dial-in to this number only** dial-in constraint of a remote access policy profile and your phone line and installed phone equipment do not support Called Line Identification (CLID).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add PPTP or L2TP ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add PPTP or L2TP ports**

1. Open Routing and Remote Access.
2. In the console tree, click **Ports**.

   **Where?**

   - Routing and Remote Access/*server name*/Ports

3. Right-click **Ports**, and then click **Properties**.
4. In the **Ports Properties** dialog box, click either **WAN Miniport (PPTP)** or **WAN Miniport (L2TP)**, and then click **Configure**.
5. In **Maximum ports**, type the number of ports, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.
- You cannot set the number of PPTP ports to 0. To disable PPTP, clear the **Remote access connections (inbound only)** and **Demand-dial routing connections (inbound and outbound)** check boxes.
- When you increase the number of ports for **WAN Miniport (PPTP)** or **WAN Miniport (L2TP)** from less than 1000 ports to greater than 1000 ports, you must restart the computer to apply the change.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Dial-up Equipment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure dial-up equipment**

- Configure a direct serial connection
- Configure modem-pooling equipment
- Configure an X.25 smart card
- Configure other security devices

# Configure a direct serial connection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure a direct serial connection**

1. Open Control Panel.
2. Double-click **Phone and Modem Options**, click the Modems tab, and then click **Add**.
3. In the Add Hardware wizard, select the **Don't detect my modem; I will select it from a list** check box, and then click **Next**.
4. In **Manufacturer**, click **Standard Modem Types**.
5. In **Models**, click **Communications cable between two computers**, and then click **Next**.
6. Follow the remaining instructions in the Install New Modem wizard.

## Notes

- To open a Control Panel item, click **Start**, click **Control Panel**, and then double-click the appropriate icon.
- A null modem must be configured on both the client and the server.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure modem-pooling equipment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure modem-pooling equipment**

1. Open Control Panel.
2. Configure your modem-pooling equipment to behave like one of the modem types listed in the Add Hardware wizard. (In other words, the modem-pooling equipment must generate and accept command strings as if it were a modem of the chosen type.) The switching equipment must also have the same RS-232 signal behavior as the specified modem.
3. Connect COM ports to the equipment and configure the ports for remote access in Routing and Remote Access.

## Notes

- To open a Control Panel item, click **Start**, click **Control Panel**, and then double-click the appropriate icon.
- It is recommended that you configure the modem-pooling equipment as a Hayes-compatible modem, a widely known standard.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Configure ports for remote access

# Configure an X.25 smart card

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure an X.25 smart card**

1. Install the X.25 smart card (according to the manufacturer's instructions).
2. Make sure your X.25 smart card is configured with the X.3-parameter values as shown in the following table.
3. Configure the X.25 ports for remote access in Routing and Remote Access.

| Parameter number | X.3 parameter | Value |
|---|---|---|
| 1 | PAD Recall | 0 |
| 2 | Echo | 0 |
| 3 | Data Fwd Char | 0 |
| 4 | Idle Timer | 1 |
| 5 | Device Control | 0 |
| 6 | PAD Service Signals | 1 |
| 7 | Break Signal | 0 |
| 8 | Discard Output | 0 |
| 9 | Padding after CR | 0 |
| 10 | Line Folding | 0 |
| 11 | *Not Set* | |
| 12 | Flow Control | 0 |
| 13 | Linefeed Insertion | 0 |
| 14 | Padding after LF | 0 |
| 15 | Editing | 0 |
| 16 | Character Delete | 0 |
| 17 | Line Delete | 0 |
| 18 | Line Display | 0 |
| 19 | Editing PAD Srv Signals | 0 |
| 20 | Echo Mask | 0 |
| 21 | Parity Treatment | 0 |
| 22 | Page Wait | 0 |

**Important**

- Failure to set these values as shown prevents remote access that uses an X.25 smart card from functioning properly. For

more information on setting these values, see the instructions provided with your X.25 smart card.

### Notes

- A communication driver for the X.25 smart card that emulates communication ports is supplied by the hardware manufacturer or by another company.

- Make sure that the speed of the leased line can support all the serial communication (COM) ports at all speeds at which clients will dial in. For example, four clients connecting at 9,600 bps (through dial-up PADs) will require a 38,400-bps (4 times 9,600) leased line on the server end. If the leased line does not have adequate bandwidth, it can cause time-outs and can cause the performance for connected clients to degrade.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure other security devices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure other security devices**

- If the modem on the remote access server is different from the modem listed in the security host section of the Modem.inf file, you need to customize the Modem.inf file on the remote access server to link the security host to the modem on the server.

- The remote user must activate the Terminal utility to interact with the security host.

**Note**

- To use a Security Dynamics security host, you must order two connectors through your Security Dynamics provider to permit initialization of the remote access server modem. When you order, specify that you want the dial-out option. The provider will then send you an AND gate and a jumper box. For the ACM/400 security host, you will also receive different software.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable EAP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable EAP**

1. Open Routing and Remote Access.
2. Right-click the server name for which you want to configure EAP, and then click **Properties**.
3. On the **Security** tab, click **Authentication Methods**.
4. In the **Authentication Methods** dialog box, select the **Extensible authentication protocol (EAP)** check box, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- When you enable EAP, all the installed EAP types are enabled. By default, EAP-MD5 CHAP and EAP-TLS are installed if the server is a member of a domain. If the server is not a member of a domain, only EAP-MD5 is installed. To see the installed EAP types, click **EAP Methods**.

# Enable reversibly encrypted passwords in a domain

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable reversibly encrypted passwords in a domain**

1. Open Active Directory Users and Computers.
2. In the console tree, double-click **Active Directory Users and Computers**, right-click the domain name, and then click **Properties**.
3. On the **Group Policy** tab, click **Default Domain Policy**, and then click **Edit**.
4. In the console tree, click **Password Policy**.

   **Where?**

   - Computer Configuration/Windows Settings/Security Settings/Account Policies/Password Policy

5. In the details pane, double-click **Store passwords using reversible encryption for all users in the domain**.
6. Click **Enabled**, and then click **OK**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- To open Group Policy on a stand-alone computer that is not a member of a domain, click **Start**, click **Run**, type **gpedit.msc**, and then click **OK**.

# Configure logging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure logging**

1. Do one of the following:

   - Open Routing and Remote Access.

     Double-click **Routing and Remote Access**, and then double-click the server name on which you want to configure logging.

   - Open Internet Authentication Service.

     Double-click **Internet Authentication Service**.

2. In the console tree, click **Remote Access Logging**.

3. In the details pane, right-click any log file, and then click **Properties**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

- To open Internet Authentication Service, click **Start**, point to **Programs**, point to **Administrative Tools**, and then click **Internet Authentication Service**.

- If the Logging folder does not appear in Routing and Remote Access, then Windows Accounting is not enabled.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure smart card remote access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure smart card remote access**

1. Open Routing and Remote Access.
2. Right-click the name of the remote access server, and then click **Properties**.
3. On the **Security** tab, click **Authentication Methods**.
4. In the **Authentication Methods** dialog box, confirm that the **Extensible authentication protocol (EAP)** check box is selected, click **OK**, and then click **OK** again.
5. In the console tree, click **Remote Access Policies**.

   **Where?**

   - Routing and Remote Access/*ServerName*/Remote Access Policies

6. In the details pane, right-click the remote access policy that your smart card remote access clients will use, click **Properties**, and then click **Edit Profile**.
7. On the **Authentication** tab, click **EAP Methods**.
8. In **Select EAP Providers**, click **Add**.
9. Click the smart card EAP method you want to use, and then click **OK**.
10. If the smart card EAP method you added requires a certificate, click the method, click **Edit**, and choose a certificate.
11. Click **OK** to save the settings of the profile, and then click **OK** again to save the settings of the policy.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. # Configure a pre-shared key on a remote access server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure a pre-shared key on a remote access server**

1. Open Routing and Remote Access.
2. Right-click the name of the server on which you want to configure a pre-shared key, and then click **Properties**.
3. On the **Security** tab, select the **Allow custom IPSec policy for L2TP connection** check box.
4. Type the pre-shared key in **Pre-shared Key**.
5. Click **Apply**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- A pre-shared key can be any non-null string of any combination of up to 255 characters. Use care when typing the pre-shared key because any differences between the pre-shared key configured on the client and the pre-shared key configured on the server will prevent connections from being made.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure a pre-shared key on a remote access client

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure a pre-shared key on a remote access client**

1. Open Network Connections.
2. Right-click the virtual private network connection for which you want to configure a pre-shared key, and click **Properties**.
3. On the **Security** tab, click **IPSec Settings**.
4. Select the **Use pre-shared key for authentication** check box, and type the pre-shared key in **Key**.
5. Click **OK** twice.

## Notes

- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.
- A pre-shared key can be any non-null string of any combination of up to 255 characters. Use care when typing the pre-shared key because any differences between the pre-shared key configured on the client and the pre-shared key configured on the server will prevent connections from being made.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Verify permissions for the RAS and IAS security group

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To verify permissions for the RAS and IAS security group**

1. Open Active Directory Users and Computers.
2. On the **View** menu, confirm that **Advanced Features** is selected.
3. In the console tree, right-click **RAS and IAS Servers Access Check**.

   **Where?**

   - Active Directory Users and Computers/*domain name*/System/RAS and IAS Servers Access Check

4. Click **Properties**.
5. On the **Security** tab, do one of the following:

   - In **Group or User names**, if **RAS and IAS Servers** is listed, click **RAS and IAS Servers (***DomainName***\RAS and IAS Servers)**, and under **Permissions for RAS and IAS Servers**, verify that the **Read**, **Write**, **Create All Child Objects**, and **Delete All Child Objects** check boxes are selected.
   - In **Group or User names**, if **RAS and IAS Servers** is not listed, add **RAS and IAS Servers**. Then, in **Group or user names**, click **RAS and IAS Servers**, and in **Permissions for RAS and IAS Servers (***DomainName***\RAS and IAS Servers)**, select the **Read**, **Write**, **Create All Child Objects**, and **Delete All Child Objects** check boxes.

**Note**

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Map a certificate to a user account

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To map a certificate to a user account**

1. Open Active Directory Users and Computers.
2. On the **View** menu, select **Advanced Features**.
3. In the console tree, click **Users**.

   **Where?**

   - Active Directory Users and Computers\domain node\Users

   Or, click the folder that contains the user account.
4. In the details pane, click the user account to which you want to map a certificate.
5. On the **Action** menu, click **Name Mappings**.
6. In the **Security Identity Mapping** dialog box, on the **X.509 Certificates** tab, click **Add**.
7. Type the name and path of the .cer file that contains the certificate you want to map to this user account, and then click **Open**.
8. Do one of the following:

| To | Do this |
|---|---|
| Map the certificate to one account (one-to-one mapping) | Confirm that both the **Use Issuer for alternate security identity** and the **Use Subject for alternate security identity** check boxes are selected. |
| Map any certificate that has the same subject to the user account, regardless of the issuer of the certificate (many-to-one mapping) | Clear the **Use Issuer for alternate security identity** check box, and confirm that the **Use Subject for alternate security identity** check box is selected. |
| Map any certificate that has the same issuer to the user account, regardless of the subject of the certificate (many-to-one mapping) | Clear the **Use Subject for alternate security identity** check box, and confirm that the **Use Issuer for alternate security identity** check box is selected. |

**Notes**

- To perform this procedure, you must be a member of the Account Operators group, Domain Admins group, or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- The certificate you are mapping to a user account must be in Distinguished Encoding Rules (DER) or Base64 encoded binary format. For instructions on exporting an existing certificate to a .cer file, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Machine Certificates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage machine certificates**

- Install the certificate of the enterprise root CA as a trusted root CA certificate
- Configure automatic certificate allocation from an enterprise CA
- Submit a user certificate request via the Web
- Install a router (offline request) certificate

# Install the certificate of the enterprise root CA as a trusted root CA certificate

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install the certificate of the enterprise root CA as a trusted root CA certificate**

1. Open Active Directory Users and Computers.

2. In the console tree, double-click **Active Directory Users and Computers**, right-click the domain name in which your CA lives, and then click **Properties**.

3. On the **Group Policy** tab, click **Default Domain Policy**, and then click **Edit**.

4. In the console tree, right-click **Trusted Root Certification Authorities**, point to **All Tasks**, and then click **Import**.

   **Where?**

   - Computer Configuration/Windows Settings/Security Settings/Public Key Policies/Trusted Root Certification Authorities

   The Certificate Manager Import wizard appears.

5. Click **Next**, and follow the instructions in the wizard to import the .crt file of the CA (located in the *systemroot*\System32\CertSrv\CertEnroll folder) into the Trusted Root Certification Authorities store.

6. Type the following at the command prompt:

   **gpupdate /Target:**{*Computer* | *User*} **/Force**

## Notes

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure automatic certificate allocation from an enterprise CA

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure automatic certificate allocation from an enterprise CA**

1. Open Active Directory Users and Computers.
2. In the console tree, double-click **Active Directory Users and Computers**, right-click the domain name in which your CA lives, and then click **Properties**.
3. On the **Group Policy** tab, click **Default Domain Policy**, and then click **Edit**.
4. In the console tree, right-click **Automatic Certificate Request Settings**, point to **New**, and then click **Automatic Certificate Request**.

   **Where?**

   - Computer Configuration/Windows Settings/Security Settings/Public Key Policies/Automatic Certificate Request Settings

5. When the Automatic Certificate Request wizard appears, click **Next**.
6. In **Certificate templates**, click **Computer**, and then click **Next**.

   Your enterprise root CA appears on the list.

7. Click the CA, click **Next**, and then click **Finish**.
8. To create a computer certificate for the CA computer, type the following at the command prompt:

   **gpupdate /target:***Computer*

## Notes

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Submit a user certificate request via the Web to a Windows Server 2003 CA

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To submit a user certificate request via the Web to a Windows Server 2003 CA**

1. Open Internet Explorer.
2. In Internet Explorer, connect to http://*servername*/certsrv, where *servername* is the name of the Web server running Windows Server 2003 where the certification authority (CA) you want to access is located.
3. Click **Request a certificate**.
4. On **Request a Certificate**, click **User Certificate**.
5. On the User Certificate - Identifying Information page, do one of the following:
   - Read the message "No further identifying information is required. To complete your certificate, press submit".
   - Enter your identifying information for the certificate request.
6. (Optional) Click **More Options** to specify the cryptographic service provider (CSP) and whether you want to enable strong private key protection. (This means that you will receive a prompt every time that the private key associated with the certificate is used.)
7. Click **Submit**.
8. Do one of the following:
   - If you see the **Certificate Pending** Web page, see Related Topics below for the procedure to check on a pending certificate.
   - If you see the **Certificate Issued** Web page, click **Install this certificate**.
9. If you are finished using the Certificate Services Web pages, close Internet Explorer.

### Note

- To open Internet Explorer, click **Start**, point to **All programs**, and then click **Internet Explorer**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Install a router (offline request) certificate

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install a router (offline request) certificate**

1. Open Internet Explorer.
2. In Internet Explorer, in **Address**, type the address of the certification authority (CA) that issues computer certificates. The address is the name of the server followed by **/certsrv**.
3. On the **Welcome** page, click **Request a certificate**, click **Advanced certificate request**, and then click **Create and submit a request to this CA**.
4. In **Certificate Template**, select **Router (Offline request)**, or the name of the template that the CA administrator directed you to choose.
5. In **Name**, type the user account name that is used by the calling router.
6. Under **Key Options**, select the **Mark keys as exportable** and **Store certificate in the local computer certificate store** check boxes.
7. Confirm the other options that you want, and then click **Submit**.
8. A message appears that asks you to confirm that you trust this Web site and that you want to request a certificate. Click **Yes**, and then, on the **Certificate Issued** page, click **Install this certificate**.

   A message informs you that a new certificate has been successfully installed.

## Notes

- To open Internet Explorer, click **Start**, point to **All programs**, and then click **Internet Explorer**.
- Windows 2000 CAs included a template, called **Router (Offline request)**, which allowed exportable keys. In the Windows Server 2003 family, CAs require you to create a special template to allow keys to be exported.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure dial-in user properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure dial-in user properties**

- Configure remote access permission for a user
- Configure caller ID and callback
- Configure static IP address assignment
- Configure static routes for a dial-in user

# Configure remote access permission for a user

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure remote access permission for a user**

1. Do one of the following:

   - If the remote access server is part of a Windows Server 2003 domain:

     | |
     |---|
     | Open Active Directory Users and Computers. |
     | In the console tree, click **Users** (console tree location is: Active Directory Users and Computers/*domain name*/Users). |
     | In the details pane, right-click a user name, and then click **Properties**. |

   - If the remote access server is a stand-alone server (not part of a domain):

     | |
     |---|
     | Open Computer Management. |
     | In the console tree, click **Users** (console tree location is: Computer Management/System Tools/Local Users and Groups/Users). |
     | In the details pane, right-click a user name, and then click **Properties**. |

2. On the **Dial-in** tab, under **Remote Access Permission (Dial-in or VPN)**, click either **Allow access**, **Control access through Remote Access Policy**, or **Deny access**, and then click **OK**.

## Notes

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Configure caller ID and callback

# Configure caller ID and callback

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure caller ID and callback**

1. Do one of the following:

| | |
|---|---|
| If the remote access server is part of a Windows Server 2003 domain: | a. Open Active Directory Users and Computers.<br>b. In the console tree, click **Users**.<br>• ***Where?***<br>Active Directory Users and Computers/*domain name*/Users<br>c. In the details pane, right-click a user name, and then click **Properties**. |
| If the remote access server is a stand-alone server (not a part of a domain): | a. Open Computer Management.<br>b. In the console tree, click **Users**.<br>• ***Where?***<br>Computer Management/System Tools/Local Users and Groups/Users<br>c. In the details pane, right-click a user name, and then click **Properties**. |

2. On the **Dial-in** tab, do the following:

   - For caller ID, select the **Verify Caller-ID** check box, and then type the number that the user is calling from.
   - For callback, under **Callback Options**, click the callback option you want to set for this user.

**Notes**

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.
- If the remote access server is part of a Windows NT 4.0 domain, you can use the Windows NT 4.0 User Manager for Domains administrative tool to set callback options for user accounts.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure static IP address assignment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure a static IP address assignment**
**If the remote access server is part of a Windows Server 2003 domain, do the following:**

1. Open Active Directory Users and Computers.
2. In the console tree, click **Users**.

   **Where?**

   - Active Directory Users and Computers/*domain name*/Users

3. In the details pane, right-click a user name, and then click **Properties**.
4. On the **Dial-in** tab, select the **Assign a Static IP Address** check box, and then type the static IP address for this user.

**If the remote access server is a stand-alone server (not part of a domain), do the following:**

1. Open Computer Management.
2. In the console tree, click **Users**.

   **Where?**

   - Computer Management/System Tools/Local Users and Groups/Users

3. In the details pane, right-click a user name, and then click **Properties**.
4. On the **Dial-in** tab, select the **Assign a Static IP Address** check box, and then type the static IP address for this user.

### Notes

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.
- The server running Routing and Remote Access will provide a dynamic IP address to a user if the static address you specify is not valid or is already in use by another user.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure static routes for a dial-in user

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure static routes for a dial-in user**

1. Do one of the following:

   - If the remote access server is part of a Windows Server 2003 domain:

     | |
     |---|
     | Open Active Directory Users and Computers. |
     | In the console tree, click **Users** (console tree location is: Active Directory Users and Computers/*domain name*/Users). |
     | In the details pane, right-click a user name, and then click **Properties**. |

   - If the remote access server is a stand-alone server (not a part of a domain):

     | |
     |---|
     | Open Computer Management. |
     | In the console tree, click **Users** (console tree location is: Computer Management/System Tools/Local Users and Groups/Users). |
     | In the details pane, right-click a user name, and then click **Properties**. |

2. On the **Dial-in** tab, select the **Apply Static Routes** check box.

3. In the **Static Routes** dialog box, click **Add Route**.

4. In **Destination**, **Network Mask**, and **Metric**, type the destination network address, the network mask, and the number of hops to the destination network for this static route, and then click **OK**.

5. Repeat steps 3 and 4 for each static route you want to configure for this user.

## Notes

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.

- Metrics greater than 99 might not function.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer the Remote Access Server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer the remote access server**

- Add a remote access server
- Monitor the Routing and Remote Access service
- Start and stop the Routing and Remote Access service
- Administer remote access servers running Windows NT 4.0
- Manage Remote Access Clients

# Add a remote access server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a remote access server**

1. Open Routing and Remote Access.
2. In the console tree, double-click **Routing and Remote Access**, right-click **Server Status**, and then click **Add Server**.
3. In the **Add Server** dialog box, do one of the following:
   - To add the computer on which Routing and Remote Access is currently running, click **This computer**.
   - To add a computer on another network, click **The following computer**, and then type the computer name or IP address of the server.
   - To add a server from a particular domain, click **All routing and remote access servers in the domain**, type the domain containing the server you want to administer, and then click **OK**.
   - To add a server, click **Browse the Active Directory**, and then click **Next**. In the **Find Routers or Remote Access Servers** dialog box, click the types of servers you want to search for, and then click **OK**.

**Note**

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Monitor the Routing and Remote Access service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To monitor the Routing and Remote Access service**

1. Open Routing and Remote Access.

2. In the console tree, double-click **Routing and Remote Access**, and then click **Server Status**.

## Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

- The Routing and Remote Access window shows the server name, the state of the Routing and Remote Access service (started or stopped), the total ports on the server, the ports in use, and the amount of time that the server has been up since the Routing and Remote Access service was last started.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Start and stop the Routing and Remote Access service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start and stop the Routing and Remote Access service**

1. Open Routing and Remote Access.
2. In the console tree, click **Server Status**.
3. In the details pane, right-click a server name, point to **All Tasks**, and do one of the following:
   - To start the service, click **Start**.
   - To stop the service, click **Stop**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

# Administer remote access servers running Windows NT 4.0

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To administer remote access servers running Windows NT 4.0**

1. On your server running Windows NT 4.0, click **Start**, click **Run**, type **rasadmin**, and then click **OK**.
2. On the **Server** menu, click **Select Domain or Server**.
3. In **Domain**, type a domain name or server name.

   Or, in **Select Domain**, click a domain or server.

## Notes

- Remote Access Admin is a tool specific to Windows NT 4.0. It is not available on computers running a member of the Windows Server 2003 family.
- If you type a server name in **Domain**, you must precede the name with two backslashes (****).
- Domains in **Select Domain** are all those trusted by the domain to which you belong. To view the servers in a domain, double-click the domain name.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Remote Access Clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage remote access clients**

- View connected remote access clients
- Disconnect a remote access client
- Send a message to a single remote access client
- Send a message to all remote access clients

# View connected remote access clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view connected remote access clients**

1. Open Routing and Remote Access.
2. In the console tree, click **Remote Access Clients**.

   **Where?**

   - Routing and Remote Access/*server name*/Remote Access Clients

3. In the details pane, right-click a user name, and then click **Status**.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Overview of remote access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Overview of remote access**

By configuring Routing and Remote Access to act as a remote access server, you can connect remote or mobile workers to organization networks. Remote users can work as if their computers are physically connected to the network.

Users run remote access software and initiate a connection to the remote access server. The remote access server, which is a server running Routing and Remote Access, authenticates users and services sessions until terminated by the user or network administrator. All services typically available to a LAN-connected user (including file and print sharing, Web server access, and messaging) are enabled by means of the remote access connection.

Remote access clients use standard tools to access resources. For example, on a server running Routing and Remote Access, clients can use Windows Explorer to make drive connections and to connect to printers. Connections are persistent: Users do not need to reconnect to network resources during their remote sessions. Because drive letters and universal naming convention (UNC) names are fully supported by remote access, most commercial and custom applications work without modification.

A server running Routing and Remote Access provides two different types of remote access connectivity:

1. Dial-up networking

   Dial-up networking is when a remote access client makes a nonpermanent, dial-up connection to a physical port on a remote access server by using the service of a telecommunications provider such as analog phone, ISDN, or X.25. The best example of dial-up networking is that of a dial-up networking client who dials the phone number of one of the ports of a remote access server.

   Dial-up networking over an analog phone or ISDN is a direct physical connection between the dial-up networking client and the dial-up networking server. You can encrypt data sent over the connection, but it is not required.

   For more information, see The remote access server as a dial-up networking server.

2. Virtual private networking

   Virtual private networking is the creation of secured, point-to-point connections across a private network or a public network such as the Internet. A virtual private networking client uses special TCP/IP-based protocols called tunneling protocols to make a virtual call to a virtual port on a virtual private networking server. The best example of virtual private networking is that of a virtual private networking client who makes a virtual private network connection to a remote access server that is connected to the Internet. The remote access server answers the virtual call, authenticates the caller, and transfers data between the virtual private networking client and the corporate network.

   In contrast to dial-up networking, virtual private networking is always a logical, indirect connection between the virtual private networking client and the virtual private networking server over a public network such as the Internet. To ensure privacy, you must encrypt data sent over the connection.

   For more information, see The remote access server as a virtual private networking server.

# Security information for remote access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security information for remote access**

Before you enable the remote access functions of Routing and Remote Access, you should carefully review your network infrastructure so that you can configure Routing and Remote Access to best meet your needs for security and functionality. Security for Routing and Remote Access can be considered in three parts: securing the server running Routing and Remote Access, securing the network traffic between the server and its clients, and using secure authentication methods.

Unless your server running Routing and Remote Access is functioning only as a remote access server, you should also consider security for your routing implementation. For more information, see Security information for routing.

In addition to understanding the security implications of enabling Routing and Remote Access on your network, you should also practice general server security, as described in Security. For example, you should use only servers that are running Microsoft® Windows® 2000 or a member of the Microsoft Windows Server 2003 family, if possible. You will decrease your network security if you use servers that are running Routing and Remote Access on the same network as servers that are running Microsoft Windows NT 4.0 and either Remote Access Service (RAS) or Routing and Remote Access Service (RRAS). For more information, see Domain and forest functionality and Member server in a domain.

Before you configure and enable the remote access features of Routing and Remote Access, you should consider the following:

- **Who can enable, configure, and disable Routing and Remote Access**. You must be a member of the Administrators group to use the Routing and Remote Access snap-in, either on its own or as part of the Microsoft Management Console (MMC). Similarly, you must be a member of the Administrators group to run most of the **netsh ras** commands from the command line. You should restrict the membership of the Administrators group to the minimum number of users necessary to administer the server. For more information, see Default local groups and Default groups.

- **How to open Routing and Remote Access**. As a security best practice, consider using the **runas** command to open Routing and Remote Access rather than logging on with administrative credentials. For more information about why you might not want to log on with administrative credentials, see Why you should not run your computer as an administrator. To open Routing and Remote Access when you are not logged on as a member of the Administrators group, type the following at the command prompt:

  **runas /user:**[*Domain/*]*UserName***"mmc %windir%\system32\rrasmgmt.msc"**

  The user name that you provide must correspond to the Administrator account or an account that is a member of the Administrators group, and you must provide the password for the account when prompted. For more information, see Runas.

- **What client operating systems to support for remote access**. You should consider requiring your remote users to run particular operating systems (such as Microsoft Windows XP, Windows 2000, and members of the Windows Server 2003 family). There are two reasons to consider requiring your users to run particular operating systems. First, not all operating systems have equal levels of security in their file systems and in their user accounting. Second, not all remote access features are available on all operating systems. For more information, see Dial-up networking clients and Virtual private networking clients. Based on what client operating systems you support, you should also consider:

  - **What authentication methods to support**. You should consider requiring your remote users to be authenticated with more secure authentication protocols, such as Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAP v2) or Extensible Authentication Protocol (EAP), rather than allowing your remote users to use protocols such as Password Authentication Protocol (PAP), Shiva Password Authentication Protocol (SPAP), and Challenge Handshake Authentication Protocol (CHAP). For more information, see Remote Access Authentication Methods.

  - **What level of data encryption to support**. You should consider requiring your remote users to encrypt data with the highest level of data encryption possible. Windows XP and the Windows Server 2003 family support 128-bit encryption keys. For more information, see Remote Access Data encryption.

- **Whether to require strong passwords**. You should consider requiring your remote users to provide passwords that contain a certain number of characters and that contain a combination of uppercase letters, lowercase letters, numerals, and special characters. One of the worst vulnerabilities for a remote access solution is the use of weak or easily guessable passwords by remote users. For more information, see Strong passwords and Passwords must meet complexity requirements.

- **Whether to provide users with a managed client**. You should consider increasing the security of your remote access solution by using the Connection Manager Administration Kit (CMAK) wizard to create a customized connection for your users. By customizing the connection, you can control how your users connect to your network, and you can also simplify troubleshooting. For more information, see Connection Manager Administration Kit.

- **How to document your remote access solution**. You should consider documenting your remote access needs and how your network is configured to meet them. This can help you maintain your network and identify potential areas for concern or improvement. For more information, see Dial-up remote access design considerations and Remote access VPN design considerations.

- **Whether to use Windows Authentication or RADIUS**. If you have more than one server running Routing and Remote Access, you should consider using Remote Authentication Dial-In User Service (RADIUS) instead of Windows Authentication. By using RADIUS, you can centralize authentication, authorization, and auditing of remote access connections, and you can more easily manage your remote access policies. If you use RADIUS, you should consider encrypting your RADIUS traffic with Internet Protocol security (IPSec). For more information, see Remote Access Authentication, Using RADIUS, and Internet Authentication Service.

- **Whether to restrict remote access**. You should consider restricting remote access to your network to certain users, user groups, times, or client configurations by configuring remote access policies. You can implement remote access policies that restrict remote access to only those users or groups who require it and who meet the security standard for your network. For more information, see Remote Access Policies.

# The remote access server as a dial-up networking server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The remote access server as a dial-up networking server**

Routing and Remote Access provides traditional dial-up remote access to support mobile users or home users who are dialing in to organization intranets. Dial-up equipment that is installed on the server running Routing and Remote Access answers incoming connection requests from dial-up networking clients. The remote access server answers the call, authenticates and authorizes the caller, and transfers data between the dial-up networking client and the organization intranet.

The following illustration shows dial-up networking functionality.

For more information, see Dial-Up Networking.

# The remote access server as a virtual private networking server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The remote access server as a virtual private networking server**

A virtual private networking connection emulates a point-to-point connection. To emulate a point-to-point connection, data is encapsulated, or wrapped, with an additional IP header that provides routing information to reach a virtual private networking server. The portion of the virtual private networking connection in which the data is encapsulated is called the tunnel.

For secure virtual private networking, data is encrypted before it is encapsulated. Intercepted packets are unintelligible without the encryption keys. The portion of the virtual private networking connection in which your data is encrypted is called the virtual private network (VPN) connection.

VPN connections are created, managed, and terminated by using special protocols called tunneling protocols. Both the virtual private networking client and the virtual private networking server must support the same tunneling protocol to create a virtual private networking connection. A server running Routing and Remote Access is a virtual private networking server for both the Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP) tunneling protocols. For more information, see VPN Tunneling Protocols.

The following illustration shows virtual private networking functionality.

For more information, see Virtual Private Networking.

**Note**

- On Microsoft® Windows Server™ 2003, Web Edition, and Microsoft Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

# New features of remote access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New features of remote access**

Routing and Remote Access provides the following new features:

- Support for pre-shared keys in L2TP/IPSec authentication

  You can configure a server running Routing and Remote Access to use a pre-shared key instead of a certificate for L2TP/IPSec VPN connections. For more information, see Pre-shared keys.

- Integration of network address translation (NAT) and static and dynamic packet filtering

  NAT interfaces can be configured to work with Basic Firewall, a simple dynamic packet filter, or with incoming or outgoing static packet filters. For more information, see Basic Firewall.

- Support for L2TP/IPSec connections over NAT

  Routing and Remote Access seamlessly translates L2TP/IPSec VPN connections over a NAT interface. For more information, see Virtual Private Networks.

- Broadcast name resolution for small networks without a local WINS or DNS server

  Small networks or branch offices without local WINS or DNS servers can resolve corporate resource network names. For more information, see Broadcast name resolution.

# Common server configurations for remote access servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Common configurations for remote access servers**

When you run the Routing and Remote Access Server Setup Wizard, the wizard prompts you to choose the configuration path that most closely resembles the remote access solution that you want to deploy. If none of the wizard configuration paths meets your needs exactly, you can further configure your server after the wizard finishes, or you can choose the custom configuration path. However, if you choose the custom configuration path, you must manually configure all elements of Routing and Remote Access. The most common remote access solutions include dial-up connections, virtual private network (VPN) connections, and secure connections between two private networks.

**Remote access (dial-up)**

If you choose this path, the server running Routing and Remote Access is configured to allow remote access clients to connect to the private network by dialing into a modem bank or other dial-up equipment. To configure this type of server in the wizard, click **Remote Access**, select the **Dial-up** check box, and follow the steps. After the wizard finishes, you can configure additional options. For example, you can configure how the server answers the call, how the server verifies which remote access clients have permission to connect to the private network, and whether the server routes network traffic between remote access clients and the private network. For more information about dial-up connections, see Dial-Up Networking and Setting Up Dial-Up Remote Access.

**Remote access (VPN)**

If you choose this path, the server running Routing and Remote Access is configured to allow remote access clients to connect to the private network across the Internet. To configure this type of server in the wizard, click **Remote Access**, select the **VPN** check box, and follow the steps. After the wizard finishes, you can configure additional options. For example, you can configure how the server verifies which VPN clients have permission to connect to the private network and whether the server routes network traffic between VPN clients and the private network. For more information about VPNs, see Deploying VPNs for Remote Access and Common configuration for the VPN server.

**Network address translation (NAT)**

If you choose this path, the server running Routing and Remote Access is configured to share an Internet connection with

computers on the private network and to translate traffic between its public address and the private network. Computers on the Internet will not be able to determine the IP addresses of computers on the private network. To configure this type of server in the wizard, click **Network address translation (NAT)**, and follow the steps. After the wizard finishes, you can configure additional options. For example, you can configure packet filters and choose what services to allow on the public interface. For more information about NAT, see Setting Up Network Address Translation and Translated Connection to the Internet.

**VPN and NAT**

If you choose this path, the server running Routing and Remote Access is configured to provide NAT for the private network and to accept VPN connections. Computers on the Internet will not be able to determine the IP addresses of computers on the private network. However, VPN clients will be able to connect to computers on the private network as if they were physically attached to the same network. To configure this type of server in the wizard, click **Virtual Private Network (VPN) access and NAT**, and follow the steps. For more information about NAT and VPN, see New features for virtual private networks and Network address translation design considerations.

**Secure connection between two private networks**

If you choose this path, two servers running Routing and Remote Access are configured to send private data securely across the Internet. You must choose this path when you run the Routing and Remote Access Server Setup Wizard on each server. The connection between the two servers can be persistent (always on) or on demand (demand-dial). To configure this type of server in the wizard, click **Secure connection between two private networks**, and follow the steps. After the wizard finishes, you can configure each server with additional options. For example, you can configure what routing protocols each server accepts and how each server routes traffic between the two networks. For more information about connections between two networks, see Deploying Router-to-Router VPNs, Branch Office over the Internet, and Dial-Up Branch Office Network.

# Understanding Remote Access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding remote access**
This section covers:

- Dial-Up Networking
- Virtual Private Networking
- Devices and ports
- VPN Tunneling Protocols
- Remote Access Security
- Remote Access Policies
- Multilink and BAP
- Logging
- The remote access server and network management
- Broadcast name resolution

# Dial-Up Networking

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dial-up networking**
This section covers:

- Components of dial-up networking
- Dial-up networking clients
- Dial-up networking servers

# Components of dial-up networking

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Components of dial-up networking**

Dial-up networking includes the following components:

- **Dial-up networking servers**

  You can configure a server running Routing and Remote Access to provide dial-up networking access to an entire network or restrict access to the shared resources of the remote access server only.

- **Dial-up networking clients**

  Remote access clients running a member of the Windows Server 2003 family, Windows XP, Windows 2000, Windows NT running Remote Access Service (RAS) or Routing and Remote Access Service (RRAS), Windows Millennium Edition, Windows 98, Windows 95, or Mac OS can all connect to a server running Routing and Remote Access.

- **LAN and remote access protocols**

  Application programs use LAN protocols to transport information. Remote access protocols are used to negotiate connections and provide framing for LAN protocol data that is sent over wide area network (WAN) links. Routing and Remote Access supports LAN protocols such as TCP/IP and AppleTalk, which enable access to Internet, UNIX, Mac OS, and Novell NetWare resources. Routing and Remote Access supports remote access protocols such as PPP.

- **WAN options**

  Clients can dial in by using standard telephone lines and a modem or modem pool. Faster links are possible by using ISDN. You can also connect remote access clients to remote access servers by using X.25 or ATM. Direct connections are also supported through an RS-232C null modem cable, a parallel port connection, or an infrared connection.

- **Security options**

  The Windows Server 2003 family provides logon and domain security, support for security hosts, data encryption, Remote Authentication Dial-In User Service (RADIUS), smart cards, remote access account lockout, remote access policies, and callback for secure network access for dial-up clients.

The following illustration shows the dial-up networking components. Your actual implementation and configuration of dial-up networking may vary.

# Dial-up networking clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dial-up networking clients**

A dial-up client that connects to a server running Routing and Remote Access can be any PPP client. The client must have installed a modem, an analog telephone line or other WAN connection, and remote access software.

You can automate the connection process for clients by using a simple batch file and the **rasdial** command. You can also schedule automatic backups to or from remote computers by using dial-up networking and Task Scheduler.

**Windows-based PPP clients**

Windows-based PPP clients that use TCP/IP can access a server running Routing and Remote Access. Windows-based PPP clients cannot use the AppleTalk protocol. The remote access server automatically negotiates authentication with PPP clients.

Remote access support for Windows-based PPP dial-up networking clients is outlined in the following table.

| Dial-up networking client | Supported remote access PPP features | Unsupported remote access PPP features |
|---|---|---|
| Microsoft® Windows Server 2003 family, Windows XP, Windows 2000 | Multilink, Bandwidth Allocation Protocol (BAP), Microsoft Challenge Handshake Authentication Protocol (MS-CHAP), Challenge Handshake Authentication Protocol (CHAP), Shiva Password Authentication Protocol (SPAP), Password Authentication Protocol (PAP), Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAP v2), and Extensible Authentication Protocol (EAP) | |
| Windows NT® version 4.0 | Multilink, MS-CHAP, CHAP, SPAP, PAP, and MS-CHAP v2 (with Windows NT 4.0 Service Pack 4 and later) | BAP and EAP |
| Windows NT version 3.5*x* | MS-CHAP, CHAP, SPAP, and PAP | Multilink, BAP, MS-CHAP v2, and EAP |
| Windows Millennium Edition, Windows 98 | Multilink, MS-CHAP, CHAP, SPAP, PAP, and MS-CHAP v2 (with the Windows 98 Service Pack 1 and later) | BAP and EAP |
| Windows 95 | MS-CHAP, CHAP, SPAP, and PAP (with the Windows Dial-Up Networking 1.3 Performance & Security Upgrade for Windows 95 and later) | MS-CHAP v2, Multilink, BAP, and EAP |

**Note**

- Windows 95 with the Windows Dial-Up Networking 1.3 Performance & Security Upgrade for Windows 95 supports MS-CHAP v2 over virtual private network (VPN) connections but not over dial-up connections. For more information about virtual private networks and networking upgrades, see the Microsoft Web site.

**Other PPP clients**

Other PPP client software that uses TCP/IP or AppleTalk can access a server running Routing and Remote Access. The remote access server automatically negotiates authentication with PPP clients. No special configuration of the server running Routing and Remote Access is required for other PPP clients except to ensure that both the remote access server and the other PPP client are configured for the same LAN and authentication protocols.

For more information, see the documentation provided with your PPP client.

# Dial-up networking servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dial-up networking servers**

Administrators can use Routing and Remote Access to configure a server to provide remote access, view connected users, and monitor remote access traffic.

For dial-up networking access, the server must have at least one modem or a multiport adapter, and analog telephone lines or other WAN connections. If the server provides access to a network, you must install and connect a separate network adapter to the network to which the server provides access.

You can configure a server running Routing and Remote Access both during and after you run the Routing and Remote Access Server Setup wizard.

For more information about installing the Routing and Remote Access service, see Enable the Routing and Remote Access service.

For more information about deploying a dial-up networking remote access server, see Setting Up Dial-Up Remote Access.

# Virtual Private Networking

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Virtual private networking**
This section covers:

- Components of virtual private networking
- Virtual private networking clients
- Virtual private networking servers

# Components of virtual private networking

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Components of virtual private networking**

A virtual private network can include the following components:

- **Virtual private network (VPN) servers**

  You can configure your computer to provide access to an entire network or to restrict access to just the resources of the computer acting as the VPN server.

- **VPN clients**

  VPN clients are either individual users who obtain a remote access VPN connection or routers that obtain a router-to-router VPN connection. VPN clients running a member of the Windows server 2003 family, Windows XP, Windows 2000, Windows NT 4.0, Windows 95, Windows 98, or Windows Millennium Edition can create remote access VPN connections to the VPN server. Computers running either a member of the Windows server 2003 family or Windows 2000 and Routing and Remote Access, or Windows NT server 4.0 and the Routing and Remote Access Service (RRAS), can create router-to-router VPN connections. VPN clients can also be any Point-to-Point Tunneling Protocol (PPTP) client or Layer Two Tunneling Protocol (L2TP) client that uses Internet Protocol security (IPSec).

- **LAN and remote access protocols**

  LAN protocols are used by application programs to transport information. Remote access protocols are used to negotiate connections and provide framing for LAN protocol data that is sent over wide area network (WAN) links. Routing and Remote Access supports the PPP remote access protocol. Windows Server 2003, Datacenter Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Web Edition; and Windows Server 2003, Standard Edition all support LAN protocols such as TCP/IP and AppleTalk, which enable access to Internet, UNIX, Apple Macintosh, and Novell NetWare resources.

- **Tunneling protocols**

  VPN clients use tunneling protocols to create secured connections to a VPN server by using the PPTP or L2TP tunneling protocols.

- **WAN options**

  VPN servers are connected to the Internet by using permanent WAN connections such as T1 or Frame Relay. VPN clients are connected to the Internet by using permanent WAN connections or by dialing in (by using standard analog telephone lines or ISDN) to a local Internet service provider (ISP).

- **Security options**

  Routing and Remote Access supports logon and domain security, support for security hosts, data encryption, smart cards, IP packet filtering, and caller ID to provide secure network access for VPN clients.

The following illustration shows all the virtual private networking components and possible configurations. Your actual implementation and configuration of virtual private networking may vary.

**Note**

- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

# Virtual private networking clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Virtual private networking clients**

Virtual private networking clients that connect to Routing and Remote Access can be computers running a member of the Windows Server 2003 family, Windows XP, Windows 2000, Windows NT 4.0, Windows 95, Windows 98, or Windows Millennium Edition. The client must be able to send TCP/IP packets to the remote access server over the Internet. Therefore, either a network adapter or modem with an analog telephone line or other WAN connection to the Internet is required.

**Tunneling protocols for Microsoft virtual private network clients**

Support for tunneling protocols by Microsoft virtual private networking clients is outlined in the following table.

| Virtual private networking client | Supported tunneling protocols | Unsupported tunneling protocols |
|---|---|---|
| Windows Server 2003 family, Windows 2000, and Windows XP | Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP) | |
| Windows NT version 4.0 | PPTP | L2TP |
| Windows Millennium Edition and Windows 98 | PPTP | L2TP |
| Windows 95 with the Windows Dial-Up Networking 1.3 Performance & Security Upgrade for Windows 95 | PPTP | L2TP |
| Windows Millennium Edition, Windows 98, Windows NT 4.0 Workstation, and Windows 95 with Microsoft L2TP/IPSec VPN Client installed | L2TP | |

**Notes**

- Windows NT version 3.5*x* does not support either PPTP or L2TP.
- For more information about virtual private networks, Microsoft L2TP/IPSec VPN Client, and networking upgrades, see the Microsoft Web site.

**Authentication for Microsoft virtual private network clients**

Support for authentication protocols by Microsoft virtual private networking clients is outlined in the following table.

| Virtual private networking client | Supported remote access authentication protocols | Unsupported remote access authentication protocols |
|---|---|---|
| Windows Server 2003 family, Windows XP, and Windows 2000 | Microsoft Challenge Handshake Authentication Protocol (MS-CHAP), Challenge Handshake Authentication Protocol (CHAP), Shiva Password Authentication Protocol (SPAP), Password Authentication Protocol (PAP), MS-CHAP version 2 (MS-CHAP v2), and Extensible Authentication Protocol (EAP) | |
| Windows NT version 4.0 | MS-CHAP, CHAP, SPAP, PAP, and MS-CHAP v2 (with the Windows NT 4.0 Service Pack 4 and later) | EAP |
| Windows 98 | MS-CHAP, CHAP, SPAP, PAP, and MS-CHAP v2 (with the Windows 98 Service Pack 1 and later) | EAP |

| | | |
|---|---|---|
| Windows 95 | MS-CHAP, CHAP, SPAP, PAP, and MS-CHAP v2 (with the Dial-Up Networking 1.4 Upgrade) | EAP |

**Note**

- Windows 95 with the Dial-Up Networking 1.4 Upgrade supports MS-CHAP v2 over virtual private network (VPN) connections but not over dial-up connections. For more information about virtual private networks and networking upgrades, see the Microsoft Web site .

**Other virtual private network (VPN) clients**

Other virtual private network clients that use PPTP or L2TP with Internet Protocol security (IPSec) can access a server running Routing and Remote Access. However, if you want secure VPN connections, you must make sure that clients support the proper encryption. For PPTP, Microsoft Point-to-Point Encryption (MPPE) must be supported. For L2TP, IPSec encryption must be supported.

For more information, see the documentation provided with the virtual private network client.

# Virtual private networking servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Virtual private networking servers**

You can use Routing and Remote Access to configure a VPN server, view connected users, and monitor remote access traffic.

For virtual private network access from the Internet, the server typically has a permanent connection to the Internet. A nonpermanent connection to the Internet is possible if the Internet service provider (ISP) supports demand-dial connections; the connection is created when traffic is delivered to the VPN server. However, this is not a common configuration. If the VPN server provides access to a network, you must install and connect a separate network adapter to the network to which the VPN server provides access.

On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

You can configure remote access servers after the Routing and Remote Access Server Setup Wizard is run.

For more information about installing the Routing and Remote Access service, see Enable the Routing and Remote Access service.

For more information about deploying a remote access VPN server, see Setting Up Remote Access VPNs.

# Devices and ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Devices and ports**
A server running Routing and Remote Access views the installed networking equipment as a series of devices and ports.

- A device represents hardware or software that can create physical or logical point-to-point connections.
- A port is a communication channel that can support a single point-to-point connection.

**Device**
A device is the hardware or software that provides ports that remote access connections can use to establish point-to-point connections. Devices are physical, such as a modem, or virtual, such as virtual private network (VPN) protocols. Devices can support a single port, such as a modem, or multiple ports, such as modem bank hardware that can terminate 64 different incoming analog phone calls. Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP) are examples of virtual multiport devices. Each of these tunneling protocols supports multiple VPN connections.

To see the installed devices, you can view the properties of **Ports** in Routing and Remote Access.

**Port**
A port is a channel of a device that can support a single point-to-point connection. For single-port devices such as modems, the device and the port are indistinguishable. For multiport devices, the port is the subdivision of the device over which a separate point-to-point connection is possible. For example, Primary Rate Interface (PRI) ISDN adapters support two separate channels called B channels. The ISDN adapter is a device. Each B channel is a port because a separate point-to-point connection can occur over each B channel.

You can view the dial-up ports by clicking **Ports** in Routing and Remote Access.

### Notes

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.
- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

# VPN Tunneling Protocols

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**VPN tunneling protocols**
This section covers:

- Point-to-Point Tunneling Protocol
- Layer Two Tunneling Protocol

# Point-to-Point Tunneling Protocol

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Point-to-Point Tunneling Protocol**
Point-to-Point Tunneling Protocol (PPTP) is a tunneling protocol first supported in Windows NT 4.0 and Windows 98. PPTP is an extension of Point-to-Point Protocol (PPP) and leverages the authentication, compression, and encryption mechanisms of PPP. Client support for PPTP is built-in to the Windows XP remote access client.

VPN server support for PPTP is built in to members of the Windows Server 2003 family. PPTP is installed with the TCP/IP protocol. Depending on your choices when running the Routing and Remote Access Server Setup Wizard, PPTP is configured for five or 128 PPTP ports. For more information, see Checklist: Installing and configuring a PPTP server.

PPTP and Microsoft Point-to-Point Encryption (MPPE) provide the primary VPN services of encapsulation and encryption of private data.

**Encapsulation**
A PPP frame (an IP, IPX, or Appletalk datagram) is wrapped with a Generic Routing Encapsulation (GRE) header and an IP header. In the IP header is the source and destination IP address that correspond to the VPN client and VPN server.

The following illustration shows PPTP encapsulation for a PPP frame.

**Encryption**
The PPP frame is encrypted with Microsoft Point-to-Point Encryption (MPPE) by using encryption keys generated from the MS-CHAP, MS-CHAP v2, or EAP-TLS authentication process. Virtual private networking clients must use the MS-CHAP, MS-CHAP v2, or EAP-TLS authentication protocol in order for the payloads of PPP frames to be encrypted. PPTP is taking advantage of the underlying PPP encryption and encapsulating a previously encrypted PPP frame.

For more information on deploying PPTP-based VPN connections, see Deploying Virtual Private Networks. For a PPTP-based VPN server checklist, see Checklist: Installing and configuring a PPTP server. For an example implementation of PPTP-based VPN connections, see Virtual Private Network Implementation Examples. For information on configuring PPTP-based VPN connections in a test lab, see Virtual Private Network Test Lab.

## Notes

- It is possible to have a nonencrypted PPTP connection where the PPP frame is sent in plaintext. However, a nonencrypted PPTP connection is not recommended for VPN connections over the Internet because communications of this type are not secure.

- The IPX/SPX protocol is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

# Layer Two Tunneling Protocol

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Layer Two Tunneling Protocol**
Layer Two Tunneling Protocol (L2TP) is an RFC-based tunneling protocol that is an industry standard and was first supported in the Windows 2000 client and server operating systems. Unlike PPTP, L2TP in servers running Windows Server 2003 does not utilize Microsoft Point-to-Point Encryption (MPPE) to encrypt Point-to-Point Protocol (PPP) datagrams. L2TP relies on Internet Protocol security (IPSec) for encryption services. The combination of L2TP and IPSec is known as L2TP/IPSec. L2TP/IPSec provides the primary virtual private network (VPN) services of encapsulation and encryption of private data.

Both L2TP and IPSec must be supported by both the VPN client and the VPN server. Client support for L2TP is built-in to the Windows XP remote access client, and VPN server support for L2TP is built in to members of the Windows Server 2003 family.

L2TP is installed with the TCP/IP protocol. Depending on your choices when running the Routing and Remote Access Server Setup Wizard, L2TP is configured for five or 128 L2TP ports. For more information, see Checklist: Installing and configuring an L2TP server.

For more information about IPSec, see Internet Protocol Security Overview.

**Encapsulation**
Encapsulation for L2TP/IPSec packets consists of two layers:

1. L2TP encapsulation

   A PPP frame (an IP datagram or an IPX datagram) is wrapped with an L2TP header and a UDP header.

2. IPSec encapsulation

   The resulting L2TP message is then wrapped with an IPSec Encapsulating Security Payload (ESP) header and trailer, an IPSec Authentication trailer that provides message integrity and authentication, and a final IP header. In the IP header is the source and destination IP address that corresponds to the VPN client and VPN server.

The following illustration shows L2TP and IPSec encapsulation for a PPP datagram.

**Encryption**
The L2TP message is encrypted with either Data Encryption Standard (DES) or Triple DES (3DES) by using encryption keys generated from the Internet Key Exchange (IKE) negotiation process.

For more information on deploying L2TP/IPSec VPN connections, see Deploying Virtual Private Networks. For configuration checklists, see VPN Checklists. For an example implementation of L2TP/IPSec VPN connections, see Virtual Private Network Implementation Examples. For information on configuring L2TP/IPSec VPN connections in a test lab, see Virtual Private Network Test Lab.

### Notes

- It is possible to have a nonencrypted L2TP connection where the PPP frame is sent in plaintext. However, a nonencrypted L2TP connection is not recommended for virtual private network connections over the Internet because communications of this type do not provide data confidentiality.

- The IPX/SPX protocol is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

# Remote Access Security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access security**
This section covers:

- Remote Access Authentication Methods
- Authentication vs. authorization
- Pre-shared keys
- Remote Access Data encryption
- Remote access dial-in permissions
- Caller ID and callback
- Remote Access Security hosts
- Remote access account lockout

# Remote Access Authentication Methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Authentication methods**
The authentication of remote access clients is an important security concern. Authentication methods typically use an authentication protocol that is negotiated during the connection establishment process. The Windows Server 2003 family also supports unauthenticated access.

This section covers:

- EAP
- MS-CHAP
- MS-CHAP version 2
- CHAP
- SPAP
- PAP
- Unauthenticated access

# EAP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**EAP**

With the Extensible Authentication Protocol (EAP), an arbitrary authentication mechanism authenticates a remote access connection. The exact authentication scheme to be used is negotiated by the remote access client and the authenticator (either the remote access server or the Remote Authentication Dial-In User Service [RADIUS] server). Routing and Remote Access includes support for EAP-TLS and MD5-Challenge by default. You can plug in other EAP modules to the server running Routing and Remote Access to provide other EAP methods.

EAP allows for an open-ended conversation between the remote access client and the authenticator. The conversation consists of authenticator requests for authentication information and the responses by the remote access client. For example, when EAP is used with security token cards, the authenticator can separately query the remote access client for a name, PIN, and card token value. As each query is asked and answered, the remote access client passes through another level of authentication. When all questions have been answered satisfactorily, the remote access client is authenticated.

A specific EAP authentication scheme is known as an EAP type. Both the remote access client and the authenticator must support the same EAP type for successful authentication to occur.

The Windows Server 2003 family includes an EAP infrastructure, two EAP types, and the ability to pass EAP messages to a RADIUS server (EAP-RADIUS).

**EAP infrastructure**

EAP is a set of internal components that provide architectural support for any EAP type in the form of a plug-in module. For successful authentication, both the remote access client and authenticator must have the same EAP authentication module installed. The Windows Server 2003 family provides two EAP types: MD5-Challenge and EAP-TLS. EAP-TLS is only available for members of a domain. You can also install additional EAP types. The components for an EAP type must be installed on every remote access client and every authenticator.

**MD5-Challenge**

Message Digest 5 Challenge (MD5-Challenge) is a required EAP type that uses the same challenge handshake protocol as PPP-based CHAP, but the challenges and responses are sent as EAP messages.

A typical use for MD5-Challenge is to authenticate the credentials of remote access clients by using user name and password security systems. You can also use MD5-Challenge to test EAP interoperability.

**EAP-TLS**

EAP-Transport Level Security (EAP-TLS) is an EAP type that is used in certificate-based security environments. If you are using smart cards for remote access authentication, you must use the EAP-TLS authentication method. The EAP-TLS exchange of messages provides mutual authentication, negotiation of the encryption method, and encrypted key determination between the remote access client and the authenticator. EAP-TLS provides the strongest authentication and key determination method.

EAP-TLS is supported only on servers that are running Routing and Remote Access, that are configured to use Windows Authentication or RADIUS, and that are members of a domain. A remote access server running as a stand-alone server or a member of a workgroup does not support EAP-TLS.

For information about configuring smart cards for remote access clients, see Using smart cards for remote access.

**EAP-RADIUS**

EAP-RADIUS is not an EAP type, but the passing of EAP messages of *any* EAP type by an authenticator to a RADIUS server for authentication. For example, for a remote access server that is configured for RADIUS authentication, the EAP messages sent between the remote access client and remote access server are encapsulated and formatted as RADIUS messages between the remote access server and the RADIUS server.

EAP-RADIUS is used in environments where RADIUS is used as the authentication provider. An advantage of using EAP-RADIUS is that EAP types do not need to be installed at each remote access server, only at the RADIUS server. In the case of an IAS server, you only need to install EAP types on the IAS server.

In a typical use of EAP-RADIUS, a server running Routing and Remote Access is configured to use EAP and to use an IAS server for authentication. When a connection is made, the remote access client negotiates the use of EAP with the remote access server. When the client sends an EAP message to the remote access server, the remote access server encapsulates the EAP

message as a RADIUS message and sends it to its configured IAS server. The IAS server processes the EAP message and sends a RADIUS-encapsulated EAP message back to the remote access server. The remote access server then forwards the EAP message to the remote access client. In this configuration, the remote access server is only a pass-through device. All processing of EAP messages occurs at the remote access client and the IAS server.

Routing and Remote Access can be configured to authenticate locally, or to a RADIUS server. If Routing and Remote Access is configured to authenticate locally, all EAP methods will be authenticated locally. If Routing and Remote Access is configured to authenticate to a RADIUS server, all EAP messages will be forwarded to the RADIUS server with EAP-RADIUS.

For more information about configuring a server running Routing and Remote Access for EAP-RADIUS, see Configure EAP-RADIUS.

**Enabling EAP**

To enable EAP-based authentication, you must do the following:

1. Enable EAP as an authentication protocol on the remote access server. For more information, see Enable EAP.

2. Enable EAP and, if needed, configure the EAP type on the appropriate remote access policy. For more information, see Introduction to remote access policies and Configure authentication.

3. Enable and configure EAP on the remote access client. For more information, see Extensible Authentication Protocol (EAP).

**Note**

- Make sure your network access server (NAS) supports EAP before you enable it on a remote access policy on an IAS server. For more information, see your NAS documentation.

# MS-CHAP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**MS-CHAP**
The Windows Server 2003 family includes support for the Microsoft Challenge Handshake Authentication Protocol (MS-CHAP), also known as MS-CHAP version 1. MS-CHAP is a nonreversible, encrypted password authentication protocol. The challenge handshake process works as follows:

1. The authenticator (the remote access server or the IAS server) sends a challenge to the remote access client that consists of a session identifier and an arbitrary challenge string.

2. The remote access client sends a response that contains the user name and a nonreversible encryption of the challenge string, the session identifier, and the password.

3. The authenticator checks the response and, if valid, the user's credentials are authenticated.

If you use MS-CHAP as the authentication protocol, then you can use Microsoft Point-to-Point Encryption (MPPE) to encrypt the data sent on the PPP or PPTP connection.

The Windows Server 2003 family also includes support for MS-CHAP version 2. MS-CHAP version 2 provides stronger security for remote access connections than MS-CHAP. You should consider using MS-CHAP version 2 instead of MS-CHAP. For more information, see MS-CHAP version 2.

**Enabling MS-CHAP**
To enable MS-CHAP-based authentication, you must do the following:

1. Enable MS-CHAP as an authentication protocol on the remote access server. For more information, see Enable authentication protocols. MS-CHAP is enabled by default.

2. Enable MS-CHAP on the appropriate remote access policy. For more information, see Introduction to remote access policies and Configure authentication. MS-CHAP is enabled by default.

3. Enable MS-CHAP on the remote access client. For more information, see Microsoft Challenge Handshake Authentication Protocol (MS-CHAP).

### Notes

- MS-CHAP (version 1 and version 2) is the only authentication protocol provided with the Windows Server 2003 family that supports password change during the authentication process.

- By default, the Windows Server 2003 family implementation of MS-CHAP v1 does not support LAN Manager authentication. If you want to allow the use of LAN Manager authentication with MS-CHAP v1 for older operating systems such as Windows NT 3.5x and Windows 95, you must set the following registry value to 1 on the authenticating server:

  **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Policy\Allow LM Authentication**

  Windows 2000 Server supports LAN Manager authentication by default. Upgrading a computer running Windows 2000 Server to a member of the Windows Server 2003 family preserves the existing **Allow LM Authentication** setting.

- If MS-CHAP v1 is used as the authentication protocol, a 40-bit encrypted connection cannot be established if the user's password is larger than 14 characters. This behavior affects both dial-up and virtual private network-based remote access and demand dial connections.

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

# MS-CHAP version 2

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**MS-CHAP version 2**

The Windows Server 2003 family includes support for version 2 of the Microsoft Challenge Handshake Authentication Protocol (MS-CHAP v2), which provides stronger security for remote access connections. MS-CHAP v2 solves some issues of MS-CHAP version 1, as shown in the following table.

| MS-CHAP version 1 issue | MS-CHAP version 2 solution |
|---|---|
| LAN Manager encoding of the response used for backward compatibility with older Microsoft remote access clients is cryptographically weak. | MS-CHAP v2 no longer allows LAN Manager encoded responses. |
| LAN Manager encoding of password changes is cryptographically weak. | MS-CHAP v2 no longer allows LAN Manager encoded password changes. |
| Only one-way authentication is possible. The remote access client cannot verify that it is dialing in to its organization's remote access server or a masquerading remote access server. | MS-CHAP v2 provides two-way authentication, also known as mutual authentication. The remote access client receives verification that the remote access server that it is dialing in to has access to the user's password. |
| With 40-bit encryption, the cryptographic key is based on the user's password. Each time the user connects with the same password, the same cryptographic key is generated. | With MS-CHAP v2, the cryptographic key is always based on the user's password and an arbitrary challenge string. Each time the user connects with the same password, a different cryptographic key is used. |
| A single cryptographic key is used for data sent in both directions on the connection. | With MS-CHAP v2, separate cryptographic keys are generated for transmitted and received data. |

MS-CHAP v2 is a one-way encrypted password, mutual authentication process that works as follows:

1. The authenticator (the remote access server or the IAS server) sends a challenge to the remote access client that consists of a session identifier and an arbitrary challenge string.

2. The remote access client sends a response that contains:

   - The user name.

   - An arbitrary peer challenge string.

   - A one-way encryption of the received challenge string, the peer challenge string, the session identifier, and the user's password.

3. The authenticator checks the response from the client and sends back a response containing:

   - An indication of the success or failure of the connection attempt.

   - An authenticated response based on the sent challenge string, the peer challenge string, the encrypted response of the client, and the user's password.

4. The remote access client verifies the authentication response and, if correct, uses the connection. If the authentication response is not correct, the remote access client terminates the connection.

**Enabling MS-CHAP v2**

To enable MS-CHAP v2-based authentication, you must do the following:

1. Enable MS-CHAP v2 as an authentication protocol on the remote access server. For more information, see Enable authentication protocols. MS-CHAP v2 is enabled by default.

2. Enable MS-CHAP v2 on the appropriate remote access policy. For more information, see Introduction to remote access policies and Configure authentication. MS-CHAP v2 is enabled by default.

3. Enable MS-CHAP v2 on the remote access client. For more information, see Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAP v2).

## Notes

- Windows 95 with the Windows Dial-Up Networking 1.3 Performance & Security Upgrade for Windows 95 supports MS-CHAP v2 for virtual private network (VPN) connections but not for dial-up connections.

- MS-CHAP (version 1 and version 2) is the only authentication protocol provided with the Windows Server 2003 family that supports password change during the authentication process.

- Make sure your network access server (NAS) supports MS-CHAP v2 before you enable it on a remote access policy on an IAS server. For more information, see your NAS documentation.

# CHAP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**CHAP**

The Challenge Handshake Authentication Protocol (CHAP) is a challenge-response authentication protocol that uses the industry-standard Message Digest 5 (MD5) hashing scheme to encrypt the response. CHAP is used by various vendors of network access servers and clients. A server running Routing and Remote Access supports CHAP so that remote access clients that require CHAP are authenticated. Because CHAP requires the use of a reversibly encrypted password, you should consider using another authentication protocol such as MS-CHAP version 2.

To enable CHAP-based authentication, you must do the following:

1. Enable CHAP as an authentication protocol on the remote access server. For more information, see Enable authentication protocols. CHAP is disabled by default.

2. Enable CHAP on the appropriate remote access policy. For more information, see Introduction to remote access policies and Configure authentication.

3. Enable storage of a reversibly encrypted form of the user's password.

   You can enable storage of a reversibly encrypted form of the user's password per user account or enable storage for all accounts in a domain. For more information, see Enable reversibly encrypted passwords in a domain.

4. Force a reset of the user's password so that the new password is in a reversibly encrypted form.

   When you enable passwords to be stored in a reversibly encrypted form, the current passwords are not in a reversibly encrypted form and are not automatically changed. You must either reset user passwords or set user passwords to be changed the next time each user logs on. For more information, see Reset a user password. Once the password is changed, it is stored in a reversibly encrypted form.

   If you set user passwords to be changed the next time a user logs on, the user must log on by using a LAN connection and change the password before they attempt to log on with a remote access connection by using CHAP. You cannot change passwords during the authentication process by using CHAP--the logon attempt fails. One workaround for the remote access user is to temporarily log on by using MS-CHAP to change the password.

5. Enable CHAP on the remote access client. For more information, see Challenge Handshake Authentication Protocol (CHAP).

**Notes**

- If your password expires, CHAP cannot change passwords during the authentication process.

- Make sure your network access server (NAS) supports CHAP before you enable it on a remote access policy on an IAS server. For more information, see your NAS documentation.

- You cannot use Microsoft Point-to-Point Encryption (MPPE) with CHAP.

# SPAP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SPAP**
The Shiva Password Authentication protocol (SPAP) is a reversible encryption mechanism employed by Shiva. A computer running Windows XP Professional, when connecting to a Shiva LAN Rover, uses SPAP, as does a Shiva client that connects to a server running Routing and Remote Access. This form of authentication is more secure than plaintext but less secure than CHAP or MS-CHAP.

To enable SPAP-based authentication, you must do the following:

1. Enable SPAP as an authentication protocol on the remote access server. For more information, see Enable authentication protocols. SPAP is disabled by default.

2. Enable SPAP on the appropriate remote access policy. For more information, see Configure authentication. SPAP is disabled by default.

3. Enable SPAP on the remote access client. For more information, see Shiva Password Authentication Protocol (SPAP).

**Important**

- When you enable SPAP as an authentication protocol, the same user password is always sent in the same reversibly-encrypted form. This makes SPAP authentication susceptible to replay attacks, where an attacker captures the packets of the authentication process and replays the responses to gain authenticated access to your intranet. The use of SPAP is discouraged, especially for virtual private network connections.

**Notes**

- If your password expires, SPAP cannot change passwords during the authentication process.

- Make sure your network access server (NAS) supports SPAP before you enable it on a remote access policy on an IAS server. For more information, see your NAS documentation.

- You cannot use Microsoft Point-to-Point Encryption (MPPE) with SPAP.

# PAP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**PAP**
Password Authentication Protocol (PAP) uses plaintext passwords and is the least secure authentication protocol. It is typically negotiated if the remote access client and remote access server cannot negotiate a more secure form of validation.

To enable PAP-based authentication, you must do the following:

1. Enable PAP as an authentication protocol on the remote access server. For more information, see Enable authentication protocols. PAP is disabled by default.

2. Enable PAP on the appropriate remote access policy. For more information, see Configure authentication. PAP is disabled by default.

3. Enable PAP on the remote access client. For more information, see Password Authentication Protocol (PAP).

### Important

- When you enable PAP as an authentication protocol, user passwords are sent in plaintext form. Anyone capturing the packets of the authentication process can easily read the password and use it to gain unauthorized access to your intranet. The use of PAP is highly discouraged, especially for virtual private network connections.

### Notes

- By disabling the support for PAP on the remote access server, plaintext passwords are never sent by the dial-up client. Disabling support for PAP increases authentication security, but remote access clients who only support PAP cannot connect.

- If your password expires, PAP cannot change passwords during the authentication process.

- Make sure your network access server (NAS) supports PAP before you enable it on a remote access policy on an IAS server. For more information, see your NAS documentation.

- You cannot use Microsoft Point-to-Point Encryption (MPPE) with PAP.

# Unauthenticated access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Unauthenticated access**
The Windows Server 2003 family supports unauthenticated access, which means that user credentials (a user name and password) are not required. There are some situations where unauthenticated access is useful. This section covers:

- DNIS authorization
- ANI/CLI authentication
- Guest authentication

**Important**

- When you enable unauthenticated access, remote access users are connected without sending user credentials. An unauthenticated remote access client does not negotiate the use of a common authentication protocol during the connection establishment process and does not send a user name or password.

  Unauthenticated access with remote access clients could occur when the authentication protocols configured by the remote access client do not match those configured on the remote access server. In this case, the use of a common authentication protocol is not negotiated and the remote access client does not send a user name and password.

# DNIS authorization

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNIS authorization**

Dialed Number Identification Service (DNIS) enables authorization of a connection attempt based on the number called. DNIS identifies the number that was called to the receiver of the call and is provided by most standard telephone companies. For example, you could allow all connections that connect through a specific toll-free number. To identify DNIS-based connections and apply the appropriate connection settings, you must do the following:

1. Enable unauthenticated access on the remote access server. For more information, see Enable authentication protocols.

2. Create a remote access policy on the authenticating server (remote access server or IAS server) for DNIS-based authorization with the Called-Station-Id condition set to the phone number. For more information, see Introduction to remote access policies and Add a remote access policy.

3. Enable unauthenticated access on the remote access policy for DNIS-based authorization. For more information, see Configure authentication.

### Notes

- If your phone service or hardware does not support DNIS, the passing of the number that was called, you can manually set the phone number of the port. For more information, see Set the phone number on a port.

- IAS does not support proxied DNIS access requests.

# ANI/CLI authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ANI/CLI authentication**
Automatic Number Identification/Calling Line Identification (ANI/CLI) authentication is the authentication of a connection attempt based on the phone number of the caller. ANI/CLI service returns the number of the caller to the receiver of the call and is provided by most standard telephone companies.

ANI/CLI authentication is different from caller ID authorization. In caller ID authorization, the caller sends a valid user name and password. The caller ID that is configured for the dial-in property on the user account must match the connection attempt; otherwise, the connection attempt is rejected. In ANI/CLI authentication, a user name and password are not sent.

To identify ANI/CLI-based connections and apply the appropriate connection settings, you must do the following:

1. Enable unauthenticated access on the remote access server. For more information, see Enable authentication protocols.

2. Enable unauthenticated access on the appropriate remote access policy for ANI/CLI-based authentication. For more information, see Introduction to remote access policies and Configure authentication.

3. Create a user account for each number that will be calling for which you want to provide ANI/CLI authentication. The name of the user account must match the number that the user is dialing from. For example, if a user is dialing in from 555-0100, create a "5550100" user account.

4. Set the following registry value to 31 on the authenticating server (either the remote access server or the IAS server):

   **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Policy\User Identity Attribute**

   This registry setting tells the authenticating server to use the calling number (RADIUS attribute 31, Calling-Station-ID) as the identity of the calling user. The user identity is set to the calling number only when there is no user name being supplied in the connection attempt.

   To always use the calling number as the user identity, set the following registry value to 1 on the authenticating server:

   **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Policy\Override User-Name**

   However, if you set **Override User-Name** to 1 and the **User Identity Attribute** to 31, the authenticating server can only perform ANI/CLI-based authentication. Normal authentication by using authentication protocols such as MS-CHAP, CHAP, and EAP is disabled.

### Note

- Changes to the registry settings will not take effect until the Routing and Remote Access service or the Internet Authentication Service are restarted.

### Caution

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

# Guest authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Guest authentication**
By default, the Windows Server 2003 family includes a user account called Guest. With guest authentication, during the authentication process, the caller does not send a user name or password. If unauthenticated access is enabled, by default the Guest account is used as the identity of the caller.

To enable Guest account access, you must do the following:

1. Enable unauthenticated access on the remote access server. For more information, see Enable authentication protocols.

2. Enable unauthenticated access on the appropriate remote access policy. For more information, see Configure authentication.

3. Enable the Guest account. For more information, see To enable a disabled user account.

4. Set the remote access permission on the Guest account to either **Allow access** or **Control access through Remote Access Policy** depending on your remote access policy administrative model. For more information, see Remote Access Policies Examples and Configure remote access permission for a user.

If you want to enable a guest account that is not named **Guest**, create a user account and set the remote access permission to either **Allow access** or **Control access through Remote Access Policy**. Then, set the following registry value on the authenticating server (either the remote access server or the IAS server) to the name of the account:

**HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Policy\Default User Identity**

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**Notes**

- Changes to the registry setting will not take effect until the Routing and Remote Access service or the Internet Authentication Service are restarted.

- For more information about how to modify registry keys and set values, see "Remote Access Server" at the Microsoft Windows Resource Kits Web site.

# Authentication vs. authorization

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Authentication vs. authorization**
The distinction between authentication and authorization is important in understanding why connection attempts are either accepted or denied:

- Authentication is the verification of the credentials of the connection attempt. This process consists of sending the credentials from the remote access client to the remote access server in an either plaintext or encrypted form by using an authentication protocol.

- Authorization is the verification that the connection attempt is allowed. Authorization occurs after successful authentication.

For a connection attempt to be accepted, the connection attempt must be both authenticated and authorized. It is possible for the connection attempt to be authenticated by using valid credentials, but not authorized. In this case, the connection attempt is denied.

If a remote access server is configured for **Windows Authentication**, the security features of the Windows Server 2003 family are used to verify the credentials for authentication, and the dial-in properties of the user account and locally stored remote access policies are used to authorize the connection. If the connection attempt is both authenticated and authorized, the connection attempt is accepted.

For more information, see Introduction to remote access policies.

If the remote access server is configured for RADIUS authentication, the credentials of the connection attempt are passed to the RADIUS server for authentication and authorization. If the connection attempt is both authenticated and authorized, the RADIUS server sends an accept message back to the remote access server and the connection attempt is accepted. If the connection attempt is either not authenticated or not authorized, the RADIUS server sends a reject message back to the remote access server and the connection attempt is rejected.

If the RADIUS server is a computer running the Internet Authentication Service (IAS), the IAS server performs authentication through selected authentication features and authorization through the dial-in properties of the user account and remote access policies stored on the IAS server.

# Pre-shared keys

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Pre-shared keys**

A pre-shared key is a string of Unicode characters used to authenticate L2TP/IPSec connections. You can configure Routing and Remote Access to authenticate VPN connections that support a pre-shared key. The use of pre-shared keys is supported on many operating systems, including the Windows Server 2003 family and Windows XP. You can also configure a server running the Windows Server 2003 family version of Routing and Remote Access to use a pre-shared key to authenticate connections from other routers.

**Advantages and disadvantages of pre-shared keys**

Pre-shared key authentication does not require the hardware and configuration investment of a public key infrastructure (PKI), which is necessary for using computer certificates for L2TP/IPSec authentication. Pre-shared keys are simple to configure on a remote access server, and they are relatively simple to configure on a remote access client. They can be made transparent to the user if they are issued within Connection Manager profiles. If you are in the process of establishing a PKI or you manage an Active Directory domain, you can configure Routing and Remote Access to accept an L2TP/IPSec connection using a computer certificate or a pre-shared key.

However, a single remote access server can utilize only one pre-shared key for all L2TP/IPSec connections that require a pre-shared key for authentication. Therefore, you must issue the same pre-shared key to all L2TP/IPSec VPN clients that connect to the remote access server using a pre-shared key. Unless you distribute the pre-shared key within a Connection Manager profile, each user must manually type the pre-shared key. This limitation further reduces the security of the deployment and increases the probability of error. Moreover, if the pre-shared key on a remote access server is changed, a client with a manually configured pre-shared key will be unable to connect to that server until the pre-shared key on the client is changed. If the pre-shared key was distributed to the client within a Connection Manager profile, that profile must be reissued with the new pre-shared key and reinstalled on the client computer. Unlike certificates, the origin and the history of a pre-shared key cannot be determined. For these reasons, the use of pre-shared keys to authenticate L2TP/IPSec connections is considered a relatively weak authentication method. If you want a long term, strong authentication method, you should consider using a PKI.

**Considerations when choosing a pre-shared key**

A pre-shared key is a sequence of characters that is configured on both the remote access server and the L2TP/IPSec client. The pre-shared key can be any non-null string of any combination of up to 256 Unicode characters. When you choose a pre-shared key, consider the fact that users who utilize the New Connection wizard to create the VPN client connection must type the pre-shared key manually. A key that is long and complex enough to provide adequate security might be difficult for the majority of your users to type accurately. If the pre-shared key presented by the VPN client deviates in any way from the pre-shared key configured on the remote access server, client authentication will fail.

When the pre-shared key is first stored, the remote access server and the VPN client attempt to convert the Unicode string into ASCII. If the attempt is successful, the ASCII version of the string will be used for authentication. This strategy ensures that the pre-shared key is not corrupted in transmission by any devices that do not comply with the Unicode standard, such as routers from other companies. If the pre-shared key cannot be stored as ASCII, the Unicode string will be used. If the Unicode pre-shared key must be processed by any device that does not comply with the Unicode standard, the connection attempt will almost certainly fail.

**Pre-shared keys and the Connection Manager Administration Kit**

By using the Connection Manager Administration Kit (CMAK) wizard, you can create a customized connection experience for your users. You can use the CMAK wizard to create a VPN connection profile that includes a pre-shared key. Because profiles are self-extracting, the user does not have to type in the pre-shared key or even to know that a pre-shared key exists. You can further increase the security of your Connection Manager profile distribution by encrypting the pre-shared key with a personal identification number (PIN). In this way, not only does the user never see or have to type the pre-shared key, you can distribute the profile and the PIN separately, reducing the chance that an unauthorized user might obtain access to your network.

For more information about Connection Manager profiles, see Connection Manager Administration Kit. For more information about VPNs, see Virtual Private Networks and Virtual private networking with IPSec. For more information about PKIs, see Deploying a Public Key Infrastructure.

# Remote Access Data encryption

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Data encryption**

You can use data encryption to protect the data that is sent between the remote access client and the remote access server. Data encryption is important for anyone who wants or needs secure data transfer, including financial institutions, law-enforcement and government agencies, and corporations. For installations where data confidentiality is required, the network administrator can set the remote access server to require encrypted communications. Users who connect to that server must encrypt their data or the connection attempt is denied.

For dial-up networking connections, you can protect your data by encrypting it on the communications link between the remote access client and the remote access server. You should use data encryption when there is a risk of unauthorized interception of transmissions on the communications link between the remote access client and the remote access server. For dial-up networking connections, Routing and Remote Access uses Microsoft Point-to-Point Encryption (MPPE).

For virtual private networking connections, you can protect your data by encrypting it between the ends of the virtual private network (VPN). You should always use data encryption for VPN connections when private data is sent across a public network such as the Internet, where there is always a risk of unauthorized interception. For VPN connections, Routing and Remote Access uses MPPE with the Point-to-Point Tunneling Protocol (PPTP) and IP Security (IPSec) encryption with the Layer Two Tunneling Protocol (L2TP).

Because data encryption is performed between the VPN client and VPN server, it is not necessary to use data encryption on the communication link between a dial-up client and its Internet service provider (ISP). For example, a mobile user uses a dial-up networking connection to dial in to a local ISP. Once the Internet connection is made, the user creates a VPN connection with the corporate VPN server. If the VPN connection is encrypted, there is no need to use encryption on the dial-up networking connection between the user and the ISP.

MPPE and IPSec are configured on the **Encryption** tab on the properties of a remote access policy to use 40-bit (the **Basic** setting), 56-bit (the **Strong** setting), or 128-bit (the **Strongest** setting) encryption keys. You should use 40-bit encryption keys to connect with older operating systems that do not support 56-bit or 128-bit encryption keys. Otherwise, use 56-bit encryption keys. Encryption keys are determined at the time of the connection. MPPE requires the use of the MS-CHAP (v1 or v2) or EAP-TLS authentication protocols.

**Notes**

- Data encryption for PPP or PPTP connections is available only if MS-CHAP (v1 or v2) or EAP-TLS is used as the authentication protocol. Data encryption for L2TP connections relies on IPSec, which does not require any specific authentication protocol.

- Remote access data encryption does not provide end-to-end data encryption. End-to-end encryption is data encryption between the client application and the server that hosts the resource or service being accessed by the client application. To get end-to-end data encryption, use IPSec to create a secure connection *after* the remote access connection has been made.

# Remote access dial-in permissions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access dial-in permissions**

After a remote access server is installed, you must specify from which users the remote access server can accept a connection. For a server running Routing and Remote Access, authorization is determined by the dial-in properties on the user account, the remote access policies, or both. For more information, see Configure Remote Access Policies.

You do not need to create user accounts just for remote access users. Remote access servers use the user accounts specified in the available user accounts databases.

**How security works at connection**

The following steps describe what happens during a call from a remote access client to a server running Routing and Remote Access that is configured to use Windows Authentication:

1. A remote access client dials a remote access server.
2. The server sends a challenge to the client.
3. The client sends an encrypted response to the server that consists of a user name, a domain name, and a password.
4. The server checks the response against the appropriate user accounts database.
5. If the account is valid and the authentication credentials are correct, the server uses the dial-in properties of the user account and remote access policies to authorize the connection.

If callback is enabled, the server hangs up the connection, calls the client back, and continues the connection negotiation process.

**Notes**

- Steps 2 and 3 assume that the remote access client and the remote access server use the MS-CHAP v1 or CHAP authentication protocols. The sending of client credentials may vary for other authentication protocols.
- If the remote access server is a member of domain and the user response does not contain a domain name, then the domain name of the remote access server is used. If you want to use a different domain name than that of the remote access server, set the following registry value on the remote access client to the name of the domain that you want to use:

  **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RasMan\PPP\ControlProtocols\BuiltIn\DefaultDomain**

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**Security after the connection is made**

Credentials used for remote access only provide a communication channel to the target network. The client does not log on to the network as a result of a remote access connection. Each time the client attempts to access a network resource, it will be challenged for credentials. If it does not respond to the challenge with acceptable credentials, the access attempt will fail. Windows XP and the Windows Server 2003 family adds a feature to simplify remote access. After a successful connection, Windows XP and Windows Server 2003 family remote access clients will cache these credentials as default credentials for the duration of the remote access connection. When a network resource challenges the remote access client, the client provides the cached credentials without requiring the user to enter them again.

# Caller ID and callback

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Caller ID and callback**
As an additional measure of security, Routing and Remote Access offers caller ID and callback features, which ensure that only users from specific locations can access the remote access server. These features also save telephone charges for the user.

**Caller ID**
When you set dial-in security by using the caller ID feature, you specify the phone number from which the user must call in. If the user does not call in from that specific phone number, the connection attempt is rejected by the remote access server.

Caller ID must be supported by the caller, the phone system between the caller and the remote access server, and the remote access server. Caller ID on the remote access server consists of call answering equipment that supports the passing of caller ID information and the appropriate drivers that support the passing of caller ID information to the Routing and Remote Access service.

If you configure a caller ID phone number for a user and you do not have support for the passing of caller ID information all the way from the caller to the Routing and Remote Access service, the connection attempt is denied.

The caller ID feature is designed to provide a higher degree of security for telecommuters. The disadvantage of configuring caller ID is that the user can only dial in from a specific phone line.

For virtual private network (VPN) connections, the caller ID is the IP address of the VPN client. If the VPN client has a fixed IP address, this can be a useful security feature.

**Callback**
When you use the callback feature, the user initiates a call and connects with the remote access server. After authentication and authorization, the remote access server then drops the call and calls back a moment later to a negotiated or preassigned callback number.

You configure each user's callback options when you grant remote access permission. For more information, see Configure dial-in user properties.

There are three callback options to choose from:

- **No callback** (the default)
- **Set by caller**
- **Always call back to**

**Note**

- Until the user has been authenticated, authorized, and called back (if callback is set), no data from the dial-up networking client or the remote access server is transferred.

**No callback**
If the user account is not configured for callback, the remote access server establishes a connection as soon as the connection attempt has been accepted. The **No callback** option does not provide any additional security.

**Set by caller**
Although the **Set by caller** option is not really a security feature, it is useful for clients who call from various locations and phone numbers. It also minimizes telephone charges for these users. When the user's call reaches the remote access server, the following events occur:

1. After authentication and authorization of the connection attempt, the **Callback** dialog box appears on the user's computer.
2. The user types the current callback number in the dialog box.

3. The callback number is sent to the server.

4. The call is terminated.

5. The server calls the client back at the callback number.

6. Once reconnected, the client and server continue the connection negotiation.

**Always call back to**

For additional security, select the **Always call back to** option and type the number of the phone to which the user's dial-up equipment is connected. When the user's call reaches the remote access server, the following events occur:

1. After authentication and authorization of the connection attempt, the server sends a message announcing that the user will be called back.

2. The server disconnects and calls the user back at the preset number.

3. Once reconnected, the client and server continue the connection negotiation.

You should set this option for stationary remote computers, such as those used by telecommuters in home offices.

The disadvantage of configuring callback to always call a specific number is that the user can only dial in from a specific location.

### Notes

- You can also configure the **Set by caller** callback option for groups by setting the **Service-Type** condition of a remote access policy to **Callback-Framed-User**. For more information, see Elements of a remote access policy.

- Because of the way that callback connections are processed, you cannot configure both a caller ID and callback that is set to either **Set by caller** or **Always call back to**.

- Callback over a primary rate interface (PRI) ISDN channel may not work properly if a service is listening on the other ISDN channel. When the remote access server calls back, an ISDN channel is picked to receive the call. If the ISDN channel is not the same one used to make the initial call, the remote access client or demand-dial router does not recognize the incoming call as the remote access server callback and drops the call.

# Remote Access Security hosts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security hosts**

A security host is an authentication device that verifies whether a caller from a remote access client is authorized to connect to the remote access server. This verification supplements security already supplied by the server running Routing and Remote Access. This verification is only applicable to dial-up or modem connections.

The security host sits between the remote access client and the remote access server. The security host generally provides an extra layer of security by requiring a hardware key of some sort in order to provide authentication. Verification that the remote access client is in physical possession of the key takes place before access to the remote access server is granted. This open architecture allows customers to choose from a variety of security hosts to augment the security in Routing and Remote Access.

For example, one kind of security system consists of two hardware devices: the security host and the security card. The security host is installed between the remote access server and its modem. The security card is a small unit the size of a credit card, resembling a pocket calculator without keys. The security card displays a different access number every minute. This number is synchronized with the same number calculated in the security host every minute. When connecting, the remote user sends the number on the security card to the host. If the number is correct, the security host connects the remote access client with the remote access server.

Another kind of security host prompts the remote access client to type in a user name (which may or may not be the same as the remote access client name) and a password (which differs from the remote access client password).

You must configure the security host to allow the remote access server to initialize the modem before the security functions take effect. The remote access server must also be able to directly initialize the modem that is connected to the security host without security checks from the security host. The security host might interpret the attempt of the remote access server to initialize the modem as an attempt to dial out.

For more information, see Configure other security devices.

# Remote access account lockout

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access account lockout**

You can use the remote access account lockout feature to specify how many times a remote access authentication fails against a valid user account before the user is denied access. Remote access account lockout is especially important for remote access virtual private network (VPN) connections over the Internet. An attacker on the Internet can attempt to access an organization intranet by sending credentials (valid user name, guessed password) during the VPN connection authentication process. During a dictionary attack, the attacker sends hundreds or thousands of credentials by using a list of passwords based on common words or phrases.

With remote access account lockout enabled, a dictionary attack is thwarted after a specified number of failed attempts. As the network administrator, you must decide on two remote access account lockout variables:

1. The number of failed attempts before future attempts are denied.

   After each failed attempt, a failed attempts counter for the user account is incremented. If the user account's failed attempts counter reaches the configured maximum, future attempts to connect are denied.

   A successful authentication resets the failed attempts counter when its value is less than the configured maximum. In other words, the failed attempts counter does not accumulate beyond a successful authentication.

2. How often the failed attempts counter is reset.

   The failed attempts counter is periodically reset to 0. If an account is locked out after the maximum number of failed attempts, the failed attempts counter is automatically reset to 0 after the reset time.

You enable the remote access account lockout feature by changing settings in the registry on the computer that provides the authentication. If the remote access server is configured for Windows Authentication, modify the registry on the remote access server computer. If the remote access server is configured for RADIUS authentication and Internet Authentication Service (IAS) is being used, modify the registry on the IAS server.

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

To enable remote access account lockout, you must set the **MaxDenials** entry in the registry to **1** or greater. **MaxDenials** is the maximum number of failed attempts before the account is locked out. You set the **MaxDenials** entry in the following registry subkey:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Parameters\AccountLockout**

By default, **MaxDenials** is set to **0**, which means that remote access account lockout is disabled.

To modify the amount of time before the failed attempts counter is reset, you must set the **ResetTime (mins)** entry in the registry to the required number of minutes. You set the **ResetTime (mins)** entry in the following registry subkey:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Parameters\AccountLockout**

By default, **ResetTime (mins)** is set to **0xb40**, or 2,880 minutes (48 hours).

**Manually resetting an account that is locked out**

To manually reset a user account that has been locked out before the failed attempts counter is automatically reset, delete the following registry subkey that corresponds to the user's account name:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Parameters\AccountLockout\ *domain name:user name***

When the lockout count for a user account is reset to 0 due to either a successful authentication or an automatic reset, the registry subkey for the user account is deleted.

**Notes**

- Remote access account lockout is not related to the **Account locked out** setting on the **Account** tab on the properties of a user account.

- The remote access account lockout feature does not distinguish between malicious users who attempt to access your intranet and authentic users who attempt remote access but have forgotten their current passwords. Users who have forgotten their current password typically try the passwords that they remember and, depending on the number of attempts and the **MaxDenials** setting, may have their accounts locked out.

- If you enable the remote access account lockout feature, a malicious user can deliberately force an account to be locked out by attempting multiple authentications with the user account until the account is locked out, thereby preventing the authentic user from being able to log on.

# Remote Access Policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access policies**
This section covers:

- Introduction to remote access policies
- Dial-in properties of a user account
- Elements of a remote access policy
- Accepting a connection attempt
- Remote Access Policies Examples

# Introduction to remote access policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Introduction to remote access policies**

In Windows NT versions 3.5, 3.51, and 4.0, authorization was based on a **Grant dial-in permission to user** option in either User Manager or the Remote Access Admin utility. An individual user configured callback options. For the Routing and Remote Access service and Internet Authentication Service (IAS) in Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and Windows 2000, network access authorization is granted on the basis of user account dial-in properties and remote access policies.

Remote access policies are an ordered set of rules that define how connections are either authorized or rejected. For each rule, there are one or more conditions, a set of profile settings, and a remote access permission setting.

If a connection is authorized, the remote access policy profile specifies a set of connection restrictions. The dial-in properties of the user account also provide a set of restrictions. Where applicable, user account connection restrictions override the remote access policy profile connection restrictions.

For information about connection restrictions that can be configured on a user account, see Dial-in properties of a user account. For information about connection restrictions that can be configured through a remote access policy profile, see Elements of a remote access policy.

Remote access policies validate a number of connection settings before authorizing the connection, including the following:

- Remote access permission
- Group membership
- Type of connection
- Time of day
- Authentication methods
- Advanced conditions:
    - Access server identity
    - Access client phone number or MAC address
    - Whether user account dial-in properties are ignored
    - Whether unauthenticated access is allowed

After the connection is authorized, remote access policies can also be used to specify connection restrictions, including the following:

- Idle timeout time
- Maximum session time
- Encryption strength
- IP packet filters
- Advanced restrictions:

- IP address for PPP connections
- Static routes

Additionally, you can vary connection restrictions based on the following settings:

- Group membership
- Type of connection
- Time of day
- Authentication methods
- Identity of the access server
- Access client phone number or MAC address
- Whether unauthenticated access is allowed

For example, you can have policies that specify different maximum session times for different types of connections or groups. Additionally, you can specify restricted access for business partners or unauthenticated connections.

**Authorizing access**
There are two ways to use remote access policies to grant authorization:

1. By user
2. By group

**Authorization by user**
If you are managing authorization by user, set the remote access permission on the user or computer account to either **Grant access** or **Deny access** and, optionally, create different remote access policies based on different types of connections. For example, you might want to have one remote access policy that is used for dial-up connections and a different remote access policy that is used for wireless connections. Managing authorization by user is recommended only when you have a small number of user or computer accounts to manage.

If you are managing authorization by user, the basic process for authorizing a connection attempt occurs as follows:

- If the connection attempt matches all policy conditions, check the remote access permission setting of the account.
    - If the remote access permission is set to **Grant access**, apply the connection settings of the policy profile and user account.
    - If the remote access permission is set to **Deny access**, reject the connection attempt.
- If the connection attempt does not match all policy conditions, process the next remote access policy.

If the connection attempt does not match all conditions of any remote access policy, reject the connection attempt.

**Authorization by group**
If you are managing authorization by group, set the remote access permission on the user account to **Control access through Remote Access Policy** and create remote access policies that are based on different types of connections and group membership. For example, you might want to have one remote access policy for dial-up connections for employees (members of the Employees group) and a different remote access policy for dial-up connections for contractors (members of the Contractors group).

If you are managing authorization by group, the basic process for authorizing a connection attempt occurs as follows:

- If the connection attempt matches all policy conditions, check the remote access permission of the remote access policy.
    - If the remote access permission is set to **Grant remote access permission**, apply the connection settings of the policy profile and user account.
    - If the remote access permission is set to **Deny remote access permission**, reject the connection attempt.
- If the connection attempt does not match all policy conditions, process the next remote access policy.

If the connection attempt does not match all conditions of any remote access policy, reject the connection attempt.

**Notes**

- Setting the remote access permission on user accounts to **Control access through Remote Access Policy** and not using groups to manage network access is not recommended.
- For more information about how connection attempts are processed, see Remote Access Policies Examples

**Remote access policies and the Routing and Remote Access service**

For servers running the Routing and Remote Access service that are configured for the Windows authentication provider, remote access policies are administered from Routing and Remote Access and apply only to the connections of the Routing and Remote Access service server. For servers running the Routing and Remote Access service that are configured for the RADIUS authentication provider, you can no longer configure remote access policies using Routing and Remote Access. If the RADIUS server is an IAS server, remote access policies are administered from Internet Authentication Service.

To centrally manage a single set of remote access policies for multiple remote access or VPN servers using an IAS server, you must do the following:

1. Install the Internet Authentication Service (IAS) as a Remote Authentication Dial-In User Service (RADIUS) server. For more information, see Checklist: Configuring IAS for dial-up and VPN access.
2. Configure IAS with RADIUS clients that correspond to each of the Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition remote access or VPN servers. For more information, see Add RADIUS clients.
3. On the IAS server, create the central set of policies that will be used by all servers running the Routing and Remote Access service. For more information, see Add a remote access policy.
4. Configure each of the servers running the Routing and Remote Access service as RADIUS clients to the IAS server. For more information, see Use RADIUS authentication.

For more information about deploying IAS for centralized remote access policy management, see Using RADIUS for multiple remote access servers.

Centralized management of remote access policies is also used when you have remote access servers that are running Windows NT 4.0 and the Routing and Remote Access Service (RRAS). You can configure this server as a RADIUS client to an IAS server. However, a remote access server running Windows NT 4.0 without RRAS cannot be configured to use centralized remote access policies.

# Dial-in properties of a user account

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dial-in properties of a user account**

In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition; the user account for a stand-alone server or server running Active Directory contains a set of dial-in properties that are used when allowing or denying a connection attempt made by a user. On a stand-alone server, you can set the dial-in properties on the **Dial-in** tab in the user account in Local Users and Groups. On a server running Active Directory, you can set the dial-in properties on the **Dial-in** tab in the user account in Active Directory Users and Computers. On these servers, you cannot use the Windows NT 4.0 User Manager for Domains administrative tool.

The dial-in properties for a user account are:

- **Remote Access Permission (Dial-in or VPN)**

  You can use this property to set remote access permission to be explicitly allowed, denied, or determined through remote access policies. In all cases, remote access policies are used to authorize the connection attempt. If access is explicitly allowed, remote access policy conditions, user account properties, or profile properties can still deny the connection attempt. The **Control access through Remote Access Policy** option is only available on user accounts in a Windows 2000 native domain, a Windows server 2003 domain, or for local accounts on stand-alone servers running Windows 2000, Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition.

  By default, the Administrator and Guest accounts on a stand-alone server or in a Windows 2000 native domain are set to **Control access through Remote Access Policy**. In a Windows 2000 mixed domain, they are set to **Deny access**. New accounts that are created on a stand-alone server or in a Windows 2000 native domain are set to **Control access through Remote Access Policy**. New accounts that are created in a Windows 2000 mixed domain are set to **Deny access**.

  For more information, see Domain and forest functionality.

- **Verify Caller ID**

  If this property is enabled, the server verifies the caller's phone number. If the caller's phone number does not match the configured phone number, the connection attempt is denied.

  Caller ID must be supported by the caller, the phone system between the caller and the remote access server, and the remote access server. On a computer running the Routing and Remote Access service, caller ID support consists of call answering equipment that provides caller ID information and the appropriate Windows Server 2003, Standard Edition ; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition driver to pass the information to the Routing and Remote Access service.

  If you configure a caller ID phone number for a user, and you do not have support for the passing of caller ID information from the caller to the Routing and Remote Access service, the connection attempt is denied.

- **Callback Options**

  If this property is enabled, the server calls the caller back during the connection process. The phone number that is used by the server is set by either the caller or the network administrator.

- **Assign a Static IP Address**

  You can use this property to assign a specific IP address to a user when a connection is made.

- **Apply Static Routes**

You can use this property to define a series of static IP routes that are added to the routing table of the server running the Routing and Remote Access service when a connection is made. This setting is designed for user accounts that a router running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition uses for demand-dial routing. For more information, see One-way initiated demand-dial connections.

For information about configuring dial-in properties for a user account, see Configure dial-in user properties.

**Support for ignoring the dial-in properties of user accounts**
In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition; you can configure a RADIUS attribute to ignore the dial-in properties of user and computer accounts in the profile properties of a remote access policy. To support multiple types of connections for which IAS provides authentication and authorization, it might be necessary to disable the processing of user account dial-in properties. This can be done to support scenarios in which specific dial-in properties are not required.

For example, the caller-ID, callback, static IP address, and static routes properties are designed for a client that is dialing into a network access server (NAS). These settings are not designed for wireless access points. A wireless access point that receives these settings in the RADIUS message from the IAS server might be unable to process them, which could cause the wireless client to become disconnected. When IAS provides authentication and authorization for users who are both dialing in and accessing the organization network through wireless technology, the dial-in properties must be configured to support either dial-in connections (by setting dial-in properties) or wireless connections (by not setting dial-in properties).

You can use IAS to enable the processing of dial-in properties for user and computer accounts in some scenarios (such as dial-in), and to disable the processing of dial-in properties for user and computer accounts in other scenarios (such as wireless and authenticating switch). This is done by configuring the **Ignore-User-Dialin-Properties** attribute on the **Advanced** tab of the profile settings for a remote access policy. For more information, see Add RADIUS attributes to a remote access policy.

The **Ignore-User-Dialin-Properties** attribute is set to the following:

- To enable the processing of dial-in properties for a user account, delete the **Ignore-User-Dialin-Properties** attribute or set it to **False**. For example, for a remote access policy that is designed for dial-in connections, no additional configuration is required.

- To disable the processing of dial-in properties for a user account, set the **Ignore-User-Dialin-Properties** attribute to the value of **True**. For example, this is set for the remote access policy that is used for wireless or authenticating switch connections. When the dial-in properties of the user account are ignored, remote access permission is determined by the setting in the remote access policy.

### Notes

- For a user account in a Windows NT 4.0 domain or a Windows 2000 mixed domain:

    - Only the dial-in properties named **Remote Access Permission (Dial-in or VPN)** (**Allow access** and **Deny access** options) and **Callback Options** are available.

    - You can use the Windows NT 4.0 User Manager for Domains administrative tool to grant or deny dial-in access and set callback options.

- If a user account is in a Windows 2000 native domain, the callback number can be up to 128 characters in length. If a user account is on a stand-alone remote access server, in a Windows NT 4.0 domain, or in a Windows 2000 mixed domain, the callback number can contain 24 through 48 characters. This is due to the compressed format for storing callback numbers.

- When a remote access server running Windows NT 4.0 uses a Windows 2000 native domain to obtain the dial-in properties of a user account, the **Control access through Remote Access Policy** remote access permission setting is retrieved as **Deny access**. Callback settings are retrieved correctly.

  For more information, see Domain and forest functionality.

- A remote access server running Windows NT 4.0 cannot use remote access policies. If you upgrade this remote access server with the Routing and Remote Access Service (RRAS) and configure it for RADIUS authentication, you can use the remote access policies of an IAS server. Alternately, you can upgrade this remote access server with a member of the Windows 2000 server family; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition.

- User accounts upgraded to Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition that were configured with dial-in permission enabled are set to **Allow access**. Those that were configured with dial-in permission disabled are set to **Deny access**.

- It is possible to ignore all of the user or computer account properties. For more information, see the section "Ignoring the dial-in properties of user accounts" in New features for IAS.

- In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition; computer accounts also have dial-in properties and are similar to user accounts. This new feature allows computers to be authenticated as if they were users, and is used when an IEEE 802.1x Ethernet client uses EAP-TLS and an installed computer certificate to authenticate itself to an Ethernet switch.

- The **Ignore-User-Dialin-Properties** attribute disables the use of all dial-in properties for the user account. Specific dial-in properties cannot be selectively disabled.

# Elements of a remote access policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Elements of a remote access policy**

A remote access policy is a named rule that consists of the following elements:

- Conditions
- Remote access permission
- Profile

**Conditions**

Remote access policy conditions are one or more attributes that are compared to the settings of the connection attempt. If there are multiple conditions, then all of the conditions must match the settings of the connection attempt in order for it to match the policy.

The following table shows the condition attributes that you can set for a remote access policy.

| Attribute name | Description |
|---|---|
| Authentication Type | The type of authentication that is being used by the access client. Authentication types include CHAP, EAP, MS-CHAP, and MS-CHAP v2. |
| Called Station ID | The phone number of the network access server (NAS). This attribute is a character string. You can use pattern matching syntax to specify area codes. For more information, see Pattern matching syntax. In order to receive called station ID information during a call, the phone line, the hardware, and the Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition driver for the hardware must support passing the called ID. Otherwise, the called station ID is manually set for each port. To manually set phone numbers on ports, see Set the phone number on a port. |
| Calling Station ID | The phone number used by the caller. This attribute is a character string. You can use pattern matching syntax to specify area codes. For more information, see Pattern matching syntax. For more information about obtaining the calling station ID, see Caller ID and callback. |
| Client Friendly Name | The name of the RADIUS client that is requesting authentication. This name is configured in **Friendly name** on the **Settings** tab in the properties of a RADIUS client in Internet Authentication Service. This attribute is a character string. You can use pattern matching syntax to specify client names. For more information, see Pattern matching syntax. This attribute is used by the IAS server. |
| Client IP Address | The IP address of the RADIUS client. This can be the IP address of either the originating RADIUS client or an intermediate RADIUS proxy. This attribute is a character string. You can use pattern matching syntax to specify IP networks. For more information, see Pattern matching syntax. This attribute is used by the IAS server. |
| Client Vendor | The vendor of the network access server (NAS) that is requesting authentication. The Routing and Remote Access service is the **Microsoft** NAS manufacturer. You can use this attribute to configure separate policies for different NAS manufacturers who are RADIUS clients to an IAS server. This attribute is used by the IAS server. Ensure that you configure the NAS as a RADIUS client on the IAS server. For more information, see Add RADIUS clients. |
| Day and Time Restrictions | The day of the week and the time of day of the connection attempt. The day and time is relative to the day and time of the server providing the authorization. |
| Framed Protocol | The type of framing for incoming packets. Examples are PPP, SLIP, Frame Relay, and X.25. This attribute is used by the IAS server. |

| | |
|---|---|
| NAS Identifier | The name of the network access server (NAS). This attribute is a character string. You can use pattern matching syntax to specify multiple NASs. For more information, see Pattern matching syntax. This attribute is used by the IAS server. |
| NAS IP Address | The IP address of the NAS (the RADIUS client) that sent the message. This attribute is a character string. You can use pattern matching syntax to specify IP networks. For more information, see Pattern matching syntax. This attribute is used by the IAS server. |
| NAS Port Type | The type of media that is used by the access client. Examples include analog phone lines (known as async), ISDN, tunnels or virtual private networks (known as virtual), IEEE 802.11 wireless, and Ethernet switches. |
| Service Type | The type of service that is being requested. Examples include framed (such as PPP connections) and login (such as Telnet connections). For more information about RADIUS service types, see RFC 2865, "Remote Authentication Dial-in User Service (RADIUS)." This attribute is used by the IAS server. |
| Tunnel Type | The type of tunnel that is being created by the requesting client. Tunnel types include the Point-to-Point Tunneling Protocol (PPTP) and the Layer Two Tunneling Protocol (L2TP), which are used by Windows XP; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and Windows 2000, remote access clients and demand-dial routers. You can use this condition to specify profile settings, such as authentication methods or encryption strengths for a specific type of tunneling technology. |
| Windows Groups | The names of the groups to which the user or computer account that is attempting the connection belongs. There is no condition attribute for a specific user or computer name. It is not necessary to have a separate remote access policy for each group. Instead, you can use multiple groups or nested groups to consolidate and delegate the administration of group membership. For a remote access or IAS server in a Windows 2000 native domain, you can use universal groups. For more information, see Domain and forest functionality. |

**Notes**

- If conditions that use an IAS server attribute are evaluated against a Routing and Remote Access service server that is configured for Windows authentication, they do not match and the policy is not applied.
- Not all access servers send all of the IAS server-specific attributes.
- You cannot use the built-in local or domain groups for the Windows Groups attribute.

**Remote access permission**

If all conditions of a remote access policy are met, remote access permission is either granted or denied. You can use either the **Grant remote access permission** option or the **Deny remote access permission** option to set remote access permission for a policy.

Remote access permission is also granted or denied for each user account. The user remote access permission overrides the policy remote access permission. When remote access permission on a user account is set to the **Control access through Remote Access Policy** option, the policy remote access permission determines whether the user is granted access.

Granting access through either the user account permission setting or the policy permission setting is only the first step in accepting a connection. The connection attempt is subject to the settings of both the user account dial-in properties and policy profile properties. If the connection attempt does not match the settings of the user account or policy profile properties, the connection attempt is rejected.

**Profile**

A remote access policy profile is a set of properties that are applied to a connection when it is authorized--either through the user account or policy permission settings. A profile consists of the following groups of properties:

- Dial-in constraints
- IP
- Multilink

- Authentication
- Encryption
- Advanced

**Dial-in constraints**

You can set the following dial-in constraints:

- **Minutes server can remain idle before it is disconnected**

  The time after which a connection is disconnected when there is no activity. By default, this property is not set. Additionally, the Routing and Remote Access service does not disconnect an idle connection.

- **Minutes client can be connected**

  The maximum amount of time that a connection is connected. The connection is disconnected by the access server after the maximum session length. By default, this property is not set and there is no maximum session limit.

- **Allow access only on these days and at these times**

  The days of the week and hours of each day that a connection is allowed. If the day and time of the connection attempt do not match the configured day and time limits, the connection attempt is rejected. By default, this property is not set and there are no day or time limits. The Routing and Remote Access service does not disconnect active connections that were previously connected at a time when connection attempts were allowed.

- **Allow access to this number only**

  The specific phone number that a caller must call in order for a connection to be allowed. If the dial-in number of the connection attempt does not match the configured dial-in number, the connection attempt is rejected. By default, this property is not set and all dial-in numbers are allowed.

- **Allow access only through these media**

  The specific types of media, such as modem (also known as async), ISDN, virtual private network (known as virtual), or 802.11 wireless that a caller must use in order for a connection to be allowed. If the dial-in medium of the connection attempt does not match the configured dial-in media, the connection attempt is rejected. By default, this property is not set and all media types are allowed.

For information about setting dial-in constraints on a profile, see Configure dial-in constraints.

**IP**

You can set IP properties that specify IP address assignment behavior. You have the following options:

- The access server must supply an IP address.
- The access client can request an IP address.
- IP address assignment is determined by the access server (this is the default setting).
- A static IP address is assigned. A static IP address assigned to the user account overrides this setting. The IP address assigned is typically used to accommodate vendor-specific attributes for IP addresses.

You can also use the **IP** tab to define IP packet filters that apply to remote access connection traffic. This is intended for use with the Routing and Remote Access service. You can configure IP traffic that is allowed to remote access clients (output filters) or from remote access clients (input filters) on an exception basis. Either all traffic is allowed, except traffic specified by filters; or all traffic is blocked, except traffic specified by filters . Remote access policy profile filtering applies to all remote access

connections that match the remote access policy.

Filters configured on the **IP** tab are applied to client connections on a Windows Server 2003 remote access server, but are not applied to dial-on-demand connections.

For information about setting IP options on a profile, see Configure IP options.

**Multilink**
You can set Multilink properties that both enable Multilink and determine the maximum number of ports that a Multilink connection can use. Additionally, you can set Bandwidth Allocation Protocol (BAP) policies that both determine BAP usage and specify when extra BAP lines are dropped. The Multilink and BAP properties are specific to the Routing and Remote Access service. By default, Multilink and BAP are disabled.

The Routing and Remote Access service must have Multilink and BAP enabled in order for the Multilink properties of the profile to be enforced. For more information about enabling Multilink and BAP for the Routing and Remote Access service, see Enable Multilink and Enable BAP and BACP.

For information about setting Multilink options on a profile, see Configure multilink options.

**Authentication**
You can set authentication properties to both enable the authentication types that are allowed for a connection and specify the EAP type that must be used. Additionally, you can configure the EAP type. By default, Microsoft Encrypted Authentication (MS-CHAP) and Microsoft Encrypted Authentication version 2 (MS-CHAP v2) are enabled. With Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition; you can specify whether users can change their expired passwords using MS-CHAP and MS-CHAP v2 (enabled by default). For more information, see Authentication methods.

The Routing and Remote Access service must have the corresponding authentication types enabled in order for the authentication properties of the profile to be enforced. For more information about enabling authentication methods for the Routing and Remote Access service, see Enable authentication protocols.

For information about setting authentication options on a profile, see Configure authentication.

**Encryption**
You can set encryption properties for the following encryption strengths:

- **No Encryption**

  This option allows a nonencrypted connection. To require encryption, clear this option.

- **Basic**

  For dial-up and PPTP-based VPN connections, Microsoft Point-to-Point Encryption (MPPE) is used with a 40-bit key. For L2TP/IPSec VPN connections, 56-bit Data Encryption Standard (DES) encryption is used.

- **Strong**

  For dial-up and PPTP VPN connections, MPPE is used with a 56-bit key. For L2TP/IPSec VPN connections, 56-bit DES encryption is used.

- **Strongest**

  For dial-up and PPTP VPN connections, MPPE is used with a 128-bit key. For L2TP/IPSec VPN connections, triple DES (3DES) encryption is used.

These settings are intended to be used with Routing and Remote Access. When other access servers are used, select **No Encryption** and clear all encryption strengths.

For information about setting encryption options on a profile, see Configure encryption.

**Advanced**
You can set advanced properties to specify the series of RADIUS attributes that are sent back by the IAS server to be evaluated by the RADIUS client. RADIUS attributes are specific to performing RADIUS authentication, and are ignored by a server that is

running the Routing and Remote Access service and is configured for Windows authentication. By default, **Framed-Protocol** is set to **PPP** and **Service-Type** is set to **Framed**.

The only advanced attributes that are used by the Routing and Remote Access service are **Account-Interim-Interval**, **Framed-Protocol**, **Framed-MTU**, **Reply-Message**, and **Service-Type**.

For information about setting advanced options on a profile, see Add RADIUS attributes to a remote access policy.

**Notes**

- Some elements of a remote access policy correspond to RADIUS attributes that are used during RADIUS-based authentication. For remote access policies on an Internet Authentication Service (IAS) server, verify that the access servers used are sending RADIUS attributes that correspond to the configured remote access policy conditions and profile settings. If a NAS does not send a RADIUS attribute that corresponds to a remote access policy condition or profile setting, then all RADIUS authentications from that NAS are denied.

- You can only use the Generate-Session-Timeout attribute if your user account database is a Security Accounts Manager (SAM) database or is the user account database for an Active Directory domain. When the value of **Generate-Session-Timeout** is set to **True**, the **ForceLogoff** value for a SAM database should be set to **0**. In the Local Security Settings console, ForceLogoff is changed to zero when **Network security: Force logoff when logon hours expire** is enabled. For information about how to change the ForceLogoff value for the SAM database at the command prompt, see Net accounts.

- You can configure wireless connection policy so that wireless clients periodically reauthenticate. This ensures that the client Wired Equivalent Privacy (WEP) encryption keys are changed often enough to provide adequate security for the wireless connection. To configure reauthentication, set the session timeout in your remote access policy or connection request policy for wireless connections (using the Session-Timeout attribute) to the required interval (for example, 10 minutes). Additionally, configure the Termination-Action attribute with the **Attribute value** set to **RADIUS-Request**. If the Termination-Action attribute is not set to **RADIUS-Request**, wireless access points might end the connection during reauthentication. For more information, see your hardware documentation.

- You can configure IAS in Windows Server 2003, Standard Edition, with a maximum of 50 RADIUS clients and a maximum of 2 remote RADIUS server groups. You can define a RADIUS client using a fully qualified domain name or an IP address, but you cannot define groups of RADIUS clients by specifying an IP address range. If the fully qualified domain name of a RADIUS client resolves to multiple IP addresses, the IAS server uses the first IP address returned in the DNS query. With IAS in Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, you can configure an unlimited number of RADIUS clients and remote RADIUS server groups. In addition, you can configure RADIUS clients by specifying an IP address range.

# Accepting a connection attempt

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Accepting a connection attempt**

When a user attempts a connection, the connection attempt is accepted or rejected, based on the following logic:

1. The first policy in the ordered list of remote access policies is checked. If there are no policies, reject the connection attempt.

2. If all conditions of the policy do not match the connection attempt, go to the next policy. If there are no more policies, reject the connection attempt.

3. If all conditions of the policy match the connection attempt, check the value of the **Ignore-User-Dialin-Properties** attribute.

4. If the **Ignore-User-Dialin-Properties** attribute is set to **False**, check the remote access permission setting for the user attempting the connection.

   - If **Deny access** is selected, reject the connection attempt.

   - If **Allow access** is selected, apply the user account and profile properties. If the connection attempt does not match the settings of the user account and profile properties, reject the connection attempt. If the connection attempt matches the settings of the user account and profile properties, accept the connection attempt.

   - If the remote access permission is not set to **Allow access** or **Deny access**, the remote access permission must be set to **Control access through Remote Access Policy**. Check the remote access permission setting of the policy.

     If **Deny remote access permission** is selected, reject the connection attempt.

     If **Grant remote access permission** is selected, apply the user account and profile properties. If the connection attempt does not match the settings of the user account and profile properties, reject the connection attempt. If the connection attempt matches the settings of the user account properties and profile, accept the connection attempt.

5. If the **Ignore-User-Dialin-Properties** attribute is set to **True**, check the remote access permission setting of the policy.

   - If **Deny remote access permission** is selected, reject the connection attempt.

   - If **Grant remote access permission** is selected, apply the profile properties. If the connection attempt does not match the settings of the profile properties, reject the connection attempt. If the connection attempt matches the settings of the profile properties, accept the connection attempt. The following illustration shows the logic of remote access policies.

**Notes**

- The profile and user account settings for the first matching policy are applied to the connection. If a connection does not match the profile or user account settings of the remote access policy, the additional remote access policies are not tried.

- A connection attempt might not match any of the remote access policies. If this is the case, the connection attempt is rejected regardless of the remote access permission setting on the user account.

- The remote access polices are tried in order. The more specific remote access policies are typically placed in order ahead of the more general remote access policies.

- The **Ignore-User-Dialin-Properties** attribute is a new feature for Windows Server 2003, Standard Edition ; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition that allows you to ignore all of the dial-in properties of a user account. For more information, see New features for IAS.

- You can configure IAS in Windows Server 2003, Standard Edition, with a maximum of 50 RADIUS clients and a maximum of 2 remote RADIUS server groups. You can define a RADIUS client using a fully qualified domain name or an IP address, but you cannot define groups of RADIUS clients by specifying an IP address range. If the fully qualified domain name of a RADIUS client resolves to multiple IP addresses, the IAS server uses the first IP address returned in the DNS query. With IAS in Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, you can configure an unlimited number of RADIUS clients and remote RADIUS server groups. In addition, you can configure RADIUS clients by specifying an IP address range.

For examples of how different connection attempts are processed, see Remote Access Policies Examples.

# Remote Access Policies Examples

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access policies examples**

Remote access policies provide a tremendous amount of flexibility in accepting connections based on policy evaluation order, policy conditions, user and policy dial-in permissions, and both policy profile and user account properties.

This section describes some examples in which remote access policies are used:

- Grant remote access per user
- Allow dial-up connection using group membership
- Restrict connections to a maximum session time
- Wireless access example
- Wireless access with secure password authentication
- Ethernet switch access
- Force VPN clients to use strongest encryption
- Apply packet filters for business partner extranet
- Send NAS-specific RADIUS attributes to a RADIUS client

# Grant remote access per user

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Grant remote access per user**

In this example, the network administrator wants to maintain the same administrative model as used in Windows NT 4.0. Dial-in access is granted on a per-user basis by modifying the remote access permission setting of the user account dial-in properties. The remote access permission is set to either **Allow access** or **Deny access**. This is the default behavior for remote access policies.

You can create a policy named **Allow access if dial-in permission is enabled**. The settings on this policy are configured as follows:

- A single condition that consists of the **Day-And-Time-Restrictions** attribute is set for all times on all days.
- The **Deny remote access permission** option is selected.
- The profile is set to the default settings.

When a user attempts a remote access connection, the following logic is used to accept or reject the attempt (assuming that the default settings are set for all the other user account dial-in properties):

1. The policy **Allow access if dial-in permission is enabled** is evaluated.
2. The settings of the connection attempt match the conditions of the policy (the connection attempt occurs on any day or at any time).
3. On the user account, the setting in **Remote Access Permission (Dial-in or VPN)** is evaluated.
    - If **Allow access** is selected, the connection is accepted, subject to the settings of the user account dial-in and profile properties.
    - If **Deny access** is selected, the connection is rejected.

# Allow dial-up connection using group membership

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Allow dial-up connection using group membership**
In this example, the network administrator is managing authorization by using groups. All user accounts have the **Remote Access Permission (Dial-in or VPN)** option set to **Control access through Remote Access Policy**.

The network administrator wants to allow dial-up connections for only those user accounts that belong to a specific set of groups. After remote access permission is set for all user accounts, the administrator completes the following steps:

1. Use the New Remote Access Policy Wizard to create a common dial-up policy with the following settings:

   - Policy name: Dial-up access for allowed groups
   - Access Method: Dial-up access
   - User or Group: Select **Group**, and then specify the set of groups for which dial-up access is allowed.
   - Authentication methods: Select **Microsoft Encrypted Authentication version 2 (MS-CHAP v2)** and **Microsoft Encrypted Authentication**.
   - Policy Encryption Level: Select all check boxes.

     For more information, see Add a remote access policy.

2. Delete the default policies.

   For more information, see Delete a remote access policy.

**Notes**

- It is not necessary to have a separate remote access policy for each group. You can specify multiple groups or you can use nested groups to both delegate administration of and consolidate group membership. For a remote access or IAS server in a Windows 2000 native domain or a Windows Server 2003 domain, you can use universal groups. For more information, see Domain and forest functionality.
- You cannot use built-in or local domain groups when specifying group names.

# Restrict connections to a maximum session time

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Restrict connections to a maximum session time**
In this example, the network administrator is managing authorization by using groups. All user accounts have the **Remote Access Permission (Dial-in or VPN)** option set to **Control access through Remote Access Policy**.

To conserve limited remote access server connection resources, the network administrator wants to limit the maximum session time for all dial-up users (members of the DialUpUsers group) to 20 minutes.

To implement this restriction through a remote access policy, the administrator completes the following steps:

**Use the New Remote Access Policy Wizard to create a custom policy with the following settings:**

- Policy name: Maximum session time of 20 minutes
- Conditions: NAS-Port-Type matches Async (Modem); Windows-Groups matches DialUpUsers
- Permission: Grant remote access permission
- Profile settings, **Dial-in Constraints** tab: Select the **Minutes client can be connected** check box, and then type **20**.

For more information, see Add a remote access policy.

**Delete the default policies.**
For more information, see Delete a remote access policy.

# Wireless access example

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Wireless access example**
In this example, the network administrator is managing authorization by using groups. All user accounts have the **Remote Access Permission (Dial-in or VPN)** option set to **Control access through Remote Access Policy**.

The network administrator requires that all IEEE 802.11 wireless clients (members of the WirelessClients group) use certificate-based authentication through the EAP-TLS authentication protocol and 128-bit encryption. Wireless clients that do not have a user certificate installed are placed on a specific virtual local area network (VLAN) from which they can obtain a user certificate. This unauthenticated connection lasts for 10 minutes.

In this case, two policies are needed:

1. A policy that requires wireless connections to use EAP-TLS.

2. A policy that accepts unauthenticated wireless connections and configures the wireless access point for a VLAN with an ID of 3. VLAN 3 contains a certificate server from which the wireless client can obtain a user certificate.

After remote access permission is set for all user accounts, the administrator completes the following steps:

1. Use the New Remote Access Policy Wizard to create a common wireless policy with the following settings:

   - Policy name: Wireless access

   - Access Method: Wireless access

   - User or Group: Select **Group**, and then specify the WirelessClients group (example).

   - Authentication methods: Select **Smart Card or other Certificate**.

   - Policy Encryption Level: Check the **Strongest encryption (MPPE 128-bit)** check box, and then clear all other check boxes.

2. Use the New Remote Access Policy Wizard to create a custom wireless policy with the following settings:

   - Policy name: First-time wireless access

   - Conditions: NAS-Port-Type matches Wireless-Other or Wireless-IEEE 802.11; Windows-Groups matches WirelessUsers; Authentication-Type matches Unauthenticated

   - Permission: Grant remote access permission

   - Profile settings, **Dial-in Constraints** tab: Select the **Minutes client can be connected** check box, and then type **10**.

   - Profile settings, **Advanced** tab: Add the **Tunnel-Type** attribute with the value of **Virtual LANs (VLAN)**; Add the **Tunnel-Pvt-Group-ID** attribute with the value of **3**.

3. Delete the default policies.

   For more information, see Delete a remote access policy.

**Notes**

- For this example, a public key infrastructure (PKI) that has allocated the required computer certificate to the IAS server is being used. Additionally, the wireless access point is configured to use both an IAS server as its RADIUS server and EAP. For more information about wireless access deployment, see Checklist: Configuring the IAS server and wireless access points for wireless access.

- You can configure wireless connection policy so that wireless clients periodically reauthenticate. This ensures that the client Wired Equivalent Privacy (WEP) encryption keys are changed often enough to provide adequate security for the wireless connection. To configure reauthentication, set the session timeout in your remote access policy or connection request policy for wireless connections (using the Session-Timeout attribute) to the required interval (for example, 10 minutes). Additionally, configure the Termination-Action attribute with the **Attribute value** set to **RADIUS-Request**. If the Termination-Action attribute is not set to **RADIUS-Request**, wireless access points might end the connection during reauthentication. For more information, see your hardware documentation.

# Wireless access with secure password authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Wireless access with secure password authentication**
In this example, the network administrator is managing authorization by using groups. All user accounts have the **Remote Access Permission (Dial-in or VPN)** option set to **Control access through Remote Access Policy**.

The network administrator requires that all IEEE 802.11 wireless clients (members of the *WirelessClientsGroupName*) use Protected Extensible Authentication Protocol, or PEAP, for secure password authentication on the network. PEAP uses Transport Level Security (TLS) to create an end-to-end (EAP client to EAP authenticator) encrypted connection after verifying the identity of the authenticator (typically, an IAS server). The IAS server authenticates itself to the client with a certificate that includes the Server Authentication purpose in Enhanced Key Usage (EKU) extensions.

Because PEAP is used with EAP-MS-CHAPv2 as the authentication type, user authentication is accomplished with password-based credentials that are typed by the user. PEAP with EAP-MS-CHAPv2, also called PEAP-EAP-MS-CHAPv2, eliminates the need to deploy certificates to wireless clients for the purpose of client computer and user authentication.

For more information, see Network access authentication and certificates.

**Note**

- You can also use PEAP with EAP-TLS (also known as PEAP-EAP-TLS), which provides strong security. PEAP-EAP-TLS uses a public key infrastructure with certificates, which are used for server authentication, and either smart cards or certificates for client computer and user authentication. When you use PEAP-EAP-TLS, client certificate information is encrypted, providing improved security over EAP-TLS without PEAP.

After remote access permission is set for all user accounts, the administrator completes the following steps:

1. Use the New Remote Access Policy Wizard to create a common wireless policy with the following settings:

   - Policy name: Wireless access
   - Access Method: Wireless access
   - User or Group: Select **Group**, and then specify the WirelessClients group (example).
   - Authentication methods: Select **Protected Extensible Authentication Protocol (PEAP)**.
   - Policy Encryption Level: Check the **Strongest encryption (MPPE 128-bit)** check box, and then clear all other check boxes.

2. Delete the default policies.

   For more information, see Delete a remote access policy.

When you select PEAP as the authentication method, the default authentication type is EAP-MS-CHAPv2. The following defaults are used:

- **Number of authentication retries:** 0
- **Allow client to change password** (not selected)

To change these settings, complete the steps in Configure PEAP and EAP methods.

**Notes**

- Although the deployment of certificates for user and client computer authentication is more difficult than using PEAP with EAP-MS-CHAPv2, certificates are more secure and PEAP with EAP-TLS with smart cards or certificates is the recommended authentication method for wireless clients.

- You can configure wireless connection policy so that wireless clients periodically reauthenticate. This ensures that the client Wired Equivalent Privacy (WEP) encryption keys are changed often enough to provide adequate security for the wireless connection. To configure reauthentication, set the session timeout in your remote access policy or connection request policy for wireless connections (using the Session-Timeout attribute) to the required interval (for example, 10 minutes). Additionally, configure the Termination-Action attribute with the **Attribute value** set to **RADIUS-Request**. If the Termination-Action attribute is not set to **RADIUS-Request**, wireless access points might end the connection during reauthentication. For more information, see your hardware documentation.

# Ethernet switch access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Ethernet switch access example**

In this example, the network administrator is managing authorization by using groups. All computer accounts have the **Remote Access Permission (Dial-in or VPN)** option set to **Control access through Remote Access Policy**.

The network administrator wants all Ethernet switch clients (members of the SwitchClients group) to use password-based authentication through the Extensible Authentication Protocol (EAP) and the Message Digest 5 (MD5) Challenge EAP type. After remote access permission is set for all computer accounts, the administrator completes the following steps:

1. Use the New Remote Access Policy Wizard to create a common dial-up policy with the following settings:

   - Policy name: Ethernet access for switch clients
   - Access Method: Ethernet
   - User or Group: Select **Group**, and then specify the SwitchClients group (example).
   - Authentication methods: Select the **MD5-Challenge** EAP type.

     For more information, see Add a remote access policy.

2. Delete the default policies.

   For more information, see Delete a remote access policy.

**Note**

- This example assumes that the Ethernet switch has been configured to use both EAP and an IAS server as its RADIUS server. For more information about Ethernet switch deployment, see Ethernet switch access with IAS

# Force VPN clients to use strongest encryption

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Force VPN clients to use strongest encryption**
In this example, the network administrator is managing authorization by using groups. All user accounts have the **Remote Access Permission (Dial-in or VPN)** option set to **Control access through Remote Access Policy**.

The network administrator wants all virtual private network (VPN) clients (members of the group VPNClients) to use strong encryption. For PPTP connections, 128-bit Microsoft Point-to-Point Encryption (MPPE) must be used. For L2TP over IPSec connections, Triple DES (3DES)must be used. After remote access permission is set for all user accounts, the administrator completes the following steps:

1. Use the New Remote Access Policy Wizard to create a common VPN policy with the following settings:

   - Policy name: VPN access with strongest encryption
   - Access Method: VPN access
   - User or Group: Select **Group**, and then specify the VPNClients group (example).
   - Authentication methods: Select **Microsoft Encrypted Authentication version 2 (MS-CHAP v2)** and **Microsoft Encrypted Authentication**.
   - Policy Encryption Level: Select the **Strongest encryption (IPSec triple DES or MPPE 128-bit)** check box, and then clear all other check boxes.

     For more information, see Add a remote access policy.

2. Delete the default policies.

   For more information, see Delete a remote access policy.

# Apply packet filters for business partner extranet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Apply packet filters for business partner extranet**
In this example, the network administrator is managing authorization by using groups. All user accounts have the **Remote Access Permission (Dial-in or VPN)** option set to **Control access through Remote Access Policy**.

The network administrator wants to restrict access for all business partner virtual private network (VPN) connections to the resources of an extranet--a specific network segment that contains Web and file servers. In this example, the extranet is the subnet of 192.168.47.0/24. All business partner user accounts are members of the Partners group.

After remote access permission is set for all user accounts, the administrator completes the following steps.

**Use the New Remote Access Policy Wizard to create a custom policy with the following settings:**

- Policy name: Business partner connections to extranet
- Conditions: Windows-Groups matches Partners
- Permission: Grant remote access permission
- Profile settings, **Dial-in Constraints** tab: Select **Allow access only through these media** and the **Virtual (VPN)** media type.
- Profile settings, **IP** tab, Input packet filter:
    - Deny all traffic except those listed below
    - Destination network, IP address: 192.168.47.0
    - Destination network, Subnet mask: 255.255.255.0
    - Protocol: Any
- Profile settings, **IP** tab, Output packet filter:
    - Deny all traffic except those listed below
    - Source network, IP address: 192.168.47.0
    - Source network, Subnet mask: 255.255.255.0
    - Protocol: Any
- Profile settings, **Authentication** tab: Select both **Microsoft Encrypted Authentication version 2 (MS-CHAP v2)** and **Microsoft Encrypted Authentication**. For both of these authentication types, select **User can change password after it has expired**.
- Clear all other check boxes.
- Profile settings, **Encryption** tab: Select the **Strongest encryption** check box, and then clear all other check boxes

  For more information, see Add a remote access policy.

**Delete the default policies.**

For more information, see Delete a remote access policy.

# Send NAS-specific RADIUS attributes to a RADIUS client

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Send NAS-specific RADIUS attributes to a RADIUS client**
In this example, the network administrator is managing authorization by using groups. All user accounts have the **Remote Access Permission (Dial-in or VPN)** option set to **Control access through Remote Access Policy**.

The network administrator wants to allow dial-up connections for only those user accounts in the DialUpUsers group and send a series of network access server (NAS) attributes that are specific to the Ascend NAS. After remote access permission is set for all user accounts, the administrator completes the following steps:

1. When the NAS is added as a RADIUS client, configure its manufacturer.

   For more information about configuring a RADIUS client for an IAS server, see Add RADIUS clients.

2. Use the New Remote Access Policy Wizard to create a custom policy with the following settings:

   - Policy name: Allow dial-up connections and send attributes to Ascend NAS
   - Conditions: Client-Vendor matches Ascend Communications, Inc.; NAS-Port-Type matches Async (Modem) ; Windows-Groups matches DialUpUsers
   - Permission: Grant remote access permission
   - Profile settings, **Advanced** tab: Add the appropriate Ascend RADIUS attributes with their correct values.

   For more information, see Add a remote access policy.

3. Delete the default policies.

   For more information, see Delete a remote access policy.

# Multilink and BAP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multilink and BAP**

A server running Routing and Remote Access supports Multilink and the Bandwidth Allocation Protocol (BAP). With Multilink, multiple physical links appear as a single logical link over which data is sent and received. A good example is the aggregation of both B channels of an ISDN Basic Rate Interface (BRI) connection. Multilink is the recommended method of combining multiple B channels of a BRI connection because the support for bonding, the combining of ISDN B channels through hardware support, is specific to the ISDN adapter. You can use Multilink for any ISDN adapter. Multilink must be supported on both sides of the connection.

While Multilink allows for multiple physical links to be aggregated, Multilink does not provide a mechanism to adapt to changing bandwidth conditions by adding extra links when needed or terminating extra links when unneeded. This additional capability is provided by the Bandwidth Allocation Protocol (BAP).

For example, a Multilink and BAP-enabled remote access client and remote access server create a Multilink connection that consists of a single physical link. As the utilization of the single link rises to a configured level, the remote access client uses a BAP request message to request an additional link. The BAP request message specifies the type of link desired, such as analog phone, ISDN, or X.25. The remote access server then sends a BAP response message that contains the phone number of an available port on the remote access server of the same type as specified by the remote access client in the BAP request.

**Enabling Multilink and BAP**

To enable Multilink and BAP, you must do the following:

1. Enable dynamic bandwidth control on the remote access server by using Routing and Remote Access. For more information, see Enable BAP and BACP. Multilink and BAP are enabled by default.

2. Enable Multilink on the appropriate remote access policy. For more information, see Configure multilink options. By default, the policy profile is configured to use the settings of the remote access server.

3. Configure Multilink and BAP behavior on the remote access client. For more information, see Configuring multiple device dialing.

To set the phone number on a port that is sent back to a BAP-enabled client, see Set the phone number on a port.

### Note

- When Multilink and BAP are used in combination with the callback feature set to always call back to the same number, a concentrator must exist on the caller side that can distribute incoming calls to the same number on various ports.

# Logging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Logging**

A server running Routing and Remote Access supports three types of logging:

1. Event logging

   Event logging is the recording of events in the system event log. Event logging is typically used for troubleshooting or for notifying network administrators of unusual events. For more information, see Remote Access Troubleshooting tools.

2. Local authentication and accounting logging

   A server running Routing and Remote Access supports the logging of authentication and accounting information for remote access connections in local logging files when Windows Authentication or Windows Accounting is enabled. This logging is separate from the events recorded in the system event log. You can use the information that is logged to track remote access usage and authentication attempts. Authentication and accounting logging is especially useful for troubleshooting remote access policy issues. For each authentication attempt, the name of the remote access policy that either accepted or rejected the connection attempt is recorded.

   The authentication and accounting information is stored in a configurable log file or files stored in the *systemroot*\System32\LogFiles folder. The log files are saved in Internet Authentication Service (IAS) or database-compatible format, meaning that any database program can read the log file directly for analysis.

   To configure authentication and accounting logging, you must first enable either Windows Authentication or Windows Accounting. For more information, see Use Windows Accounting. Then, you can configure the type of activity to log (accounting or authentication activity) and log file settings such as log file format. For more information, see Configure logging.

   For information about the database-compatible format of the log file, see Interpreting database-import log files.

   For information about the IAS format of the log file, see IAS-Formatted Log Files.

3. RADIUS-based authentication and accounting logging

   A server running Routing and Remote Access supports the logging of authentication and accounting information for remote access connections at a Remote Authentication Dial-In User Service (RADIUS) server when RADIUS authentication and accounting are enabled. This logging is separate from the events recorded in the system event log. You can use the information that is logged on your RADIUS server to track remote access usage and authentication attempts. For more information, see Use RADIUS authentication and Use RADIUS accounting.

   If your RADIUS server is running IAS, then authentication and accounting information is logged in log files stored on the IAS server. For more information, see Logging user authentication and accounting requests.

You can also use the Netsh command-line utility available in the Windows Server 2003 family to collect detailed logs and information about a remote access connection. For instance, you can use the **netsh ras set tracing** command to enable or disable tracing for a specific component. For more information, see Netsh commands for remote access (ras).

# The remote access server and network management

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The remote access server and network management**

A server running Routing and Remote Access can participate in a Simple Network Management Protocol (SNMP) environment as an SNMP agent. For this configuration, you need to install the SNMP service. For more information, see Install the SNMP service.

The remote access server records management information in various object identifiers of the Internet MIB II that is installed with the SNMP service. Objects in the Internet MIB II are documented in RFC 1213, "Management Information Base for Network Management of TCP/IP-based internets: MIB-II."

For more information about the SNMP service, see SNMP.

# Broadcast name resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Broadcast name resolution**
If you enable broadcast name resolution on a server running Routing and Remote Access, a remote access client can resolve full computer names and NetBIOS names of computers and other resources on a remote network that does not have either a DNS or a WINS server configured. This feature requires no configuration of the remote access clients, and it is enabled by default on the remote access server.

When broadcast name resolution is enabled, the remote access server uses a NetBIOS over TCP/IP (NetBT) proxy to resolve names as follows:

1. A remote access client that must resolve a name to an IP address broadcasts a NetBIOS Name Query packet across all interfaces.

2. The remote access server receives the NetBIOS Name Query packet and checks its cache for the appropriate mapping of name to IP address.

   - If the remote access server has the appropriate mapping, it sends a NetBIOS Name Query Response packet to the remote access client.

   - If the remote access server does not have the appropriate mapping, it broadcasts the NetBIOS Name Query packet on all its LAN interfaces. The resource whose name is being resolved sends a NetBIOS Name Query Response packet to the remote access client.

   After the remote access server routes the NetBIOS Name Query Response packet from the resource to the remote access client, the mappings remain in the cache of the server for a limited period of time. The default period of time is 10 minutes.

3. After this point, the remote access client uses the IP address of the resource to send packets to that resource.

As a result, a remote access client can resolve names of resources on a remote network as if the remote access client were on the same LAN as the resources.

By default, broadcast name resolution allows remote access clients to resolve names on a remote network but not for resources on a LAN to resolve the names of remote access clients. Remote access servers with broadcast name resolution enabled do not, by default, broadcast NetBIOS Name Query packets to interfaces that connect to the Internet. Unless you change this behavior, a remote access client cannot resolve the name of another remote access client. If you have a network that averages 10 connections or fewer, you might want to change this behavior.

**A broadcast name resolution example**
Remote Access Client A has established a connection to the remote access server for a small business network. The remote access server has three LAN interfaces (LAN1, LAN2, and LAN3) and an external interface. One of the resources on the small business network is Network Printer B, which is accessed through LAN3. Remote Access Client A has the NetBIOS name but not the IP address of Network Printer B. Remote Access Client A broadcasts a NetBIOS Name Query packet for Network Printer B. The remote access server broadcasts the NetBIOS Name Query packet to LAN1, LAN2, and LAN3 but not to the external interface. Network Printer B responds with a NetBIOS Name Query Response packet that is addressed to Remote Access Client A. The remote access server routes the NetBIOS Name Query Response packet to Remote Access Client A.

# Using Remote Access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using remote access**
This section covers:

- Installing the remote access server
- Managing remote access from the command line
- Installing Dial-Up Equipment
- Deploying Remote Access
- Remote Access Scenarios

# Installing the remote access server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing the remote access server**
To enable and configure the remote access server, you must be logged on as a member of the Administrators group.

**Hardware requirements**
Before you install the Routing and Remote Access service, all hardware should be installed and working. Depending on your network and your requirements, you might need the following hardware:

- Network adapter with a WHQL signed driver
- One or more compatible modems and an available COM port
- Multiport adapter for acceptable performance with multiple remote connections
- X.25 smart card (if you are using an X.25 network)
- ISDN adapter (if you are using an ISDN line)

To verify the compatibility of all hardware in a computer running Routing and Remote Access, see Support resources.

**Installing the software**
When you install a member of the Windows Server 2003 family, the remote access component is automatically installed. However, the Routing and Remote Access service is installed in a disabled state.

For more information, see Enable the Routing and Remote Access service.

# Managing remote access from the command line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing remote access from the command line**

In addition to using the Routing and Remote Access snap-in, you can use command-line utilities to manage and troubleshoot remote access for users, computers, or services. For example, you can use Tracert to check the path to a remote access client and record the results. Used for diagnostic purposes only, Ping verifies IP-level connectivity to another TCP/IP computer. You can use Netsh overview to perform more advanced management tasks, such as server configuration and scripting.

For information about other command-line utilities, see Command-line reference A-Z. For more information about managing remote access with Netsh, see Netsh commands for remote access.

# Installing Dial-Up Equipment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing dial-up equipment**

This section provides information about the types of dial-up and remote access equipment used by the remote access server:

- Modems
- ISDN
- X.25
- ATM

# Modems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Modems**
Modems are the most commonly used dial-up equipment and offer up to 56,000 bps over an analog phone line. To ensure that your modems work with the Windows Server 2003 family, see Support resources. Microsoft has tested and verified the modems on this list with a server running Routing and Remote Access.

Modems from different manufacturers, and even different models from one manufacturer, may be incompatible in some settings and circumstances. Even modems that claim to follow the Hayes AT command set may, at times, be unable to communicate with other Hayes-compatible modems.

For general information about modems, see Installing and configuring Modems.

For information about troubleshooting modems, see Troubleshooting modems.

**Connecting without a modem**
You can connect two computers without a modem through a direct serial, direct parallel, or infrared connection. Although a direct connection eliminates the need for a network adapter, it is a slow link.

For more information, see:

- Using direct connections
- Establishing infrared network connections between computers

**Modem-pooling equipment**
The Windows Server 2003 family works with a variety of modem-pooling equipment.

For more information, see Configure modem-pooling equipment.

# ISDN

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ISDN**

Integrated Services Digital Network (ISDN) offers a much faster communication speed than an analog telephone line. The analog telephone line can communicate at speeds up to 56 kilobits per second (Kbps), whereas ISDN communicates at speeds of 64 or 128 Kbps. Businesses that need this kind of speed usually have a large telecommuting workforce or need to do extensive administrative tasks remotely, such as install software on off-site workstations.

**Installing an ISDN adapter**

A primary rate interface (PRI) ISDN line comes with two B channels and one D channel. Each B channel transmits data at 64 Kbps. The D channel is for signaling and transmits data at 16 Kbps.

You need to install ISDN adapters on the server and on each client. Then you can configure each B channel to act as a port, or you can configure all B channels to act as a single port. For instructions on installing an ISDN adapter, see the adapter's documentation. If you cannot configure all of the B channels on your ISDN adapter to act as a single port, then use Multilink to aggregate the multiple B channels into a single logical port.

If your business has a large number of people calling in to the remote access server, you can configure each channel to operate as a separate port. This configuration allows the greatest number of people to call in.

However, if your business has few people calling in, but needs more data-transmission speed, you can configure both channels to act as a single port. With this configuration, line speed increases to 128 Kbps. If you have installed more than one adapter, you can combine the channels on each adapter and get even faster transmission speed.

For information about installing an ISDN adapter, see To install an Install an ISDN adapter.

# X.25

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**X.25**

X.25 is a packet-switching technology that transmits data reliably across a packet-switching network. You can reach the X.25 network through a direct connection or through an asynchronous connection that dials in to a packet assembler/disassembler (PAD). A server running Routing and Remote Access only supports direct connections to X.25 networks by using an X.25 smart card.

After you install and enable the Routing and Remote Access service, you can set up the remote access server for an X.25 network. For more information, see Configure an X.25 smart card.

**Notes**

- The remote access server does not support callback on X.25 networks.
- An X.25 smart card is not related to a smart card that is used for authentication.

# ATM

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ATM**

Asynchronous transfer mode (ATM) is a fixed-length, cell-based, packet-switching technology that transmits data across an ATM network. You can reach the ATM network through a direct connection such as digital subscriber line (DSL) or cable modem, or through an ATM on-demand connection. The Routing and Remote Access service supports Point-to-Point Protocol (PPP) connections over switched virtual circuit (SVC) or permanent virtual circuit (PVC) ATM connections.

PPP connections over ATM require an ATM adapter with the appropriate support for the physical connection to the ATM network. Once installed, the ATM adapter appears as a dial-up device. For more information, see Devices and ports.

For more information on ATM and ATM support in the Windows Server 2003 family, see Windows ATM Services.

# Deploying Remote Access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying remote access**
This section covers:

- Using smart cards for remote access
- Setting Up Dial-Up Remote Access
- Setting Up Remote Access VPNs
- Remote Access Authentication
- Using RADIUS

# Using smart cards for remote access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using smart cards for remote access**

The use of smart cards for user authentication is the strongest form of authentication in the Windows Server 2003 family. For remote access connections, you must use the Extensible Authentication Protocol (EAP) with the **Smart card or other certificate (TLS)** EAP type, also known as EAP-Transport Level Security (EAP-TLS). To use smart cards for remote access authentication, you must do the following:

- Configure remote access on the remote access server.
- Install a computer certificate on the remote access server computer.
- Configure the **Smart card or other certificate (TLS)** EAP type in remote access policies.
- Enable smart card authentication on the dial-up or VPN connection on the remote access client.

**Configuring the remote access server to provide remote access**

You can configure the server running Routing and Remote Access as described in Using the remote access server as a corporate remote access server for dial-in remote access or Deploying Remote Access VPNs for VPN remote access.

**Installing a computer certificate on the remote access server**

In order to configure EAP-TLS on the remote access server, you must install a computer certificate, also known as a machine certificate. To install a computer certificate on the remote access server, a certification authority must be present to issue certificates. Once the certification authority is configured, you can install a certificate on the remote access server in two different ways:

1. By configuring the automatic allocation of computer certificates to computers in a domain.
2. By using Certificate Manager to obtain a computer certificate.

Based on the certificate policies in your organization, you only need to perform one of these two allocations.

To configure a certification authority and install the computer certificate, perform the following steps:

1. Install the Certificate Services component as an enterprise root certification authority. This step is only necessary if you do not already have an enterprise root certification authority (CA). For more information, see Install an enterprise root certification authority.
2. Do one of the following:
   - For auto-enrollment of computer certificates, configure the domain. For more information, see Configure automatic certificate allocation from an enterprise CA.

     To create a computer certificate for the remote access server computer that is a member of the domain for which auto-enrollment is configured (as well as other computers that are members of the domain), restart the remote access server or type **secedit /refreshpolicy machine_policy** from the command prompt.
   - To manually enroll computer certificates, use Certificate Manager to install the CA root certificate. For more information, see Manage certificates for a computer and Request a certificate.

**Important**

- EAP-TLS authentication requires that the remote access client computer certificate is configured with the Client

Authentication purpose and the remote access server computer certificate is configured with the Server Authentication purpose. A certificate purpose is identified using an object identifier (also known as OID). EAP-TLS checks the EKU extension for the client computer certificate to determine whether the Client Authentication purpose is present. When the EKU extension includes the Client Authentication purpose, EAP-TLS can use the certificate for authentication. For more information, see Network access authentication and certificates.

**Enabling a smart card logon process for the domain**

To enable a smart card logon process for the domain, you can perform the following procedures:

1. Prepare a certification authority to issue smart card certificates

2. Prepare a smart card certificate enrollment station

**Configuring the remote access server for smart card remote access**

To configure the server running Routing and Remote Access for smart card remote access, see Configure smart card remote access.

**Configuring the remote access client for smart card remote access**

You need to install a smart card reader on the remote access client computer. For more information, see Install a smart card reader on a computer.

Once a smart card reader is installed on the computer, you are prompted whether you want to use the smart card for authentication when you create dial-up or VPN connections.

For existing dial-up or VPN connections, you can enable smart card authentication on the properties of the dial-up or VPN connection. For more information, see Enable smart card or other certificate authentication.

# Setting Up Dial-Up Remote Access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up dial-up remote access**

This section covers:

- Dial-up remote access design considerations
- Dial-up remote access security
- Deploying Dial-Up Remote Access

# Dial-up remote access design considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dial-up remote access design considerations**
To prevent problems, you should consider the following design issues before you implement dial-up remote access connections.

**IP address allocation**
Determine whether the remote access server will use DHCP or a static IP address pool to obtain addresses for dial-up clients. If you use a static IP address pool, determine whether the pool will be ranges of addresses that are a subset of addresses from the IP network to which the server is attached or a separate subnet. If the static IP address pool address ranges represent a different subnet, ensure that routes to the address ranges exist in the routers of your intranet so that traffic to connected remote access clients is forwarded to the remote access server.

**Number of incoming ports needed**
Determine the maximum number of dial-up remote access clients that dial in at one time. Based on the number, you need to obtain modem bank equipment and phone lines that meet that need. Once the driver for the modem bank adapter is installed, verify that all of the ports of the modem bank device are configured to allow remote access. For more information, see Configure ports for remote access.

**Deciding on a remote access policy administrative model**
Before setting the dial-in permission on user accounts and creating remote access policies, you need to decide on a remote access policy administrative model. In the Windows Server 2003 family, there are two primary models for administering remote access permissions and connection settings:

1. Access by user.

2. Access by policy in an Active Directory domain.

Controlling access by policy centralizes many basic administrative tasks. For more information, see Introduction to remote access policies and Remote Access Policies Examples.

**Creating a remote access policy for dial-up remote access connections**
By using remote access policies, you can create a policy that requires dial-up connections to use a specific authentication method and encryption strength.

For example, you can create a group called Dial-up Users whose members are the user accounts of the users who are creating dial-up remote access connections. Then, you create a policy with two conditions on the policy: the **NAS-Port-Type** is set to all types except **Virtual (VPN)** and the **Windows-Groups** is set to *Dial-up Users* (the name of the group you created). Finally, you configure the profile for the policy to select a specific authentication method and encryption strength.

For more information, see Introduction to remote access policies.

**Using an IAS server for centralized authentication, authorization, and accounting**
If you have multiple remote access servers, you need to configure remote access policies and logging for each remote access server. If you want to take advantage of centralized remote access policies, accounting, and logging, configure the remote access servers as Remote Authentication Dial-In User Service (RADIUS) clients to a single server running the Internet Authentication Service (IAS) as a RADIUS server.

You should also use an IAS server if you have servers running Windows NT 4.0 and the Routing and Remote Access Service (RRAS) and you want to take advantage of remote access policies. You cannot configure remote access servers running Windows NT 4.0 as RADIUS clients. You must upgrade a remote access server running Windows NT 4.0 to a server running Windows NT 4.0 and RRAS.

For more information, see Using RADIUS for multiple remote access servers.

**Using Connection Manager**
For a large remote access deployment, you can use Connection Manager and the Connection Manager Administration Kit to provide a custom dialer with preconfigured connections to all remote access clients across your organization.

For more information about Connection Manager, see Connection Manager Administration Kit.

# Dial-up remote access security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dial-up remote access security**
You can enhance dial-up remote access security through:

- Strong authentication
- Data encryption

**Strong authentication**
For authentication, use the strongest authentication scheme that is possible for your dial-up remote access configuration. The strongest authentication is the use of EAP-TLS with smart cards. For more information, see Using smart cards for remote access.

Otherwise, use MS-CHAP v2 authentication and enforce the use of strong passwords on your network. For more information, see MS-CHAP version 2.

**Data encryption**
For encryption, you can use either link encryption or end-to-end encryption:

- Link encryption encrypts the data only on the link between the remote access client and the remote access server, or the two servers running Routing and Remote Access. For dial-up remote access connections, you must use Microsoft Point-to-Point Encryption (MPPE) in conjunction with either MS-CHAP or EAP-TLS authentication.
- End-to-end encryption encrypts the data between the source host and its final destination. You can use IPSec to encrypt data from the remote access client to the destination host after the remote access connection is made.

To require encryption, clear the **No Encryption** option and select the appropriate encryption strengths on the **Encryption** tab of the remote access policy profile that is used by your dial-up remote access clients. For more information, see Configure encryption.

# Deploying Dial-Up Remote Access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying dial-up remote access**

This section covers:

- Using the remote access server as a corporate remote access server
- Using the remote access server for Internet access

# Using the remote access server as a corporate remote access server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using the remote access server as a corporate remote access server**

You can use a server running Routing and Remote Access to provide dial-up access to your corporate intranet. If you want the remote access server to support multiple, dial-up networking TCP/IP-based connections, complete the following steps:

- Configure the connection to the intranet.
- Configure the connection to the dial-up networking clients.
- Configure the dial-in ports.
- Configure the remote access server.
- Configure multicast support.
- Configure remote access policies.

The following illustration shows the elements of a server running Routing and Remote Access that provides dial-up access to a corporate intranet.

**Configuring the connection to the intranet**

The connection to the intranet from Routing and Remote Access is a LAN adapter installed in the computer. To verify that the LAN adapter is compatible with Windows, see Support resources.

You need to configure the following TCP/IP settings on the LAN adapter:

- IP address and subnet mask assigned from the network administrator.
- Default gateway of a local router.
- IP address of DNS and WINS servers of corporate intranet servers.

**Configuring the connection to dial-up networking clients**

To allow the connection of multiple, simultaneous dial-up clients, you must have modem pooling equipment (hereafter known as the modem bank) with the appropriate connections to the local telecommunications provider.

Remote access hardware devices include an adapter that installs on the server running Routing and Remote Access. To verify that the hardware is compatible with Windows, see Support resources.

The modem bank adapter includes drivers that are installed on the server running Routing and Remote Access so that the modem bank appears as a device with multiple modem ports.

**Configuring the dial-in ports**

All the modem bank ports are listed as separate ports under **Ports** in Routing and Remote Access. You should configure all the modem bank ports for remote access.

For more information about configuring ports for remote access, see Configure ports for remote access.

**Configuring the remote access server**

You can configure the properties of the remote access server in Routing and Remote Access. For more information, see View properties of the remote access server.

To allow multiple dial-up networking clients to access the corporate intranet, you need to configure the following settings:

- **General**

  Verify that the **Remote access server** check box is selected.

- **Security**

  - **Authentication Methods**

    The server is configured by default to accept certain authentication methods. You can control which authentication methods you accept through remote access policies, except for CHAP.

  - **Authentication Provider**

    You can verify the credentials of dial-up networking clients by using Windows Authentication or a RADIUS server. If RADIUS is selected, you need to configure RADIUS server settings for your RADIUS server or RADIUS proxy.

  - **Accounting Provider**

    You can record dial-up client networking activity for analysis or accounting purposes by selecting and configuring an accounting provider.

- **IP**

  Verify that the **Enable IP routing** and **Allow IP-based remote access and demand-dial connections** check boxes are selected.

  If you are using a DHCP server to allocate IP addresses for remote access clients, click **Dynamic Host Configuration Protocol (DHCP)**. If not, click **Static address pool** and configure the ranges of IP addresses that are dynamically allocated to dial-up networking clients.

  If the static IP address pool consists of ranges of IP addresses that are for a separate subnet, then you need to either enable an IP routing protocol on the remote access server computer or add static IP routes for each range to all the routers on the other intranet. If the routes are not added, then remote access clients cannot receive traffic from resources on the intranet.

  For more information about configuring IP address pools, see Create a static IP address pool.

**Configuring multicast support**

Depending on the options selected when the Routing and Remote Access Server Setup Wizard was run, multicast support may already be enabled. To configure multicast support, you need to complete the following steps:

1. Add the IGMP Router and Proxy routing protocol. For more information, see Add the IGMP routing protocol.

2. Add the **Internal** interface to the IGMP routing protocol and configure it in IGMP router mode. For more information, see Enable IGMP router and IGMP proxy mode.

3. Add the interface that represents the permanent connection to the intranet to the IGMP routing protocol and configure the interface in IGMP proxy mode. For more information, see Enable IGMP router and IGMP proxy mode.

**Configuring remote access policies**

If you want to authorize remote access to the dial-up networking clients based on the access-by-user administrative model, do the following:

1. For a stand-alone remote access server, use Local Users and Groups and set dial-in properties to **Allow access** for those users who will be making remote access connections.

2. For a remote access server in an Active Directory domain, use Active Directory Users and Computers and set dial-in properties to **Allow access** for those users who will be making remote access connections.

If you want to grant remote access to the dial-up networking clients based on group membership and an access-by-policy administrative model, do the following:

1. For a stand-alone remote access server, use Local Users and Groups and set dial-in properties to **Control access through Remote Access Policy** for all users.

2. Do one of the following:

   - For a remote access server that is a member of a Windows 2000 mixed domain, use Active Directory Users and Computers and set dial-in properties to **Allow access** for all users.

   - For a remote access server that is a member of a Windows 2000 native or Windows Server 2003 domain, use Active Directory Users and Computers and set dial-in properties to **Control access through Remote Access Policy** for all users.

3. Create a group whose members will be able to create dial-up networking connections with the remote access server. For example, create a group named Remote_Users.

4. Add the appropriate user accounts to the new group.

5. Delete the default remote access policies.

6. Create a new remote access policy with the following properties:

   - Set **Policy name** to **Remote Access if member of RAS_Users** (example).

   - Set the **Windows-Groups** attribute to **RAS_Users** (example).

   - Select the **Grant remote access permission** option.

For more information, see Remote Access Policies Examples.

For encryption, the default setting allows Microsoft Point-to-Point Encryption (MPPE) when requested by the remote access client. To force encryption for dial-up networking connections, you need to modify the encryption settings on the policy profile to require encryption. For dial-up networking connections, clear the **No encryption** option and select the following options on the **Encryption** tab on the properties of the remote access policy profile:

- **Basic**

  You should use this option when communicating with Microsoft dial-up networking clients who are using lower encryption. This option uses Microsoft Point-to-Point Encryption (MPPE) and a 40-bit encryption key.

- **Strong**

  You should use this option when communicating with Windows Server 2003 family, Windows XP, Windows 2000, Windows Millennium Edition, and Windows 98 dial-up networking clients who are using moderate encryption. This option uses MPPE and a 56-bit encryption key.

- **Strongest**

You should use this option when communicating with dial-up networking clients who are using the highest level of encryption. This option uses MPPE and a 128-bit encryption key.

For more information, see Configure encryption.

# Using the remote access server for Internet access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using the remote access server for Internet access**

You can use a server running Routing and Remote Access to provide both access to the Internet and traditional dial-up Internet service provider (ISP) services. If you want the remote access server to support multiple dial-up TCP/IP-based connections, complete the following steps:

- Configure the connection to the Internet.
- Configure the connection to the dial-up clients.
- Configure the dial-in ports.
- Configure the remote access server.
- Configure multicast support.
- Configure remote access policies.

The following illustration shows the elements of an ISP based on the Windows Server 2003 family.

**Configuring the connection to the Internet**

The connection to the Internet from Routing and Remote Access is a dedicated connection--a WAN adapter installed in the computer. The WAN adapter is typically a DDS, T1, Fractional T1, or Frame Relay adapter. As the ISP, you must contract with a local telephone company to run the appropriate physical wiring to your premises. You need to verify that the WAN adapter is compatible with Windows. (See Support resources.)

The WAN adapter includes drivers that are installed on the server running Routing and Remote Access so that the WAN adapter appears as a network adapter.

You need to configure the following TCP/IP settings on the WAN adapter:

- IP address and subnet mask assigned from the Internet Assigned Numbers Authority (IANA) or a downstream ISP.
- Default gateway of the downstream ISP or network access point (NAP) router.

**Configuring the connection to the dial-up clients**

To allow the connection of multiple, simultaneous dial-up clients, you must have modem pooling equipment (hereafter known as the modem bank) with the appropriate connections to the local telecommunications provider.

Typical modem banks include an adapter that installs on the server running Routing and Remote Access. You need to verify that the modem bank adapter is compatible with Windows. (See Support resources.)

The modem bank adapter includes drivers that are installed on the server running Routing and Remote Access so that the modem bank appears as a series of modem ports.

**Configuring the remote access server**

You can configure the properties of the remote access server in Routing and Remote Access. For more information, see View properties of the remote access server.

You can configure the remote access server to allow multiple dial-up clients access to the Internet during the Routing and Remote Access Server Setup wizard. If you did not configure this during setup, you need to manually configure the following settings:

- **General**

  Verify that the **Remote access server** check box is selected.

- **Security**

  - **Authentication Methods**

    Select the authentication methods that are supported by the remote access server to authenticate the credentials of dial-up clients. Microsoft dial-up networking clients typically use MS-CHAP authentication. Other dial-up networking clients might use CHAP, SPAP, and PAP authentication.

  - **Authentication Provider**

    You can verify the credentials of dial-up clients by using Windows Server 2003 family security features or a RADIUS server. If RADIUS is selected, you need to configure RADIUS server settings for your RADIUS server or RADIUS proxy.

  - **Accounting Provider**

    You can record dial-up client activity for analysis or accounting purposes by selecting and configuring an accounting provider.

- **IP**

  Verify that the **Enable IP routing** and **Allow IP-based remote access and demand-dial connections** check boxes are selected.

  Click **Static address pool** and configure the ranges of IP addresses that are dynamically allocated to dial-up networking clients. Or, if a DHCP server is available, click **Dynamic Host Allocation Protocol (DHCP)**.

  For more information about configuring IP address pools, see Create a static IP address pool.

**Configuring multicast support**

Depending on the options selected when the Routing and Remote Access Server Setup Wizard was run, multicast support might already be enabled. To configure multicast support manually, you need to complete the following steps:

1. Add the IGMP Router and Proxy routing protocol. For more information, see Add the IGMP routing protocol.

2. Add the **Internal** interface to the IGMP routing protocol and configure it in IGMP router mode. For more information, see Enable IGMP router and IGMP proxy mode.

3. Add the interface that represents the permanent connection to the Internet to the IGMP routing protocol and configure the interface in IGMP proxy mode. For more information, see Enable IGMP router and IGMP proxy mode.

**Configuring remote access policies**

If you want to authorize remote access to the dial-up networking clients by user, do the following:

1. For a stand-alone remote access server, use Local Users and Groups and set dial-in properties to **Allow access** for those users who will be making remote access connections.

2. For a remote access server in an Active Directory domain, use Active Directory Users and Computers and set dial-in properties to **Allow access** for those users who will be making remote access connections.

If you want to grant remote access to the dial-up networking clients based on group membership and an access-by-policy administrative model, do the following:

1. For a stand-alone remote access server, use Local Users and Groups and set dial-in properties to **Control access through Remote Access Policy** for all users.

2. Do one of the following:

    - For a remote access server that is a member of a Windows 2000 mixed domain, use Active Directory Users and Computers and set dial-in properties to **Allow access** for all users.

    - For a remote access server that is a member of a Windows 2000 native or Windows Server 2003 domain, use Active Directory Users and Computers and set dial-in properties to **Control access through Remote Access Policy** for all users.

3. Create a user group whose members will be able to create dial-up networking connections with the remote access server. For example, create a group named Clients.

4. Add the appropriate user accounts to the new group.

5. Delete the default remote access policies.

6. Create a new remote access policy with the following properties:

    - Set **Policy name** to **Remote Access if member of Clients** (example).

    - Set the: **Windows-Groups** attribute to **Clients** (example).

    - Select the **Grant remote access permission** option.

# Setting Up Remote Access VPNs

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up remote access VPNs**

This section covers:

- Remote access VPN design considerations
- Remote access VPN security considerations
- Deploying Remote Access VPNs

# Remote access VPN design considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access VPN design considerations**

To prevent problems, you should consider the following design issues before you implement remote access VPN connections:

- Choosing between PPTP-based connections or L2TP/IPSec connections
- Installing certificates
- Configuring firewall packet filters
- Creating a remote access policy for remote access VPN connections
- Using an IAS server
- Using Connection Manager

For more information, see Remote access VPN connection.

**Note**

- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

**Choosing between PPTP-based connections or L2TP/IPSec connections**

A VPN server running Windows Server 2003 provides support for both Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP). When choosing between PPTP-based and L2TP/IPSec remote access VPN solutions, consider the following:

- PPTP can be used with a variety of Microsoft clients including Windows 95 (with the Dial-up Networking Upgrade 1.3 and later), Windows 98, Windows Millennium Edition, Windows NT 4.0, Windows 2000, and Windows XP. PPTP does not require a public key infrastructure (PKI) to issue computer certificates. By using encryption, PPTP-based VPN connections provide data confidentiality (captured packets cannot be interpreted without the encryption key). PPTP-based VPN connections, however, do not provide data integrity (proof that the data was not modified in transit) or data origin authentication (proof that the data was sent by the authorized user).
- L2TP can only be used with client computers running Windows 2000 or Windows XP. L2TP supports either computer certificates or a preshared key as the authentication method for Internet Protocol security (IPSec). Computer certificate authentication, the recommended authentication method, requires a PKI to issue computer certificates to the VPN server computer and all VPN client computers. By using IPSec, L2TP/IPSec VPN connections provide data confidentiality, data integrity, and data authentication.

**Installing certificates**

In order to create L2TP/IPSec remote access VPN connections using computer certificate authentication for IPSec, you must install computer certificates, also known as machine certificates, on the VPN client and the VPN server. For more information, see Network access authentication and certificates and Computer certificates for L2TP/IPSec VPN connections.

**Configuring firewall packet filters**

If you have a firewall, you must configure packet filters on the firewall to allow traffic between VPN clients on the Internet and the VPN server. For more information, see VPN servers and firewall configuration.

**Creating a remote access policy for remote access VPN connections**
By using remote access policies, you can create a policy that requires remote access VPN connections to use a specific authentication method and encryption strength.

For example, you can create an Active Directory group called VPN Users whose members are the user accounts of the users creating remote access VPN connections across the Internet. Then, you create a policy with two conditions on the policy: **NAS-Port-Type** is set to **Virtual (VPN)** and **Windows-Group** is set to **VPN Users**. Finally, you configure the profile for the policy to select a specific authentication method and encryption strength.

For more information, see Introduction to remote access policies.

**Using an IAS server**
If you have multiple VPN servers running Windows Server 2003 , you need to configure remote access policies and logging for each VPN server. If you want to take advantage of centralized remote access policies and logging, you can configure the VPN servers as Remote Authentication Dial-In User Service (RADIUS) clients to a single computer (a RADIUS server) running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition; and Internet Authentication Service (IAS).

You should also use an IAS server if you have VPN servers running Windows NT 4.0 with the Routing and Remote Access Service (RRAS), and you want to take advantage of remote access policies available in products in the Windows Server 2003 family. You cannot configure VPN servers running Windows NT 4.0 as RADIUS clients. You must upgrade a VPN server running Windows NT 4.0 to a VPN server running Windows NT 4.0 and RRAS.

For more information, see Using RADIUS for multiple remote access servers.

**Using Connection Manager**
For a large remote access VPN deployment, you can use Connection Manager and the Connection Manager Administration Kit to provide a custom dialer with preconfigured VPN connections to all remote access clients across your organization.

For more information about Connection Manager, see Connection Manager Administration Kit. For information about implementing VPN support with the Connection Manager Administration Kit, see Implementing VPN support.

# Remote access VPN security considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access VPN security considerations**
You can enhance remote access VPN security through:

- L2TP connections
- Strong authentication
- Data encryption
- PPTP or L2TP/IPSec packet filtering
- Firewall packet filtering
- Multi-use VPN servers
- Preventing traffic routed from remote access clients
- Remote access policy profile packet filtering

For more information, see Remote access VPN connection.

**Note**

- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

**L2TP connections**
A VPN server running Windows Server 2003 provides support for both Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP). By using encryption, PPTP-based VPN connections provide data confidentiality (captured packets cannot be interpreted without the encryption key). PPTP-based VPN connections, however, do not provide data integrity (proof that the data was not modified in transit) or data origin authentication (proof that the data was sent by the authorized user). By using Internet Protocol Security (IPSec), L2TP/IPSec VPN connections provide data confidentiality, data integrity, and data origin authentication. However, L2TP can only be used with Windows 2000 and Windows XP clients.

L2TP/IPSec connections can use the following methods to authenticate the IPSec security association:

- A computer certificate

  Computer certificates are the recommended method of authentication as they provide strong authentication and are very difficult to impersonate or compromise. Computer certificate authentication requires a public key infrastructure (PKI) to issue computer certificates to the VPN server computer and all VPN client computers.

- A preshared key

  A preshared key is a string of text that is configured on both the VPN client and VPN server. Preshared key is a relatively weak authentication method, therefore it is only recommended that you use preshared key authentication while your PKI is being deployed or when preshared key is required by the VPN server to which your VPN clients are connecting.

**Strong user authentication**
For user authentication, use the strongest authentication scheme that is possible for your remote access VPN configuration. The strongest authentication scheme is the use of EAP-TLS with certificates. For more information, see Deploying Certificate-based Authentication for VPN Connections and Network access authentication and certificates.

Otherwise, use MS-CHAP version 2 authentication and enforce the use of strong passwords on your network. For more information, see MS-CHAP version 2.

**Data encryption**
For encryption, you can use either link encryption or end-to-end encryption with link encryption:

- Link encryption encrypts the data only on the link between the VPN client and the VPN server. For PPTP connections, you must use Microsoft Point-to-Point Encryption (MPPE) in conjunction with either MS-CHAP, MS-CHAP v2, or EAP-TLS authentication. For L2TP/IPSec connections, IPSec provides encryption on the link between the VPN client and the VPN server.

- End-to-end encryption encrypts the data between the source host and its final destination. You can use IPSec *after* the VPN connection is made to encrypt data from the source host to the destination host.

To require encryption, select the appropriate encryption strengths on the **Encryption** tab of the remote access policy profile that is used by your remote access VPN clients. For more information, see Configure encryption.

Encryption on client computers is configured in the properties of the network connection.

**PPTP or L2TP/IPSec filtering**
To secure the VPN server from sending or receiving any traffic on its Internet interface except VPN traffic, you need to ensure that PPTP or L2TP/IPSec input and output filters are configured on the interface that corresponds to the connection to the Internet. For more information about PPTP filters, see Add PPTP Filters. For more information about L2TP/IPSec filters, see Add L2TP over IPSec Filters.

Because IP routing is enabled on the Internet interface, if PPTP or L2TP/IPSec filters are not configured on the Internet interface, then any traffic received on the Internet interface is routed, which may forward unwanted Internet traffic to your intranet.

**Firewall packet filtering**
It is a common practice to provide protection to intranet hosts, such as a VPN server, from Internet hosts using a firewall. If you have a firewall, you must configure packet filters on the firewall to allow traffic to and from VPN clients on the Internet and the VPN server. For more information, see VPN servers and firewall configuration.

**Multi-use VPN servers**
Due to the way in which routes are created on VPN remote access clients, it is possible for the VPN client to send some unencrypted traffic to the VPN server rather than through the encrypted tunnel of the VPN connection. For example, the VPN client might connect to other services running on the VPN server without routing traffic across the VPN connection. Only traffic that is destined to the public IP address of the VPN server is sent in the clear. If traffic from the client uses the internal or private interface IP address of the VPN server, however, it will be encrypted.

When a remote access VPN client creates a VPN connection with a VPN server, it creates a series of routes in the IP routing table on the VPN client:

- Default route that uses the VPN connection

  The new default route for the VPN connection effectively replaces the existing default route for the duration of the connection. After the connection is made, all traffic that does not match an address on the directly connected network or the address of the VPN server is sent in an encrypted form over the VPN connection.

- Host route to the VPN server that uses the local network connection

  The host route for the address of the VPN server is created so that the VPN server is reachable using the locally attached network. If the host route is not present, VPN traffic to the VPN server cannot be sent.

The result of having the host route for the VPN server is that all traffic that is sent to applications running on the VPN server is not sent across the VPN connection, but is instead sent in an unencrypted form across the network between the VPN client and VPN server.

For example, when a remote access VPN client creates a VPN connection with a VPN server and then accesses a shared file on the VPN server computer, that traffic is not sent using the VPN connection. The file sharing traffic is sent in plaintext over the network between the VPN client and VPN server.

Additionally, if packet filters are configured on the VPN server that only allow VPN connection traffic, all other traffic sent to the VPN server is discarded. In this situation, all attempts to connect to services running on the VPN server will fail because traffic attempting to connect to those services are not sent over the VPN connection.

The key to which address is used by the VPN client to access services running on the VPN server lies in the way that the name of the VPN server is resolved. Typical users and applications refer to network resources using names, rather than IP addresses. The name must be resolved to an IP address using either DNS or WINS. If the intranet DNS and WINS infrastructures never contain a record mapping the name of the VPN server to the public IP address of the VPN server, traffic to services running on the VPN server is always sent across the VPN connection.

To prevent the VPN server from dynamically registering the public IP address of its Internet interface in the intranet DNS, obtain properties of the **Internet Protocol (TCP/IP)** component of the Internet connection in the **Network Connections** folder. Click **Advanced**. In the **Advanced TCP/IP Settings** dialog box, click the **DNS** tab, and then clear the **Register this connection's addresses in DNS** check box.

To prevent the VPN server from registering the public IP address of its Internet interface with intranet WINS servers, obtain properties of the **Internet Protocol (TCP/IP)** component of the Internet connection in the **Network Connections** folder. Click **Advanced**. In the **Advanced TCP/IP Settings** dialog box, click the **WINS** tab, and then click **Disable NetBIOS over TCP/IP**.

Before the VPN connection is made, the VPN client uses the Internet DNS infrastructure to resolve the name of the VPN server computer to its public IP addresses. After the VPN connection is made, assuming that intranet DNS and WINS servers are configured either during the PPP connection process or through the relaying of the DHCPInform message, the VPN client uses the intranet DNS and WINS infrastructures to resolve the name of the VPN server computer to its intranet IP addresses.

**Preventing traffic routed through remote access clients**

Once a remote access client successfully establishes a PPTP or L2TP connection, by default any packet sent over the connection is received by the VPN server and forwarded. Packets sent over the connection can include:

- Packets originated from the remote access client computer.
- Packets sent to the remote access client computer by other computers.

When the remote access client computer makes the VPN connection, by default it creates a default route so that all traffic that matches the default route is sent over the VPN connection. If other computers are forwarding traffic to the remote access VPN client, treating the remote access client computer as a router, then that traffic may also be forwarded across the VPN connection. This is a security problem because the computer that is sending traffic to the remote access VPN client has not been authenticated by the VPN server. The computer sending traffic to the remote access VPN client computer has physical network access to the same resources as the authenticated remote access VPN client computer.

To prevent the VPN server from sending traffic across the VPN connection for computers other than authenticated remote access VPN client computers, configure the following remote access policy packet filters on the remote access policy that is used for your VPN connections:

- From client filter:

  Filter action set to **Deny all traffic except those listed below**.

| IP Packet Filter Field | Setting |
|---|---|
| Source Address | User's address |
| Source Network Mask | User's mask |
| Destination Address | Any |
| Destination Network Mask | Any |
| Protocol | Any |

- To client filter:

  Filter action set to **Deny all traffic except those listed below**.

| IP Packet Filter Field | Setting |
|---|---|
| Source Address | Any |
| Source Network Mask | Any |
| Destination Address | User's address |
| Destination Network Mask | User's mask |
| Protocol | Any |

This set of IP packet filters will cause the VPN server to discard all traffic sent across the VPN connection except those that either originated from or is sent to authenticated remote access VPN clients.

**Remote access policy profile packet filtering**

To define the specific types of IP traffic that are allowed for remote access VPN connections, you need to configure IP packet filters on the profile for the remote access policy that is used for your remote access VPN connections. With profile packet filters, you can configure the IP traffic that is allowed from remote access clients (**From client** filters) or to remote access clients (**To client** filters) on an exception basis: either all traffic except traffic specified by filters or no traffic except traffic specified by filters. Remote access policy profile filtering applies to all remote access connections that match the remote access policy. For more information, see Elements of a remote access policy and Configure IP options.

# Deploying Remote Access VPNs

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying remote access VPNs**

This section covers:

- PPTP-based remote access VPN deployment
- L2TP-based remote access VPN deployment

# PPTP-based remote access VPN deployment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**PPTP-based remote access VPN deployment**

You can use remote access with products in the Windows Server 2003 family to provide access to a corporate intranet for remote access clients who are making PPTP connections across the Internet. If you want your remote access server to support multiple PPTP connections, complete the following steps:

- Configure the connection to the Internet.
- Configure the connection to the intranet.
- Configure the remote access server as a corporate intranet router.
- Configure the VPN server.
- Configure firewall packet filters.
- Configure remote access policies.

The following illustration shows the elements of a remote access server running Windows Server 2003 that provides PPTP-based remote access to a corporate intranet.

For more information, see Remote access VPN connection and Point-to-Point Tunneling Protocol.

**Note**

- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

**Configuring the connection to the Internet**

The connection to the Internet from a computer running a Windows Server 2003 operating system is a dedicated connection--a WAN adapter installed in the computer. The WAN adapter is typically a DDS, T1, Fractional T1, or Frame Relay adapter. You must contract with a local telephone company to run the appropriate physical wiring to your premises. You need to verify that the WAN adapter is compatible with products in the Windows Server 2003 family. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

The WAN adapter includes drivers that are installed in memobers of the Windows Server 2003 family so that the WAN adapter appears as a network adapter.

You need to configure the following TCP/IP settings on the WAN adapter:

- IP address and subnet mask assigned from the InterNIC or an Internet service provider (ISP).
- Default gateway of the ISP router.

So that VPN clients can connect to your VPN server by name (rather than IP address), you can request DNS registration of your VPN server by your ISP.

**Configuring the connection to the intranet**
The connection to the intranet from a computer running a Windows Server 2003 operating system is a LAN adapter that is installed in the computer. You need to verify that the LAN adapter is compatible with products in the Windows Server 2003 family. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

You need to configure the following TCP/IP settings on the LAN adapter:

- IP address and subnet mask assigned from the network administrator.
- DNS and WINS name servers of corporate intranet name servers.

**Configuring the remote access server as a corporate intranet router**
In order for the remote access server to properly forward traffic on the corporate intranet, you must configure it as a router with either static routes or routing protocols so that all of the locations of the intranet are reachable from the remote access server. For information about routing concepts, see Routing Overview. For information about setting up the remote access server as a router, see Deploying Routing.

**Configuring the VPN server**
You can configure your VPN server by running the Routing and Remote Access Server Setup Wizard. You can configure the following settings using the wizard:

- A basic firewall on the public interface.
- The method by which the VPN server assigns addresses to remote access clients (either using addresses that the VPN server obtains from a DHCP server or using addresses from a specified range of addresses that you have configured on the VPN server).
- Forwarding of authorization and authentication messages to a Remote Access Dial-In User Service (RADIUS) server (configuration of the VPN server as a RADIUS client).

Once the wizard is run, these Routing and Remote Access settings are automatically configured:

- Network interfaces
- PPTP and L2TP ports (5 or 128 of each, depending on your choices when running the wizard)
- Multicast support using Internet Group Messaging Protocol (IGMP)
- IP routing
- Installation of the DHCP Relay Agent component.

For more information on enabling Routing and Remote Access and running the wizard, see Enable the Routing and Remote Access service.

**Configuring firewall packet filters**
If you are using a firewall, you need to configure PPTP packet filters on your firewall to allow PPTP traffic between Internet-based VPN clients and the VPN server computer. For more information, see VPN servers and firewall configuration.

**Configuring remote access policies**
For an access-by-user administrative model, you need to set the remote access permission to **Allow access** on the user accounts for those users who will be making VPN connections. For an access-by-policy model, make the appropriate changes to the remote access permission of the user accounts. For more information, see Introduction to remote access policies.

To configure a remote access policy to control the authentication and encryption options for VPN connections, you can create a remote access policy with the following settings:

- Set **Policy name** to **VPN Access** (example).
- For conditions, set the **NAS-Port-Type** condition to **Virtual (VPN)** and the **Tunnel-Type** condition to **Point-to-Point Tunneling Protocol**.
- Select the **Grant remote access permission** option.
- For profile settings, select the appropriate authentication and encryption options.

Then, either delete the default remote access policies or position them after the new policy. This remote access policy allows all users with remote access permission to create a VPN connection.

If you want to distinguish dial-up remote access users from VPN remote access users, do the following:

1. Create an Active Directory group whose members can create virtual private networking connections with the VPN server. For example, VPN_Users.
2. Add the appropriate user accounts to the new Active Directory group.
3. Create a new remote access policy with the following properties:
    - Set **Policy name** to **VPN Access if member of VPN_Users** (example).
    - For conditions, set the **Windows-Groups** condition to **VPN_Users** (example), set the **NAS-Port-Type** condition to **Virtual (VPN)**, and set the **Tunnel-Type** condition to **Point-to-Point Tunneling Protocol**.
    - Select the **Grant remote access permission** option.
4. Move the default remote access policies after the new policy.

The default encryption settings allow no encryption and all levels of encryption strength. To require encryption, clear the **No Encryption** option and select the appropriate encryption strengths on the **Encryption** tab of the remote access policy profile. The encryption strengths are:

- **Basic**

  You can use this option when communicating with older Microsoft dial-up networking clients. This option uses Microsoft Point-to-Point Encryption (MPPE) and a 40-bit encryption key.

- **Strong**

  You can use this option when communicating with dial-up networking clients running Windows 98, Windows 2000, or Windows XP. This option uses MPPE and a 56-bit encryption key.

- **Strongest**

  You can use this option when communicating with dial-up networking clients running Windows 98, Windows 2000, or Windows XP. This option uses MPPE and a 128-bit encryption key.

For more information, see Configure encryption.

# L2TP-based remote access VPN deployment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**L2TP-based remote access VPN deployment**

You can use remote access with products in the Windows Server 2003 family to provide access to a corporate intranet for remote access clients who are making Layer Two Tunneling Protocol over Internet Protocol security (L2TP/IPSec) connections across the Internet. If you want your remote access server to support multiple L2TP/IPSec connections, complete the following steps:

- Configure the connection to the Internet.
- Configure the connection to the intranet.
- Configure the remote access server as a corporate intranet router.
- Configure the VPN server.
- Install certificates.
- Configure firewall packet filters.
- Configure remote access policies.

The following illustration shows the elements of a remote access server running Windows Server 2003 that provides L2TP/IPSec remote access to a corporate intranet.

For more information, see Remote access VPN connection and Layer Two Tunneling Protocol.

### Notes

- The following configuration assumes that computer certificates, also known as machine certificates, are already installed on the VPN server and remote access client computers. For more information, see Computer certificates for L2TP/IPSec VPN connections and Network access authentication and certificates.
- On Windows Server 2003, Web Edition, and Windows Server 2003, Standard Edition, you can create up to 1,000 Point-to-Point Tunneling protocol (PPTP) ports, and you can create up to 1,000 Layer Two Tunneling protocol (L2TP) ports. However, Windows Server 2003, Web Edition, can accept only one virtual private network (VPN) connection at a time. Windows Server 2003, Standard Edition, can accept up to 1,000 concurrent VPN connections. If 1,000 VPN clients are connected, further connection attempts are denied until the number of connections falls below 1,000.

**Configuring the connection to the Internet**

The connection to the Internet from a computer running a Windows Server 2003 family operating system is a dedicated connection--a WAN adapter installed in the computer. The WAN adapter is typically a DDS, T1, Fractional T1, or Frame Relay adapter. You must contract with a local telephone company to run the appropriate physical wiring to your premises. You need to verify that the WAN adapter is compatible with products in the Windows Server 2003 family. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

The WAN adapter includes drivers that are installed in members of the Windows Server 2003 family so that the WAN adapter appears as a network adapter.

You need to configure the following TCP/IP settings on the WAN adapter:

- IP address and subnet mask assigned from the InterNIC or an Internet service provider (ISP).
- Default gateway of the ISP router.

To enable VPN clients to connect to your VPN server by name rather than by IP address, request that your ISP register your VPN server in DNS.

**Configuring the connection to the intranet**
The connection to the intranet from a computer running a Windows Server 2003 operating system is a LAN adapter that is installed in the computer. You need to verify that the LAN adapter is compatible with products in the Windows Server 2003 family. To verify compatibility, see the Compatible Hardware and Software section at Support resources.

You need to configure the following TCP/IP settings on the LAN adapter:

- IP address and subnet mask assigned from the network administrator.
- DNS and WINS name servers of corporate intranet name servers.

**Configuring the remote access server as a corporate intranet router**
In order for the remote access server to properly forward traffic on the corporate intranet, you must configure it as a router with either static routes or routing protocols so that all of the locations of the intranet are reachable from the remote access server. For information about routing concepts, see Routing Overview. For information about setting up the remote access server as a router, see Deploying Routing.

**Configuring the VPN server**
You can configure your VPN server by running the Routing and Remote Access Server Setup Wizard. You can use the wizard to configure the following settings:

- A basic firewall on the public interface.
- The method by which the VPN server assigns addresses to remote access clients (either using addresses that the VPN server obtains from a DHCP server or using addresses from a specified range of addresses that you configure).
- Forwarding of authorization and authentication messages to a Remote Authentication Dial-In User Service (RADIUS) server (configuration of the VPN server as a RADIUS client).

Once the wizard is run, the following Routing and Remote Access settings are automatically configured:

- Network interfaces
- PPTP and L2TP ports (five or 128 of each, depending on the choices you made when you ran the wizard)
- Multicast support using Internet Group Management Protocol (IGMP)
- IP routing
- Installation of the DHCP Relay Agent component.

For more information about enabling Routing and Remote Access and running the wizard, see Enable the Routing and Remote Access service.

**Installing certificates**
In order to create L2TP/IPSec remote access VPN connections using computer certificate authentication for IPSec, you must install computer certificates, also known as machine certificates, on the VPN client and the VPN server. For more information, see Network access authentication and certificates and Computer certificates for L2TP/IPSec VPN connections.

**Configuring firewall packet filters**

If you are using a firewall, you need to configure L2TP/IPSec packet filters on your firewall to allow L2TP/IPSec traffic between Internet-based VPN clients and the VPN server computer. For more information, see VPN servers and firewall configuration.

**Configuring remote access policies**

For an access-by-user administrative model, you need to set the remote access permission to **Allow access** on the user accounts for those users who will be making VPN connections. For an access-by-policy model, make the appropriate changes to the remote access permission of the user accounts. For more information, see Introduction to remote access policies.

To configure a remote access policy to control the authentication and encryption options for VPN connections, create a remote access policy with the following settings:

- Set **Policy name** to **VPN Access** (example).
- For conditions, set the **NAS-Port-Type** condition to **Virtual (VPN)** and the **Tunnel-Type** condition to **Layer Two Tunneling Protocol**.
- Select the **Grant remote access permission** option.
- For profile settings, select the appropriate authentication and encryption options.

Then, either delete the default remote access policies or position them after the new policy. This remote access policy allows all users with remote access permission to create a VPN connection.

If you want to distinguish dial-up remote access users from VPN remote access users, do the following:

1. Create an Active Directory group whose members can create virtual private networking connections with the VPN server. For example, VPN_Users.
2. Add the appropriate user accounts to the new Active Directory group.
3. Create a new remote access policy with the following properties:
    - Set **Policy name** to **VPN Access if member of VPN_Users** (example).
    - For conditions, set the **Windows-Groups** condition to **VPN_Users** (example), set the **NAS-Port-Type** condition to **Virtual (VPN)**, and set the **Tunnel-Type** condition to **Layer Two Tunneling Protocol**.
    - Select the **Grant remote access permission** option.
4. Move the default remote access policies after the new policy.

The default encryption settings allow no encryption and all levels of encryption strength. To require encryption, clear the **No Encryption** option and select the appropriate encryption strengths on the **Encryption** tab of the remote access policy profile. The encryption strengths are:

- **Basic**

  This option uses 56-bit DES encryption.

- **Strong**

  This option uses 56-bit DES encryption.

- **Strongest**

  This option uses triple DES (3DES) encryption.

For more information, see Configure encryption.

# Remote Access Authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Authentication**

This section provides information about administering user dial-in properties on a remote access server that is configured as a:

- Stand-alone server
- Member server in a domain

# Stand-alone server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Stand-alone server**

For a server running Routing and Remote Access that is not a member of a domain, only the local accounts database is available for setting remote access permissions. You cannot use domain-based account databases.

You can administer user account dial-in properties through the properties of a dial-up connection in the Network Connections folder or through Local Users and Groups. The list of users is based on the local user accounts.

# Member server in a domain

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Member server in a domain**

For a server running Routing and Remote Access that is a member server in a domain, four accounts databases are available:

1. Local.
2. Windows NT 4.0 domain.
3. Windows 2000 mixed domain.
4. Windows 2000 native or Windows Server 2003 domain.

The following table describes the management of user dial-in properties for each accounts database.

| Accounts database | User dial-in properties |
|---|---|
| Local | Administered by using Local Users and Groups. |
| Windows NT 4.0 domain | Administered by using the Windows NT 4.0 User Manager for Domains administrative tool. |
| Windows 2000 mixed domain | Administered by using either Active Directory Users and Computers or the Windows NT 4.0 User Manager for Domains administrative tool. |
| Windows 2000 native domain | Administered by using Active Directory Users and Computers. |

**Note**

- In order for the remote access server to access user account dial-in properties stored in Active Directory, the Routing and Remote Access service must run in the security context of a computer account that is a member of the **RAS and IAS Servers** security group. When you run the Routing and Remote Access Server Setup Wizard to configure Routing and Remote Access in a domain, the computer account of the remote access server is automatically added to the **RAS and IAS Servers** security group. If the remote access server needs to access user dial-in properties in other domains, you must manually add the computer account to the **RAS and IAS Servers** security group of the other domains either through Active Directory Users and Computers or by typing **netsh ras add registeredserver** at a command prompt. For more information, see Netsh commands for remote access and Remote Access Troubleshooting.

# Using RADIUS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using RADIUS**

This section covers:

- Using RADIUS for multiple remote access servers
- Using RADIUS in a heterogeneous remote access infrastructure

# Using RADIUS for multiple remote access servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using RADIUS for multiple remote access servers**

If you have more than one remote access server, rather than administer the remote access policies of all the remote access servers separately, you can configure a single server with the Internet Authentication Service (IAS) as a Remote Authentication Dial-In User Service (RADIUS) server and configure the remote access servers as RADIUS clients. The IAS server provides centralized remote access authentication, authorization, accounting, and auditing.

For more information about IAS, see Features of IAS.

If you want to configure the remote access servers and the IAS server, complete the following steps:

- Configure the remote access server.
- Configure the remote access server for RADIUS authentication.
- Configure the remote access server for RADIUS accounting.
- Configure the IAS server.

**Configuring the remote access server**

You must configure the server running Routing and Remote Access to provide remote access to either dial-up networking clients or virtual private networking clients. For more information, see the following:

- Using the remote access server as a corporate remote access server
- Using the remote access server for Internet access
- Deploying Remote Access VPNs
- Router-to-router VPN Deployment

**Configuring the remote access server for RADIUS authentication**

When you configure the properties of the server running Routing and Remote Access, select **RADIUS authentication** as the authentication provider. For more information, see Use RADIUS authentication.

When you add a RADIUS server, you must configure the following:

- **server name**

  The host name or IP address of the IAS server.

- **Secret**

  The server running Routing and Remote Access and the IAS server share a secret that is used to encrypt messages sent between them. You must configure both the remote access server and the IAS server to use the same shared secret.

- **Port**

  The remote access server must send its authentication requests to the UDP port on which the IAS server is listening. The default value of 1812 is based on RFC 2865, "Remote Authentication Dial-in User Service (RADIUS)" and does not need to be changed when you are using an IAS server.

**Configuring the remote access server for RADIUS accounting**

When you configure the properties of the server running Routing and Remote Access, select **RADIUS accounting** as the accounting provider. For more information, see Use RADIUS accounting.

When you add a RADIUS server, you must configure the following:

- **server name**

  The host name or IP address of the IAS server.

- **Secret**

  The server running Routing and Remote Access and the IAS server share a secret that is used to encrypt messages sent between them. You must configure both the remote access server and the IAS server to use the same shared secret.

- **Port**

  The remote access server must send its accounting requests to the UDP port on which the IAS server is listening. The default value of 1813 is based on RFC 2866, "RADIUS Accounting" and does not need to be changed when using an IAS server.

**Configuring the IAS server**

You need to configure the IAS server for domains and port numbers and register each of the remote access servers as clients. For more information, see Checklist: Configuring IAS for dial-up and VPN access.

Once the remote access servers are configured to use RADIUS authentication, the remote access policies stored on the remote access servers are no longer used. Instead, the remote access policies stored on the IAS server are used. Therefore, if one of the remote access servers contains the current set of remote access policies that are applied to all of the remote access servers, you can copy the remote access policies to the IAS server. For more information, see Copy the IAS configuration to another server.

### Notes

- If you have servers running Windows NT 4.0 and the Routing and Remote Access Service (RRAS) and you want to use remote access policies to authenticate incoming remote access connection attempts, you must configure the server running RRAS as a RADIUS client to an IAS server. You cannot configure remote access servers running Windows NT 4.0 as RADIUS clients. You must upgrade a remote access server running Windows NT 4.0 to a server running Windows NT 4.0 and RRAS.

- To provide redundancy and fault tolerance, configure two IAS servers, a primary and a backup, and copy the remote access policies from the primary to the backup. Then configure each remote access server with two RADIUS servers that correspond to the primary and backup IAS servers. If the primary IAS server becomes unavailable, then the remote access servers automatically begin to use the secondary IAS server.

- IAS is included as a part of Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

# Using RADIUS in a heterogeneous remote access infrastructure

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using RADIUS in a heterogeneous remote access infrastructure**

For some Internet service providers and corporate remote access environments, the remote access equipment consists of multiple remote access devices of different types from different manufacturers. In a heterogeneous remote access environment, a single standard must exist for providing authentication of remote access user credentials and accounting of remote access activity.

In many of these environments, the Remote Authentication Dial-In User Service (RADIUS) is used. RADIUS is a client/server protocol where RADIUS clients send authentication and accounting requests to a RADIUS server. The RADIUS server checks the remote access authentication credentials on the user accounts and logs remote access accounting events.

You can configure a server running Routing and Remote Access as a RADIUS client. In this scenario, the network also includes a RADIUS server called Internet Authentication Service (IAS) that can be used by Routing and Remote Access. For more information about IAS, see Features of IAS.

If you want to configure a server running Routing and Remote Access as a RADIUS client, complete the following steps:

- Configure the remote access server.
- Configure the remote access server for RADIUS authentication.
- Configure the remote access server for RADIUS accounting.

The following illustration shows the elements of a server running Routing and Remote Access that uses RADIUS in a heterogeneous remote access infrastructure.

**Configuring the remote access server**

You must configure the server running Routing and Remote Access to provide remote access to either dial-up networking clients or virtual private networking clients. For more information, see the following:

- Using the remote access server as a corporate remote access server
- Using the remote access server for Internet access
- Deploying Remote Access VPNs
- Router-to-router VPN Deployment

**Configuring the remote access server for RADIUS authentication**

When you configure the properties of the server running Routing and Remote Access, select **RADIUS authentication** as the authentication provider. For more information, see Use RADIUS authentication.

When you add a RADIUS server, you must configure the following:

- **Server Name**

The host name or IP address of the computer that is running the RADIUS server process.

- **Secret**

  The RADIUS client (the server running Routing and Remote Access) and the RADIUS server share a secret that is used to encrypt messages sent between them. You must configure both the RADIUS client and the RADIUS server to use the same shared secret.

- **Port**

  The RADIUS client must send its authentication requests to the UDP port on which the RADIUS server is listening. The default value of 1812 is based on RFC 2865, "Remote Authentication Dial-in User Service (RADIUS)." For some older RADIUS servers based on the earliest implementations of RADIUS, the port should be set to 1645.

**Configuring the remote access server for RADIUS accounting**

When you configure the properties of the server running Routing and Remote Access, select **RADIUS accounting** as the accounting provider. For more information, see Use RADIUS accounting.

When you add a RADIUS server, you must configure the following:

- **Server Name**

  The host name or IP address of the computer that is running the RADIUS server process.

- **Secret**

  The RADIUS client (the server running Routing and Remote Access) and the RADIUS server share a secret that is used to encrypt messages sent between them. You must configure both the RADIUS client and the RADIUS server to use the same shared secret.

- **Port**

  The RADIUS client must send its accounting requests to the UDP port on which the RADIUS server is listening. The default value of 1813 is based on RFC 2866, "RADIUS Accounting." For some older RADIUS servers, the port should be set to 1646.

# Remote Access Scenarios

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access scenarios**
This section covers:

- Internet access for A. Datum Corporation
- Remote Access for Electronic, Inc.

# Internet access for A. Datum Corporation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet access for A. Datum Corporation**
This section describes how remote access is configured for a fictional company using the features available in the Windows Server 2003 family. While your network configuration may be different than described here, you can apply the basic concepts.

A. Datum Corporation is an Internet service provider that provides dial-up Internet access and Internet services for customers in the greater Los Angeles metropolitan area. A. Datum has implemented a remote access solution that connects dial-up customers to the Internet.

**The network configuration**
The A. Datum network is configured as follows:

- A. Datum has obtained a class B network ID of 131.107.0.0 with a subnet mask of 255.255.0.0 from the Internet Assigned Numbers Authority (IANA). A. Datum connects to the Internet backbone by using a T3 WAN link. The IP address of the WAN adapter is 131.107.0.1.

- To receive up to 512 simultaneous incoming calls, A. Datum is using a modem bank switch that is connected to the local telephone service provider. The modem bank switch connects to the remote access server by using a modem bank adapter. Dial-up clients can dial in to A. Datum at the phone number 555-0122.

The following illustration shows the network configuration of the A. Datum remote access server.

The remote access server computer is configured as follows:

**1. Install the WAN adapter in the remote access server**
The network adapter that is used to connect to the Internet is installed according to the adapter manufacturer's instructions. Once the driver is installed and functioning, the adapter appears as a local area connection in the Network Connections folder.

**2. Configure TCP/IP on the WAN adapter**
The IP address of 131.107.0.1 with the subnet mask 255.255.255.255 is configured. DNS server addresses are configured. WINS server addresses and a default gateway are not configured.

**3. Install the Routing and Remote Access service**
The Routing and Remote Access Server Setup Wizard is run. Within the wizard, both remote access and routing for LAN and demand-dial routing are enabled, and all ports are enabled for both routing and remote access. For more information, see Enable the Routing and Remote Access service.

**4. Install the modem bank adapter in the remote access server**
The modem bank adapter that is used to connect to the modem bank switch is installed according to the adapter manufacturer's instructions. Once the driver is installed and functioning, the device and its ports appear under **Ports** in Routing and Remote Access.

**5. Configure the ports of the modem bank device for remote access**
All of the ports of the modem bank device are enabled for remote access. For more information, see Configure ports for remote access.

**6. Configure a static IP address pool**
A static IP address pool with a starting IP address of 131.107.192.1 and an ending IP address of 131.107.255.254 is configured. This creates a static address pool for up to 16,381 remote access clients.

For more information, see Create a static IP address pool.

**7. Configure a static route to reach Internet locations**

To reach Internet locations, a static route is configured with the following settings:

- Interface: The WAN adapter attached to the Internet
- Destination: 0.0.0.0
- Network mask: 0.0.0.0
- Gateway: 0.0.0.0
- Metric: 1

### Note

- Because the WAN adapter creates a point-to-point connection to the ISP, any address can be entered for the gateway address. The gateway address of 0.0.0.0 is an example. 0.0.0.0 is reserved as the unspecified IP address.

**User accounts and remote access policy configuration**

The A. Datum remote access server is a stand-alone server that uses the access-by-user administrative model. Access is controlled by setting the dial-in permission of individual user accounts to either **Allow access** or **Deny access**. The default remote access policies are not deleted.

### Note

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Remote Access for Electronic, Inc.

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote access for Electronic, Inc.**
This section describes how remote access is configured for a fictional company by using the features available in the Windows Server 2003 family. While your network configuration may be different than described here, you can apply the basic concepts.

Electronic, Inc. is an electronics design and manufacturing company that has implemented a remote access solution that connects dial-up and VPN remote access users to the Electronic, Inc. intranet.

To deploy a remote access solution for Electronic, Inc., the network administrator performs an analysis and makes design decisions regarding:

- The network configuration
- The remote access policy configuration
- The domain configuration

**The network configuration**
The key elements of the network configuration are:

- The Electronic, Inc. corporate intranet uses the private network address block of 172.16.0.0 with a subnet mask of 255.240.0.0.
- The remote access server computer is connected to an intranet network that contains a router that connects to the rest of the Electronic, Inc. corporate intranet. The network ID of the intranet network segment attached to the remote access server computer is 172.31.248.0 with a subnet mask of 255.255.255.0.
- The remote access server computer is configured with a static pool of IP addresses that represents the separate subnet of 172.31.252.0 with a subnet mask of 255.255.252.0.

The following illustration shows the network configuration of the Electronic, Inc. remote access server.

Based on the network configuration of the Electronic, Inc. corporate campus intranet, the remote access server computer is configured as follows.

**1. Install hardware in the remote access server**
The network adapter that is used to connect to the intranet segment is installed according to the adapter manufacturer's instructions. Once the driver is installed and functioning, the adapter appears as a local area connection in the Network Connections folder.

**2. Configure TCP/IP on the LAN adapter**
The IP address of 172.31.248.1 with the subnet mask 255.255.255.0 is configured. DNS and WINS server addresses are also configured. A default gateway is not configured.

**3. Install the Routing and Remote Access service**
The Routing and Remote Access Server Setup Wizard is run. Within the wizard, both remote access and LAN and demand-dial routing are enabled, and all ports are enabled for both routing and remote access. For more information, see Enable the Routing and Remote Access service.

**4. Configure a static IP address pool**

A static IP address pool with a starting IP address of 172.31.252.1 and an ending IP address of 172.31.255.254 is configured. This creates a static address pool for up to 1,021 remote access clients.

For more information, see Create a static IP address pool.

**5. Configure a static route on the remote access server computer to reach intranet locations**
To reach intranet locations, a static route is configured on the remote access server computer with the following settings:

- Interface: The LAN adapter attached to the intranet
- Destination: 172.16.0.0
- Network mask: 255.240.0.0
- Gateway: 172.31.248.2
- Metric: 1

For more information, see Add a static route.

**6. Configure a static route on the router to reach remote access clients**
To reach remote access clients, a static route is configured on the router with the following settings:

- Interface: The LAN adapter attached to the network segment of the remote access server
- Destination: 172.31.252.0
- Network mask: 255.255.252.0
- Gateway: 172.31.248.1
- Metric: 1

This static route is propagated to the other routers in the Electronic, Inc. intranet through the use of routing protocols.

For more information, see Add a static route.

**The remote access policy configuration**
To ease the transition from a Windows NT 4.0 environment, the network administrator for Electronic, Inc. decides on an access-by-user administrative model. Remote access is controlled by setting the dial-in permission of individual user accounts to either **Allow access** or **Deny access**. Remote access policies are used to apply different connection settings based on group membership. The default remote access policies are deleted.

**The domain configuration**
To take advantage of the ability to apply different connection settings to different groups, the following groups are created:

- DialUp_Users

  Used for dial-up remote access connections.

- VPN_Users

  Used for remote access VPN connections.

Based on this configuration, the following remote access scenarios are described:

- Dial-up remote access for employees
- VPN remote access for employees

- Centralized authentication by using IAS

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# Dial-up remote access for employees

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dial-up remote access for employees**
Employees of Electronic, Inc. use MS-CHAP or MS-CHAP v2 authentication for dial-up remote access and encryption is allowed but not required. To deploy remote access for Electronic, Inc. employees by using dial-up remote access connections, the following configuration is implemented.

**Network configuration**
For dial-up remote access, the Electronic, Inc. network is also configured as follows:

- To receive up to 48 simultaneous incoming calls, Electronic, Inc. uses a modem bank switch that is connected to the local telephone service provider. The modem bank switch connects to the remote access server by using a modem bank adapter. Dial-up clients can dial in to the Electronic, Inc. intranet at the phone number 555-0111.

The following illustration shows the configuration of the Electronic, Inc. remote access server for dial-up remote access connections.

The remote access server computer is configured as follows:

**1. Install modem bank adapter in the remote access server**
The modem bank adapter that is used to connect to the modem bank switch is installed according to the adapter manufacturer's instructions. Once the driver is installed and functioning, the device and its ports appear under **Ports** in Routing and Remote Access.

**2. Configure the ports of the modem bank device for remote access**
All of the ports of the modem bank device are enabled for remote access. For more information, see Configure ports for remote access.

**Domain configuration**
For each employee that is allowed dial-up remote access:

- The remote access permission on the dial-in properties of the user account is set to **Allow access**.
- The user account is added to the DialUp_Users group.

**Remote access policy configuration**
To define the authentication and encryption settings for remote access dial-up clients, the following remote access policy is created:

- Policy name: Dial-up Remote Access Clients
- Conditions:
    - **NAS-Port-Type** is set to all types *except* Virtual (dial-up)
    - **Windows-Groups** is set to DialUp_Users

- Permission is set to **Grant remote access permission**
- Profile settings:
    - **Authentication** tab: **Microsoft Encrypted Authentication version 2 (MS-CHAP v2)** and **Microsoft Encrypted Authentication (MS-CHAP)** are enabled.
    - **Encryption** tab: Select all the options.

**Note**

- In the access-by-user administrative model, the remote access permission on the remote access policy has no effect on granting remote access permission. However, the network administrator for Electronic, Inc. set the remote access permission on the policy to **Grant remote access permission** so that an eventual transition to an access-by-policy administrative model does not require changing all the remote access permission settings on all of the configured remote access policies.

**Dial-up remote access client configuration**

The New Connection wizard is used to create a dial-up connection with the following setting:

- Phone number: 555-0111

**Note**

- The example companies, organizations, products, people and events depicted herein are fictitious. No association with any real company, organization, product, person or event is intended or should be inferred.

# VPN remote access for employees

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**VPN remote access for employees**
VPN remote access for employees of Electronic, Inc. is PPTP-based, uses MS-CHAP v2 authentication, and requires strong encryption. To deploy remote access for Electronic, Inc. employees by using remote access VPN connections across the Internet, the following configuration is implemented.

**Network configuration**
For VPN remote access, the Electronic, Inc. network is configured as follows:

- The remote access server computer is directly attached to the Internet by using a T3 (also known as a DS-3) dedicated WAN link.
- The IP address of the T3 WAN adapter on the Internet is 157.54.130.1 as allocated by Electronic, Inc.'s Internet service provider (ISP). The IP address of the WAN adapter is referred to on the Internet by the name vpn.electronic.microsoft.com.

The following illustration shows the configuration of the Electronic, Inc. remote access server for remote access VPN connections.

The remote access server computer is configured as follows:

**1. Install T3 WAN adapter in the remote access server**
The T3 WAN adapter that is used to connect to the Internet is installed according to the adapter manufacturer's instructions. Once the driver is installed and functioning, the adapter appears as a local area connection in Device Manager or the properties of Ports.

**2. ConfigureTCP/IPon the WAN adapter**
For the WAN adapter, the IP address of 157.54.130.1 with a subnet mask 255.255.255.255 is configured. A default gateway is not configured.

**3. Configure a static route to reach Internet locations**
To reach Internet locations, a static route is configured with the following settings:

- Interface: The WAN adapter attached to the Internet
- Destination: 0.0.0.0
- Network mask: 0.0.0.0
- Gateway: 157.54.130.1
- Metric: 1

**Note**
