Windows System Resource Manager (WSRM) is a tool used to programmatically manage server resources such as processor utilization and memory allocation. Using policies, Windows System Resource Manager allocates specific amounts of resources to applications or processes. These policies allow system administrators to set usage limits based on a percentage of available CPU resources as well as set affinities between managed applications and certain CPUs in the case of multi-processor servers. Windows System Resource Manager consists of two components: the service and the client. The service component can be installed only on the 32-bit and 64-bit versions of Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition. The client component can be installed only on 32-bit versions of the Windows Server 2003 family. The client component does not support the 64-bit versions of these operating systems.

**Resource and Memory Management Scenarios**

The resource and memory management technologies described in this collection are typically used in server consolidation scenarios and other enterprise systems that make use of large servers with large amounts of memory and multiple CPUs.

4GT is most commonly used when servers are hosting memory intensive applications, such as database management systems, whose performance is directly affected by the availability of physical memory. Servers can take advantage of 4GT provided they have at least 2 GB of RAM available.

PAE X86 is used on servers with more than 4 GB of physical memory. PAE X86 allows the Windows executive software (also known as the kernel) to take full advantage of all available physical memory, including memory above 4 GB, up to 64 GB. Certain data-intensive applications, such as database management systems and scientific and engineering software that need access to very large caches of data, can use the Application Windowing Extensions (AWE) API set to access the memory that PAE can provide beyond 4 GB.

Windows System Resource Manager is most effective on systems where the CPU is in high demand. In these situations, Windows System Resource Manager manages competing processes by raising and lowering process priority. Windows System Resource Manager also provides a mechanism to store and retrieve records of the behavior of managed processes. With this information, Windows System Resource Manager can be used to generate reports of process-resource usage on a per-user, per-application, or other relevant basis. This accounting data can also be used to provide charge-back accounting.

# 4GT Technical Reference

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**4GT Technical Reference**
The technology called 4-gigabyte tuning (4GT), also known as application memory tuning, or the **/3GB** switch, is one of two technologies that increase the amount of physical memory available to user mode applications. The other technology is Physical Address Extension (PAE) X86. For more information about PAE X86, see PAE X86 Technical Reference.

4GT allows memory-intensive applications running on 32-bit versions of the Microsoft Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition, operating systems to use 50 percent more virtual memory by making less virtual memory available to the operating system. This subject will provide an overview of 4GT along with an in-depth description of how 4GT works.

### Note

- 4GT is not required on the 64-bit versions of the Windows Server 2003 family.

# What Is 4GT?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is 4GT?**

**In this section**

- Common 4GT Scenarios
- Technologies Related to 4GT
- Related Information

The technology called 4-gigabyte tuning (4GT), also known as application memory tuning, or the **/3GB** switch, is one of two technologies that increase the amount of physical memory available to user mode applications. The other technology is Physical Address Extension (PAE) X86. For more information about PAE X86, see "PAE X86 Technical Reference."

4GT allows memory-intensive applications running on Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition, 32-bit, to use 50 percent more virtual memory by making less virtual memory available to the operating system. In addition, 4GT can be used on Windows Server 2003, Standard Edition, but only in non-production environments.

Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, provide applications with a flat 32-bit virtual address space that can describe up to 4 gigabytes (GB) of virtual memory. The address space is usually split so that 2 GB of virtual address space is directly accessible to the applications and the other 2 GB is only accessible to the Windows executive software (also known as the kernel). Because of this 2 GB virtual memory limit, applications that are memory intensive and that manage their memory directly through their own caching methods, such as database management systems (DBMS), can experience reduced performance.

4GT makes more of the computer's virtual memory available to applications by making less virtual memory available to the operating system. By enabling 4GT, applications are able to access 3 GB of virtual memory instead of the 2 GB normally allocated for user mode processes. This is a 50 percent increase in virtual memory, allowing more data to be cached and potentially significantly increasing performance.

**Common 4GT Scenarios**

4GT is most commonly used when servers are hosting memory intensive applications, such as database management systems, the performance of which is directly affected by the availability of physical memory. However, it would be ineffective for every application to automatically be provided with the 3 GB address space that 4GT allows. Thus, to provide a selective use of 4GT, 4GT must first be explicitly enabled in the operating system and the application must also be explicitly configured to make use of the extended memory. For more information about 4GT, see "How 4GT Works."

4GT should not be used if either of the following is true:

- Greater than 16 GB of physical memory are available and PAE X86 is enabled on the server.
- Important performance characteristics of the application are adversely affected by limiting the kernel to 1 GB of RAM, for example, more than 1 GB of RAM might be needed to support the maximum number of concurrent connections.

**Note**

- 4GT is not required on the 64-bit versions of the Windows Server 2003 family.

**Technologies Related to 4GT**

The following technologies and components are integral in understanding 4GT.

**Memory Manager**

The 32-bit versions of Windows are able to address $2^{32}$ bytes (4 GB) of memory by default. Windows splits that memory, allocating 2 GB of memory to the kernel and up to 2 GB of memory to each application's private address space. This is done in order to provide protection for both the operating system and the applications. The kernel mode functions get 2 GB so that

they will have enough room to perform mandatory processes without running out of space. User mode applications therefore cannot address memory in the kernel mode space and accidentally corrupt kernel mode memory.

Each application can also utilize up to 2 GB of memory. This is true regardless of the number of applications on the server and despite the operating system's ability to natively recognize only 4 GB of total memory. If the total memory requirements of all applications exceed 4 GB, the memory manager uses a paging file to substitute for RAM. This process is described in the following paragraphs.

The memory manager is responsible for allocating and tracking memory assignments for both the kernel and applications. The memory manager translates virtual memory addresses used by the operating system and applications to actual physical memory locations. The translation of virtual memory to physical memory is transparent to the applications. User mode processes are never able to directly write to real memory and never actually know where their data resides. A user mode process can request a block of memory and write to it. The data written to the memory location might be written to real memory, or might be written to a paging file. A paging file (also known as a swap file) is a file on the hard disk that the memory manager uses to hold data that does not fit in memory. The memory manager moves data from the paging file to memory as needed and moves data from memory to the paging file to make room for new data.

The paging process allows the operating system to overcome its native 2 GB limit. However, it also has a direct impact on performance because of the time necessary to write or retrieve data from disk. 4GT modifies the way the memory manager works, allowing user mode applications that can effectively use greater virtual address space to achieve higher performance.

The kernel address space can also use up to 2 GB of address virtual memory, but all processes in the kernel space share the same 2 GB. Each process does not get its own unique memory space use without affecting the other kernel mode processes. Much of the memory in the kernel mode space also uses a virtual address and depending upon the function, some memory can be paged out to disk as well. However, there is a special type of memory that cannot be paged out to disk. One of the key items that reside in this space is the portion of the memory manager that handles virtual address translation and its related items and drivers for disk access. These items must remain resident in physical memory at all times.

**Page Table Entries**

As described in the previous section, the memory manager translates, tracks, and organizes real and virtual memory for applications and for portions of the kernel. Because of this, the memory manager must index where in real memory or where in a page file the data resides. When an application asks for the data, the memory manager can refer to the index to determine where that data actually resides and then retrieve it for the application. The following diagram shows a simplified explanation of the translation process.

**Use of Page Table Entries**

Page Table with Page Table Entries (PTEs)

The Page Table, one of the internal tables used by the memory manager in translating virtual memory addresses to physical addresses, resides in the kernel's memory space. The kernel's allocated memory space (either 2 GB by default, or 1 GB with 4GT enabled) is divided into two sections, the Paged Pool area and the Page Table Area, as shown in the following figure.

**Paged Pool and Page Table Areas**

On a computer in the Windows Server 2003 family, the Page Table area, which contains the page table entries (PTEs), is 64 MB by default when 4GT is enabled. The Paged Pool space is approximately 256 MB. While these different allocations share the same memory area, the partition between them is fixed at startup. If the operating system runs out of space in either the PTE area or the Paged Pool area, the other area cannot donate space to it, and programs may begin to encounter unexpected errors. This can happen in certain scenarios when using 4GT. For more information about PTEs and 4GT, see "How 4GT Works." By editing the registry, it is possible to limit the size of the Paged Pool space, which will then free additional memory for system PTEs.

### Note

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**Physical Address Extension (PAE) X86**

Physical Address Extension (PAE) X86 is another memory management technology that can, in certain scenarios, but used in conjunction with 4GT.

As described earlier in this section, the operating system, by default, can only address up to a total of 4 GB of physical memory. PAE X86 allows the operating system to access additional memory beyond 4 GB. This offers a direct benefit to the applications because more physical memory can be mapped into the application's virtual address space.

Applications that are specifically designed and written to use additional physical memory can benefit from increased performance using PAE X86. Through the use of the Address Windowing Extensions (AWE) API set, the operating system can make the additional physical memory directly available to the application. This is particularly beneficial for large, data intensive application such as database management applications.

Applications not specifically designed to use the additional memory can also benefit from PAE X86 because the operating system uses the larger physical memory to reduce paging and thus increase performance. This is particularly beneficial on consolidation servers hosting multiple applications.

In many situations, it is valuable to use both 4GT and PAE X86. The combination of these two technologies maximizes the amount of physical memory available to applications. However, 4GT cannot be used with PAE X86 when the server has more than 16 GB of physical memory. In this situation, 4GT should be disabled and only PAE X86 should be used.

# How 4GT Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How 4GT Works**

**In this section**

- 4GT Architecture
- 4GT Processes and Interactions

The technology called 4-gigabyte tuning (4GT) is a scale up component in the Windows Server 2003 family. The Microsoft operating environment delivers scalability via two methods: scale up and scale out. Scaling up refers to running a single application or image on a single server and having the ability to incrementally add system hardware resources (processors and memory) to increase overall system performance. Scaling out refers to distributing the computing workload among multiple servers with the ability to add or subtract servers to increase or decrease capacity.

Enterprises are required to scale flexibly to respond to spikes in business and to support the rapid roll out of new products and services. It is therefore increasingly important that an organization's computing infrastructure provides the ability to increase or decrease computing capacity almost instantly, while continuing to deliver value. 4GT helps provide this scalability.

There are few restrictions regarding the environment in which 4GT can be enabled. 4GT has the following hardware and software requirements:

- x86-based processor
- 2 gigabytes (GB) or more of RAM
- Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition
- Windows Server 2003, Standard Edition, but only in non-production environments.

4GT should not be used if either of the following is true:

- Greater than 16 GB of physical memory are available and Physical Address Extension (PAE) X86 is enabled on the server.
- Important performance characteristics of the application are adversely affected by limiting the kernel to 1 GB of RAM, for example, more than 1 GB of RAM might be needed to support the maximum number of concurrent connections.

**Note**

- 4GT is not required on the 64-bit versions of the Windows Server 2003 family.

**4GT Architecture**

4GT alters the way the memory manager allocates the virtual address space available on the computer. The following diagram and corresponding table illustrate this process.

**4GT Architecture**

When virtual memory space is requested by the user mode applications or the kernel, the memory manager determines where that memory will physically reside. The virtual address to physical address translation information is kept in the page table, which is part of the kernel's virtual address space. Using this translation data, the memory manager accesses the data

The following table describes the components related to the 4GT architecture.

**Components of the 4GT Architecture**

| Component | Description |
|---|---|
| Kernel or User Application | The user mode application or kernel process that requests data at a specific virtual address space. |
| Memory Manager | Operating system component that allocates, organizes, and tracks memory assignments. |
| 4 GB Virtual Address Space | Virtual addresses representing the 4 GB of RAM that is recognized by default by the operating system. Using 4GT, this 4 GB is divided to give user mode applications 3 GB of virtual address space and the kernel 1 GB of virtual address space. The kernel's 1 GB is further allocated into many other specific sections, including the page table area. |
| Page Table | A portion of the kernel's virtual address space that indexes virtual memory addresses to physical addresses. |
| Paging File | The files on a hard disk where data is stored instead of storing that data in RAM. |
| RAM | The physical RAM where data is stored. |

**4GT Processes and Interactions**

4GT is not enabled by default. In order to enable 4GT, the **/3GB** switch must be added to the server's Boot.ini file. The addition of this option causes the operating system to change the default virtual address allocations for applications and the kernel. Upon starting an application, the operating system examines the header file for that application. If the application header includes the "IMAGE_FILE_LARGE_ADDRESS_AWARE" flag and the **/3GB** switch has been used to enable 4GT, then the application has access to the greater virtual address space.

Instead of dividing the available 4 GB of virtual memory evenly between the kernel and any specific user mode application, 4GT provides less virtual address space to the kernel. This results in 3 GB of virtual memory to be allocated to the application. With 4GT, the virtual addresses available to the application range from 0x00000000 through 0XBFFFFFF. This is an increase of the default range of 0x00000000 through 0x7FFFFFFF. The virtual memory address range for the kernel shrinks from 0x80000000 through 0xFFFFFFFF to 0xC0000000 through 0xFFFFFFFF, as shown in the following diagram.

**Virtual Memory Allocation**

4GT can be used with Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition. In addition, 4GT can be used with Windows Server 2003, Standard Edition, but only in non-production environments.

**The /Userva Parameter**

In some cases, restricting the kernel to only 1 GB of memory might not be desirable, but the kernel might not need 2 GB either. In order to further refine memory management options, a new parameter, **/Userva**, has been introduced in Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition. This parameter can only be used in conjunction with the **/3GB** switch. The **/Userva** parameter allows an administrator to determine the specific size of the user mode virtual address space between 2 GB and 3 GB. The value specified by the **/Userva** parameter in the Boot.ini files (expressed in MB) determines the amount of memory the memory manager will return to the kernel. The amount of memory returned is 3072 MB less the value specified by the **/Userva** parameter. For example, to increase the kernel's memory space by 172 MB, the following parameter combination would be used in the Boot.ini file:

**3GB /Userva=2900**

This additional kernel address space is held in reserve and used as additional address space for Page Table Entries (PTEs) in the event that the system runs out of free PTE space. This address space is not allocated to PTEs until the system runs low on PTE space. For more information about PTEs, see "Page Table Entries" later in this section.

**Page File**

Page files store data that cannot be kept in RAM. The default page file size is equal to 1.5 times the amount of physical memory on the system. On a 4 GB computer, this can result in a page file larger than 4 GB. Under such circumstances, the effectiveness of this large of page file could be minimal, based on the usage of the system, such as when hosting database management applications. However, there are also times when even larger page files are needed, such as when multiple applications are consolidated on to one system. Therefore, on servers with 4 GB or more of memory, it is often preferable to change the default size of the page file based on the usage of the server. Regardless, on x86-based computers with 4 GB or more of physical memory there should be a page file sufficiently large to capture a kernel memory dump.

A page file size of at least 2,050 MB is the minimum size necessary for computers with 4 GB or more of physical memory to capture a complete kernel memory dump. The page file can be much larger (up to three times the physical RAM is typical) if the system is being used for application consolidation.

**Page Table Entries**

The page table is used by the memory manager to track the physical location of the page files. When using 4GT, because of the smaller amount of virtual memory allocated to the kernel, the number of Page Table Entries (PTEs) that can be recorded by the memory manager in the page table is also significantly reduced. In a standard configuration (without 4GT), there are typically 80,000 to 140,000 PTEs available. This is reduced to only 40,000 PTEs when using 4GT. This can lead to problems when the amount of physical memory increases and the kernel is required to keep track of larger and larger amounts of PTEs.

**4GT and PAE X86**

PAE X86 is another technology that allows access to additional physical memory. 4GT and PAE X86 can be combined to provide applications large amounts of virtual memory and provide a significant performance boost. However, using 4GT reduces the amount of PTE space available to the kernel, while using PAE X86 dramatically increases the amount of memory that must be indexed and translated by the memory manager. Thus this combination will exhaust system kernel space much earlier than normal. Because of this, the memory manager imposes a virtual memory limit of 16 GB on a system with both 4GT and PAE X86 enabled. Even if a system has 32 GB or more of physical memory, if both options are enabled, only 16 GB of memory will be recognized.

### Note

- Even though the memory manager imposes a hard limit of 16 GB when both 4GT and PAE X86 are enabled, it is possible to encounter problems with lesser amount of memory, such as 8 GB or 12 GB. Therefore, the kernel should be given as much memory as possible.

# 4GT Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**4GT Tools and Settings**

### In this section

- 4GT Registry Entry
- Related Information

The following section describes one registry entry associated with 4-gigabyte tuning (4GT).

### Note

- 4GT is not required on the 64-bit versions of the Windows Server 2003 family.

**4GT Registry Entry**

The following registry entry is associated with 4GT.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**PagedPoolSize**

**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management\

**Version**

Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition

This registry key determines the number of bytes allocated to the paged pool. It can be reduced in order to provide additional space for Paged Table Entries (PTEs). Because some computers require a certain amount of paged pool area size, reducing this value will not be an option in all cases. You should not typically need to change this registry value. The operating system calculates an optimal value for this entry based on the amount of physical memory on the computer.

### Note

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**Related Information**

# PAE X86 Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**PAE X86 Technical Reference**
Physical Address Extension (PAE) X86 is one of two technologies that increase the amount of physical or virtual memory available to applications. The other technology is 4-gigabyte tuning (4GT). For more information about 4GT, see "4GT Technical Reference."

PAE X86 allows applications using the Address Windowing Extensions (AWE) API set and running on a computer with more than 4 gigabytes (GB) of physical memory to map additional physical memory into the application's virtual address space. Applications not using the AWE API set can also benefit from PAE X86 because the operating system uses the larger physical memory to reduce paging and thus increase performance. This is of particular benefit to consolidation servers hosting multiple applications.

### Note

- PAE X86 is not required on the 64-bit versions of the Microsoft Windows Server 2003 family.

### In this subject

# What Is PAE X86?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is PAE X86?**

### In this section

- Common PAE X86 Scenarios
- Technologies Related to PAE X86
- Related Information

Physical Address Extension (PAE) X86 is one of two technologies that increase the amount of physical or virtual memory available to user mode applications. The other technology is 4-gigabyte tuning (4GT). For more information about 4GT, see "4GT Technical Reference."

By default, servers running the 32-bit editions of Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, support only 32-bit memory addressing and thus are able to access only 4 gigabytes (GB) of physical memory. However, hardware that offers much larger amounts of physical memory is available. Both the operating system and many applications can benefit from using this additional memory.

PAE X86 allows servers running Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, on a 32-bit hardware platform to access physical memory beyond 4 GB. To do this, PAE changes the memory addressing from 32-bit addressing mode to 64-bit addressing mode, allowing the operating system and high performance drivers and applications access to the additional physical memory. When using the larger amount of physical memory made available by PAE X86, operating system performance can be increased, particularly when the server is hosting multiple applications. Applications can also have direct access to the physical memory beyond 4 GB provided they use the Address Windowing Extensions (AWE) API set.

When using PAE X86, all of the physical memory in the system is treated as general purpose memory. The operating system is able to use this memory for caching and virtual memory management without major changes.

Applications can also use this memory without major changes. The most noticeable difference is that more applications can be running before paging occurs because there is more memory for each process and its associated virtual address space. This also means that more processes can be resident in memory. Because applications not needing larger physical memory do not need to be modified or use the AWE API set, virtually all applications can benefit from PAE X86.

**Common PAE X86 Scenarios**

PAE X86 allows the Windows executive software (also known as the kernel) to take full advantage of all available physical memory, including memory above 4 GB, up to 64 GB. This can result in a significant reduction in paging operations and can improve the performance of the server when multiple applications are hosted on a single computer, such as in application consolidation scenarios.

Additionally, certain data-intensive applications, such as database management systems and scientific and engineering software that need access to very large caches of data can also use PAE to address memory beyond 4 GB. These applications can use the AWE API to access up to 64 GB of memory using a memory window inside their 4 GB process. Just four system calls are used to declare the AWE window and to map additional physical memory inside that window.

### Note

- PAE X86 is not required on the 64-bit versions of the Windows Server 2003 family.

**Technologies Related to PAE X86**

The following technologies and components are integral in understanding PAE X86.

**Memory Manager**

The memory manager translates virtual memory addresses used by the operating system and applications to actual physical memory locations. The translation of virtual memory to physical memory is transparent to the application. User mode processes are never able to directly write to real memory and never actually know where their data resides. A user mode

process can request a block of memory and write to it. The data written to the memory location might be written to real memory, or might be written to a paging file. A paging file (also known as a swap file) is a file on the hard disk that the memory manager uses to hold data that does not fit in memory. The memory manager moves data from the paging file to memory as needed and moves data from memory to the paging file to make room for new data.

The 32-bit versions of Windows are able to address 232 bytes (4 GB) of memory by default. PAE X86 changes that addressing from 32-bit to 64-bit addressing mode. Even with the additional memory made available through PAE X86, if the total memory requirements of all applications exceeds the physical memory available, the memory manager uses the paging file to substitute for real memory; overcoming the physical memory limitation.

The paging process allows the operating system to overcome the real physical memory limits. However, it also has a direct impact on performance because of the time necessary to write or retrieve data from disk. PAE X86 modifies the way the memory manager translates the 32-bit virtual memory address to a physical address, allowing the address to be translated into $2^{36}$ potential physical memory addresses. Access to the additional memory then reduces the amount of paging operations needed.

**Page Table Entries**

As described in the previous section, the memory manager translates, tracks, and organizes real and virtual memory for applications and for portions of the kernel. Because of this, the memory manager must index where in real memory or where in a page file the data resides. When an application asks for the data, the memory manager can refer to the index to determine where that data actually resides and then retrieve it for the application. The following diagram shows a simplified explanation of the translation process.

### Use of Page Table Entries

Page Table with Page Table Entries (PTEs)

The Page Table, one of the internal tables used by the memory manager in translating virtual memory addresses to physical addresses, resides in the kernel's memory space. The kernel's allocated memory space (either 2 GB by default, or 1 GB with 4GT enabled) is divided by function into numerous sections, two of which are the Paged Pool area and the Page Table area, as shown in the following figure.

### Page Pool and Page Table Areas

On a computer running a member of the Windows Server 2003 family, the Page Table area, which contains the Page Table Entries (PTEs), is 64 megabytes (MB) by default when 4GT is enabled. The Paged Pool space is approximately 256 MB. While these different allocations share the same memory area, the partition between them is fixed at startup. This becomes important

when PAE X86 is enabled because the access to additional physical memory that PAE X86 allows requires additional PTEs for tracking and translation. If the operating system runs out of space in either the PTE area or the Paged Pool area, the other area cannot donate space to it, and programs may not receive requested resources, which can lead to unexpected errors for the application. By editing the registry, it is possible to limit the size of the Paged Pool space, which will then free additional memory for system PTEs.

**Note**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**4-gigabyte tuning (4GT)**

Another memory management technology is 4-gigabyte tuning (4GT) that can, in certain scenarios, but used in conjunction with PAE X86.

By default, the 32-bit editions of Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, provide applications with a flat 32-bit virtual address space that can address up to 4 GB of virtual memory. The address space is usually split so that 2 GB of virtual address space is directly accessible to the applications and the other 2 GB is only accessible to the kernel. Because of this 2 GB virtual memory limit, applications that are memory intensive and that manage their memory directly through their own caching methods, such as database management systems (DBMS), can experience reduced performance.

4GT can make more of the computer's virtual memory available to applications by making less virtual memory available to the operating system. With 4GT enabled, applications that are designed to be aware of this larger address space are able to address 3 GB of virtual memory instead of the 2 GB normally allocated for user mode processes. This is a 50 percent increase in virtual memory, allowing more data to be cached and potentially significantly increasing performance.

In many situations, it is valuable to use both 4GT and PAE X86. The combination of these two technologies maximizes the amount of physical memory available to applications. However, 4GT cannot be used with PAE X86 when the server has more than 16 GB of physical memory. In this situation, 4GT should be disabled and only PAE X86 should be used.

**Application Windowing Extensions (AWE)**

Because an application's virtual address space can only be extended to a maximum of 3 GB (using 4GT) in a 32-bit operating environment, in order to increase performance, applications (and database applications in particular because they use large datasets and do extensive swapping of data from disk to memory) need a method to map large portions of data into memory and keep that data in real memory at all times. This ability should also allow an application to map and remap data into its virtual memory space very quickly.

Application Windowing Extensions (AWE) is the solution to this need. AWE is an application programming interface (API) set that complements PAE X86. AWE is a set of APIs that allows software developers to create applications that use up to 64 GB of physical non-paged memory in a 32-bit virtual address space on 32-bit platforms. This technology allows for windowed views to this physical memory from within the application's virtual address space.

AWE allows an application to reserve sections of real memory that cannot be paged out to the paging file or otherwise manipulated, except by the reserving application. AWE will instead keep the data in real memory at all times. Because the memory manager does not manage this memory, it will never be swapped out to the paging file.

Unlike PAE, AWE is not an option set at startup. Applications must directly invoke the AWE APIs in order to use them, and the applications must be developed using the AWE APIs in order for the applications to benefit from the AWE APIs.

# How PAE X86 Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How PAE-X86 Works**

**In this section**

- PAE X86 Architecture
- PAE X86 Processes and Interactions

Physical Address Extension (PAE) X86 is one of the scale up technologies in the Windows Server 2003 family. The Microsoft operating environment delivers scalability through two methods: scale up and scale out. Scaling up refers to the ability to incrementally add system hardware resources (processors and memory) to increase overall system performance. Scaling out refers to distributing the computing workload among multiple servers with the ability to add or subtract servers to increase or decrease capacity.

Enterprises are required to scale flexibly to respond to spikes in business and to support the rapid rollout of new products and services. It is therefore increasingly important that an organization's computing infrastructure provides the ability to increase or decrease computing capacity almost instantly, while continuing to deliver on value. PAE X86 helps provide this scalability.

**Note**

- PAE X86 is not required on the 64-bit versions of the Windows Server 2003 family.

**PAE X86 Architecture**

PAE X86 alters the way the memory manager translates memory addresses. The memory manager moves from a two-level linear address translation to a three-level address translation. The extra layer of translation is what provides access to physical memory beyond 4 gigabytes (GB). The components used in the PAE X86 method of translation are shown in the following diagram.

The following table describes the components related to the PAE X86 architecture.

**Components of the PAE X86 Architecture**

| Component | Description |
|---|---|
| Virtual Address | A virtual address that is translated into a specific physical address. This is the address that an application or the kernel uses when accessing data in memory. |
| Page Directory Pointer Index (PDPI) | A table listing pointers to specific page directories. |
| Page Directory | A table with 512 entries, each pointing to a specific page table. |
| Page Table | A table with 512 entries, each pointing to a specific 4 kilobyte (KB) portion of memory. |

| | |
|---|---|
| 4 KB Page | A 4 KB portion of physical memory. |

**PAE X86 Processes and Interactions**
PAE X68 is not automatically enabled. It must first be enabled by adding the **/PAE** switch to the Boot.ini file. By using this switch, the operating system loads a different kernel from \i386\Driver.cab file. The kernel file is Ntkrnlpa.exe for uniprocessor systems and Ntkrpamp.exe for multiprocessor systems. The kernel is loaded based on only the switch and independently from the existing physical memory.

Physical memory is treated as general purpose memory, so no new APIs are needed for the kernel to access the memory above 4 GB. Direct I/O can be done to addresses above 4 GB. This requires Dual Address Cycle (DAC) capable or 64-bit Peripheral Component Interconnect (PCI) devices. Devices and drivers offering this capability are called Large Memory Enabled (LME).

Because the 32-bit editions of Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, do not have a kernel PAE or LME API interface, the PAE X86 kernel ensures that many items are identical to the standard kernel, including:

- Kernel memory space organization is unchanged.
- Registry flags work the same.
- Non-paged pool size remains the same.
- The 4-gigabyte tuning (4GT) feature is supported for up to 16 GB of RAM.
- The application header IMAGE_FILE_LARGE_ADDRESS_AWARE, which allows applications to make use of 4GT, will continue to work.
- "Well-known" kernel addresses remain in the same locations.

Applications do not need to be aware of PAE X86. Once enabled, the kernel will automatically make use of the additional memory for file caching, potentially improving the performance of applications running on the server.

**Virtual Address Translation without PAE X86**
When an application or the kernel requests access to physical memory, the memory manager must first translate the request, from a virtual address to a physical address. The normal implementation of virtual address translation uses a two-level page table structure. When PAE X86 is not enabled, the 32-bit virtual address is interpreted as three separate components: a 10-bit Page Directory Index, a 10-bit Page Table Index, and a 12-bit Byte Index. The following figure shows the translation of the linear virtual memory address to a physical memory location when PAE X86 is not enabled.

The following actions are involved in translating a virtual address when PAE X86 is not enabled:

- The memory manager locates the Page Directory for the current process. The memory manager is informed of the

location of the Page Directory for the process by a special control register.

- The 10-bit Page Directory Index in the virtual address is used to locate a Page Directory Entry (PDE) that defines the location of the Page Table needed to translate the virtual memory address.
- The 10-bit Page Table Index in the virtual address is used to locate the correct Page Table Entry (PTE).
- The PTE is used to locate the correct 4 KB page of memory.
- After accessing this page, the 12-bit Byte Index in the virtual address is used to locate the physical address of the desired data.

**Virtual Address Translation with PAE X86**

With PAE X86 enabled, the operating system moves from a two-level linear address translation to a three-level address translation. The memory manager still implements Page Directories and Page Tables, but a third level of translation, the Page Directory Pointer Table, is also added. The extra layer of translation is what provides access to physical memory beyond 4 GB. The following figure shows the translation of the virtual address to a physical memory location when PAE X86 is enabled.

Instead of splitting the virtual memory address into three separate components for indexing into memory tables, it is split into four separate components: a 2-bit Page Directory Pointer Index (PDPI), two 9-bit components (a Page Directory Index and a Page Table Index), and a 12-bit Byte Index.

The control register now points the memory manager to the Page Directory Pointer Index (PDPI) that is 2-bits wide. The first two bits of the virtual address are used as an index into the table, with the resulting value pointing to a Page Directory. The first 9-bit field in the virtual address is then used to index the Page Directory. The indexed value then points to a Page Table. The second 9-bit field is an index into the Page Table. The resulting Page Table Entry (PTE) points to the actual 4 KB page in memory where the desired byte is located. The remaining 12 bits of data in the virtual address point to the specific byte of data on that page.

**Page Table Entries**

As described earlier in this section, the Page Table is used by the memory manager as part of the translation process between virtual memory addresses and physical memory addresses. When using the large amounts of memory made available through PAE X86, the number of PTEs needed to track that physical memory can increase dramatically. This can lead to problems when the amount of physical memory allocated to the kernel for storing PTEs is reduced, such as when using 4GT. With 4GT, the smaller amount of virtual memory allocated to the kernel means that the number of PTEs that can be recorded by the memory manager is much smaller. In a standard configuration (without 4GT), there are typically 80,000 to 140,000 PTEs available. This is reduced to only 40,000 PTEs when using 4GT. The next section describes the implications of this change.

**PAE X86 and 4GT**

4GT is another technology that makes more physical memory available to user applications. PAE X86 and 4GT can be combined to provide applications large amounts of virtual memory and provide a significant performance boost. However, using 4GT reduces the amount of PTEs available to the kernel, while using PAE X86 dramatically increases the amount of memory that must be indexed and translated by the memory manager. This combination will exhaust system kernel space much earlier than normal. Because of this, the memory manager imposes a virtual memory limit of 16 GB on a system with

both 4GT and PAE X86 enabled. Even if a system has 32 GB or more of physical memory, if both options are enabled, only 16 GB of memory will be recognized. Thus, if PAE X86 is enabled on a system with more that 16 GB of physical memory, 4GT should not be used.

**Note**

- Even though the memory manager imposes a hard limit of 16 GB when both 4GT and PAE X86 are enabled, it is possible to encounter problems with lesser amount of memory, such as 8 GB or 12 GB. Therefore, the kernel should be given as much memory as possible.

**Application Windowing Extensions (AWE)**

Virtually all applications can benefit from the increased performance resulting from the kernel's use of PAE X86. However, in order to directly access the additional physical memory enabled by PAE X86, applications must use the Application Windowing Extensions (AWE) API set specifically designed for this purpose.

AWE is an API set that complements PAE X86. Unlike PAE X68, AWE is not an option set at startup and applications must directly invoke the AWE APIs in order to use them. Applications must be developed using the AWE API set in order to benefit from it.

Because an application's virtual address space can only be extended to 3 GB (using 4GT) on a 32-bit operating environment, applications (and database applications in particular, since they use large data sets and do a lot of swapping of data from disk to memory) need a method to map large portions of data into memory and keep that data in real memory at all times in order to increase performance.

AWE provides applications with this ability. AWE allows an application to reserve portions of real memory that cannot be paged out to the paging file or otherwise manipulated except by the reserving application. AWE will keep this data in real memory at all times. Because the memory manager does not manage this memory, it will never be swapped out to the paging file. The application is completely responsible for handling the memory.

AWE places the following restrictions on how this additional memory may be used, primarily because these restrictions allow extremely fast mapping, remapping, and freeing. Fast memory management is important for these potentially enormous address spaces and for attaining the highest possible performance.

- Virtual address ranges allocated for AWE are not sharable with other processes (and therefore not inheritable). Similarly, two different AWE virtual addresses within the same process are not allowed to map the same physical page. These restrictions provide fast remapping and cleanup when memory is freed.

- Since this memory is never paged, the physical pages that can be allocated for an AWE region are limited by the number of physical pages present on the computer. The memory is reserved until the application explicitly frees it or exits. The physical pages allocated for a given process can be mapped into any AWE virtual region within the same process. Applications that use AWE must be careful not to take so much physical memory that they cause other applications to page excessively or prevent creation of new processes or threads due to lack of resources.

- AWE virtual addresses are always read/write and cannot be protected. Read-only memory, no access memory, guard pages, or other similar calls cannot be specified.

- AWE address ranges cannot be used to buffer data for graphics or video calls.

- An AWE memory range cannot be split, nor can pieces of it be deleted. Instead, the entire virtual address range must be deleted as a unit when deletion is required.

- Applications can map multiple regions simultaneously, provided they do not overlap.

- Applications that use AWE are not supported in emulation mode. That is, an x86-based application that uses AWE functions must be recompiled to run on another processor, whereas most applications can run without recompiling under an emulator on other operating environments.

**Paging File**

Page files store data that cannot be kept in RAM. The default page file size is equal to 1.5 times the amount of physical memory on the system. On a 4 GB computer, this can result in a page file larger than 4 GB. Under such circumstances, the effectiveness

of this large of page file could be minimal, based on the usage of the system, such as when hosting database management applications. However, there are also times when even larger page files are needed, such as when multiple applications are consolidated on to one system. Therefore, on servers with 4 GB or more of memory, it is often preferable to change the default size of the page file based on the usage of the server. Regardless, on x86-based computers with 4 GB or more of physical memory there should be a page file sufficiently large to capture a kernel memory dump.

A page file size of at least 2,050 megabytes (MB) is the minimum size necessary for computers with 4 GB or more of physical memory to capture a complete kernel memory dump. The page file can be much larger (up to three times the physical RAM is typical) if the system is being used for application consolidation.

**PAE X86 Tools and Settings**

### In this section

- PAE X86 Registry Entry
- Related Information

The following section describes one registry entry associated with Physical Address Extension (PAE) X86.

### Note

- PAE X86 is not required on the 64-bit versions of the Windows Server 2003 family.

**PAE X86 Registry Entry**

The following registry entry is associated with PAE X86.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**PagedPoolSize**

**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management\

**Version**

Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition

This registry key determines the number of bytes allocated to the paged pool. It can be reduced in order to provide additional space for Paged Table Entries (PTEs). This is sometimes necessary when using PAE X86 in conjunction with 4-gigabyte tuning (4GT). However, because some computers require a certain amount of paged pool area size, reducing this value will not be an option in all cases. You should not typically need to change this registry value. The operating system calculates an optimal value for this entry based on the amount of physical memory on the computer.

### Note

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

# Windows System Resource Manager Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windows System Resource Manager Technical Reference**
Windows System Resource Manager is a feature of Microsoft Windows Server 2003, Enterprise Edition, and Microsoft Windows Server 2003, Datacenter Edition.

With Windows System Resource Manager, administrators can control how CPU and memory resources are dynamically allocated to applications, services, and processes. Managing resources in this way improves system performance and reduces the chance that applications, services, or processes will interfere with the rest of the system. It also creates a more consistent and predictable experience for users of applications and services running on the computer.

You can use Windows System Resource Manager to manage multiple applications on a single computer or users on a computer on which Terminal Services is installed.

# What is Windows System Resource Manager?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Windows System Resource Manager?**

**In this section**

- Common Windows System Resource Manager Scenarios

With Windows System Resource Manager, administrators can control how CPU and memory resources are dynamically allocated to applications, services, and processes. Managing resources in this way improves system performance and reduces the chance that applications, services, or processes will interfere with the rest of the system. It also creates a more consistent and predictable experience for users of applications and services running on the computer.

**Common Windows System Resource Manager Scenarios**

Windows System Resource Manager is designed for scenarios that involve running multiple applications on a single physical computer. Using Windows System Resource Manager, you can create resource-allocation policies, which determine how CPU and memory resources are allocated to running processes, and process-matching criteria, which use matching logic to group processes for easy management. Windows System Resource Manager supports the following scenarios:

- Allocating resources through server consolidation, to reduce the ability of applications to interfere with each other, such as when running multiple instances of a single application, or combining line-of-business applications with other applications or services.
- Managing users, either individually or by security group, in large terminal server systems by application, which limits the effect heavily used resources have on other users.
- Administering resource usage of multiple SQL Server instances sharing a server.
- Administering resource usage of Internet Information Services (IIS) 6.0 application pools on a server, such as when one server hosts multiple Web sites.
- Reports on memory usage and CPU time to support service level agreement (SLA) metrics.

Windows System Resource Manager is included with only Microsoft Windows Server 2003, Enterprise Edition, and Microsoft Windows Server 2003, Datacenter Edition.

# How Windows System Resource Manager Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Windows System Resource Manager Works**

**In this section**

- Terms and Definitions
- Windows System Resource Manager Architecture
- Windows System Resource Manager Processes and Interactions

Windows System Resource Manager (WSRM) is designed to manage multiple applications on a single computer or multiple users on a computer on which Terminal Services is in use. This supports a variety of scenarios, including consolidation, and can increase the efficiency with which physical hardware on a server is used by running applications.

Resource usage is controlled by using a dynamic process priority management algorithm that determines how to allocate system resources among multiple processes. You can administer resource policies and monitor resource usage with Windows System Resource Manager using Microsoft Management Console (MMC) or a command-line interface.

Windows System Resource Manager is available only on Microsoft Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition. The following condition increases the effectiveness of Windows System Resource Manager:

- CPU consumption targets are more likely to be met if processes are contesting for CPU bandwidth. This is because there is more contention among processes for scarce CPU resources when the system is experiencing heavy load. Windows System Resource Manager does not enforce resource allocation policies until CPU consumption reaches 75 percent. Before this point, all running processes are already getting all the CPU resources they can use. Windows System Resource Manager is needed only if one or more running processes are unable to use CPU resources because of other running processes using too much CPU bandwidth.

The following restrictions must be considered before using Windows System Resource Manager:

- Do not use Windows System Resource Manager in conjunction with another resource manager because neither resource manager is aware that the other is attempting to control system resources.
- Do not use Windows System Resource Manager to manage applications or processes that modify their process priority, memory limits, or processor affinity dynamically because this can have an adverse effect on the application being managed. Instead, use the application's own interface for controlling resources.
- Processes running in job objects cannot be managed because job objects include a management layer. Instead, use the application that creates the job objects to control the resources allocated to processes in the job object.
- The service component of Windows System Resource Manager can be installed only on the 32-bit and 64-bit versions of Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition.
- The client component of Windows System Resource Manager can be installed only on all versions of Windows 2000 and Windows XP Professional, as well as the 32-bit versions of the Windows Server 2003 operating systems. The client component does not support the 64-bit versions of these operating systems.

**Terms and Definitions**

The following terms are associated with Windows System Resource Manager.

**committed memory**

Memory that either resides in the working set of a process or maps to a disk file, such as a page file or other memory-mapped

file.

**CPU consumption target or CPU allocation**
Specifies a target CPU bandwidth for the resource allocation. Windows System Resource Manager uses a dynamic process priority management algorithm to try to limit the CPU usage of a process to the target specified in the matching resource-allocation policy of that process.

**default group**
Includes all running processes not matched by a specific process-matching criterion. Processes in the default group are allocated all of the managed CPU resources that are not allocated to processes matching the active resource-allocation policy.

**managed CPU**
The total CPU resources being used by managed processes.

**managed process**
All running processes, except those on the system-defined exclusion list or the user-defined exclusion list. They are managed by Windows System Resource Manager.

**process**
An object created by Windows to represent an executing program. This includes the virtual address space and the control information necessary for the program to run.

**process-matching criterion**
The mechanism Windows System Resource Manager uses to match running processes to a resource-allocation policy.

**process priority**
A value for each process that helps determine how CPU resources are used. Windows System Resource Manager dynamically changes the priority of a process so the CPU usage matches the targeted CPU allocation for that process.

**processor affinity**
On systems with more than one processor, processor affinity specifies the set of processors on which the process is exclusively allowed to run. Also known as CPU affinity.

**resource allocation**
The part of a resource-allocation policy that specifies the set of resources to be allocated to the processes matching to a single process-matching criterion.

**resource-allocation policy**
An ordered list of resource allocations that specifies the management behavior of Windows System Resource Manager at a given time.

**sub-allocation**
The process by which a resource allocation is divided by multiple child resource allocations.

**system-defined exclusion list**
The list of system processes that are excluded from management by Windows System Resource Manager. The system-defined exclusion list is built into Windows System Resource Manager and cannot be modified by users.

**unmanaged process**
A process on either the system-defined exclusion list or the user-defined exclusion list. Windows System Resource Manager never applies a resource-allocation policy to an unmanaged process, even if a resource-allocation policy would otherwise match.

**user-defined exclusion list**
A modifiable list of processes to be excluded from management by Windows System Resource Manager.

**working set memory**
For a process, the physical memory that is consumed during the time when the process is running and can be paged to disk.

**Windows System Resource Manager Architecture**
Windows System Resource Manager consists of two components: the service and the client. For the client, two administrative interfaces are provided: the command-line administration tool (Wsrmc.exe) and the WSRM snap-in available in Microsoft Management Console (MMC). The administrator creates resource-allocation policies and process-matching criteria to control how CPU and memory resources are allocated to applications, services, and processes. These policies are managed by the Windows System Resource Manager service, which then uses the memory manager and kernel scheduler to implement the policies.

The following figure illustrates the different components of Windows System Resource Manager and the interactions between

the components.

**Windows System Resource Manager Architecture**

The following table describes the principal components related to Windows System Resource Manager architecture.

**Components of Windows System Resource Manager Architecture**

| Component | Description |
|---|---|
| Command-line Interface (Wsrmc.exe) | Provides administrative control of the Windows System Resource Manager service using the command-line interface. The command-line interface provides equivalent administrative control to the WSRM snap-in. |
| WSRM Snap-in (MMC interface) | Provides administrative control of the Windows System Resource Manager service using the MMC interface. |
| Distributed Common Object Model (DCOM) Interface | The remote application programming interface (API) through which the client and Windows System Resource Manager service communicate. |
| WSRM Service | Performs resource management by using logic components that interact with the operating system and running processes.<br><br>The service continually monitors the resource usage of each managed process in the group. If a process exceeds its resource allocation, the service attempts to bring the resource usage of the process back to its specified target. |
| Accounting Database | Stores information about managed processes on a per-process basis. Provides a mechanism through which data on the behavior of managed processes can be stored, grouped, and retrieved. |
| Policy Store | Stores all resource-allocation policies, process-matching criteria, and other related information. |
| WSRM Settings | Stores the current management settings. |
| Calendar | Stores all calendar-related information, such as calendar events and schedules. |
| Memory Manager | Allocates memory to running processes. |
| Kernel Scheduler | Determines when and for how long each process in the system is allowed to use the processors in the computer. |

**Windows System Resource Manager Processes and Interactions**

This section describes the different processes and interactions of Windows System Resource Manager.

**Windows System Resource Manager Service**

The Windows System Resource Manager (WSRM) service monitors the state of managed processes and takes action when those processes do not meet their target CPU allocations. The service does the actual resource management work by using logic components that interact with the Windows scheduler and running processes.

Logic components are defined in the following table.

**Logic Components**

| Logic Components | Description |
|---|---|
| Exclusion logic | Matches all processes on either the user-defined or system-defined exclusion lists and marks them to be excluded from management by Windows System Resource Manager. |
| Matching logic | Examines all processes not on the exclusion lists and groups them by matching process-matching criterion for management. |

| | |
|---|---|
| Process priority logic | Implements the dynamic process priority management algorithm to raise and lower the priority of a running process. Changing the priority of a process affects how CPU resources are allocated among running processes. |
| Memory logic | Sets the memory limits specified in the associated resource allocation, if the limits are defined. |
| Affinity logic | When processor affinity is specified in the managing resource allocation policy, configures the process to run on the set of processors specified. |
| Job accounting logic | Periodically writes resource consumption statistics to a private job accounting database. Also, provides an interface for querying and exporting stored resource consumption statistics from the job accounting database. Job accounting logic is not included in the figures that appear later in this document because it does not apply to the interactions illustrated in those figures. |

While management is active, the Windows System Resource Manager service continually monitors the resource usage of each managed process in the group. If a process momentarily exceeds its resource allocation, the service attempts to bring the resource usage of the process back to its specified target.

**How the Service Matches Processes**

A running process is matched when the Windows System Resource Manager service discovers it, or when the active resource-allocation policy is changed, which causes the service to re-poll all processes again. The system-defined exclusion list and the user-defined exclusion list are checked first and all matching processes are placed in the excluded processes group. Processes that do not match any process-matching criterion are automatically assigned to the default group. After a process is assigned to a group, the service enforces the associated resource allocation for the process by setting resource limits or modifying the priority of the process. No changes are ever made to processes in the system-defined exclusion list or the user-defined exclusion list.

The service makes no other changes to the process or the process-matching criterion unless the process-matching criterion or the resource-allocation policy is edited. Changes made to the user-defined exclusion list do not take effect until a new resource-allocation policy is set to manage, or the current resource-allocation policy is stopped and restarted. If either the process-matching criterion or the resource-allocation policy is edited, the service re-polls all of the processes running on the system following the standard allocation algorithm.

**The Dynamic Process Priority Management Algorithm**

During each poll, the service checks to determine whether the processes match their target allocations and whether any new processes have been created since the last poll.

If a process exceeds its target allocation, the service uses the dynamic process priority management algorithm to try to make the process conform to its target allocation. If changing the priority of the process does not make the CPU usage of the process conform to its target, the algorithm adjusts the target allocation of the process. It does so by using a process called re-allocation, which is described below.

If a new process is identified during the polling interval, the Windows System Resource Manager service takes the following steps to determine whether the new process should be managed:

- The Windows System Resource Manager service matches the properties of the new process to each process-matching criterion in the managing policy. It does so in the order of the process-matching criteria that is specified in the resource-allocation policy.

- When the properties of the new process are found to match a process-matching criterion, the new process is then grouped with other processes that have properties matching the same process-matching criterion. The new process is then subject to the resource allocations specified in the resource-allocation policy.

- If the process does not match any of the process-matching criteria, it is added to the default group. Processes matching in the default group are given CPU bandwidth not allocated to other running processes. No memory limits are applied to processes in the default group.

**Process-Matching Criterion**

Process matching is the mechanism that Windows System Resource Manager uses to match processes and then aggregate them into groups to be managed.

A process-matching criterion creates an association between a group of one or more matched processes and a resource-allocation policy. Windows System Resource Manager then manages all of the matched processes using the resource allocations specified in the resource-allocation policy. If a CPU allocation is specified, the CPU resources are distributed evenly

among all the processes in the group. If a memory limit is specified, the limit is applied on a per-process basis to all the processes in the group.

Windows System Resource Manager maintains the specified resource allocations until the managing policy is changed.

The following table defines the entries that each process-matching criterion can include.

**Events for Process-Matching Criterion**

| Event | Description |
|---|---|
| Included files or command lines | Lists wildcard or regular expression match strings. |
| Excluded files or command lines | Lists wildcard or regular expression match strings. |
| Included users or groups | Lists user account names or group account names. |
| Excluded users or groups | Lists user account names or group account names. |

Windows System Resource Manager uses the following process to decide if a process matches a given process-matching criterion.

- If the process-matching criterion has entries for included files or commands lines, Windows System Resource Manager attempts to match each match string against the process properties in the following order, stopping on the first match:

  1. Process file name
  2. Fully-qualified process path and file name
  3. Full process command line

- If the process matches the included files or command-line entries, then Windows System Resource Manager attempts to match the entries for excluded files or command lines, if they are defined. The process for matching the excluded entries is identical to the process for included entries. If the process matches against the excluded entries, then the process is treated as one that does not match the process-matching criterion.

- If the process-matching criterion has entries for included users or groups, Windows System Resource Manager matches each user or group name against the user account used to create the process, stopping on the first match. A user account matches if it is the same as the user account in the process. A group matches if the user account used to create the process is a member of the group. If the process matches against the excluded entries, then the process is treated as one that does not match the process-matching criterion.

- If the process matches the included users or groups entries, then Windows System Resource Manager attempts to match the entries for excluded users or groups if they are present. The process for matching the excluded entries is identical to that of the included entries. If the process matches against the excluded users or groups entries, then the process is treated as one that does not match the process-matching criterion.

- If both a files or command-line entry and user or group entry are provided, then both must match in order for the process to match the process-matching criterion.

**Resource-Allocation Policies**

A resource-allocation policy is the mechanism that specifies the resource usage for a managed process.

After a process-matching criterion is defined, it can be used by any number of resource-allocation policies. Only one resource-allocation policy can be in effect and managing at a time. The managing resource-allocation policy determines the resource usage for all managed processes, in other words, those processes not included in the system-defined or user-defined exclusion lists. A resource-allocation policy is an ordered list of resource allocations. Each resource allocation consists of a process-matching criterion and one or more allocations, such as a CPU consumption target, memory limit, or processor affinity. The allocations specified apply to all processes that match the process-matching criterion associated with the resource allocation.

**The Default Group**
All running processes that are not matched by any of the process-matching criteria in the managing resource-allocation policy are grouped in the default group.

The default group is allocated any CPU bandwidth that is unaccounted for by the managing policy. This bandwidth is distributed on an equal-shares basis. This ensures that all processes in the default group get an equal proportion of the total CPU bandwidth that is available to the default group. Windows System Resource Manager enforces this allocation, which prevents one or more applications in the default group from using more than their share of CPU bandwidth.

**Exclusion Lists**
While Windows System Resource Manager can effectively manage most applications, it is best not to use Windows System Resource Manager to manage processes that many applications depend on, such as Windows system services. This is likely to have adverse effects, so Windows System Resource Manager maintains a fixed list of Windows processes that should not be managed. This list is called the system-defined exclusion list. In addition, there is a user exclusion list intended for any other services or processes that might not behave properly under management. A process that is included on either of these lists is known as an unmanaged process.

**The System-Defined Exclusion List**
The system-defined exclusion list cannot be modified; however, you can exclude additional processes that you do not want Windows System Resource Manager to manage by manually adding them to the user-defined exclusion list.

To ensure that only designated system processes are excluded from being managed, the processes on the system-defined exclusion list are matched using the exact process path. This prevents other processes with similar names from being matched by mistake.

The following system processes are included by default on the system-defined exclusion list:

- Csrss.exe
- Dfssvc.exe
- Dumprep.exe
- Dwwin.exe
- Llssrv.exe
- Lsass.exe
- Msdtc.exe
- Smss.exe
- Services.exe
- Spoolsv.exe
- System.exe
- Taskmgr.exe
- Winlogon.exe
- Wmiprvse.exe
- Wsrm.exe
- Wsrmc.exe

**The User-Defined Exclusion List**
Processes on the user-defined exclusion list are either added manually or the system adds several processes by default. The processes included on the user-defined exclusion list by default are several Svchost.exe processes. Important operating system services run inside the Svchost.exe processes. To ensure that these processes have access to their required CPU bandwidth, they are excluded from management. It is not usually necessary to manage these processes; however, if one or more of these processes start to consume excessive CPU bandwidth, you can manage them by removing them from the user-defined exclusion list. This allows Windows System Resource Manager to control the CPU bandwidth usage of these processes.

Although it is rarely necessary, you can include processes on the user-defined exclusion list that do not respond well to management and any other processes that you do not want Windows System Resource Manager to manage. Processes that Windows System Resource Manager does not control are unmanaged and can, therefore, consume resources freely.

Because the behavior of unmanaged applications cannot be controlled, the effectiveness of Windows System Resource Manager can decrease if you include on the user-defined exclusion list multiple processes or processes that use resources intensively.

**Calendar**
The Windows System Resource Manager calendar schedules the automatic activation of resource-allocation policies. Policies can be activated on a one-time or recurring basis. Schedules provide flexibility to manage multiple resource-allocation policies and to activate various resource-allocation policies at different, predefined times over a 24-hour period.

When the calendar is enabled, and no policy is scheduled for the current time, the default calendar resource-allocation policy is in effect. The default calendar policy is configurable and can be a user-defined resource-allocation policy or the default calendar resource-allocation policy. The default calendar policy is configurable and can be set to any policy.

The following table describes the three types of calendar events you can use to schedule resource-allocation policies.

### Types of Calendar Events

| Type of Calendar Event | Description |
|---|---|
| One time | Create a one-time calendar event to schedule one resource-allocation policy or schedule to run once. Requires a starting date and time and duration (or ending date and time), and a specified resource-allocation policy to run. |
| Recurring event | Create a recurring event to schedule one resource-allocation policy or schedule to run more than once. Requires a starting date and time and duration (or ending date and time), a recurrence pattern, a recurrence length, and a specified resource-allocation policy to run. |
| Schedule (day schedule applied to calendar dates) | Create a schedule to activate multiple resource-allocation policies to run over a 24-hour period. Policy schedules can be reused and applied to one or more dates on the calendar. You can change the date on which to apply the schedule without affecting the entire schedule. |

**Accounting**
Windows System Resource Manager provides a mechanism to store and retrieve records of the behavior of managed processes. Accounting information is stored in an accounting database for easy administration and retrieval. This information is logged in the accounting database at a default interval of 10 minutes, which is configurable. The interval determines the frequency with which the data for all managed processes on the computer managed by Windows System Resource Manager is logged to the accounting database. With this information, process-resource usage reports can be generated on a per-user, per-application, or other relevant basis.

**How CPU Resources Are Managed**
CPU resources are represented as both a percentage of total CPU bandwidth and as a set of physical processors. These resources are controlled through the use of CPU consumption targets and processor affinity, respectively. Windows System Resource Manager uses the dynamic process priority management algorithm to determine how CPU bandwidth is allocated.

**Managed CPU and Total CPU**
CPU bandwidth targets in resource allocation policies are expressed as a percentage from 0 to 100. This represents the total managed CPU resources of the managed computer. The total bandwidth for both a one-processor system and an eight-processor system is 100 percent. The maximum CPU bandwidth percentage you can specify in a resource allocation, however, is 99 percent because a minimum of 1 percent is always reserved for the default group.

Managed CPU corresponds to the CPU bandwidth that is available to the processes Windows System Resource Manager is managing.

Total CPU corresponds to the total CPU bandwidth on the system. The total CPU resources available for Windows System Resource Manager to manage might not match the total CPU resources on the computer.

The difference between the managed CPU and the total CPU in a system is determined by how CPU is used by unmanaged and managed processes. Unmanaged processes can consume as much of the available CPU resources as needed. Windows System Resource Manager can manage only those CPU resources that are not being consumed by unmanaged processes. This means that the managed available CPU might be less than the total CPU available in the system. As the percentage of total CPU resources consumed by unmanaged processes increases, the ability of Windows System Resource Manager to meet target CPU allocations for managed processes decreases. Thus, if you limit the number of unmanaged processes in the system, you can maximize the accuracy of overall system resource management.

**CPU Targets**
To control the allocation of managed CPU, you can set CPU consumption targets for each resource allocation. The CPU consumption target is expressed as a percentage that corresponds to the total managed CPU available on the system when the resource allocation is created. After you create a CPU allocation, the consumption target percentage is deducted from the total available managed CPU resources. For example, if you create a resource allocation with 30 percent as the CPU consumption target, subsequent resource allocations will have only 69 percent available.

CPU consumption targets are applied to the group of processes matched by the resource allocation's associated process-matching criterion.

For example, if you create a resource allocation with a CPU consumption target of 10 percent CPU and a process-matching criterion that matches 10 processes, the 10 percent CPU is applied to the group of processes rather than to each process individually.

The distribution of CPU bandwidth among multiple processes in a group is controlled by the Management Rule property of each resource allocation. The Management Rule can take one of three possible values:

- **Standard.** This is the default setting. It means that Windows System Resource Manager does not control the distribution of CPU bandwidth among processes in the group.

- **Equal per process.** Windows System Resource Manager will manage individual processes in the group according to equal targets, each an equal share of the group's target.

- **Equal per user.** Windows System Resource Manager will manage sub-groups of processes in the group, assigning equal shares according to the user that started the process.

**Allocation**
In order to manage processes toward their CPU allocation targets, Windows System Resource Manager samples the CPU consumption of all managed processes in the system and computes a moving average of each over the last few samples. The priorities of processes consuming above their targets are lowered to prevent the consumption of CPU bandwidth that is allocated to other processes. Similarly, processes consuming below their targets have their priorities raised to give them better access to CPUs in the system. Processes that are unable to consume their allocated CPU bandwidth, even after appropriate priority adjustments have been made to the priorities of other processes, will have their unconsumed allocation re-allocated to other processes. This occurs according to the proportions specified in the resource allocations.

**Sub-allocation**
A sub-allocation is a subdivision of a resource allocation. Each subdivided resource allocation is referred to as the parent allocation, and each of its sub-allocations is a child resource allocation. Sub-allocations can be further subdivided, so there is no effective limit to the size of the resource hierarchy. A sub-allocation behaves similarly to a resource allocation; however, its CPU percentage targets are interpreted as a percentage of its parent's CPU allocation, rather than a percent of the managed CPU of the whole machine.

In a sub-allocation, CPU resources are allocated first to the child resource-allocation policies, starting with the child that is at the bottom of the hierarchy. This last child in the hierarchy gets as close to its specified CPU allocation as possible. The remaining CPU resources that this last child does not use become available to its parent. The parent consumes bandwidth up to its specified CPU allocation. Any remaining CPU bandwidth then becomes available to its parent, if one exists. If a parent does not exist, the remaining CPU resources are allocated back to the default group.

The only relationship between an allocation and its parent or sub-allocation concerns CPU bandwidth. That is, although an allocation and its parent or sub-allocation share the same CPU bandwidth, the processes matched to these allocations are different.

**Priority-order Chain**

You can use resource sub-allocation to create a specific type of resource-allocation hierarchy called a priority-order chain.

You can configure a single resource allocation with multiple child resource allocations, each with its own relative allocation. Doing so, you can create a hierarchy.

To create the priority-order chain, you order the sub-allocations in increasing priority as you move down the hierarchy. That is, the lower priority resource allocation should be matched at the higher levels, and the higher-priority resource allocation should be matched at the lower levels of the hierarchy.

This is illustrated in the following example:

- A resource-allocation named *ra0* is created with a process-matching criterion named *pmc0* and allocated 30 percent of CPU.
- A sub-allocation named *sub_ra1* is created for a different process-matching criterion, such as *pmc1*; it is allocated 20 percent of CPU.
- In turn, *sub_ra1* has a sub-allocation named *sub_ra2* with a different process-matching criterion, such as *pmc2*, and is allocated 30 percent of CPU.
- *sub_ra2* has a sub-allocation named *sub_ra3* with yet another process-matching criterion, such as *pmc3*, and is allocated 40 percent of CPU.
- The resource sub-allocations are numbered in an increasing order that corresponds to their preferred relative priority. Each sub-allocation and associated process-matching criterion have a higher precedence than their associated parent resource allocation, which is described as follows:
    - *sub_ra3* has the highest relative priority and will consume up to 40 percent of the total CPU bandwidth allocated in the policy.
    - *sub_ra2* can consume 30 percent of the remaining total bandwidth allocated that was not consumed by *sub_ra3*.
    - *sub_ra1* can consume 20 percent of the remaining total bandwidth allocated in the policy that was not consumed by *sub_ra2* and *sub_ra3*.
    - *ra0* has the lowest relative priority and will be able to consume only 10 percent of the total bandwidth allocated in the policy, assuming there is any that is unused by its sub-allocations, because the remaining 90 percent of the total bandwidth available to the entire resource allocation is allocated to its sub-allocations.

If any of the sub-allocations cannot use all of their allocation, the unused percentage is returned to the parent allocation. This process continues until either an allocation can use the unused allocation, or the parent allocation is the default group. In the latter case, the unused allocation is redistributed in the usual procedure as defined by the standard allocation algorithm.

**Re-allocation**

The amount of CPU bandwidth a process consumes does not always match its allocation. If a process cannot consume any part of its CPU bandwidth allocation, the unconsumed portion is re-allocated to other processes that can consume it. This is known as resource re-allocation.

The resource re-allocation sequence occurs as follows:

- The unconsumed allocation is passed from the process to its parent process-matching criterion and any sibling process-matching criteria that might exist. Other processes matched by either the parent or sibling process-matching criteria can then try to use the unconsumed allocation. The unconsumed allocation is redistributed to the other processes in proportion to their CPU consumption targets, as specified in the resource-allocation policy. For example, if a policy has resource allocations with process-matching criterion A allocated 20 percent and B allocated 40 percent, it would also implicitly have the default group at 40 percent. If the default group is only able to consume 20 percent, but A and B could each consume more than their allocation, then the other 20 percent not used by default would be reallocated to A and B proportionally. Process-matching criterion A would get one-third of the 20 percent, and B would get the other two-thirds.
- If the processes matched by either the parent or sibling process-matching are unable to use all of the unconsumed re-

allocation, the remaining unused portion is passed to the parent of the parent process-matching criterion.

- The re-allocation sequence continues until the re-allocation is consumed or the process-matching criterion has no parent. In the latter case, the unconsumed allocation is distributed among all top-level process-matching criteria, including the default group.

When a process attempts to use more than the allocated CPU bandwidth, Windows System Resource Manager lowers the priority of that process. This allows competing processes to use the CPU bandwidth equal to the difference between all remaining CPU bandwidth and the CPU bandwidth allocated to the process.

If a process is using less bandwidth than its allocated amount, the extra bandwidth is re-allocated to other managed processes. This occurs according to the default bandwidth allocation rules.

Because Windows System Resource Manager attempts to meet the CPU needs of running processes, it does not prevent an application from using unconsumed CPU bandwidth that no other process is using. Instead, a process is limited to its allocation only if there is not enough CPU bandwidth to satisfy the CPU demands of every running process.

**CPU Consumption Target Interactions**

In the following figure, a resource allocation policy is running and includes a CPU consumption target. To achieve the target CPU consumption, the Windows System Resource Manager service sends information to the kernel scheduler to control how managed processes are scheduled for CPU resources.

**Interactions that Occur When a CPU consumption Target Is Set**

**How Memory Resources Are Managed**

In Windows System Resource Manager, memory-allocation policies are configurable properties in a resource allocation. Memory-allocation policies limit the amount of working set memory and committed memory processes are allowed to consume.

Limits are applied on a per-process basis. For example, if you create a resource allocation that specifies a working set limit of 10 megabytes (MB) and a process-matching criterion that matches six processes, the limit of 10 MB is applied individually to each of the six processes.

**Working Set Memory**

You can set an upper limit on the process working set of the resource-allocation policy's process groups. Through the memory manager, Windows System Resource Manager prevents the working set of a process from exceeding the limit defined in the resource allocation. If the limit is reached, subsequent memory allocations do not fail, but existing pages in the working set of the process are replaced. This meets the memory limit without inducing any failures in the running application. Applications are generally unaware that the memory manager is reusing physical memory because applications are running in a virtual memory space.

**Committed Memory**
You can set an upper limit on the committed memory that a process consumes. Typically, if there is a constant increase in the committed memory a process consumes, it is due to a memory leak. By setting a limit on the amount of committed memory a process consumes, you can have Windows System Resource Manager intervene if a memory leak occurs. When the limit is reached, Windows System Resource Manager can either terminate the process or log an error in the event log.

The Windows System Resource Manager service maintains the committed memory limits in the current active resource allocation policy and actively monitors the committed memory usage of each matching process to determine when the limit is reached.

**Memory Limit Interactions**
Windows System Resource Manager enforces limits on committed memory and working set memory for processes. Windows System Resource Manager is not involved in the actual allocation of memory to a process, other than to signal the memory manager when there are memory limits in the currently active policy to be enforced. If the memory manager receives a signal from Windows System Resource Manager that a process is exceeding its memory limit, it will not allocate additional memory to a process.

In the following figure, a resource allocation policy is running and includes a memory limit.

**Interactions That Occur When a Memory Limit Is Set**

**Network Ports Used by Windows System Resource Manager**
Windows System Resource Manager uses only the ports already used by the Distributed Common Object Model (DCOM) service running on the computer. For more information about the ports used by DCOM, see "Using Distributed COM with Firewalls" at the Microsoft Web site.

# Networking Collection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Networking Collection**
Microsoft Windows Server 2003 offers a wide variety of technologies to meet the complex needs of today's connected environments. The networking technologies in Windows Server 2003 are designed to support all types of businesses, from small-inter-office network configurations to the largest enterprise solutions. The Windows Server 2003 networking technologies that are described in the Networking Collection are grouped into the following sub-collections:

- Core Networking Technologies
- Routing Technologies
- Network Monitoring Technologies
- Name Resolution Technologies
- Network Configuration Technologies
- Network Access Technologies
- Network Interoperability Technologies
- Remote Access Technologies
- Data Streaming and E-mail Technologies
- Network Security Technologies

**Core Networking Technologies**
The sub-collection "Core Networking Technologies" contains information about the TCP/IP protocol suite that is installed by default with Windows Server 2003. TCP/IP is an industry-standard suite of protocols designed to enable enterprise-wide network communications. There are two versions of TCP/IP that are supported by Windows Server 2003:

- TCP/IP with Internet Protocol version 4 (IPv4)
- TCP/IP with Internet Protocol version 6 (IPv6)

**IPv4**
IPv4 is a suite of protocols and standards based on the original IP specification described in RTF 791 in the IETF RFC Database and is in widespread use today on the Internet and on private networks. IPv4 has a relatively small address space that is quickly being depleted as Internet use expands. The need for more IP addresses and support for newer networking technologies are motivating factors in the adoption of IPv6.

**IPv6**
IPv6 is a suite of protocols and standards that supports a much larger address space than IPv4. IPv6 has 128-bit (16-byte) source and destination IP addresses. In contrast, IPv4 has 32-bit (4 bytes) source and destination IP addresses. IPv6 has many other security and efficiency improvements.

**Routing Technologies**
The sub-collection "Routing Technologies" contains information about the routing technologies that are supported by Windows Server 2003. Routing technologies manage the flow of data between network segments, also known as subnets. These routing technologies include:

- Unicast routing

- Multicast routing
- Network address translation (NAT)

**Unicast Routing**
Unicast routing forwards packets from one host to another host using the unicast destination IP address. This topic describes the IPv4 unicast routing technologies included in the Routing and Remote Access service

**Multicast Routing**
Multicast IP routing forwards packets from one host to multiple hosts using the multicast destination IP address. This topic describes the IPv4 multicast forwarding technologies included in the TCP/IP (IPv4) protocol and the Routing and Remote Access service.

**NAT**
Network address translation (NAT) functionality is part of the Routing and Remote Access service. A server that has been configured as a NAT-enabled router, with a private IP address and at least one public IP address, translates the private addresses (and TCP or UDP port numbers) in outgoing packets. The outgoing packets can then be forwarded to a resource on a public network, such as the Internet. The NAT-enabled router also translates incoming traffic and forwards the incoming packets to the appropriate address on the private network.

**Network Monitoring Technologies**
The sub-collection "Network Monitoring Technologies" contains information about network data-gathering services that are supported by Windows Server 2003. These services include:

- Computer Browser service
- Simple Network Management Protocol (SNMP)

**Computer Browser Service**
Computer Browser service is used by Windows-based computers to collect, distribute, and obtain the browser list, a collection of information about workgroups, domains, and the computers within them. The browser list is available to programs that request it, such as My Network Places.

**SNMP**
Simple Network Management Protocol (SNMP) is a network management protocol and infrastructure widely used in TCP/IP networks to remotely monitor, configure, and troubleshoot network resources from a centrally located SNMP management system.

**Name Resolution Technologies**
The sub-collection "Name Resolution Technologies" contains information about Windows Server 2003 support for name resolution services that include:

- Domain Name System (DNS)
- Windows Internet Name Service (WINS)

**DNS**
Domain Name System (DNS) is a domain name resolution service that allows client computers to register their domain names and IP addresses in a dynamic, distributed database and to resolve the domain names of network resources to their IPv4 or IPv6 addresses.

**WINS**
WINS is a NetBIOS name resolution service that allows client computers to register their NetBIOS names and IP addresses in a dynamic, distributed database and to resolve the NetBIOS names of network resources to their IPv4 addresses.

**Network Configuration Technologies**
The sub-collection "Network Configuration Technologies" contains information about Windows Server 2003 support for network configuration services that include:

- Dynamic Host Configuration Protocol (DHCP)

- Windows Time Service

**DHCP**
Dynamic Host Configuration Protocol (DHCP) is used to automate the configuration of hosts on a network. DHCP clients request and DHCP servers allocate IP addresses and network configuration settings. DHCP servers maintain a database of IP address ranges, configuration settings, and the current set of allocated IP addresses.

**Windows Time Service**
Windows Time service uses the Network Time Protocol (NTP) to enable date and time synchronization among network resources on a Windows-based network. The Windows Time service can be used to automatically synchronize the time of a local computer with other computers on a network.

**Network Access Technologies**
The sub-collection "Network Access Technologies" contains information about Windows Server 2003 support for secure network access solutions including:

- 802.11 Wireless
- Virtual Private Network (VPN)
- Internet Authentication Service (IAS)
- Connection Manager

**802.11 Wireless**
The IEEE 802.11 is a set of standards for wireless LAN connectivity that allows the extension of a wired LAN to include wireless, mobile clients. For secure wireless connections, 802.11-based wireless networks use authentication (the IEEE 802.1X standard) and encryption (either Wired Equivalent Privacy or Wi-Fi Protected Access).

**VPN**
Virtual Private Network (VPN) technologies allow the creation of secure point-to-point logical links across shared or public networks such as the Internet. Remote access VPN connections allow VPN clients to securely connect to a private network over the Internet. Site-to-site VPN connections allow routers to connect the sites of an organization together across the Internet.

**IAS**
Internet Authentication Service (IAS) is the Microsoft implementation of a Remote Authentication Dial-in User Service (RADIUS) server and proxy. IAS RADIUS servers perform centralized connection authentication and authorization. IAS RADIUS servers also provide network access accounting services. IAS RADIUS proxies forward authentication and accounting messages from RADIUS clients to RADIUS servers, and from RADIUS servers to RADIUS clients.

**Connection Manager**
Connection Manager is a set of components that is used to create and maintain customized remote access client service profiles that enable users to connect to a network using administrator-defined connection parameters.

**Network Interoperability Technologies**
The sub-collection "Network Interoperability Technologies" contains information about technologies that support the core functionality that enables remote administration and directory service synchronization including:

- Remote Procedure Call (RPC)
- Services for NetWare (SFN)

**RPC**
Remote Procedure Call (RPC) is an interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality residing in a different process. That process can be on the same computer, on the local area network (LAN), or across the Internet.

**Services for NetWare**
Services for Netware (SFN) provides directory object migration and synchronization between computers that are running Windows Server 2003 with Active Directory and computers that are running Novell's NetWare operating system with NDS, eDirectory, and Bindery directory services.

**Remote Access Technologies**
The sub-collection “Remote Access Technologies” contains information about Windows Server 2003 support for remote access solutions including:

- Dial-up Remote Access
- Telnet
- Terminal Services

**Dial-up Remote Access**
Dial-up Remote Access enables remote access clients to connect to a network. Remote access clients use the available telecommunications infrastructure to create a temporary physical or virtual circuit to a port on a remote access server that is connected to a network. After the connection between the remote access client and the remote access server is established, the remote access server forwards packets between the remote access client and the network.

**Telnet**
Telnet is a protocol that enables remote connections from a remote access client to a host. A local command prompt on a remote access client can be used to run command-line programs, shell commands, and scripts in a remote command console session.

**Terminal Services**
Terminal Services delivers the Windows Server 2003 desktop and the latest Windows-based applications to a wide variety of desktops, including those that cannot normally run Windows. Terminal Services uses terminal emulation to host multiple, simultaneous client sessions. Terminal Services enables process scheduling, application-sharing, and multi-user functionality.

**Data Streaming and E-mail Technologies**
The sub-collection “Data Streaming and E-mail Technologies” contains information about Windows Server 2003 support for technologies that provide a baseline network infrastructure for streaming multimedia data. This sub-collection also contains information about Windows Server 2003 support for the transfer and retrieval of e-mail. The technologies in this sub-collection include:

- Asynchronous Transfer Mode (ATM)
- Quality of Service (QoS)
- POP3 Mail Server

**ATM**
Asynchronous Transfer Mode (ATM) is connection-oriented networking technology that establishes a defined network path, called a virtual channel, between two endpoints for the purpose of sending isochronous (time-dependent) network traffic. When the virtual channel is established, ATM also negotiates a QoS contract for the virtual channel. The QoS contract between the endpoints defines the bandwidth, the maximum transit delay, and an acceptable variance in the transit delay.

**QoS**
Quality of Service (QoS) is a set of service requirements that a network must meet to ensure an adequate service level for data transmission. QoS allows real-time programs to make the most efficient use of network bandwidth.

**POP3 Mail Server**
The POP3 service is a standard messaging protocol that is supported in Windows Server 2003. POP3 provides e-mail transfer and retrieval services.

**Network Security Technologies**
The sub-collection "Network Security Technologies" contains information about Windows Server 2003 network security technologies, which can help protect your network from intrusions, malicious software (malware), viruses, worms, and attacks that rely on unsolicited incoming traffic.

**Windows Firewall**
Windows Firewall is a stateful host-firewall technology that inspects and filters all IP version 4 (IPv4) and IP version 6 (IPv6) network traffic. As a stateful firewall, Windows Firewall tracks the state of each network connection and determines whether unsolicited incoming traffic is allowed or dropped. Windows Firewall blocks unsolicited incoming traffic unless the traffic is a response to a request by the host (solicited traffic) or it is specifically allowed (in which case, it has been added to the Windows

Firewall exceptions list). Exceptions can be specified by program name, UDP or TCP port number, or system service name. Aside from a few Internet Control Message Protocol (ICMP) messages, Windows Firewall allows all outgoing traffic.

# Core Networking Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In Microsoft Windows Server 2003, core networking tasks are accomplished by using TCP/IP. TCP/IP consists of a suite of protocols, of which TCP and IP are two. This suite of protocols was originally designed to solve a communications problem among the branches of the United States military. In the 1960s, each of the military branches obtained bids from different vendors to provide computer systems for their branch. The Army chose Digital Equipment Corporation (DEC), the Air Force chose International Business Machines (IBM), and the Navy chose Unisys. Soon after, the military branches discovered that they needed their computer systems to communicate with each other to facilitate coordination between the military branches. The Department of Defense (DoD) launched a research project in 1969 to connect the systems of various vendors together to form a network of networks. The DoD developed TCP/IP with IP version 4 (IPv4) to connect this network of networks — the collection of networks now known as the Internet. TCP/IP is still used to connect business networks across the world.

**Note**

- The word internetwork refers to multiple TCP/IP networks connected with routers. The Internet is a worldwide public IP internetwork. An intranet is a private IP internetwork.

IPv4 proved to be robust, easily implemented and interoperable. It has also stood the test of scalability from an internetwork to today's global Internet. However, the initial design did not fully allow for the following:

- The exponential growth of the Internet and the impending depletion of the IPv4 address space.

  The scarcity of IPv4 addresses has forced some organizations to use a network address translator to map multiple private addresses to a single public IP address. Network address translators promote reuse of the private address space, but they do not support standards-based network layer security or the correct mapping of all higher layer protocols. Moreover, the translators can create problems when connecting two organizations that use the private address space.

  Additionally, the rising prominence of Internet-connected devices and appliances ensures that the public IPv4 address space will eventually be depleted.

- The requirement for security at the IP level.

- Private communication over a public medium, such as the Internet, requires encryption services that protect the data being sent from being viewed or modified in transit. Although a standard now exists for providing security for IPv4 packets, known as Internet Protocol Security, or IPSec, this standard is optional.

- The growth of the Internet and the ability of Internet backbone routers to maintain large routing tables.

  Because of the way that IPv4 network IDs have been and are currently allocated, there are often over 85,000 routes in the routing tables of Internet backbone routers. The current IPv4 Internet routing infrastructure is a combination of both flat and hierarchical routing.

- The need for better support for real-time delivery of data, or Quality of Service (QoS).

  QoS standards exist for IPv4, but real-time traffic support relies on the IPv4 Type of Service (ToS) field and the identification of the payload, typically using either a User Datagram Protocol (UDP) or TCP port. Unfortunately, the IPv4 ToS field has limited functionality, and over time there have been various local interpretations. In addition, payload identification using a TCP and User Datagram Protocol (UDP) port is not possible when the IPv4 packet payload is encrypted.

To address these and other concerns, the Internet Engineering Task Force (IETF) developed IP version 6 (IPv6). IPv6, previously called IP next generation, incorporates the concepts of many proposed methods for updating the IPv4 protocol. The design of IPv6 is intentionally targeted for minimal impact on upper and lower layer protocols by avoiding the random addition of new features.

Windows Server 2003 supports TCP/IP with IPv4 and IPv6.

**Core Networking Components**
The core networking protocol, TCP/IP, which is installed by default on computers that run Windows Server 2003 is an industry-standard suite of protocols designed for large internetworks spanning wide area network (WAN) links. TCP/IP in Windows Server 2003 was designed to make it easy to integrate Microsoft systems into large-scale corporate, government and public networks, and to provide the ability to operate over those networks in a more secure manner. There are two versions of TCP/IP available for use with Windows Server 2003: TCP/IP version 4 (with IPv4) and TCP/IP version 6 (with IPv6).

**TCP/IP (with IPv4)**
TCP/IP in Windows Server 2003 enables enterprise networking and connectivity that have the following features:

- A standard, routable enterprise networking protocol that is the most complete and accepted protocol available. All modern, network operating systems offer TCP/IP support, and most large networks rely on TCP/IP for much of their network traffic.

- A technology for connecting dissimilar systems. Many standard connectivity tools are available to access and transfer data between dissimilar systems, including File Transfer Protocol (FTP) and Telnet, a terminal emulation protocol. Several of these standard tools are included with Windows Server 2003.

- A robust, scalable, cross-platform client/server framework. TCP/IP in Windows Server 2003 offers the Windows Sockets (Winsock) interface, which is ideal for developing client/server applications that can run on Winsock-compliant TCP/IP protocol implementations from other vendors.

- A method of gaining access to the Internet. The Internet consists of thousands of networks worldwide, connecting research facilities, universities, libraries, and private companies.

For more information about Windows Server 2003 TCP/IP, see TCP/IP Technical Reference.

**IPv6**
The following features of the IPv6 protocol overcome the limitations of IPv4:

- New header format

- Large address space

- Efficient and hierarchical addressing and routing infrastructure

- Stateless and stateful address configuration

- Built-in security measures

- Better support for QoS

- New protocol for neighboring node interaction

- Extensibility

IPv6 includes new capabilities such as scoped addresses, stateless autoconfiguration, lowering the complexity and management burden, and mandatory IPSec, permitting end-to-end data authentication, data integrity, and privacy of connections. In addition to the new capabilities, IPv6 brings back the capability of end-to-end communications; making networking applications simpler as the network again becomes transparent

### Note

- In IPv4, end-to-end communications have been largely replaced by a client/server model because network address translators are better behaved for client/server communications. The translators also extend the lifetime of IPv4 by enabling multiple operating systems to share a single, public IPv4 address.

IPv6 supports always-on technologies such as Digital Subscriber Line (DSL) and cable modems, personal data assistants (PDAs), and cellular Mobile Information Appliances. Windows Server 2003 supports the capability to send IPv6 traffic over existing IPv4 networks.

For more detailed information about these features, see IPv6 Technical Reference.

**Core Networking Scenarios**

Computers that run Windows operating systems use TCP/IP to communicate with other computers in corporate intranets, and across the Internet. As such, TCP/IP is an essential component of any Windows network configuration. Windows Server 2003 is the first release of the Windows operating system that includes IPv6. Ideally, IPv6 is used in a pure environment, meaning an environment where IPv6 is the exclusive Internet protocol used between computers. Currently, however, pure IPv6 environments are attainable only when you use computers running Windows operating systems that support IPv6 and routers that support IPv6 routing. As IPv6 replace IPv4, pure IPv6 environments will eventually replace IPv4. Until that occurs, the transition technologies described in this technical reference can be used to facilitate coexistence and provide a migration path from IPv4 to IPv6.

# TCP/IP Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Transmission Control Protocol/Internet Protocol, or TCP/IP, is a protocol suite developed for communications over, often dissimilar, networks. Microsoft Windows Server 2003 provides extensive support for the TCP/IP suite for IP version 4 (IPv4), as both a protocol and a set of services for connectivity and management of IP internetworks. Knowledge of the basic concepts of TCP/IP is an absolute requirement for the proper understanding of the configuration, deployment, and troubleshooting of Windows Server 2003.

This subject describes how TCP/IP with IPv4 relates to other networking protocols, the functions it performs, how addresses are structured and assigned, and how packets are structured and routed.

# What Is TCP/IP?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is TCP/IP?**

**In this section**

- Windows Server 2003 TCP/IP
- TCP/IP Core Protocols
- TCP/IP Services
- Related Information

Transmission Control Protocol/Internet Protocol, or TCP/IP, is an industry-standard suite of protocols designed for large internetworks. TCP/IP, which was developed in 1969 by the U.S. Department of Defense (DoD) Advanced Research Projects Agency (DARPA), is the result of a resource-sharing experiment called Advanced Research Projects Agency Network (ARPANET). The TCP/IP protocol was developed to provide high-speed communication network links. Since 1969, ARPANET has grown into a worldwide community of networks known as the Internet.

Before TCP/IP, there was no way for computers to communicate easily and securely on public networks. Windows Server 2003 TCP/IP was designed to make it easy to integrate Microsoft systems into large-scale corporate, government, and public networks, and to provide the ability to operate over those networks in a secure manner. The Windows Server 2003 TCP/IP protocol is installed by default and, unlike previous versions of Windows, cannot be uninstalled. However, you can reset the TCP/IP configuration to a default state with the **netsh interface ip reset** command.

The Windows TCP/IP suite contains *core protocol elements*, *services*, and the *interfaces* between them. The Transport Driver Interface (TDI) and the Network Device Interface Specification (NDIS) are public, and their specifications are available from Microsoft. In addition, there are a number of higher-level interfaces available to user-mode applications. The most commonly used are Windows Sockets and NetBIOS.

**Windows Server 2003 TCP/IP**

Windows Server 2003 TCP/IP enables enterprise networking and connectivity. Adding TCP/IP to a Windows Server 2003 configuration offers the following advantages:

- A standard, routable enterprise networking protocol that is the most complete and accepted protocol available. All modern network operating systems offer TCP/IP support, and most large networks rely on TCP/IP for much of their network traffic.
- A technology for connecting dissimilar systems. Many standard connectivity utilities are available to access and transfer data between dissimilar systems, including File Transfer Protocol (FTP) and Telnet, a terminal emulation protocol. Several of these standard utilities are included with Windows Server 2003.
- A robust, scalable, cross-platform client/server framework. Windows Server 2003 TCP/IP offers the Windows Sockets interface, which is ideal for developing client/server applications that can run on Windows Sockets–compliant TCP/IP protocol implementations from other vendors.
- A method of gaining access to the Internet. The Internet consists of thousands of networks worldwide, connecting research facilities, universities, libraries, private companies, and individuals.

**Note**

- The term Internet refers to the worldwide public Internet. An intranet refers to a private IP-based internetwork.

**Support for Standard Features**

Windows Server 2003 TCP/IP supports the following standard features:

- Ability to bind to multiple network adapters with different media types.
- Logical and physical multihoming.
- Internal IP routing capability.
- Internet Group Management Protocol (IGMP) (IP multicasting).
- Duplicate IP address detection.
- Multiple configurable default gateways.
- Dead gateway detection.
- Automatic Path Maximum Transmission Unit (PMTU) discovery.
- Internet Protocol security (IPSec).
- Quality of Service (QoS).
- Asynchronous Transfer Mode Tutorial (ATM) services.
- Virtual Private Networks (VPNs) with the Point-to-Point Tunneling Protocol (PPTP) and the Layer Two Tunneling Protocol with IPSec (L2TP/IPSec).

**Windows Server 2003 TCP/IP Features**

The features and improvements of TCP/IP for Windows Server 2003 include the following:

- Windows Server 2003 and Windows XP (Service Pack 1 or later) now include a production-quality IPv6 protocol stack. For more information about IPv6, see IPv6 Technical Reference.
- Auto-negotiation of RFC 1323 options (window scaling and TCP timestamps).
- Default support of network interface cards providing large send offload (LSO) and checksum offload.
- Internet Group Management Protocol (IGMP) version 3.
- Reliable multicast with Pragmatic General Multicast (PGM).
- Alternate configuration of a static IP address configuration.
- Automatic determination of the interface-related and default route metrics.

**TCP/IP Standards**

The standards for TCP/IP are published in a series of documents that are called Requests for Comments (RFCs). RFCs describe the internal workings of the Internet. Some RFCs describe network services or protocols and their implementations, whereas others summarize policies. TCP/IP standards are always published as RFCs, although not all RFCs specify standards.

TCP/IP standards are not developed by a committee, but rather by consensus. Anyone can submit a document for publication as an RFC. Documents are reviewed by a technical expert, a task force, or the RFC editor, and then assigned a status. The status specifies whether a document is being considered for becoming a standard.

There are five RFC status assignments, shown below.

**RFC Status Assignments**

| Status | Description |
|---|---|
| Required | Must be implemented on all TCP/IP-based hosts and gateways. |
| Recommended | Encouraged that all TCP/IP-based hosts and gateways implement the RFC specifications. Recommended RFCs are usually implemented. |
| Elective | Implementation is optional. Application has been agreed to but is not a requirement. |
| Limited Use | Not intended for general use. |
| Not Recommended | Not recommended for implementation. |

If a document is being considered for becoming a standard, it goes through stages of development, testing, and acceptance known as the Internet Standards Process. These stages are formally labeled maturity levels. The following table lists the three maturity levels for Internet Standards.

**Maturity Levels for Internet Standards**

| Maturity Level | Description |
|---|---|
| Proposed Standard | This specification is generally stable, has resolved known design issues, is believed to be well understood, has received significant community review, and appears to hold enough community interest to be considered valuable. |
| Draft Standard | This must be well understood and known to be quite stable, both in its semantics and as a basis for developing an implementation. |
| Internet Standard | This specification is characterized by a high degree of technical maturity, and it is generally agreed that the specified protocol or service provides significant benefit to the Internet community. |

When a document is published, it is assigned an RFC number. If changes are required, a new RFC is published with a new number. The original RFC is never updated. Therefore, it is important to verify that you have the most recent RFC on a particular topic.

RFCs can be obtained in several ways. To obtain any RFC, or a full and current indexed listing of all RFCs published to date, see the IETF RFC Database.

#### TCP/IP Core Protocols

The TCP/IP protocol component that is installed in your network operating system is a series of interconnected protocols called the TCP/IP core protocols. All other applications and other protocols in the TCP/IP protocol suite rely on the basic services provided by the following protocols: IP, ARP, ICMP, IGMP, TCP, and UDP. For more information about these protocols, see How TCP/IP Works.

#### TCP/IP Services

The Windows Server 2003 operating system provides the following TCP/IP-related services:

- Dynamic Host Configuration Protocol (DHCP) client and server and DHCP Relay Agent (with the Routing and Remote Access service).
- In the absence of a DHCP server, Automatic Private IP Addressing (APIPA) or an alternate static IP address configuration is used.
- Windows Internet Name Service (WINS), a NetBIOS name client and server.
- Domain Name System (DNS) client and server, including support for DNS dynamic updates.
- Dial-up support using the Point-to-Point Protocol (client and server) and Serial Line Internet Protocol (client only).
- PPTP and L2TP/IPSec, used for remote access and site-to-site VPN connections.
- TCP/IP network printing (client only with the Lpr.exe and Lpq.exe tools).

- SNMP agent.
- NetBIOS interface.
- Network Location Service.
- Windows Sockets version 2 (Winsock2) interface.
- Remote Procedure Call (RPC) support.
- Network Dynamic Data Exchange (NetDDE).
- Computer browsing (My Network Places) across IP routers.
- Reliable multicast with the Pragmatic General Multicast (PGM) protocol.
- Basic TCP/IP connectivity utilities, including: **finger, ftp, rcp, rexec, rsh, telnet,** and **tftp.**
- Server and client software for simple network protocols, including: Character Generator, Daytime, Discard, Echo, and Quote of the Day.
- Routing Information Protocol (RIP) listener (for Windows XP Professional) and RIP and Open Shortest Path First (OSPF) (with the Routing and Remote Access service).
- Network Address Translator (NAT) capabilities using either the Internet Connection Service (ICS) or the NAT/Basic Firewall routing protocol component of the Routing and Remote Access Service.
- Stateful firewalling capabilities using either the Internet Connection Firewall (ICF) or the NAT/Basic Firewall routing protocol component of the Routing and Remote Access service.
- Multicast forwarding and IGMP router and proxy capabilities with the Routing and Remote Access Service.
- TCP/IP management and diagnostic tools, including: **arp, ipconfig, nbtstat, netsh, netstat, ping, pathping, route, nslookup,** and **tracert**.

**How TCP/IP Works**

**In this section**

- TCP/IP Protocol Architecture
- IPv4 Addressing
- Name Resolution
- IPv4 Routing
- Physical Address Resolution
- Related Information

TCP/IP for IP version 4 (IPv4) is a networking protocol suite that Microsoft Windows uses to communicate over the internet with other computers. It interacts with Windows naming services like DNS and security technologies, such as IPsec primarily, as these help facilitate the successful and secure transfer of IP packets between machines.

Ideally, TCP/IP is used whenever Windows-based computers communicate over networks.

This subject describes the components of the TCP/IP Protocol Suite, the protocol architecture, which functions TCP/IP performs, how addresses are structured and assigned, and how packets are structured and routed.

Microsoft Windows Server 2003 provides extensive support for the Transmission Control Protocol/Internet Protocol (TCP/IP) suite, as both a protocol and a set of services for connectivity and management of IP internetworks. Knowledge of the basic concepts of TCP/IP is an absolute requirement for the proper understanding of the configuration, deployment, and troubleshooting of IP-based Windows Server 2003 and Microsoft Windows 2000 intranets.

**TCP/IP Protocol Architecture**

TCP/IP protocols map to a four-layer conceptual model known as the DARPA model, named after the U.S. government agency that initially developed TCP/IP. The four layers of the DARPA model are: Application, Transport, Internet, and Network Interface. Each layer in the DARPA model corresponds to one or more layers of the seven-layer Open Systems Interconnection (OSI) model.

The following figure shows the TCP/IP protocol architecture.

**TCP/IP Protocol Architecture**

**Note**

- The architectural diagram above corresponds to the Internet Protocol TCP/IP and does not reflect IP version 6. To see a

TCP/IP architectural diagrm that includes IPv6, see *How IPv6 Works* in this technical reference.

**Network Interface Layer**
The Network Interface layer (also called the Network Access layer) handles placing TCP/IP packets on the network medium and receiving TCP/IP packets off the network medium. TCP/IP was designed to be independent of the network access method, frame format, and medium. In this way, TCP/IP can be used to connect differing network types. These include local area network (LAN) media such as Ethernet and Token Ring and WAN technologies such as X.25 and Frame Relay. Independence from any specific network media allows TCP/IP to be adapted to new media such as asynchronous transfer mode (ATM).

The Network Interface layer encompasses the Data Link and Physical layers of the OSI model. Note that the Internet layer does not take advantage of sequencing and acknowledgment services that might be present in the Network Interface layer. An unreliable Network Interface layer is assumed, and reliable communication through session establishment and the sequencing and acknowledgment of packets is the function of the Transport layer.

**Internet Layer**
The Internet layer handles addressing, packaging, and routing functions. The core protocols of the Internet layer are IP, ARP, ICMP, and IGMP.

- The Internet Protocol (IP) is a routable protocol that handles IP addressing, routing, and the fragmentation and reassembly of packets.
- The Address Resolution Protocol (ARP) handles resolution of an Internet layer address to a Network Interface layer address, such as a hardware address.
- The Internet Control Message Protocol (ICMP) handles providing diagnostic functions and reporting errors due to the unsuccessful delivery of IP packets.
- The Internet Group Management Protocol (IGMP) handles management of IP multicast group membership.

The Internet layer is analogous to the Network layer of the OSI model.

**Transport Layer**
The Transport layer (also known as the Host-to-Host Transport layer) handles providing the Application layer with session and datagram communication services. The core protocols of the Transport layer are Transmission Control Protocol (TCP) and the User Datagram Protocol (UDP).

- TCP provides a one-to-one, connection-oriented, reliable communications service. TCP handles the establishment of a TCP connection, the sequencing and acknowledgment of packets sent, and the recovery of packets lost during transmission.
- UDP provides a one-to-one or one-to-many, connectionless, unreliable communications service. UDP is used when the amount of data to be transferred is small (such as data that fits into a single packet), when you do not want the overhead of establishing a TCP connection, or when the applications or upper layer protocols provide reliable delivery.

The TCP/IP Transport layer encompasses the responsibilities of the OSI Transport layer.

**Application Layer**
The Application layer lets applications access the services of the other layers and defines the protocols that applications use to exchange data. There are many Application layer protocols and new protocols are always being developed.

The most widely known Application layer protocols are those used for the exchange of user information:

- The Hypertext Transfer Protocol (HTTP) is used to transfer files that make up the Web pages of the World Wide Web.
- The File Transfer Protocol (FTP) is used for interactive file transfer.
- The Simple Mail Transfer Protocol (SMTP) is used for the transfer of mail messages and attachments.
- Telnet, a terminal emulation protocol, is used for logging on remotely to network hosts.

Additionally, the following Application layer protocols help facilitate the use and management of TCP/IP networks:

- The Domain Name System (DNS) is used to resolve a host name to an IP address.
- The Routing Information Protocol (RIP) is a routing protocol that routers use to exchange routing information on an IP internetwork.
- The Simple Network Management Protocol (SNMP) is used between a network management console and network devices (routers, bridges, intelligent hubs) to collect and exchange network management information.

Examples of Application layer interfaces for TCP/IP applications are Windows Sockets and NetBIOS. Windows Sockets provides a standard application programming interface (API) under Windows Server 2003. NetBIOS is an industry-standard interface for accessing protocol services such as sessions, datagrams, and name resolution. More information on Windows Sockets and NetBIOS is provided later in this chapter.

The TCP/IP Application layer encompasses the responsibilities of the OSI Session, Presentation, and Application layers.

**TCP/IP Core Protocols**

The TCP/IP protocol component that is installed in your network operating system is a series of interconnected protocols called the core protocols of TCP/IP. All other applications and other protocols in the TCP/IP protocol suite rely on the basic services provided by the following protocols: IP, ARP, ICMP, IGMP, TCP, and UDP.

**IP**

IP is a connectionless, unreliable datagram protocol primarily responsible for addressing and routing packets between hosts. Connectionless means that a session is not established before exchanging data. Unreliable means that delivery is not guaranteed. IP always makes a "best effort" attempt to deliver a packet. An IP packet might be lost, delivered out of sequence, duplicated, or delayed. IP does not attempt to recover from these types of errors. The acknowledgment of packets delivered and the recovery of lost packets is the responsibility of a higher-layer protocol, such as TCP. IP is defined in RFC 791.

An IP packet consists of an IP header and an IP payload. The following table describes the key fields in the IP header.

**Key Fields in the IP Header**

| IP Header Field | Function |
|---|---|
| Source Address | The IP address of the original source of the IP datagram. |
| Destination Address | The IP address of the final destination of the IP datagram. |
| Identification | Used to identify a specific IP datagram and to identify all fragments of a specific IP datagram if fragmentation occurs. |
| Protocol | Informs IP at the destination host whether to pass the packet up to TCP, UDP, ICMP, or other protocols. |
| Checksum | A simple mathematical computation used to verify the bit-level integrity of the IP header. |
| Time to Live (TTL) | Designates the number of network segments on which the datagram is allowed to travel before being discarded by a router. The TTL is set by the sending host and is used to prevent packets from endlessly circulating on an IP internetwork. When forwarding an IP packet, routers are required to decrease the TTL by at least one. |

**Fragmentation and reassembly**

If a router receives an IP packet that is too large for the network to which the packet is being forwarded, IP fragments the original packet into smaller packets that fit on the downstream network. When the packets arrive at their final destination, IP on the destination host reassembles the fragments into the original payload. This process is referred to as fragmentation and reassembly. Fragmentation can occur in environments that have a mix of networking media, such as Ethernet and Token Ring.

The fragmentation and reassembly works as follows:

- When an IP packet is sent by the source, it places a unique value in the **Identification** field.
- The IP packet is received at the router. The IP router notes that the maximum transmission unit (MTU) of the network

onto which the packet is to be forwarded is smaller than the size of the IP packet.

- IP divides the original IP payload into fragments that fit on the next network. Each fragment is sent with its own IP header that contains:
    - The original **Identification** field identifying all fragments that belong together.
    - The **More Fragments Flag** indicating that other fragments follow. The **More Fragments Flag** is not set on the last fragment, because no other fragments follow it.
    - The **Fragment Offset** field indicating the position of the fragment relative to the original IP payload.

When the fragments are received by IP at the remote host, they are identified by the **Identification** field as belonging together. The **Fragment Offset** field is then used to reassemble the fragments into the original IP payload.

**ARP**
When IP packets are sent on shared access, broadcast-based networking media — such as Ethernet or Token Ring — the media access control (MAC) address corresponding to a forwarding IP address must be resolved. ARP uses MAC-level broadcasts to resolve a known forwarding or next-hop IP address to its MAC address. ARP is defined in RFC 826.

**ICMP**
Internet Control Message Protocol (ICMP) provides troubleshooting facilities and error reporting for packets that are undeliverable. For example, if IP is unable to deliver a packet to the destination host, ICMP sends a Destination Unreachable message to the source host. The following table shows the most common ICMP messages.

**Common ICMP Messages**

| ICMP Message | Function |
|---|---|
| Echo Request | Troubleshooting message used to check IP connectivity to a desired host. The ping utility sends ICMP Echo Request messages. |
| Echo Reply | Response to an ICMP Echo Request. |
| Redirect | Sent by a router to inform a sending host of a better route to a destination IP address. |
| Source Quench | Sent by a router to inform a sending host that its IP datagrams are being dropped due to congestion at the router. The sending host then lowers its transmission rate. Source Quench is an elective ICMP message and is not commonly implemented. |
| Destination Unreachable | Sent by a router or the destination host to inform the sending host that the datagram cannot be delivered. |

The following table describes the most common ICMP Destination Unreachable ICMP messages.

**Common ICMP Destination Unreachable Messages**

| Destination Unreachable Message | Description |
|---|---|
| Host Unreachable | Sent by an IP router when a route to the destination IP address cannot be found. |
| Protocol Unreachable | Sent by the destination IP node when the **Protocol** field in the IP header cannot be matched with an IP client protocol currently loaded. |
| Port Unreachable | Sent by the destination IP node when the Destination Port in the UDP header cannot be matched with a process using that port. |
| Fragmentation Needed and DF Set | Sent by an IP router when fragmentation must occur but is not allowed due to the source node setting the **Don't Fragment (DF)** flag in the IP header. |

| | |
|---|---|
| Source Route Failed | Sent by an IP router when delivery of the IP packet using source route information (stored as source route option headers) fails. |

ICMP does not make IP a reliable protocol. ICMP attempts to report errors and provide feedback on specific conditions. ICMP messages are carried as unacknowledged IP datagrams and are themselves unreliable. ICMP is defined in RFC 792.

**IGMP**

Internet Group Management Protocol (IGMP) is a protocol that manages host membership in IP multicast groups on a network segment. An IP multicast group, also known as a host group, is a set of hosts that listen for IP traffic destined for a specific IP multicast address. IP multicast traffic is sent to a single MAC address but processed by multiple IP hosts. A specific host listens on a specific IP multicast address and receives all packets to that IP address.

The following are some of the additional aspects of IP multicasting:

- Host group membership is dynamic, hosts can join and leave the group at any time.
- A host group can be of any size.
- Members of a host group can span IP routers across multiple networks. This situation requires IP multicast support on the IP routers and the ability for hosts to register their group membership with local routers. Host registration is accomplished using IGMP.
- A host can send traffic to an IP multicast address without belonging to the corresponding host group.

For a host to receive IP multicasts, an application must inform IP that it will receive multicasts at a specified IP multicast address. If the network technology supports hardware-based multicasting, the network interface is told to pass up packets for a specific IP multicast address. In the case of Ethernet, the network adapter is programmed to respond to a multicast MAC address corresponding to the specified IP multicast address.

A host supports IP multicast at one of the following levels:

- Level 0: No support to send or receive IP multicast traffic.
- Level 1: Support exists to send but not receive IP multicast traffic.
- Level 2: Support exists to both send and receive IP multicast traffic. Windows Server 2003, Windows 2000, Microsoft Windows NT version 3.5 and later, and TCP/IP support level 2 IP multicasting.

The protocol to register host group information is IGMP, which is required on all hosts that support level 2 IP multicasting. IGMP packets are sent using an IP header.

IGMP messages take three forms.

- **Host Membership Report**. When a host joins a host group, it sends an IGMP Host Membership Report message to the all-hosts IP multicast address (224.0.0.1) or to the specified IP multicast address declaring its membership in a specific host group by referencing the IP multicast address. A host can also specify the specific sources from which multicast traffic is needed.
- **Host Membership Query**. When a router polls a network to ensure that there are members of a specific host group, it sends an IGMP Host Membership Query message to the all-hosts IP multicast address. If no responses to the poll are received after several polls, the router assumes no membership in that group for that network and stops advertising that multicast group information to other routers.
- **Group Leave**. When a host is no longer interested in receiving multicast traffic sent to a specific IP multicast address and it sent the last IGMP Host Membership Report message in response to an IGMP Host Membership Query, it sends an IGMP Group Leave message to the specific IP multicast address. Local routers verify that the host sending the IGMP Group Leave message is the last group member for that multicast address on that subnet. If no responses to the poll are received after several polls, the router assumes no membership in that group for that subnet and stops advertising that multicast group information to other routers.

For IP multicasting to span routers across an internetwork, multicast routing protocols are used by routers to communicate host group information so that each router supporting multicast forwarding is aware of which networks contain members of which host groups. IGMP is defined in RFCs 1112 and 2236.

**TCP**

TCP is a reliable, connection-oriented delivery service. The data is transmitted in segments. Connection-oriented means that a connection must be established before hosts can exchange data. Reliability is achieved by assigning a sequence number to each segment transmitted. An acknowledgment is used to verify that the data is received. For each segment sent, the receiving host must return an acknowledgment (ACK) within a specified period for bytes received. If an ACK is not received, the data is retransmitted. TCP is defined in RFC 793.

TCP uses byte-stream communications, wherein data within the TCP segment is treated as a sequence of bytes with no record or field boundaries. The following table describes the key fields in the TCP header.

**Key Fields in the TCP Header**

| Field | Function |
|---|---|
| Source Port | TCP port of sending host. |
| Destination Port | TCP port of destination host. |
| Sequence Number | Sequence number of the first byte of data in the TCP segment. |
| Acknowledgment Number | Sequence number of the byte the sender expects to receive next from the other side of the connection. |
| Window | Current size of a TCP buffer on the host sending this TCP segment to store incoming segments. |
| TCP Checksum | Verifies the bit-level integrity of the TCP header and the TCP data. |

**TCP ports**

A TCP port provides a specific location for delivery of TCP segments. Port numbers below 1024 are well-known ports and are assigned by the Internet Assigned Numbers Authority (IANA). The following table lists a few well-known TCP ports.

**Well-Known TCP Ports**

| TCP Port Number | Description |
|---|---|
| 20 | FTP (Data Channel) |
| 21 | FTP (Control Channel) |
| 23 | Telnet |
| 80 | HTTP used for the World Wide Web |
| 139 | NetBIOS session service |

**TCP three-way handshake**

A TCP connection is initialized through a three-way handshake. The purpose of the three-way handshake is to synchronize the sequence number and acknowledgment numbers of both sides of the connection and exchange TCP window sizes or the use of large window sizes or TCP timestamps. The following steps outline the process:

1. The initiator of the TCP connection, typically a client, sends a TCP segment to the server with an initial Sequence Number for the connection and a window size indicating the size of a buffer on the client to store incoming segments from the server.

2. The responder of the TCP connection, typically a server, sends back a TCP segment containing its chosen initial Sequence Number, an acknowledgment of the client's Sequence Number, and a window size indicating the size of a buffer on the server to store incoming segments from the client.

3. The initiator sends a TCP segment to the server containing an acknowledgment of the server's Sequence Number.

TCP uses a similar handshake process to end a connection. This guarantees that both hosts have finished transmitting and that all data was received.

**UDP**

UDP provides a connectionless datagram service that offers unreliable, best-effort delivery of data transmitted in messages. This means that neither the arrival of datagrams nor the correct sequencing of delivered packets is guaranteed. UDP does not recover from lost data through retransmission. UDP is defined in RFC 768.

UDP is used by applications that do not require an acknowledgment of receipt of data and that typically transmit small amounts of data at one time. NetBIOS name service, NetBIOS datagram service, and SNMP are examples of services and applications that use UDP. The following table describes the key fields in the UDP header.

**Key Fields in the UDP Header**

| Field | Function |
|---|---|
| Source Port | UDP port of sending host. |
| Destination Port | UDP port of destination host. |
| UDP Checksum | Verifies the bit-level integrity of the UDP header and the UDP data. |

**UDP ports**

To use UDP, an application must supply the IP address and UDP port number of the destination application. A port provides a location for sending messages. A port functions as a multiplexed message queue, meaning that it can receive multiple messages at a time. Each port is identified by a unique number. It is important to note that UDP ports are distinct and separate from TCP ports even though some of them use the same number. The following table lists a few well-known UDP ports.

**Well-Known UDP Ports**

| UDP Port Number | Description |
|---|---|
| 53 | Domain Name System (DNS) name queries |
| 69 | Trivial File Transfer Protocol (TFTP) |
| 137 | NetBIOS name service |
| 138 | NetBIOS datagram service |
| 161 | SNMP |

**TCP/IP Application Interfaces**

For applications to access the services offered by the core TCP/IP protocols in a standard way, network operating systems like Windows Server 2003 make industry-standard application programming interfaces (APIs) available. APIs are sets of functions and commands that are programmatically called by application code to perform network functions. For example, a Web browser application connecting to a Web site needs access to TCP's connection establishment service.

The following figure shows two common TCP/IP APIs, Windows Sockets and NetBIOS, and their relation to the core protocols.

**APIs for TCP/IP**

**Windows Sockets Interface**

The Windows Sockets API is a standard API under Windows Server 2003 for applications that use TCP and UDP. Applications written to the Windows Sockets API run on many versions of TCP/IP. TCP/IP utilities and the SNMP service are examples of applications written to the Windows Sockets interface.

Windows Sockets provides services that allow applications to bind to a particular port and IP address on a host, initiate and accept a connection, send and receive data, and close a connection. There are two types of sockets:

- A stream socket provides a two-way, reliable, sequenced, and unduplicated flow of data using TCP.
- A datagram socket provides a one-way or two-way flow of data using UDP.

A socket is defined by a protocol and an address on the host. The format of the address is specific to each protocol. In TCP/IP, the address is the combination of the IP address and port. Two sockets, one for each end of the connection, form a bi-directional communications path.

To communicate, an application specifies the protocol, the IP address of the destination host, and the port of the destination application. After the application is connected, information can be sent and received.

**NetBIOS Interface**

NetBIOS allows applications to communicate over a network. NetBIOS defines two entities, a session-level interfaceand a session management and data transport protocol.

The NetBIOS interface is a standard API for user applications to submit network input/output (I/O) and control directives to underlying network protocol software. An application program that uses the NetBIOS interface API for network communication can be run on any protocol software that supports the NetBIOS interface.

NetBIOS also defines a protocolthat functions at thesession/transport level. This is implemented by the underlying protocol software (such as the NetBIOS Frames Protocol NBFP — a component of NetBEUI or NetBIOS over TCP/IP (NetBT)), which performs the network I/O required to accommodate the NetBIOS interface command set. NetBIOS over TCP/IP is defined in RFCs 1001 and 1002. NetBT is enabled by default, however Windows Server 2003 allows you to disable NetBT for an environment that contains no NetBIOS-based network clients or applications.

NetBIOS provides commands and support for NetBIOS Name Management, NetBIOS Datagrams, and NetBIOS Sessions.

**NetBIOS name management**

NetBIOS name management services provide the following functions:

- **Name registration and release**. When a TCP/IP host initializes, it registers its NetBIOS names by broadcasting or directing a NetBIOS name registration request to a NetBIOS Name Server such as a WINS server. If another host has registered the same NetBIOS name, either the host or a NetBIOS Name Server responds with a negative name registration response. The initiating host receives an initialization error as a result. When the workstation service on a host is stopped, the host discontinues broadcasting a negative name registration response when someone else tries to use the name and sends a name release to a NetBIOS Name Server. The NetBIOS name is said to be released and available for use by another host.
- **Name Resolution**. When a NetBIOS application wants to communicate with another NetBIOS application, the IP address of the NetBIOS application must be resolved. NetBT performs this function by either broadcasting a NetBIOS name query on the local network or sending a NetBIOS name query to a NetBIOS Name Server.

The NetBIOS name service uses UDP port 137.

**NetBIOS datagrams**
The NetBIOS datagram service provides delivery of datagrams that are connectionless, unsequenced, and unreliable. Datagrams can be directed to a specific NetBIOS name or broadcast to a group of names. Delivery is unreliable in that only the users who are logged on to the network receive the message. The datagram service can initiate and receive both broadcast and directed messages. The NetBIOS datagram service uses UDP port 138.

**NetBIOS sessions**
The NetBIOS session service provides delivery of NetBIOS messages that are connection-oriented, sequenced, and reliable. NetBIOS sessions use TCP connections and provide session establishment, keepalive, and termination. The NetBIOS session service allows concurrent data transfers in both directions using TCP port 139.

**IPv4 Addressing**
For IP version 4, each TCP/IP host is identified by a logical IP address. The IP address is a Network layer address and has no dependence on the Data-Link layer address (such as a MAC address of a network adapter). A unique IP address is required for each host and network component that communicates using TCP/IP and can be assigned manually or by using Dynamic Host Configuration Protocol (DHCP).

The IP address identifies a system's location on the network in the same way a street address identifies a house on a city block. Just as a street address must identify a unique residence, an IP address must be globally unique to the internetwork and have a uniform format.

Each IP address includes a network ID and a host ID.

- The network ID (also known as a network address) identifies the systems that are located on the same physical network bounded by IP routers. All systems on the same physical network must have the same network ID. The network ID must be unique to the internetwork.

- The host ID (also known as a host address) identifies a workstation, server, router, or other TCP/IP host within a network. The host address must be unique to the network ID.

**IPv4 Address Syntax**
An IP address consists of 32 bits. Instead of expressing IPv4 addresses 32 bits at a time using binary notation ($Base_2$), it is standard practice to segment the 32 bits of an IPv4 address into four 8-bit fields called *octets*. Each octet is converted to a decimal number (base 10) from 0–255 and separated by a period (a dot). This format is called *dotted decimal notation*. The following table provides an example of an IP address in binary and dotted decimal formats.

### An IP Address in Binary and Dotted Decimal Formats

| Binary Format | Dotted Decimal Notation |
|---|---|
| 11000000 10101000 00000011 00011000 | 192.168.3.24 |

For example, the IPv4 address of 11000000101010000000001100011000 is:

- Segmented into 8-bit blocks: 11000000 10101000 00000011 00011000.

- Each block is converted to decimal: 192 168 3 24

- The adjacent octets are separated by a period: 192.168.3.24.

The notation *w.x.y.z* is used when referring to a generalized IP address, and is shown the following figure.

### IP Address

**Types of IPv4 Addresses**

The Internet standards define the following types of IPv4 addresses:

- *Unicast*. Assigned to a single network interface located on a specific subnet on the network and used for one-to-one communications.

- *Multicast*. Assigned to one or more network interfaces located on various subnets on the network and used for one-to-many communications.

- *Broadcast*. Assigned to all network interfaces located on a subnet on the network and used for one-to-everyone-on-a-subnet communications.

The following sections describe these types of addresses in detail.

**IPv4 Unicast Addresses**

The IPv4 unicast address identifies an interface's location on the network in the same way a street address identifies a house on a city block. Just as a street address must identify a unique residence, an IPv4 unicast address must be globally unique to the network and have a uniform format.

Each IPv4 unicast address includes a network ID and a host ID.

- The network ID (also known as a network address) is the fixed portion of an IPv4 unicast address that identifies the set of interfaces that are located on the same physical or logical network segment as bounded by IPv4 routers. A network segment on TCP/IP networks is also known as a subnet. All systems on the same physical or logical subnet must use the same network ID and the network ID must be unique to the entire TCP/IP network.

- The host ID (also known as a host address) is the variable portion of an IPv4 unicast address that is used to identify a network node's interface on a subnet. The host ID must be unique to the network ID.

If the network ID is unique to the TCP/IP network and the host ID is unique to the network ID, then the entire IPv4 unicast address consisting of the network ID and host ID is unique to the entire TCP/IP network.

**IPv4 Multicast Addresses**

IPv4 multicast addresses are used for single-packet one-to-many delivery. On an IPv4 multicast-enabled intranet, an IPv4 packet addressed to an IPv4 multicast address is forwarded by routers to the subnets on which there are hosts listening to the traffic sent to the IPv4 multicast address. IPv4 multicast provides an efficient one-to-many delivery service for many types of communication.

IPv4 multicast addresses are defined by the class D Internet address class: 224.0.0.0/4. IPv4 multicast addresses range from 224.0.0.0 through 239.255.255.255. IPv4 multicast addresses for the 224.0.0.0/24 address prefix (224.0.0.0 through 224.0.0.255) are reserved for local subnet multicast traffic.

**IPv4 Broadcast Addresses**

IPv4 uses a set of broadcast addresses to provide a one-to-everyone on the subnet delivery service. Packets sent to IPv4 broadcast addresses are processed by all the interfaces on the subnet. The following are the different types of IPv4 broadcast addresses:

- **Network broadcast**. Formed by setting all the host bits to 1 for a classful address prefix. An example of a network broadcast address for the classful network ID 131.107.0.0/16 is 131.107.255.255. Network broadcasts are used to send packets to all interfaces of a classful network. IPv4 routers do not forward network broadcast packets.

- **Subnet broadcast**. Formed by setting all the host bits to 1 for a classless address prefix. An example of a network broadcast address for the classless network ID 131.107.26.0/24 is 131.107.26.255. Subnet broadcasts are used to send packets to all hosts of a classless network. IPv4 routers do not forward subnet broadcast packets. For a classful address prefix, there is no subnet broadcast address, only a network broadcast address. For a classless address prefix, there is no network broadcast address, only a subnet broadcast address.

- **All-subnets-directed broadcast.** Formed by setting all the original classful network ID host bits to 1 for a classless address prefix. A packet addressed to the all-subnets-directed broadcast was defined to reach all hosts on all of the subnets of a subnetted class-based network ID. An example of an all-subnets-directed broadcast address for the subnetted network ID 131.107.26.0/24 is 131.107.255.255. The all-subnets-directed broadcast is the network broadcast address of the original classful network ID. IPv4 routers can forward all-subnets directed broadcast packets, however the use of the all-subnets-directed broadcast address is deprecated in RFC 1812.

- **Limited broadcast.** Formed by setting all 32 bits of the IPv4 address to 1 (255.255.255.255). The limited broadcast address is used for one-to-everyone delivery on the local subnet when the local network ID is unknown. IPv4 nodes typically only use the limited broadcast address during an automated configuration process such as Boot Protocol (BOOTP) or DHCP. For example, with DHCP, a DHCP client must use the limited broadcast address for all traffic sent until the DHCP server acknowledges the use of the offered IPv4 address configuration. IPv4 routers do not forward limited broadcast packets.

**Internet Address Classes**

The Internet community originally defined address classes to accommodate different types of addresses and networks of varying sizes. The class of address defined which bits were used for the network ID and which bits were used for the host ID. It also defined the possible number of networks and the number of hosts per network. Of five address classes, class A, B, and C addresses were defined for IPv4 unicast addresses. Class D addresses were defined for IPv4 multicast addresses and class E addresses were defined for experimental uses.

**Class A**

Class A network IDs were assigned to networks with a very large number of hosts. The high-order bit in a class A address is always set to zero, which makes the address prefix for all class A networks and addresses 0.0.0.0/1 (or 0.0.0.0, 128.0.0.0). The next seven bits (completing the first octet) are used to enumerate class A network IDs. Therefore, address prefixes for class A network IDs have an 8-bit prefix length (/8 or 255.0.0.0). The remaining 24 bits (the last three octets) are used for the host ID. The address prefix 0.0.0.0/0 (or 0.0.0.0, 0.0.0.0) is a reserved network ID and 127.0.0.0/8 (or 127.0.0.0, 255.0.0.0) is reserved for loopback addresses. Out of a total of 128 possible class A networks, there are 126 networks and 16,777,214 hosts per network.

### Note

- All-Zeros and All-Ones Host IDs are Reserved

- When enumerating host IDs for a given network ID, the two host IDs in which all the bits in the host ID are set to 0 (the all-zeros host ID) and all the bits in the host ID is set to 1 (the all-ones host ID) are reserved and cannot be assigned to network node interfaces. Hence, in the calculation above in which there are 24 bits for class A host IDs, the total number of possible host IDs is 16,777,216 (224). When you subtract the two reserved host IDs, the total number of usable host IDs is 16,777,214.

The following figure illustrates the structure of class A addresses.

**Structure of class A addresses**

**Class B**

Class B network IDs were assigned to medium to large-sized networks. The two high-order bits in a class B address are always set to 10, which makes the address prefix for all class B networks and addresses 128.0.0.0/2 (or 128.0.0.0, 192.0.0.0). The next 14 bits (completing the first two octets) are used to enumerate class B network IDs. Therefore, address prefixes for class B network IDs have a 16-bit prefix length (/16 or 255.255.0.0). The remaining 16 bits (last two octets) are used for the host ID. With 14 bits to express class B network IDs and 16 bits to express host IDs, this allows for 16,384 networks and 65,534 hosts per network.

The following figure illustrates the structure of class B addresses.

**Structure of class B addresses**

**Class C**

Class C addresses were assigned to small networks. The three high-order bits in a class C address are always set to 110, which makes the address prefix for all class C networks and addresses 192.0.0.0/3 (or 192.0.0.0, 224.0.0.0). The next 21 bits (completing the first three octets) are used to enumerate class C network IDs. Therefore, address prefixes for class C network IDs have a 24-bit prefix length (/24 or 255.255.255.0). The remaining 8 bits (the last octet) are used for the host ID. With 21 bits to express class C network IDs and 8 bits to express host IDs, this allows for 2,097,152 networks and 254 hosts per network.

The following figure illustrates the structure of class C addresses.

**Structure of class C addresses**

**Class D**

Class D addresses are reserved for IPv4 multicast addresses. The four high-order bits in a class D address are always set to 1110, which makes the address prefix for all class D addresses 224.0.0.0/4 (or 224.0.0.0, 240.0.0.0).

**Class E**

Class E addresses are reserved for experimental use. The high-order bits in a class E address are set to 1111, which makes the address prefix for all class E addresses 240.0.0.0/4 (or 240.0.0.0, 240.0.0.0)

The following table is a summary of the Internet address classes A, B, and C that can be used for IPv4 unicast addresses.

**Internet Address Class Summary**

| Class | Value for *w* | Network ID Portion | Host ID Portion | Network IDs | Host IDs per Network |
|---|---|---|---|---|---|
| A | 1-126 | *w* | *x.y.z* | 126 | 16,777,214 |
| B | 128-191 | *w.x* | *y.z* | 16,384 | 65,534 |
| C | 192-223 | *w.x.y* | *z* | 2,097,152 | 254 |

**Modern Internet Addresses**

The Internet address classes are an obsolete unicast address allocation method that proved to be an inefficient way to assign network IDs and addresses to organizations connected to the Internet. For example, a large organization with a class A network ID can have up to 16,777,214 hosts. However, if the organization only uses 70,000 host IDs, then 16,707,214 potential IPv4 unicast addresses for the Internet are wasted.

On the modern-day Internet, IPv4 address prefixes are handed out to organization's based on the organization's actual need for Internet-accessible IPv4 unicast addresses using a method known as Classless Inter-Domain Routing (CIDR). For example, an organization determines that it needs 2,000 Internet-accessible IPv4 unicast addresses. The Internet Corporation for Assigned Names and Numbers (ICANN) or an Internet service provider (ISP) allocates an IPv4 address prefix in which 21 bits are fixed, leaving 11 bits for host IDs. From the 11 bits for host IDs, the organization can create 2,032 possible IPv4 unicast addresses.

CIDR-based address allocations typically start at 8 bits. The following table lists the required number of host IDs and the corresponding prefix length for CIDR-based address allocations.

**Host IDs Needed and CIDR-based Prefix Lengths**

| Number of Host IDs | Prefix Length | Dotted Decimal |
|---|---|---|
| 2–254 | /24 | 255.255.255.0 |
| 255–510 | /23 | 255.255.254.0 |

| | | |
|---|---|---|
| 511–1,022 | /22 | 255.255.252.0 |
| 1,021–2,046 | /21 | 255.255.248.0 |
| 2,047–4,094 | /20 | 255.255.240.0 |
| 4,095–8,190 | /19 | 255.255.224.0 |
| 8,191–16,382 | /18 | 255.255.192.0 |
| 16,383–32,766 | /17 | 255.255.128.0 |
| 32,767–65,534 | /16 | 255.255.0.0 |

**Public and Private Addresses**

If you want direct (routed) connectivity to the Internet, then you must use public addresses. If you want indirect (proxied or translated) connectivity to the Internet, you can use either public or private addresses. If your intranet is not connected to the Internet in any way, you can use any unicast IPv4 addresses that you want. However, you should use private addresses to avoid network renumbering when your intranet is eventually connected to the Internet.

**Public addresses**

Public addresses are assigned by ICANN and consist of either historically allocated class-based network IDs or, more recently, CIDR-based address prefixes that are guaranteed to be globally unique on the Internet. For CIDR-based address prefixes, the value of *w* (the first octet) is in the ranges of 1 through 126 and 128 through 223, with the exception of the private address prefixes described in "Private Addresses."

When the public addresses are assigned, routes are added to the routers of the Internet so that traffic sent to an address that matches the assigned public address prefix can reach the assigned organization. For example, when an organization is assigned an address prefix in the form of a network ID and prefix length, that address prefix also exists as a route in the routers of the Internet. IPv4 packets destined to an address within the assigned address prefix are routed to the proper destination.

**Private addresses**

Each IPv4 interface requires an IPv4 address that is globally unique to the IPv4 network. In the case of the Internet, each IPv4 interface on a subnet connected to the Internet requires an IPv4 address that is globally unique to the Internet. As the Internet grew, organizations connecting to the Internet required a public address for each interface on their intranets. This requirement placed a huge demand on the pool of available public addresses.

When analyzing the addressing needs of organizations, the designers of the Internet noted that for many organizations, most of the hosts on an organization's intranet did not require direct connectivity to the Internet. Those hosts that did require a specific set of Internet services, such as Web access and e-mail, typically access the Internet services through Application layer gateways such as proxy servers and e-mail servers. The result is that most organizations only required a small amount of public addresses for those nodes (such as proxies, servers, routers, firewalls, and translators) that were directly connected to the Internet.

For the hosts within the organization that do not require direct access to the Internet, IPv4 addresses that do not duplicate already-assigned public addresses are required. To solve this addressing problem, the Internet designers reserved a portion of the IPv4 address space and named this space the private address space. An IPv4 address in the private address space is never assigned as a public address. IPv4 addresses within the private address space are known as private addresses. Because the public and private address spaces do not overlap, private addresses never duplicate public addresses.

The private address space specified in RFC 1918 is defined by the following address prefixes:

- 10.0.0.0/8 (10.0.0.0, 255.0.0.0)

  Allows the following range of valid IPv4 unicast addresses: 10.0.0.1 to 10.255.255.254. The 10.0.0.0/8 address prefix has 24 host bits that can be used for any addressing scheme within the private organization.

- 172.16.0.0/12 (172.16.0.0, 255.240.0.0)

  Allows the following range of valid IPv4 unicast addresses: 172.16.0.1 to 172.31.255.254. The 172.16.0.0/12 address prefix has 20 host bits that can be used for any addressing scheme within the private organization.

- 192.168.0.0/16 (192.168.0.0, 255.255.0.0)

Allows the following range of valid IPv4 unicast addresses: 192.168.0.1 to 192.168.255.254. The 192.168.0.0/16 address prefix has 16 host bits that can be used for any addressing scheme within the private organization.

Because the IPv4 addresses in the private address space will never be assigned by ICANN to an organization connected to the Internet, there will never be routes for the private address prefixes in Internet routers. You cannot connect to a private address over the Internet. Therefore, a host that has a private address must send its Internet traffic requests to an Application layer gateway (such as a proxy server) that has a valid public address or through a network address translator (NAT) that translates the private address into a valid public address.

**Illegal addresses**
Private organization intranets that do not need an Internet connection can choose any address scheme they want, even using public address prefixes that have been assigned by ICANN. If that organization later decides to connect to the Internet, its current address scheme might include addresses already assigned by ICANN to other organizations. These addresses conflict with existing public addresses assigned by ICANN and are known as illegal addresses. Connectivity from illegal addresses to Internet locations is not possible because the routers of the Internet send traffic destined to ICANN-allocated address prefixes to the assigned organizations, not to the organizations using illegal addresses.

For example, a private organization chooses to use the 206.73.118.0/24 address prefix for its intranet. The public address prefix 206.73.118.0/24 has been assigned by ICANN to the Microsoft Corporation and routes exist on the Internet routers to send all packets for IPv4 addresses on 206.73.118.0/24 to Microsoft routers. As long as the private organization does not connect to the Internet, there is no problem because the two address prefixes are on separate IPv4 networks; therefore they are unique to each separate network. If the private organization later connects directly to the Internet and continues to use the 206.73.118.0/24 address prefix, any Internet response traffic to locations matching the 206.73.118.0/24 address prefix is sent to Microsoft routers, not to the routers of the private organization.

**Automatic Private IP Addressing**
An interface on a computer running Windows Server 2003 and Windows XP that is configured to obtain an IPv4 address configuration automatically that does not successfully contact a Dynamic Host Configuration Protocol (DHCP) server uses its alternate configuration, as specified on the Alternate Configuration tab.

If the Automatic Private IP Address option is selected on the Alternate Configuration tab and a DHCP server cannot be found, Windows TCP/IP uses Automatic Private IP Addressing (APIPA). Windows TCP/IP randomly selects an IPv4 address from the 169.254.0.0/16 address prefix and assigns the subnet mask of 255.255.0.0. This address prefix has been reserved by the ICANN and is not reachable on the Internet. APIPA allows single-subnet Small Office/Home Office (SOHO) networks to use TCP/IP without static configuration or the administration of a DHCP server. APIPA does not configure a default gateway. Therefore, only local subnet traffic is possible.

**Special IPv4 Addresses**
The following are special IPv4 addresses:

- 0.0.0.0

  Known as the unspecified IPv4 address, it is used to indicate the absence of an address. The unspecified address is used only as a source address when the IPv4 node is not configured with an IPv4 address configuration and is attempting to obtain an address through a configuration protocol such as Dynamic Host Configuration Protocol (DHCP).

- 127.0.0.1

  Known as the IPv4 loopback address, it is assigned to an internal loopback interface, enabling a node to send packets to itself.

**Unicast IPv4 Addressing Guidelines**
When assigning network IDs to the subnets of an organization, use the following guidelines:

- The network ID must be unique on the IPv4 network.

  If the network ID is for a subnet on which there are hosts that are directly accessible from the Internet, you must use a public IPv4 address prefix assigned by ICANN or an Internet service provider. If the network ID is for a subnet that is not directly accessible by the Internet, use either a legal public address prefix or a private address prefix that is unique on your private intranet.

- The network ID cannot begin with the numbers 0 or 127.

  Both of these values for the first octet are reserved and cannot be used for IPv4 unicast addresses.

When assigning host IDs to the interfaces of nodes on an IPv4 subnet, use the following guidelines:

- The host ID must be unique on the subnet.
- You cannot use the all-zeros or all-ones host IDs.

When defining the range of valid IPv4 unicast addresses for a given address prefix, use the following standard practice:

- For the first IPv4 unicast address in the range, set all the host bits in the address to 0, except for the low-order bit, which is set to 1.
- For the last IPv4 unicast address in the range, set all the host bits in the address to 1, except for the low-order bit, which is set to 0.

For example, to express the range of addresses for the address prefix 192.168.16.0/20:

- The first IPv4 unicast address in the range is 11000000 10101000 0001**000000000001** (host bits are bold), or 192.168.16.1.
- The last IPv4 unicast address in the range is 11000000 10101000 0001**111111111110** (host bits are bold), or 192.168.31.254.

**Name Resolution**

While IP is designed to work with the 32-bit IP addresses of the source and the destination hosts, computers users are much better at using and remembering names than IP addresses.

When a name is used as an alias for an IP address, a mechanism must exist for assigning that name to the appropriate IP node — to ensure its uniqueness and resolution to its IP address.

In this section, the mechanisms used for assigning and resolving host names (which are used by Windows Sockets applications), and NetBIOS names (which are used by NetBIOS applications) are discussed.

**Host Name Resolution**

A host name is an alias assigned to an IP node to identify it as a TCP/IP host. The host name can be up to 255 characters long and can contain alphabetic and numeric characters and the "-" and "." characters"." Multiple host names can be assigned to the same host. For Windows Server 2003–based computers, the host name does not have to match the Windows Server 2003 computer name.

Windows Sockets applications, such as Microsoft Internet Explorer, can use one of two values to connect to the destination: the IP address or a host name. When the IP address is specified, name resolution is not needed. When a host name is specified, the host name must be resolved to an IP address before IP-based communication with the desired resource can begin.

Host names most commonly take the form of a domain name with a structure that follows Internet conventions. Name resolution, and domain names work the same whether they are used for IPv4 or IPv6 addresses.

**Domain Names**

To meet the need for a scaleable, customizable naming scheme for a wide variety of organizations, InterNIC has created and maintains a hierarchical namespace called the Domain Name System (DNS). The DNS naming scheme looks like the directory structure for files on a disk. Usually, you trace a file path from the root directory through subdirectories to its final location and its file name. However, a host name is traced from its final location back through its parent domains up to the root. The unique name of the host, representing its position in the hierarchy, is its Fully Qualified Domain Name (FQDN). The top-level domain namespace with second-level and subdomains is shown in the following figure.

**Domain Name System**

The domain namespace includes the following categories:

- The root domain, which is indicated by "" (null), represents the root of the namespace.
- Top-level domains, directly below the root, represent types of organizations. InterNIC is responsible for the maintenance of top-level domain names on the Internet. The following table has a partial list of the Internet's top-level domain names.

**Internet Top-Level Domain Names**

| **Domain Name** | **Meaning** |
|---|---|
| com | Commercial organization |
| edu | Educational institution |
| gov | Government institution |
| mil | Military group |
| net | Major network support center |
| org | Organization other than those above |
| int | International organization |
| *<country/region code>* | Each country/region (geographic scheme) |

- Second-level domains, below the top-level domains, represent specific organizations within the top-level domains. InterNIC is responsible for maintaining and ensuring uniqueness of second-level domain names on the Internet.
- Subdomains are below the second-level domain. Individual organizations are responsible for the creation and maintenance of subdomains.

For example, for the FQDN **websrv.wcoast.reskit.com**:

- The trailing period (**.**) denotes that this is an FQDN with the name relative to the root of the domain namespace. The trailing period is usually not required for FQDNs and if it is missing it is assumed to be present.
- **com** is the top-level domain, indicating a commercial organization.
- **reskit** is the second-level domain, indicating the Resource Kit Corporation.
- **wcoast** is a subdomain of **reskit.com** indicating the West Coast division of the Resource Kit Corporation.
- **websrv** is the name of the Web server in the West Coast division.

Domain names are not case-sensitive.

Organizations not connected to the Internet can implement whatever top and second-level domain names they want. However, typical implementations follow InterNIC specifications so that eventual participation in the Internet will not require a renaming process.

**Host Name Resolution Using a Hosts File**

One common way to resolve a host name to an IP address is to use a locally stored database file that contains IP-address-to-host-name mappings. On most UNIX systems, this file is /etc/hosts. On Windows Server 2003 systems, it is the Hosts file in the **%systemroot%\System32\Drivers\Etc** directory.

The following is an example of the contents of the Hosts file:

```
#
Table of IP addresses and host names
#
127.0.0.1    localhost
131.107.34.1    router
172.30.45.121    server1.central.reskit.com s1
```

Within the Hosts file:

- Multiple host names can be assigned to the same IP address. Note that the server at the IP address 172.30.45.121 can be referred to by its FQDN (server1.central.reskit.com) or a nickname (s1). This allows the user at this computer to refer to this server using the nickname **s1** instead of typing the entire FQDN.

- Entries can be case sensitive depending on the platform. Entries in the Hosts file for UNIX computers are case-sensitive. Entries in the Hosts file for Windows Server 2003, Windows XP, and Windows 2000–based computers are not case sensitive.

For computers running Windows Server 2003, Windows XP, and Windows 2000, the entries in the Hosts file are loaded into the DNS client resolver cache. When resolving host names, the DNS client resolver cache is always checked.

The advantage of using a Hosts file is that it is customizable for the user. Users can create whatever entries they want, including easy-to-remember nicknames for frequently accessed resources. However, the individual maintenance of the Hosts file does not scale well to storing large numbers of FQDN mappings.

**Host Name Resolution Using a DNS Server**

To make host name resolution scalable and centrally manageable, IP address mappings for FQDNs are stored on DNS servers. To enable the querying of a DNS server by a host computer, a component called the DNS resolver is enabled and configured with the IP address of the DNS server. The DNS resolver is a built-in component of TCP/IP protocol stacks supplied with most network operating systems, including Windows Server 2003.

When a Windows Sockets application is given an FQDN as the destination location, the application calls a Windows Sockets function to resolve the name to an IP address. The request is passed to the DNS resolver component in the TCP/IP protocol. The DNS resolver packages the FQDN request as a DNS Name Query packet and sends it to the DNS server.

DNS is a distributed naming system. Instead of storing all the records for the entire namespace on each DNS server, each DNS server stores only the records for a specific portion of the namespace. The DNS server is authoritative for the portion of the namespace that corresponds to records stored on that DNS server. In the case of the Internet, hundreds of DNS servers store various portions of the Internet namespace. To facilitate the resolution of any valid domain name by any DNS server, DNS servers are also configured with pointer records to other DNS servers.

The following process outlines what happens when the DNS resolver component on a host sends a DNS query to a DNS server. This process is shown in the following figure and is simplified so that you can gain a basic understanding of the DNS resolution process.

1. The DNS resolver component of the DNS client formats a DNS Name Query Request message containing the FQDN and sends it to the configured DNS server.

2. The DNS server checks the FQDN in the DNS Name Query Request message against locally stored address records. If a record is found, the IP address corresponding to the requested FQDN is sent back to the client.

3. If the FQDN is not found, the DNS server forwards the request to a DNS server that is authoritative for the FQDN.

4. The authoritative DNS server returns the reply, which contains the resolved IP address, back to the original DNS server.

5. The original DNS server sends the IP address mapping information to the client.

**Resolving an FQDN by using DNS servers**

To obtain the IP address of a server that is authoritative for the FQDN, DNS servers on the Internet go through an iterative process of querying multiple DNS servers until the authoritative server is found. For more information about DNS name-resolution processes, see the DNS Technical Reference.

**Combining a Local Database File with DNS**

TCP/IP implementations, including Windows Server 2003, allow the use of both a local database file and a DNS server to resolve host names. When a user specifies a host name in a Windows Sockets–based TCP/IP application:

- TCP/IP checks the DNS client resolver cache (loaded with entries from the Hosts file and other previously resolved host names) for a matching name. If a matching name is not found in the local database file, the host name is packaged as a DNS Name Query Request message and sent to the configured DNS server.

Combining methods allows the user to have a local database file for resolving personalized nicknames and to use the globally distributed DNS database to resolve FQDNs.

**NetBIOS Name Resolution**

NetBIOS name resolution is the process of successfully mapping a NetBIOS name to an IP address. A NetBIOS name is a 16-byte address used to identify a NetBIOS resource on the network. A NetBIOS name is either a unique (exclusive) or group (nonexclusive) name. When a NetBIOS process communicates with a specific process on a specific computer, a unique name is used. When a NetBIOS process communicates with multiple processes on multiple computers, a group name is used.

The NetBIOS name acts as a Session layer application identifier. For example, the NetBIOS session service operates over TCP port 139. All NetBT session requests are addressed to TCP destination port 139. When identifying a NetBIOS application with which to establish a NetBIOS session, the NetBIOS name is used.

An example of a process using a NetBIOS name is the File and Printer Sharing for Microsoft Networks component (the Server service) on a Windows Server 2003–based computer. When you start your computer, the Server service registers a unique NetBIOS name based on your computer's name. The exact name used by the Server service is the 15-character computer name plus a sixteenth character of 0x20. If the computer name is not 15 characters long, it is padded with spaces up to 15 characters long. Other network services, such as the Workstation or Messenger service, also use the computer name to build their NetBIOS names. The sixteenth character is used to uniquely identify each service.

**Note**

- The Messenger service refered to here is not Windows Messenger. Windows Messenger is a Microsoft application included in Windows Server 2003 that allows real-time messaging and collaboration.

The Server service on the file server you specify corresponds to a specific NetBIOS name. For example, when you attempt to connect to the computer called CORPSERVER, the NetBIOS name corresponding to the Server service is "CORPSERVER <20>" (note the padding using the space character). Before a file and print sharing connection can be established, a TCP connection must be created. In order for a TCP connection to be established, the NetBIOS name "CORPSERVER <20>" must be resolved to an IP address.

To view the NetBIOS names registered by NetBIOS processes running on a Windows Server 2003 computer, type **nbtstat -n** at the Windows Server 2003 command prompt.

**NetBIOS Node Types**

The exact mechanism by which NetBIOS names are resolved to IP addresses depends on the node's configured NetBIOS Node Type. RFC 1001 defines the NetBIOS Node Types listed in the following table.

**NetBIOS Node Types**

| Node Type | Description |
|---|---|
| B-node (broadcast) | B-node uses broadcasted NetBIOS name queries for name registration and resolution. B-node has two major problems: (1) In a large internetwork, broadcasts can increase the network load, and (2) Routers typically do not forward broadcasts, so only NetBIOS names on the local network can be resolved. |
| P-node (peer-peer) | P-node uses a NetBIOS name server (NBNS), such as Windows Internet Name Service (WINS), to resolve NetBIOS names. P-node does not use broadcasts; instead, it queries the name server directly. The most significant problem with P-node is that all computers must be configured with the IP address of the NBNS, and if the NBNS is down, computers are not able to communicate even on the local network. |
| M-node (mixed) | M-node is a combination of B-node and P-node. By default, an M-node functions as a B-node. If it is unable to resolve a name by broadcast, it uses the NBNS of P-node. |
| H-node (hybrid) | H-node is a combination of P-node and B-node. By default, an H-node functions as a P-node. If it is unable to resolve a name through the NetBIOS name server, it uses a broadcast to resolve the name. |

When NetBT is enabled, Windows Server 2003–based computers are B-node by default and become H-node when configured for a WINS server. Windows Server 2003 also uses a local database file called Lmhosts to resolve remote NetBIOS names.

**IPv4 Routing**

After the host name or NetBIOS name is resolved to an IP address, the IP packet must be sent by the sending host to the resolved IP address. Routing is the process of forwarding a packet based on the destination IP address. Routing involves both the TCP/IP host and an IP router. A router is a device that forwards the packets from one network to another. Routers are also commonly referred to as gateways. Both the sending host and router need to make a determination about how the packet is forwarded.

To make these determinations, the IP layer consults a routing table stored in memory. Routing table entries are created by default when TCP/IP initializes and additional entries are added either manually by a system administrator or automatically through communication with routers.

**Direct and Indirect Delivery**

IP packets use at least one of two types of delivery based on whether the final destination is located on a directly attached network. These two types of delivery are known as direct and indirect delivery.

- Direct delivery occurs when the IP node (either the sending node or an IP router) forwards a packet to the final destination on a directly attached network. The IP node encapsulates the IP packet in a frame format for the Network Interface layer (such as Ethernet or Token Ring) addressed to the destination's MAC address.

- Indirect delivery occurs when the IP node (either the sending node or an IP router) forwards a packet to an intermediate node (an IP router) because the final destination is not on a directly attached network. The IP node encapsulates the IP packet in a frame format for the Network Interface layer (such as Ethernet or Token Ring) addressed to the IP router's MAC address.

IP routing is a combination of direct and indirect deliveries.

In the following figure, when sending packets to node B, node A performs a direct delivery. When sending packets to node C, node A performs an indirect delivery to Router 1, and Router 1 performs an indirect delivery to Router 2, and then Router 2 performs a direct delivery to node C.

**Direct and Indirect Deliveries**

**IP Routing Table**

A routing table is present on all IP nodes. The routing table stores information about IP networks and how they can be reached (either directly or indirectly). Because all IP nodes perform some form of IP routing, routing tables are not exclusive to IP routers. Any node loading the TCP/IP protocol has a routing table. There are a series of default entries according to the configuration of the node and additional entries can be entered either manually through TCP/IP utilities or dynamically through interaction with routers.

When an IP packet is to be forwarded, the routing table is used to determine:

- **The next-hop IP address.** For a direct delivery, the next-hop IP address is the destination IP address in the IP packet. For an indirect delivery, the next-hop IP address is the IP address of a router.

- **The next-hop interface.** The next-hop interface identifies the physical or logical interface, such as a network adapter, that is used to forward the packet to either its destination or the next router.

**IP Routing Table Entry Types**

Entries in the IP routing table contain the following information:

- **Network ID.** The network ID or destination corresponding to the route. The network ID can identify a specific subnet, be a summarized route, or an IP address for a host route. In the Windows Server 2003 IP routing table, this is the Network Destination column.

- **Network mask.** The mask that is used to match a destination IP address to the network ID. In the Windows Server 2003 IP routing table, this is the Netmask column.

- **Next hop.** The IP address of the next hop. In the Windows Server 2003 IP routing table, this is the Gateway column.

- **Interface.** An indication of which network interface is used to forward the IP packet.

- **Metric.** A number used to indicate the cost of the route so the best route among possible multiple routes to the same destination can be selected. A common use of the metric is to indicate the number of hops (routers crossed) to the network ID.

Entries in the routing table can be used to store the following types of routes:

- **Directly attached network ID.** Aroute for network IDs that are directly attached. For directly attached networks, the Next Hop field can be blank or contain the IP address of the interface on that network.

- **Remote network ID.** A route for network IDs that are not directly attached but are available across other routers. For remote networks, the Next Hop field is the IP address of a local router.

- **Host route.** A route to a specific IP address. Host routes allow routing to occur on a per-IP address basis. For host routes, the network ID is the IP address of the specified host and the network mask is 255.255.255.255.

- **Default route.** The default route is designed to be used when a more specific network ID or host route is not found. The default route network ID is 0.0.0.0 with a network mask of 0.0.0.0.

**Route Determination Process**
To determine which routing table entry is used to find the next-hop address and interface, IP uses the following process:

- For each entry in a routing table, IP performs a bit-wise logical AND operation between the destination IP address and the network mask. It compares the result with the network ID of the entry for a match.

- A list of matching routes is compiled. The route that has the longest match (the route with the largest number of bits that match the destination IP address) is chosen. The longest matching route is the most direct route to the destination IP address. If multiple matching entries are found (for example, multiple routes to the same network ID), the router uses the lowest metric to select the best route. If multiple entries have the longest match and the lowest metric, the router designates one of them as the routing table entry. For Windows Server 2003 TCP/IP, the route chosen corresponds to the route associated with the interface that is first in the network binding order.

The end result of the route-determination process is a single route in the routing table that yields a next-hop IP address and interface. If the route-determination process fails to find a route, IP indicates a routing error. For the sending host, an IP routing error message is sent to the upper layer protocol, such as TCP or UDP. For a router, an ICMP Destination Unreachable–Host Unreachable message is sent to the sending host.

**Routing Table for Windows Server 2003**
The following table shows the default routing table for a Windows Server 2003–based host (not a router). The host has a single network adapter and has the IP address 157.60.27.90, subnet mask 255.255.240.0, and a default gateway of 157.60.16.1.

### Windows Server 2003 Routing Table

| Network Destination | Netmask | Gateway | Interface | Metric | Purpose |
|---|---|---|---|---|---|
| 0.0.0.0 | 0.0.0.0 | 157.60.16.1 | 157.60.27.90 | 1 | Default Route |
| 127.0.0.0 | 255.0.0.0 | 127.0.0.1 | 127.0.0.1 | 1 | Loopback Network |
| 157.60.16.0 | 255.255.240.0 | 157.60.27.90 | 157.60.27.90 | 1 | Directly Attached Network |
| 157.60.27.90 | 255.255.255.255 | 127.0.0.1 | 127.0.0.1 | 1 | Local Host |
| 157.60.255.255 | 255.255.255.255 | 157.60.27.90 | 157.60.27.90 | 1 | Network Broadcast |
| 224.0.0.0 | 240.0.0.0 | 157.60.27.90 | 157.60.27.90 | 1 | Multicast |
| 255.255.255.255 | 255.255.255.255 | 157.60.27.90 | 157.60.27.90 | 1 | Limited Broadcast |

**Default Route**
The entry corresponding to the default gateway configuration is a network destination of 0.0.0.0 with a network mask (netmask) of 0.0.0.0. Any destination IP address that is logically ANDed with 0.0.0.0 results in 0.0.0.0. Therefore, for any IP address, the default route produces a match. If the default route is chosen because no better routes were found, the IP packet is forwarded to the IP address in the Gateway column (the default gateway of 157.60.16.1), by using the interface assigned the IP address in the Interface column.

**Loopback Network**
The loopback network entry is designed to take any IP address of the form 127.x.y.z and forward it to the special loopback address of 127.0.0.1.

**Directly Attached Network**
The local network entry corresponds to the directly attached network. IP packets destined for the directly attached network are not forwarded to a router but sent directly to the destination. Note that the Gateway and Interface columns match the IP address of the node. This indicates that the packet is sent from the network adapter corresponding to the node's IP address.

**Local Host**
The local host entry is a host route (network mask of 255.255.255.255) corresponding to the IP address of the host. All IP packets sent to the IP address of the host are forwarded to the loopback address.

**Network Broadcast**
The network broadcast entry is a host route (network mask of 255.255.255.255) corresponding to the all-subnets directed broadcast address (all subnets of class B network ID 157.60.0.0). Packets addressed to the all-subnets directed broadcast are

sent from the network adapter corresponding to the node's IP address.

**Multicast**
The multicast addresses route is used to send any multicast IP packets from the network adapter corresponding to the node's IP address.

**Limited Broadcast**
The limited broadcast address is a host route (network mask of 255.255.255.255). Packets addressed to the limited broadcast are sent from the network adapter corresponding to the node's IP address.

**Viewing the IP Routing Table**
To view the IP routing table on a Windows Server 2003-based computer, type **route print** at a Windows Server 2003 command prompt.

When determining the next-hop IP address and interface from a route in the routing table:

- If the gateway address is the same as the interface address, the next-hop IP address is set to the destination IP address of the IP packet.
- If the gateway address is not the same as the interface address, the next-hop IP address is set to the gateway address.

For example, when traffic is sent to 157.60.16.48, the most specific matching route is the route for the directly attached network (157.60.16.0/20). The next-hop IP address is set to the destination IP address (157.60.16.48) and the interface is the network adapter that has been assigned the IP address 157.60.27.90.

When sending traffic to 192.168.0.79, the most specific matching route is the default route (0.0.0.0/0). The next-hop IP address is set to the gateway address (157.60.16.1) and the interface is the network adapter that has been assigned the IP address 157.60.27.90.

**Maintenance of Routing Table Entries**
For IP routing to occur efficiently between routers in the IP internetwork, routers must be configured with remote network IDs or a default route. On large IP internetworks, one of the challenges faced by network administrators is how to maintain the routing tables on their IP routers so that IP traffic flow is traveling the best path and is fault tolerant.

There are two methods of maintaining routing table entries on IP routers.

**Manual**
Static IP routers have routing tables that do not change unless manually changed by a network administrator.

Static routing relies on the manual administration of the routing table. Remote network IDs are not discovered by static routers and must be manually configured. Static routers are not fault-tolerant. If a static router goes down, neighboring routers do not sense the fault and inform other routers.

**Automatic**
Dynamic IP routers have routing tables that change automatically based on the exchange of routing information with other routers.

Dynamic routing employs the use of routing protocols, such as Routing Information Protocol (RIP) and Open Shortest Path First (OSPF), to dynamically update the routing table through the exchange of routing information between routers. Remote network IDs are discovered by dynamic routers and automatically entered into the routing table. Dynamic routers are fault-tolerant. If a dynamic router goes down, the fault is detected by neighboring routers, which send the changed routing information to the other routers in the internetwork.

**Physical Address Resolution**
Based on the destination IP address and the route determination process, IP determines the next-hop IP address and interface. IP then sends the IP packet, the next-hop IP address, and the interface to ARP.

If the next-hop IP address is the same as the destination IP address, then ARP performs a direct delivery. In a direct delivery, the MAC address corresponding to the destination IP address must be resolved.

If the next-hop IP address is not the same as the destination IP address, then ARP performs an indirect delivery. The next-hop IP address is the IP address of a router between the current IP node and the final destination. In an indirect delivery, the MAC address corresponding to the IP address of the router must be resolved.

To resolve a next-hop IP address to its MAC address, ARP uses broadcast traffic on shared access networking media (such as Ethernet or Token Ring) to send out a broadcasted ARP Request frame. An ARP Reply, containing the MAC address

corresponding to the requested next-hop IP address, is sent back to the sender of the ARP Request.

**ARP Cache**
To keep the number of broadcasted ARP Request frames to a minimum, many TCP/IP protocol stacks incorporate an ARP cache, which is a table of recently resolved IP addresses and their corresponding MAC addresses. TCP/IP checks the ARP cache before sending an ARP Request frame. Each interface has its own ARP cache.

Depending on the vendor implementation, the ARP cache can have the following qualities:

- ARP cache entries can be dynamic (based on ARP Replies) or static. Static ARP entries are permanent and are manually added by using a TCP/IP utility such as the ARP tool provided with Windows Server 2003. Static ARP cache entries are used to prevent ARP Requests for commonly used local IP addresses, such as routers and servers. The problem with static ARP entries is that they have to be manually updated when network interface equipment changes.

- Dynamic ARP cache entries have a time-out value associated with them to remove entries in the cache after a specified period of time. Dynamic ARP cache entries for Windows Server 2003 TCP/IP are given a maximum time of 10 minutes before being removed.

To view the ARP cache on a Windows Server 2003–based computer, type **arp -a** at a Windows Server 2003 command prompt.

**ARP Process**
IP sends ARP the IP packet, the next-hop IP address, and the next-hop interface. Whether performing a direct or indirect delivery, ARP carries out the following process, as shown in the following figure.

**ARP process**

1. Based on the next-hop address and interface, ARP consults the appropriate ARP cache for an entry for the next-hop IP address. If an entry is found, ARP skips to step 6.

2. If an entry is not found, ARP builds an ARP Request frame containing the MAC address of the interface sending the ARP Request, the IP address of the interface sending the ARP Request, and the next-hop IP address. ARP then broadcasts the ARP Request using the appropriate interface.

3. All hosts receive the broadcasted frame and the ARP Request is processed. If the receiving host's IP address matches the requested IP address (the next-hop IP address), its ARP cache is updated with the address mapping of the sender of the ARP Request.

4. If the receiving host's IP address does not match the requested IP address, the ARP Request is silently discarded.

5. The receiving host formulates an ARP Reply containing the requested MAC address and sends it directly to the sender of the ARP Request.

6. When the ARP Reply is received by the sender of the ARP Request, it updates its ARP cache with the address mapping.

7. The ARP Request host and the ARP Reply host have each other's address mappings in their ARP caches.

8. ARP sends the IP packet to the next-hop node by addressing it to the resolved MAC address.

**End-to-End Delivery**
The IP routing processes for all nodes involved in the delivery of an IP packet include the sending host, the intermediate routers, and the destination host.

**IP on the Sending Host**
When a host sends a packet, the packet is transmitted from an upper layer protocol (TCP, UDP, or ICMP) to IP, and then IP on the sending host does the following:

1. Sets the Time-to-Live (TTL) value to either a default or application-specified value.

2. Checks its routing table for the best route to the destination IP address.

   If no route is found, IP sends a routing error message to the upper layer protocol (TCP, UDP, or ICMP).

3. Determines the next-hop IP address and the interface, based on the most specific matching route.

4. Sends the packet, the next-hop IP address, and the next-hop interface to Address Resolution Protocol (ARP), and then ARP resolves the next-hop IP address to its media access control (MAC) address and forwards the packet.

**IP on the Router**
When a packet is received at a router, the packet is passed to IP, and IP on the router does the following:

1. Verifies the IP header checksum.

   If the IP header checksum fails, the IP packet is discarded without notification to the user. This is known as a silent discard.

2. Verifies whether the destination IP address in the IP packet corresponds to an IP address assigned to a router interface.

   If so, the router processes the IP packet as the destination host (see step 3 in the following "IP on the Destination Host" section).

3. If the destination IP address is not the router, IP decrements the Time-to-Live (TTL).

   If the TTL is 0, the router discards the packet and sends an ICMP Time Expired–TTL Expired in Transit message to the sender.

4. If the TTL is 1 or greater, IP updates the TTL field and calculates a new IP header checksum.

5. IP checks its routing table for the best route to the destination IP address in the IP packet.

   If no route is found, the router discards the packet and sends an ICMP Destination Unreachable–Host Unreachable message to the sender.

6. Based on the best route found, IP determines the next-hop IP address and interface.

7. IP sends the packet, the next-hop IP address, and the interface to ARP, and then ARP forwards the packet to the appropriate MAC address.

This entire process is repeated at each router in the path between the source and destination host.

**IP on the Destination Host**
When a packet is received at the destination host, it is passed up to IP, and IP on the destination host does the following:

1. Verifies the IP header checksum.

   If the IP header checksum fails, the IP packet is silently discarded.

2. Verifies that the destination IP address in the IP packet corresponds to an IP address assigned to the host.

   If the destination IP address is not assigned to the host, the IP packet is silently discarded.

3. Passes the IP packet without the IP header to the appropriate upper-level protocol, based on the IP protocol field.

   If the protocol does not exist, ICMP sends a Destination Unreachable–Protocol Unreachable message back to the sender.

4. For TCP and UDP packets, IP checks the destination port and processes the TCP segment or UDP header.

   If no application exists for the UDP port number, ICMP sends a Destination Unreachable–Port Unreachable message back to the sender. If no application exists for the TCP port number, TCP sends a Connection Reset segment back to the sender.

# TCP/IP Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP Tools and Settings**

**In this section**

TCP/IP Tools

Microsoft Windows Server 2003 and Microsoft Windows XP Professional support many TCP/IP diagnostic and remote networking tools that help manage and troubleshoot your network. Windows Server 2003 adds new IPv6 tools and updates several standard IPv4 tools to include IPv6 functionality.

**TCP/IP Tools**

The following sections "TCP/IP Diagnostic Tools" and "TCP/IP Remote Networking Tools" describe the diagnostic and remote networking tools associated with TCP/IP.

**Other Tools**

In addition to the Microsoft TCP/IP tools described in this document, Windows Server 2003 supports the tools shown in the following table. The Ipsec6 and Ttcp tools are new IPv6 tools.

**Other TCP/IP-Related Tools**

| Tool | Description |
|---|---|
| Ipsec6 | You can use **Ipsec6** to experiment with managing Internet Protocol security (IPSec) in an IPv6 test environment by configuring IPSec policies and security associations. |
| Ttcp | You can use this tool to troubleshoot TCP and UDP traffic. You can find the **Ttcp** tool in the **Valueadd\Msft\Net\Tools** folder of the Windows Server 2003 CD-ROM. |
| Event Viewer | Tracks errors and events recorded in Application, Security, and System logs. |
| Network Monitor | Captures and displays network traffic. The full version, which can capture all frames sent on a network segment, is part of the Microsoft Systems Management Server (SMS) product. A limited version, which can capture frames that are sent to or from the network adapter of the computer on which Network Monitor is installed, is included with Windows Server 2003. |
| Registry Editor | The registry editor Regedit.exe allows viewing and editing of registry parameters. |
| Simple Network Management Protocol (SNMP) service | Provides statistical information about network devices to SNMP management systems, such as HP OpenView, IBM NetView, or Sun Net Manager. |
| System Monitor | Analyzes TCP/IP network performance. System Monitor is a component of in the Performance Logs and Alerts snap-in. |

**TCP/IP Diagnostic Tools**

TCP/IP supports several diagnostic tools in Windows Server 2003 that include new support for IPv6:

- Netstat
- Pathping
- Ping
- Tracert

In addition, Windows Server 2003 introduces the **Netsh** commands for both IPv6 and for Ipv6 6to4. You can use the first set of

tools to query and configure IPv6 interfaces, addresses, caches, and routes. You can use the second set of commands to query or configure the 6to4 service on either a 6to4 host or a 6to4 router.

The following table lists TCP/IP diagnostic tools that you can use to identify and resolve TCP/IP networking problems.

**TCP/IP Diagnostic Tools**

| Tool | Description |
|---|---|
| Arp | View and manage the Address Resolution Protocol (ARP) cache on the interfaces of the local computer. |
| Hostname | Display the name of the computer. |
| Ipconfig | Display current TCP/IP network configuration values, update or release Dynamic Host Configuration Protocol (DHCP) allocated leases, and display, register, or flush Domain Name System (DNS) names. |
| Nbtstat | Check the state of current NetBIOS over TCP/IP (NetBT) connections, view and update the NetBIOS name cache, and determine the names registered with Windows Internet Name Service (WINS). |
| Netdiag | Check the state of a network client to help isolate TCP/IP-related connectivity problems, including verifying that DNS is available and functioning correctly. |
| Netsh | Provides thirteen sets of commands (called contexts) for performing a wide range of network configuration tasks. Windows Server 2003 adds a new context for managing IPv6 to the **netsh** command set. |
| Netstat | Display statistics for current TCP/IP connections. Windows Server 2003 adds IPv6 parameters to the **netstat** command. |
| Nslookup | Check records, domain host aliases, domain host services, and operating system information by querying DNS servers. |
| Pathping | Trace a path to a remote system and report packet losses at each router along the way. Windows Server 2003 adds IPv6 parameters to the **pathping** command. |
| Ping | Send Internet Control Message Protocol (ICMP) Echo messages to verify IP connectivity. Windows Server 2003 adds IPv6 parameters to the **ping** command. |
| Route | Display the IP routing table, and add, edit, or delete IPv4 routes. Route for Windows Server 2003 also displays IPv6 routes. |
| Tracert | Trace a path to a destination. Windows Server 2003 adds IPv6 parameters to the **tracert** command. |

All of the tools in the previous table, except **Netdiag**, are installed with the Windows Server 2003 operating system. **Netdiag** is one of the support tools delivered with the second Windows Server 2003 operating system CD, which you install separately from the operating system itself.

**Arp.exe: Arp**
**Category**
The **Arp** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Arp** command-line tool to display and modify entries in the local Address Resolution Protocol (ARP) cache. The ARP cache, which is a memory-resident list, contains one or more tables that store IP addresses and the corresponding Ethernet, Token Ring, or wireless LAN physical addresses that have been resolved from other computers on the same subnet. Typically, a physical address is the Media Access Control (MAC) address. A separate table exists for each network adapter installed on the computer.

**Hostname.exe: Hostname**
**Category**
The **Hostname** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Hostname** command-line tool to display the host name of the computer on which you run the command.

**Hostname** does not display the fully qualified domain name (FQDN) of the computer. You can find the computer name and its FQDN through Control Panel on the computer.

**Ipconfig.exe: Ipconfig**
**Category**
The **IPconfig** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Ipconfig** command-line tool to display the current configuration of the installed IP stack on a networked computer and to refresh DCHP and DNS settings. The **Ipconfig** command is often one of the first commands you use to check the status of the connection when you experience communication problems on a TCP/IP network. Ipconfig is most useful for managing computers that obtain an IP address automatically, such as by using DHCP or through alternate configuration.

When used without a parameter, **Ipconfig** displays the IPv4 address, subnet mask, and default gateway for all adapters on a computer. If the computer has the IPv6 protocol installed, **Ipconfig** also displays the IPv6 address information.

**Nbstat.exe: Nbtstat**
**Category**
The **Nbtstat** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Nbtstat** command-line tool to troubleshoot NetBIOS name-resolution problems.

When a network is functioning correctly, NetBIOS over TCP/IP (NetBT) resolves NetBIOS names to IP addresses. NetBT uses several options for NetBIOS name resolution, including local NetBIOS name cache lookup, WINS server query, broadcast, and LMHOSTS lookup. After NetBT methods are exhausted, Windows TCP/IP converts the NetBIOS name to a host name and attempts host name resolution, including checking the local host name, checking the DNS client resolver cache, and querying DNS servers.

Use **Nbtstat** to display a variety of information, including:

NetBT protocol statistics.

NetBIOS name tables for both the local computer and for remote computers. The NetBIOS name table is the list of NetBIOS names that corresponds to NetBIOS applications running on that computer.

NetBIOS name cache. The NetBIOS name cache is the table that contains NetBIOS name-to-IP address mappings.

Also use **Nbtstat** to refresh the NetBIOS name cache and the names registered with WINS.

**Netdiag.exe: Netdiag**
**Category**
**Netdiag** is a command-line tool delivered with the support tools on the second Windows Server 2003 operating system CD, which you install separately from the operating system itself.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Netdiag** command-line tool, which is one of the support tools delivered with the second Windows Server 2003 operating system CD, to help isolate TCP/IP-related connectivity problems. After you install the Support Tools, Netdiag.exe appears in the Program Files\Support Tools folder on the drive on which the Support Tools are installed.

**Netdiag** provides tests that report information about a computer and its network configuration, which can help diagnose network problems. Use the **Netdiag** logging parameter (**-l**) to capture and store output from **Netdiag** tests. One use of **Netdiag** logging is to add the output of Netdiag tests to your network's baseline documentation and to create updated test logs each time important changes to a computer's configuration are made.

In addition to troubleshooting TCP/IP issues, you can also use Netdiag to examine a computer's Internetwork Packet Exchange (IPX) and NetWare configurations.

### Note

- The IPX protocol is supported only on the 32-bit platforms in Windows Server 2003.

Despite the name similarity and some overlap in function, the Netdiag command-line tool that you install from the Windows Server 2003 operating system CD as part of the set of Support Tools is not the same as the following two versions of a different network diagnostic tool:

**Network Diagnostics**, which you access under Help and Support Center Tools in Help and Support Center for Windows Server 2003.

**Netsh diagnostic** (**diag**)commands, which you access by typing **netsh -c diag** at a command prompt.

**Network Diagnostics** and the **Netshdiag** commands use the same Dynamic Link Library (DLL) and run the same set of tests. However, **Netsh** lets you test user-defined destinations, whereas **Network Diagnostics** does not.

Although there is some overlap between these tools and the **Netdiag** support tool described here, for the most part **Netdiag** provides a different set of tests.

**Netsh.exe: Netsh**
**Category**
The **Netsh** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Netsh** command-line tool to locally or remotely display or modify the configuration of services or protocols on computers running Windows. In addition, the **Netsh** command-line interface is scriptable, which lets you perform batch configurations or administration from a centralized location.

The **Netsh** commands, which were first introduced in Windows 2000, help you manage a standard TCP/IP network, that is, an IPv4 network. For organizations that have begun to explore IPv6 by introducing IPv6 into their network, Windows Server 2003 and Windows XP add a new set of **Netsh** commands for IPv6.

For administrative convenience, the **Netsh** commands are grouped into sets, called contexts. Each context provides commands appropriate for a specific area of networking functionality. A context is implemented through an associated **Netsh** helper, which is a dynamic link library (DLL) file that provides the capabilities for that context. **Netsh** directs the context command that you enter to the appropriate helper, and the helper then carries out the command. The **Netsh** helper DLLs interact with other operating system components, such as WINS or TCP/IP. For example, Winsmon.dll provides the set of commands for managing the WINS service, and Ifmon.dll provides the set of commands for managing IPv4 interfaces.

A context can contain one or more additional contexts, called a subcontext. For example, the IPv6 context contains the 6to4 subcontext, which provides a separate set of commands for managing the 6to4 service (which encapsulates IPv6 traffic with an IPv4 header before it is sent over an IPv4 network) on either a 6to4 host or a 6to4 router.

**Netsh** is extensible. Developers can create additional contexts to manage networking services in addition to the contexts provided by Windows.

**Netstat.exe: Netstat**
**Category**
The **Netstat** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Netstat** command-line tool to display active TCP/IP connections, ports on which the computer is listening, Ethernet statistics, the IP routing table, IPv4 statistics (for the IP, ICMP, TCP, and UDP protocols), and IPv6 statistics (for the IPv6, ICMPv6, TCP over IPv6, and UDP over IPv6 protocols).

**Nslookup.exe: Nslookup**
**Category**
The **Nslookup** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Nslookup** command-line tool for querying and troubleshooting the DNS infrastructure. For example, **Nslookup** can provide host-name resolution.

**Pathping.exe: Pathping**
**Category**
The **Pathping** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use **Pathping**, a command-line tool that combines features of **Ping** and **Tracert**, to obtain additional information that neither of those tools provides. Specifically, you can use **Pathping** to identify the route to a remote host, then ping the remote host for a period of time to collect and report statistics. Pathping information includes information about the intermediate routers visited on the path, the Round-Trip Time (RTT) value, and link-loss information.

**Ping.exe: Ping**
**Category**
The **Ping** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Ping** command-line tool as your primary tool for troubleshooting IP-level connectivity between two TCP/IP computers. **Ping** sends ICMP Echo or ICMPv6 Echo Request messages to perform network diagnostics and to test ability to reach a specific destination. **Ping** can use IPv4 or IPv6 addresses. If a name is specified, **Ping** uses the address that is resolved.

**Ping** lets you specify the size of packets to use (the default is 32 bytes), how many to send, whether to record the route used, what Time-To-Live (TTL) value to use, whether or not to set the **Don't Fragment** flag, and so on.

**Route.exe: Route**
**Category**
The **Route** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Route** command-line tool to view and modify the local IP routing table.

For two hosts to exchange IP datagrams, they must both have a route to each other, or they must use a default gateway that knows a route between the two. Typically, routers exchange information using a protocol such as Routing Information Protocol (RIP) or Open Shortest Path First (OSPF). The RIP Listening service is available for Microsoft Windows XP Professional, and full routing protocols are supported by Windows Server 2003 in the Routing and Remote Access service.

All symbolic names used for the specified network destination of the route are looked up in the network database file NETWORKS. The symbolic names for the gateway are looked up in the host name database file HOSTS. If the command is **print** or **delete**, the destination value can be a wildcard value specified by an asterisk ("*****"). If the destination specified contains a ***** or **?**, it is treated as a shell pattern and only matching destination routes are printed. The asterisk matches any string, and the question mark matches any one character. For example, **157.*.1**, **157.***, **127.***, and ***224*** are all valid uses of the wildcard asterisk.

Using an invalid combination of a destination and netmask value generates a "The route addition failed: The specified mask parameter is invalid. (Destination & Mask) != Destination." error. This sort of error message appears, for example, when a bitwise logical AND between the destination and mask does not equal the destination value.

**Tracert.exe: Tracert**
**Category**
The **Tracert** command-line tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Tracert** command-line route-tracing tool to display the path between the sending host and a destination.

The path that **Tracert** displays is a list of near-side router interfaces of the routers in the path between the source host and destination. **Tracert** uses the IP Time-to-Live (TTL) field in Internet Control Message Protocol (ICMP) Echo Requests and ICMP Time Exceeded-TTL Exceeded in Transit messages to determine the path from a source to a destination through an IP internetwork.

Note that some routers silently drop packets with expired TTLs. These routers do not appear in the **Tracert** display.

**Tracert** works by incrementing the TTL value by one for each ICMP Echo Request it sends, and then waiting for an ICMP Time Exceeded-TTL Exceeded in Transit message. The TTL values of the **Tracert** packets start with an initial value of one; the TTL of each trace after the first is incremented by one. A packet sent out by **Tracert** travels one hop further on each successive trip.

### Note

- The UNIX version of **Tracert** performs the same function as the Windows version, except that the IP payload is a UDP packet addressed to a (presumably) unknown destination UDP port. Intermediate routers send back ICMP Time Expired-TTL Exceeded in Transit messages recording the route taken, and the final destination sends back an ICMP Destination Unreachable-Port Unreachable message.

- The UDP payload from the UNIX **Tracert** tool can cross routers and some firewalls, whereas the ICMP Echo Request messages might not, due to ICMP filtering. To avoid this problem in Windows Server 2003, turn off packet filtering and then try using **Tracert** again.

**TCP/IP Remote Networking Tools**

Microsoft TCP/IP includes several remote networking tools. The following table lists the tools included with Microsoft TCP/IP that you can use to communicate with remote computers.

**TCP/IP Remote Tools**

| Tool | Description |
|---|---|
| Finger | Displays information about a user or users on a specified remote computer (typically, a computer running UNIX) that is running the Finger service. |
| Ftp | Transfers files over the Internet to, and from, a computer running a File Transfer Protocol (FTP) server service, such as the FTP component of Microsoft Internet Information Services (IIS). |
| Rcp | Copies files between a computer running Windows Server 2003 and a computer running Rshd, the UNIX remote shell service. |
| Rexec | Runs commands on a remote computer (typically, a computer running UNIX). |
| Rsh | Runs commands on remote hosts using the Rsh service, the UNIX remote shell service. |
| Telnet | Starts terminal emulation with a remote host running a Telnet server service. |
| Tftp | Transfers files to and from a remote computer (typically, a computer running UNIX) that is running the Trivial File Transfer Protocol (TFTP) service. |

**Note**

- All passwords used by Windows networking services are encrypted. However, the **Ftp**, **Rexec**, and **Telnet** connectivity tools rely on plaintext password authentication by the remote computer. Plaintext passwords are not encrypted before being sent over the network. This enables another user equipped with a network capture tool such as Network Monitor on the same network to obtain a user's remote account password. For this reason, choose different passwords from those used for computers running Windows Server 2003 or domains when connecting to non-Microsoft remote computers with the **Ftp**, **Rexec**, or **Telnet** tools. Note that the protocols themselves prohibit encryption; the use of plaintext passwords is not recommended by Microsoft.

**Finger.exe: Finger**
**Category**
The **Finger** connectivity tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Finger** connectivity tool to display information about a user or users on a specified remote computer (typically, a host computer running UNIX) that is running the Finger service. Output varies based on how the remote host specifies **Finger** output format.

**Ftp.exe: Ftp**
**Category**
The **Ftp** connectivity tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

FTP is a protocol that defines how to transfer files from one computer to another over a TCP/IP network, such as the Internet or a company intranet. Use the **Ftp** connectivity tool to transfer files to and from a host running an FTP server service, such as the FTP component of Microsoft Internet Information Services (IIS). You can use **Ftp** interactively or in batch mode to process ASCII text files.

### Note

- The FTP service is a component of Microsoft Internet Information Services (IIS). However, when you install IIS on a server, FTP is not installed unless you explicitly specify that it be installed. If you install IIS without FTP, you can use **Add or Remove Windows Components** in **Add or Remove Programs** in **Control Panel** to install FTP later.

Typically, users use **Ftp** to download files from a location on the Internet or to upload files to a location on the Internet. Before a user can log on to an FTP server, the server administrator must grant the user permission to access the **inetput\ftproot** folder, which is created along with the Default FTP site by default when you install IIS FTP, or a folder for the use of a particular user or group under the ftproot folder. Alternatively, you can create a new FTP site, and you can use folders other than ftproot and its children for FTP files.

Similarly, users can upload a file from the local computer to an FTP server using the **put** command. However, for users to successfully use the **put** command, the administrator must grant them write permissions for the FTP folder to which the file will be uploaded.

**Rcp.exe: Rcp**
**Category**
The **Rcp** connectivity tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Rcp** connectivity tool to copy files between a computer running Windows Server 2003 and a computer running **Rshd**, the UNIX remote shell server service or daemon. **Rshd** stands for **Rsh d**aemon; daemon is the UNIX term for service. In addition to running **Rsh**, the remote computer must also support the **Rcp** tool.

Also use **Rcp** for third-party transfer to copy files between two computers running **Rsh** when the command is issued from computers running Windows Server 2003. The UNIX **Rsh** server service is not available on computers running Windows Server 2003, but the computer running Windows Server 2003 can participate as the computer from which the commands are issued.

**Permitting Network Access**
The .rhosts file typically permits network access on UNIX systems. The .rhosts file lists computer names and associated logon names that have access to remote computers. When you run **Rcp**, **Rexec**, or **Rsh** tools remotely with a correctly configured .rhosts file, you do not need to provide logon and password information for the remote computer. The .rhosts file must be in the user's home directory on the remote computer.

The .rhosts file specifies which remote computers or users can access a local account using the **Rcp** or **Rsh** commands (**Rsh** is described later in this chapter). For you to access the remote computer using **Rcp**, the .rhosts file (or a file called Hosts.equiv) must exist on the remote computer. **Rcp** transmits the local user name to the remote computer. The remote computer uses this name and the IP address (usually resolved to a computer name) of the requesting computer to determine whether to grant access. No provision exists for specifying a password to access an account using **Rcp**.

If the user is logged on to a Windows Server 2003 domain, the domain controller must be available to resolve the currently logged-on name because the logged-on name is not cached on the local computer. Because the user name is required as part of the Rcp protocol, the command fails if it cannot obtain the user name.

The .rhosts file is a text file in which each line is an entry. An entry consists of the local host name, the local user name, and any comments about the entry. Each entry is separated by a tab or space, and comments begin with the number sign (**#**).

For more information about the implementation of the .rhosts file on a remote computer, see the remote computer's documentation.

**Specifying Computers (Hosts)**
Use Host.user to specify a user name other than the current user name. If you use Host.user with **Source** (which specifies which files to copy), the .rhosts file on the remote computer must contain an entry for user. For example:

```
Rcp host99.user7:file1 corp7.admin:file2
```

In this example, the .rhosts file on Corp7 must have an entry for User7 on Host99.

If you type a computer name as a fully qualified domain name (FQDN) containing periods, you must append a user name to the host name. This prevents the last element of the domain name from being interpreted as a user name. For example:

```
Rcp domain-name1.user:johns domain-name2.user:buddyg
```

**Performing Remote Processing**
Remote processing is performed by a command run from the user's logon shell on most UNIX computers. The user's **.profile** or **.cshrc** file is run before file names are parsed. You can specify that exported shell variables be used in remote file names by using one of the escape characters. The escape characters are the backslash (\), quotation mark ("), and apostrophe (').

**Copying Files**
If you try to copy several files to a file rather than to a directory, only the last file is copied. Also, the **rcp** command cannot copy a file onto itself (*Source* and *Path/Destination* cannot be the same).

**Rexec.exe: Rexec**
**Category**
The **Rexec** connectivity tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Rexec** connectivity tool to run commands on a remote computer that is running the Rexecd service, the UNIX remote execute service. Rexecd stands for Rexec daemon; daemon is the UNIX term for service. Before carrying out the specified command, **Rexec** authenticates the user name on the remote host by prompting for a password. Windows Server 2003 does not provide the Rexec service.

**Rexec** copies standard input to the remote command, standard output of the remote command to its standard output, and the standard error of the remote command to its standard error. Interrupt, Quit, and Terminate signals are propagated to the remote command. **Rexec** generally terminates when the remote command completes.

You cannot use **Rexec** to run most interactive commands. For example, you cannot use **Rexec** to run **vi** or **emacs** commands. Use Telnet to run interactive commands.

**Rsh.exe: Rsh**
**Category**
The **Rsh** connectivity tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Rsh** connectivity tool to run commands on remote computers that are running the Rsh service, the UNIX remote shell service. For information about the .rhosts file used to enable this tool, see the description of the **Rcp** tool earlier in this section.

If the user is logged on to a Windows Server 2003 domain, the domain controller must be available to resolve the user name, because it is not cached on the local computer. Because the user name is required as part of the Rsh protocol, the command fails if the user name cannot be obtained.

**Rsh** copies standard input to the remote command, standard output of the remote command to its standard output, and the standard error of the remote command to its standard error. **Rsh** generally terminates when the remote command completes.

**Telnet.exe: Telnet**
**Category**
The **Telnet** connectivity tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

The **Telnet** connectivity tool starts terminal emulation with a remote host running a Telnet server service. The remote computer must also be using TCP/IP. Telnet provides DEC VT 100, DEC VT 52, or ANSI emulation, using the connection-based services of TCP.

To provide terminal emulation from a computer running Windows, the remote host must be running TCP/IP and a Telnet Server service. The Windows-based Telnet user must also have a user account on the remote Telnet Server.

**Note**

- Windows Server 2003 and Microsoft Windows XP Professional provide the Telnet Client and Telnet Server components. These are built in, but you must use the Services snap-in to start the **Telnet** service before it can serve Telnet clients.

**Tftp.exe: Tftp**
**Category**
The **Tftp** connectivity tool is installed with the operating system.

**Version compatibility**
This tool is included with all versions of Windows that include TCP/IP.

Use the **Tftp** connectivity tool to transfer files over the Internet to and from a remote computer (typically, a computer running UNIX) that is running the Trivial File Transfer Protocol (TFTP) service. This tool is similar to **Ftp**, but it does not provide user authentication. However, the files you transfer using **Tftp** do require UNIX read and write permissions. You can use **Tftp** only for unidirectional transfer of files.

# IPv6 Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The current Internet has fueled significant innovation and growth in network computing. To support this growth and the demand for more collaborative communication experiences, the current version of the Internet Protocol (IP), called IP Version 4 (IPv4), is being replaced with a new standard.

IPv4 is an agreed-upon set of protocols, or rules, that allow computers to communicate with each other by specifying the format of packets and the addressing scheme.

The new version of IP, called IP version 6 (IPv6), performs the same functions as IPv4 but resolves unanticipated IPv4 design issues.

As a core networking protocol in the Microsoft Windows Server 2003 operating systems, IPv6 serves as one of two Internet protocols that enable computers that are running Microsoft Windows operating systems to communicate on intranets and over the Internet.

This subject describes how IPv6 relates to other networking protocols, the functions that IPv6 performs, how IPv6 addresses are structured and assigned, how IPv6 packets are structured and routed, and how IPv6 can interoperate with IPv4.

# What Is IPv6?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is IPv6?**

**In this section**

- Introduction to IPv6
- IPv6 in Windows Server 2003
- Transitioning from IPv4 to IPv6
- Limitations of IPv4
- IPv6 Features that Fix IPv4 Limitations
- Differences Between IPv4 and IPv6
- Related Information

**Introduction to IPv6**

Microsoft is delivering support for the emerging update to the Internet Protocol, commonly referred to as IP version 6 — or simply IPv6 (RFC 2460). This protocol suite is based on a standard from the Internet Engineering Task Force (IETF), and it is designed to significantly increase the size of the address space used to identify communication endpoints in the Internet, thereby allowing it to continue its tremendous growth rate. As a core networking protocol in Windows Server 2003, IPv6 serves as one of two Internet protocols that enable computers running Windows to communicate on intranets and over the Internet.

The recent broad adoption of always-on technologies such as Digital Subscriber Line (DSL) and cable modems, coupled with the pending integration of personal data assistants (PDAs) and cellular phones into always-addressable Mobile Information Appliances, significantly elevates the urgency to expand the address space that Internet-connected systems use to communicate. The address space currently used is defined as part of the Internet Protocol, or IP (the network layer of the TCP/IP protocol suite). The version of IP commonly used today, Version 4 (IPv4), has not been substantially changed since RFC 791 was published in 1981. Since then, IPv4 has proven to be robust, easily implemented, and interoperable. It has withstood the test of scaling an internetwork (a network of networks) to a global utility the size of today's Internet.

IPv6 will continue the tradition of the IPv4 protocol, which gained much of its acceptance by defining mechanisms to tie systems together over a wide variety of disparate networking technologies. Already defined link-layer mappings for transporting IPv6 include Ethernet, Point-to-Point Protocol (PPP), Fiber Distributed Data Interface (FDDI), Token Ring, Asynchronous Transfer Mode (ATM), Frame Relay, and IEEE 1394. From an architectural perspective, an IPv4-based infrastructure appears to systems that are enabled for IPv6 as a single segment non-broadcast multi-access (NBMA) network. The capability to send IPv6 traffic over existing IPv4 networks will provide an initial reach as broad as the current Internet, limited only by the endpoints' ability and readiness to make use of it.

New capabilities that are expected to drive rapid adoption include scoped addresses; stateless autoconfiguration, which lowers complexity and management burden; and mandatory IP security (IPSec), which permits end-to-end data authentication and integrity and increases privacy of connections. In addition, technologies that extend the lifetime of IPv4 (such as network address translation, or NATs) frequently do not work with existing applications, and those technologies are already restricting the flexibility to deploy new applications. NATs are popular today because they allow multiple systems to share a single public IPv4 address. However, they tend to enforce a client/server usage model where the client uses private address space with only the server existing in public address space. IPv6 brings back the capability of "end-to-end control of communications," making networking applications simpler as the network again becomes transparent.

**IPv6 in Windows Server 2003**

Wireless technologies are emerging in ways that make ad-hoc networks between personal devices more feasible. Setting up systems to work in an ad-hoc mode is challenging enough, but many of these personal devices will also need to perform in the managed environment of the workplace. Switching between these modes is frequently frustrating and is significantly more

involved than using either mode on its own. To reduce the complexity, IPv6 has defined an architectural principle that systems are required to simultaneously support multiple addresses. Coupling this capability with scoped addresses results in the ability to move easily and automatically between ad-hoc and managed environments. Tthe IPv6 implementation will automatically adapt itself to the current needs, be it ad-hoc, home, or business connections.

To address concerns about security and privacy, the Microsoft IPv6 implementation includes IPSec, which provides data authenticity, data integrity, and data confidentiality across the array of protocols used by the various applications. Providing the capability at the network layer frees developers from having to add specific security capabilities to every application.

In addition, Microsoft helped standardize temporary addresses. To make stateless autoconfiguration work well and to ensure global uniqueness, the standards community chose the underlying hardware address (the MAC address) for use as part of an IPv6 address. The side effect of this approach is that all communications are traceable to the specific hardware device.

Although it is technically necessary to have a published (over some scope), globally unique address to receive incoming connections, the address of an originator requires only current global uniqueness (not publication). To alleviate this potential privacy concern, Microsoft has authored RFC 3041 to define a locally generated address mechanism where the result is valid only for a period that the local system or application determines. The ability of IPv6 systems to simultaneously support multiple addresses allows each application to use an independent address, an application to use a different address for each service to which it connects, or both.

Peer-to-peer applications that are made easier using IPv6 include IP telephony and video tele-conferencing. These and similar applications are likely to take advantage of the Quality of Service (QoS) features defined for IPv6. Although many QoS features have also been defined as add-ons for IPv4, the mechanism selected was to redefine the meaning for the Type of Service field of the IP header, which caused collisions with historical implementations. The effort to provide QoS for IPv4 has been a struggle due to differing models of deployment. This effort is not wasted though, because it is forcing many details to be worked through — from hardware capabilities to business practices. Systems that are enabled for IPv6 will be able to leverage this effort to provide an array of service levels that are consistent from end to end.

**Transitioning from IPv4 to IPv6**

The conversion from IPv4 to IPv6 will be a larger task for the industry than was the preparation for year 2000. This protocol change will affect nearly all networked applications, end systems, infrastructure systems, and network architectures. This change must be approached with responsibility to prevent the costly, unproductive missteps that often result from broad, premature availability of technologies. Unlike the year 2000 issue, the conversion to IPv6 has no specific timeline. However, as noted earlier, the rate of IPv4 address consumption is rapidly increasing. Simplicity of deployment will be the key to rapid adoption.

Like IPv4 (where early deployments frequently transited X.25 networks), IPv6 deployment will start at the edge of the network, taking advantage of framing within any available network technology. Internet service providers (ISPs) will deploy native IPv6 routing based on customer demand. However, this conversion may be slow because ISPs will need several years to replace network equipment. Microsoft is taking the approach that encapsulating IPv6 packets within IPv4 will allow incremental deployments of end systems that will, in turn, demonstrate the demand to the ISPs.

To stay on the high performance path of the existing routers, computers that are running Windows and that are enabled for IPv6 will default to tunneling over IPv4 unless the ISP provides a specific indication to do otherwise and a native IPv6 path exists end to end. The only requirement is that systems that are directly connected to an ISP must receive at least one public IPv4 address. (The address ranges specified in RFC 1918 are not public.) Other systems in a home or business will receive 6to4 (RFC 3056) prefix Router Advertisement messages from the directly connected system.

In the presence of NATs that are not enabled for IPv6 where only private addresses are available, a supplementary technology will be used. This technology will tunnel IPv6 traffic over NATs by including a User Datagram Protocol (UDP) header that can be used to provide a mechanism for 6to4-type tunneling across the IPv4 Internet. In enterprise environments, an incremental upgrade to IPv6 is possible using the Intra-Site Automatic Tunnel Addressing Protocol (ISATAP). ISATAP allows IPv6-only hosts and subnets to fully co-exist and interoperate with IPv4 hosts and subnets in an intranet. In partnership with 6to4 technology, a comprehensive incremental migration solution is available to businesses that are taking their corporate networks through this transition.

Despite these approaches, the transition will not be easy. Most manufacturers will produce systems that support both IPv4 and IPv6 so that, if connections are not possible using IPv6, the systems can fall back and succeed using IPv4 (if IPv4 connectivity existed before the introduction of IPv6). The overall goal is to ensure a smooth transition and deployments where updated applications can take advantage of the new protocol without breaking existing functionality. To this end, new Windows APIs have been defined to specifically isolate the legacy applications from unintentional exposure to protocol differences, including the larger IPv6 addresses.

Microsoft has taken four key steps to deliver IPv6:

- In 1998, Microsoft Research released an IPv6 implementation to help the community that was developing standards for IPv6 understand and test the protocol during its definition.

- In March 2000, a technology preview was released for computers that were running Windows 2000. This release helped developers become familiar with the concepts and capabilities they would encounter when they enabled their applications to use IPv6.

- In October 2001, Windows XP was released with a developer preview IPv6 stack and key components of the system enabled for IPv6 so developers could begin the task of enabling their applications for IPv6. It is also expected that early adoption customers will start using IPv6 in test labs. This testing will allow those customers to have better visibility into managing their eventual rollout, and it will help identify any issues that need to be addressed in networked products.

- In November 2001, beta 3 for Windows Server 2003 was released with the first edition of the Microsoft production stack and components enabled for IPv6.

Current releases, including both Windows Server 2003 and Windows XP with Service Pack 1, provide general availability of this stack. Customers can begin production rollout of systems and applications that take advantage of this protocol.

The Microsoft implementation of IPv6 is easy to deploy because it includes stateless address autoconfiguration (including temporary addresses), automatic tunneling over existing IPv4 networks, and appropriate use of scoped addresses.

Because IP is a fundamental and pervasive technology within the operating system, it is not feasible to retrofit versions of Windows prior to Windows Server 2003 and Windows XP. However, to maintain backwards compatibility, versions of Windows that are enabled for IPv6 will also provide the capability to natively communicate using IPv4 for the foreseeable future. Although translation between IPv4 and IPv6 will be necessary in some cases (such as late in a transition when new IPv6-only devices need to access yet-to-be-retired IPv4-only systems), it is not expected to be the norm for early deployments. Whenever the IPv6-only devices arrive, the issues that surround address translation are typically specific to a given application. Thus as they arise, these scenarios will require targeted development on a case-by-case basis.

**Limitations of IPv4**
IPv4's initial design did not anticipate the following:

- The recent exponential growth of the Internet and the impending exhaustion of the IPv4 address space.

  Because IPv4 addresses have become relatively scarce, some organizations have been forced to use NATs to map multiple private addresses to a single public IP address. NATs promote reuse of the private address space, but they do not support standards-based network-layer security or the correct mapping of all upper layer protocols. NATs can also create problems when they connect two organizations that use the private address space.

  Additionally, the rising prominence of Internet-connected devices and appliances ensures that the public IPv4 address space will eventually be depleted.

- The requirement for security at the Internet layer.

  Private communication over a public medium such as the Internet requires encryption services that protect the data being sent from being viewed or modified in transit. IPSec provides security for IPv4 packets, but this standard is optional, and proprietary solutions prevail.

- 7The growth of the Internet and the ability of Internet backbone routers to maintain large routing tables.

  Because of the way that IPv4 network IDs have been and are currently allocated, the routing tables of Internet backbone routers routinely contain more than 85,000 routes. The routing infrastructure of the IPv4 Internet combines both flat and hierarchical routing.

- The need to better support real-time delivery of data — also called quality of service (QoS).

  QoS standards exist for IPv4, but real-time traffic support relies on the IPv4 Type of Service (TOS) field and the identification of the payload, which is typically done using a UDP or TCP port. Unfortunately, the IPv4 TOS field has limited functionality, and various local interpretations developed over time. In addition, payload identification using a TCP

and UDP port is not possible when the payload is encrypted.

**IPv6 Features that Fix IPv4 Limitations**
IPv6 includes the following features:

- New header format
- Larger address space
- Efficient and hierarchical addressing and routing infrastructure
- Stateless and stateful address configuration
- Built-in security
- Better support for QoS
- New protocol for neighboring node interaction
- Extensibility

The following subsections discuss each of these new features in detail.

**New Header Format**
The IPv6 header has a new format that is designed to minimize header overhead. This optimization is achieved by moving both non-essential fields and optional fields to extension headers that appear after the IPv6 header. Intermediate routes can process the streamlined IPv6 header more efficiently.

IPv4 headers and IPv6 headers do not interoperate. IPv6 is not a superset of functionality that is backward compatible with IPv4. A host or router must use an implementation of both IPv4 and IPv6 to recognize and process both header formats. The IPv6 header is only twice as large as the IPv4 header, even though IPv6 addresses are four times as large as IPv4 addresses.

**Larger Address Space**
IPv6 has 128-bit (16-byte) source and destination IP addresses. Although 128 bits can express over 3.4×1038 possible combinations, the large address space of IPv6 has been designed for multiple levels of subnetting and address allocation from the Internet backbone to the individual subnets within an organization.

Even though only a small number of the possible addresses are currently allocated for use by hosts, plenty of addresses are available for future use. With a much larger number of available addresses, address-conservation techniques, such as the deployment of NATs, are no longer necessary.

**Efficient and Hierarchical Addressing and Routing Infrastructure**
IPv6 global addresses that are used on the IPv6 portion of the Internet are designed to create an efficient, hierarchical, and summarizable routing infrastructure that is based on the common occurrence of multiple levels of Internet service providers.

**Stateless and Stateful Address Configuration**
To simplify host configuration, IPv6 supports both stateful address configuration (as in the presence of a DHCP server) and stateless address configuration (as in the absence of a DHCP server). With stateless address configuration, hosts on a link automatically configure themselves with IPv6 addresses for the link (called link-local addresses) and with addresses that they derive from prefixes that local routers advertise. Even in the absence of a router, hosts on the same link can configure themselves with link-local addresses and communicate without manual configuration.

**Built-in Security**
The IPv6 protocol suite requires support for IPSec. This requirement provides a standards-based solution for network security needs and promotes interoperability between different IPv6 implementations.

**Better Support for QoS**
New fields in the IPv6 header define how traffic is handled and identified. Traffic identification (using a Flow Label field in the IPv6 header) allows routers to identify and provide special handling for packets belonging to a flow, which is a series of packets between a source and a destination. Because the IPv6 header identifies the traffic, QoS can be supported even when the packet payload is encrypted through IPSec.

**New Protocol for Neighboring Node Interaction**
The Neighbor Discovery protocol for IPv6 is a series of Internet Control Message Protocol for IPv6 (ICMPv6) messages that manage the interaction of nodes on the same link (known as neighboring nodes). Neighbor Discovery replaces the broadcast-based Address Resolution Protocol (ARP), ICMPv4 Router Discovery, and ICMPv4 Redirect messages with efficient multicast and unicast Neighbor Discovery messages.

**Extensibility**
IPv6 can easily be extended by adding extension headers after the IPv6 header. Unlike options in the IPv4 header, which can support only 40 bytes of options, the size of IPv6 extension headers is constrained only by the size of the IPv6 packet.

**Differences Between IPv4 and IPv6**
The following table highlights some of the key differences between IPv4 and IPv6.

### Differences between IPv4 and IPv6

| IPv4 | IPv6 |
|---|---|
| Source and destination addresses are 32 bits (4 bytes) in length. | Source and destination addresses are 128 bits (16 bytes) in length. For more information, see "IPv6 Addressing" in "How IPv6 Works." |
| IPSec support is optional. | IPSec support is required. |
| IPv4 header does not identify packet flow for QoS handling by routers. | IPv6 header contains Flow Label field, which identifies packet flow for QoS handling by router. |
| Both routers and the sending host fragment packets. | Only the sending host fragments packets; routers do not. |
| Header includes a checksum. | Header does not include a checksum. |
| Header includes options. | All optional data is moved to IPv6 extension headers. |
| Address Resolution Protocol (ARP) uses broadcast ARP Request frames to resolve an IP address to a link-layer address. | Multicast Neighbor Solicitation messages resolve IP addresses to link-layer addresses. For more information, see "Neighbor Discovery" in "How IPv6 Works." |
| Internet Group Management Protocol (IGMP) manages membership in local subnet groups. | Multicast Listener Discovery (MLD) messages manage membership in local subnet groups. |
| ICMP Router Discovery is used to determine the IPv4 address of the best default gateway, and it is optional. | ICMPv6 Router Solicitation and Router Advertisement messages are used to determine the IP address of the best default gateway, and they are required. For more information, see "Neighbor Discovery" in "How IPv6 Works." |
| Broadcast addresses are used to send traffic to all nodes on a subnet. | IPv6 uses a link-local scope all-nodes multicast address. |
| Must be configured either manually or through DHCP. | Does not require manual configuration or DHCP. |
| Uses host address (A) resource records in Domain Name System (DNS) to map host names to IPv4 addresses. | Uses host address (AAAA) resource records in DNS to map host names to IPv6 addresses. |
| Uses pointer (PTR) resource records in the IN-ADDR.ARPA DNS domain to map IPv4 addresses to host names. | Uses pointer (PTR) resource records in the IP6.ARPA DNS domain to map IPv6 addresses to host names. |
| Must support a 576-byte packet size (possibly fragmented). | Must support a 1280-byte packet size (without fragmentation). |

# How IPv6 Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How IPv6 Works**
**In this section**

- IPv6 Architecture
- IPv6 Addressing
- Neighbor Discovery
- IPv6 Routing
- End-to-End IPv6 Delivery Process
- IPv6 Transition Technologies
- Related Information

Internet Protocol version 6 (IPv6) is a networking protocol that allows Windows users to communicate with other users over the Internet. It interacts with Windows naming services such as Domain Name System (DNS) and uses security technologies such as Internet Protocol security (IPSec), because they help facilitate the successful and secure transfer of IP packets between computers.

Ideally, IPv6 is used in a pure environment, that is, an environment where IPv6 is the exclusive Internet protocol used between computers. Currently, however, pure IPv6 transmissions are attainable only with routers that support IPv6 and computers that are running Windows and that support IPv6. As IPv6 supplants IPv4, pure IPv6 across the Internet will become more prevalent and will eventually replace IPv4. Until that occurs, the transition technologies described in this reference can be used to bridge the technological gap between IPv4 and IPv6.

In addition to describing the transition technologies between IPv4 and IPv6, this subject describes how IPv6 relates to other networking protocols, which functions IPv6 performs, how IPv6 addresses are structured and assigned, and how IPv6 packets are structured and routed.

**IPv6 Architecture**
The IPv6 protocol component that is installed in Windows operating systems is a series of interconnected protocols that include Internet Control Message Protocol version 6 (ICMPv6), Multicast Listener Discovery (MLD), and Neighbor Discovery. These core protocols replace the Internet layer protocols in the Defense Advanced Research Projects Agency (DARPA) model. All protocols above the Internet layer rely on the basic services that IPv6 provides. Protocols at the Host-to-Host Transport and Application layers are largely unchanged, except when addresses are part of the payload or part of the data structures that the protocol maintains. For example, both Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) must be updated to perform new checksum calculations that include IPv6 addresses. TCP must be updated to store IPv6 addresses in its internal Transmission Control Block (TCB). Routing Information Protocol (RIP) must be updated to send and receive IPv6 route prefixes.

The following figure shows the architecture of the IPv6 core protocols in relation to the Open Systems Interconnection (OSI) model, the TCP/IP protocol architecture, and the other protocols in the TCP/IP suite.

**IPv6 Architecture**

The following table explains each of the IPv6 core protocols in more detail.

**IPv6 Core Protocols**

| Protocol | Function |
|---|---|
| IPv6 | IPv6 is a routable protocol that is responsible for the addressing, routing, and fragmenting of packets by the sending host. IPv6 replaces Internet Protocol version 4 (IPv4). |
| ICMPv6 | ICMPv6 is responsible for providing diagnostic functions and reporting errors due to the unsuccessful delivery of IPv6 packets. ICMPv6 replaces ICMPv4. |
| Neighbor Discovery | Neighbor Discovery is responsible for the interaction of neighboring nodes and includes message exchanges for address resolution, duplicate address detection, router discovery, and router redirects. Neighbor Discovery replaces Address Resolution Protocol (ARP), ICMPv4 Router Discovery, and the ICMPv4 Redirect message. |
| Multicast Listener Discovery | Multicast Listener Discovery is a series of three ICMPv6 messages that replace version 2 of the Internet Group Management Protocol (IGMP) for IPv4 to manage subnet multicast membership. |

**IPv6**

Like IPv4, IPv6 is a connectionless, unreliable datagram protocol that is primarily responsible for addressing and routing packets between hosts. Connectionless means that a session is not established before data is exchanged. Unreliable means that delivery is not guaranteed. IPv6 always makes a best effort attempt to deliver a packet. An IPv6 packet might be lost, delivered out of sequence, duplicated, or delayed. IPv6 does not attempt to recover from these types of errors. The acknowledgment of packets delivered and the recovery of lost packets is the responsibility of an upper layer protocol, such as TCP.

An IPv6 packet consists of an IPv6 header and an IPv6 payload. The IPv6 payload consists of zero or more IPv6 extension headers and an upper layer protocol data unit, such as an ICMPv6 message, a TCP segment, or a UDP message. The following figure shows the structure of an IPv6 packet.

**Structure of an IPv6 Packet**

The following table describes the key fields in the IPv6 header.

**Key Fields in the IPv6 Header**

| IP Header Field | Function |
|---|---|
| Source Address | Identifies the IPv6 address of the original source of the packet. |
| Destination Address | Identifies the IPv6 address of the intermediate or final destination of the packet. |

| | |
|---|---|
| Next Header | Identifies either the extension header immediately following the IPv6 header or an upper layer protocol, such as ICMPv6, TCP, or UDP. |
| Hop Limit | Designates the number of subnets, or network segments, on which the packet is allowed to travel before being discarded by a router. The sending host sets the Hop Limit, which prevents packets from endlessly circulating on an IPv6 internetwork. When forwarding an IPv6 packet, routers decrement the Hop Limit by one. |

**IPv6 Extension Headers**

Zero or more extension headers of varying lengths can be present. If any extension headers are present, a Next Header field in the IPv6 header indicates the first extension header. In a typical IPv6 packet, no extension headers are present. The sending host adds one or more extension headers only if either an intermediate router or the destination requires special handling.

Within each extension header is another Next Header field that indicates the next extension header. The last extension header indicates the upper layer protocol (such as TCP, UDP, or ICMPv6) contained within the upper layer protocol data unit.

The IPv6 header and extension headers replace the existing IPv4 header with options. The new extension header format allows IPv6 to be augmented to support future needs and capabilities. Unlike options in the IPv4 header, IPv6 extension headers have no maximum size and can expand to accommodate all the extension data needed for IPv6 communication.

RFC 2460 defines the following extension headers, which all IPv6 nodes must support:

- Hop-by-Hop Options header
- Destination Options header
- Routing header
- Fragment header
- Authentication header
- Encapsulating Security Payload header

**Fragmentation in IPv6**

If an IPv4 router receives a packet that is too large for the network segment to which the packet is being forwarded and fragmentation of the packet is allowed, IPv4 fragments the original packet into smaller packets that fit on the downstream network segment. In IPv6, only the sending host performs fragmentation. If an IPv6 router cannot forward a packet because it is too large, the router sends an ICMPv6 Packet Too Big message to the sending host and discards the packet.

Use of the Fragment extension header facilitates sending host fragmentation and destination host reassembly.

**ICMPv6**

Like IPv4, IPv6 does not provide facilities for reporting errors. Instead, IPv6 uses an updated version of the Internet Control Message Protocol (ICMP) named ICMPv6. ICMPv6 has the common ICMPv4 functions of reporting delivery or forwarding errors and providing a simple echo service for troubleshooting.

The ICMPv6 protocol also provides a framework for the following:

- Neighbor Discovery

  Neighbor Discovery is a series of five ICMPv6 messages that manage node-to-node communication on a link. Neighbor Discovery replaces Address Resolution Protocol (ARP), ICMPv4 Router Discovery, and the ICMPv4 Redirect message. For more information about Neighbor Discovery, see "Neighbor Discovery" later in this section.

- Multicast Listener Discovery (MLD)

  Multicast Listener Discovery is a series of three ICMP messages that manage subnet multicast membership. Multicast Listener Discovery replaces version 2 of the Internet Group Management Protocol (IGMP) for IPv4. For more information about Multicast Listener Discovery, see "Multicast Listener Discovery" later in this section.

ICMPv6 is required for an IPv6 implementation. The following table lists and describes the ICMPv6 messages that are defined in RFC 2463.

**Common ICMPv6 Messages**

| ICMPv6 Message | Function |
|---|---|
| Echo Request | Sent to check IPv6 connectivity to a particular host. |
| Echo Reply | Sent in response to an ICMPv6 Echo Request. |
| Destination Unreachable | Sent by a router or the destination host to inform the sending host that the packet or payload cannot be delivered. |
| Packet Too Big | Sent by a router to inform a sending host that a packet is too large to forward. |
| Time Exceeded | Sent by a router to inform a sending host that the Hop Limit of an IPv6 packet has expired. |
| Parameter Problem | Sent by a router to inform a sending host that an error was encountered in processing the IPv6 header or an IPv6 extension header. |

A series of defined Destination Unreachable messages has been defined. The following table lists and describes the most common of these messages.

**Common Destination Unreachable Messages**

| Destination Unreachable Message | Description |
|---|---|
| No Route Found | Sent by an IPv6 router when a route to the destination IPv6 address cannot be found. |
| Communication Prohibited by Administrative Policy | Sent when administrative policy prohibits communication with the destination host. This message is typically sent when a firewall discards a packet. |
| Destination Address Unreachable | Sent when the destination address is unreachable. This message is typically sent when the destination's link layer address cannot be resolved. |
| Destination Port Unreachable | Sent when the destination port is unreachable. This message is typically sent when an IPv6 packet containing a UDP message arrived at the destination but no applications were listening on the destination UDP port. |

ICMPv6 does not make IPv6 a reliable protocol. ICMPv6 attempts to report errors and to provide feedback on specific conditions. ICMPv6 messages are carried as unacknowledged IPv6 datagrams and are themselves unreliable.

**Path MTU Discovery**

The maximum transmission unit (MTU) for a path is the minimum link MTU of all links on a path between a source and a destination. IPv6 packets that are smaller than the path MTU do not require fragmentation by the host and are successfully forwarded by all routers on the path. To discover the path MTU, the sending host uses the receipt of ICMPv6 Packet Too Big messages.

Sending hosts discover the path MTU through the following process:

1. The sending host assumes that the path MTU is the link MTU of the interface on which the traffic is being forwarded.

2. The sending host sends IPv6 datagrams at the path MTU size.

3. If a router on the path is unable to forward the packet over a link because the packet is larger than the link MTU, the router sends an ICMPv6 Packet Too Big message back to the sending host and discards the packet. The Packet Too Big message contains the MTU of the link on which the forwarding failed.

4. The sending host sets the path MTU for packets being sent to the destination to the value of the MTU field in the Packet Too Big message.

The sending host starts again at step 2 and repeats steps 2 through 4 as many times as necessary to discover the path MTU. The sending host determines the path MTU when the node receives either an acknowledgement from the destination or no more Packet Too Big messages.

RFC 1981 recommends that IPv6 nodes support path MTU discovery. Nodes that do not provide this support must use the minimum link MTU of 1280 bytes as the path MTU.

**Changes in Path MTU**
Changes in routing topology can change the path between source and destination. If a path MTU becomes smaller, sending hosts receive Packet Too Big messages, and the nodes must repeat steps 2 through 4 to discover the new path MTU. If a path MTU becomes larger, sending hosts can detect this change (as described in RFC 1981) by attempting to send a larger IPv6 packet after a minimum of 5 minutes (10 minutes are recommended) upon receiving a Packet Too Big message.

**Neighbor Discovery**
Neighbor Discovery is a set of ICMPv6 messages and processes that determine relationships between neighboring nodes. Neighbor Discovery replaces ARP, ICMP Router Discovery, and ICMP Redirect used in IPv4, and Neighbor Discovery provides additional functionality.

Hosts use Neighbor Discovery to:

- Discover neighboring routers.
- Discover addresses, address prefixes, and other configuration parameters.

Routers use Neighbor Discovery to:

- Advertise their presence, host configuration parameters, and on-link prefixes.
- Inform hosts of a better next-hop address to forward packets for a specific destination.

Nodes use Neighbor Discovery to:

- Resolve the link-layer address of a neighboring node to which an IPv6 packet is being forwarded.
- Determine when the link-layer address of a neighboring node has changed.
- Determine whether a neighbor is still reachable.

The following table lists and describes the Neighbor Discovery processes that RFC 2461 describes.

**IPv6 Neighbor Discovery Processes**

| Neighbor Discovery Process | Description |
|---|---|
| Router discovery | The process by which hosts discover the local routers on attached links. Equivalent to ICMPv4 Router Discovery. For more information, see “Router Discovery” later in this section. |
| Prefix discovery | The process by which hosts discover the network prefixes for local link destinations. Similar to the ICMPv4 Address Mask Request/Reply. For more information, see “Router Discovery” later in this section. |
| Parameter discovery | The process by which hosts discover additional operating parameters, including the link MTU and the default hop limit for outgoing packets. For more information, see “Router Discovery” later in this section. |
| Address autoconfiguration | The process for configuring IP addresses for interfaces in either the presence or absence of a server that provides stateful address configuration using a protocol such as Dynamic Host Configuration Protocol version 6 (DHCPv6). For more information, see “Address Autoconfiguration” later in this section. |
| Address resolution | The process by which nodes resolve a neighbor’s IPv6 address to its link-layer address. Equivalent to ARP in IPv4. For more information, see “Address Resolution” later in this section. |

| | |
|---|---|
| Next-hop determination | The process by which nodes determine the IPv6 address of the neighbor to which a packet is being forwarded based on the destination address. The forwarding or next-hop address is either the destination address or the address of an on-link default router. For more information, see "End-to-End IPv6 Delivery Process" later in this section. |
| Neighbor unreachability detection | The process by which nodes determine that a neighbor is no longer receiving packets. For more information, see "Neighbor Unreachability Detection" later in this section. |
| Duplicate address detection | The process by which nodes determine whether an address considered for use is already in use by a neighboring node. Equivalent to using gratuitous ARP frames in IPv4. For more information, see "Duplicate Address Detection" later in this section. |
| Redirect function | The process of informing a host of a better first-hop IPv6 address to reach a destination. Equivalent to the use of the IPv4 ICMP Redirect message. For more information, see "Redirect Function" later in this section. |

**Multicast Listener Discovery**

Multicast Listener Discovery (MLD) is the IPv6 equivalent of Internet Group Management Protocol version 2 (IGMPv2) for IPv4. MLD is a set of ICMPv6 messages that routers and nodes exchange to enable routers to discover which multicast addresses have listening nodes for each attached interface. As with IGMPv2, MLD discovers only those multicast addresses for which at least one listener exists, not the list of individual multicast listeners for each multicast address. MLD is described in RFC 2710.

In contrast to IGMPv2, MLD uses ICMPv6 messages instead of defining its own message structure. The three types of MLD messages are:

- Multicast Listener Query

  Routers send Multicast Listener Query messages to query a link for multicast listeners. Multicast Listener Query messages are either General Query messages or Multicast-Address-Specific Query messages. Routers send General Query messages to query for multicast listeners of all multicast addresses. Routers send Multicast-Address-Specific Query messages to query for multicast listeners of a specific multicast address. The two message types are distinguished by the multicast destination address in the IPv6 header and a multicast address within the Multicast Listener Query message.

- Multicast Listener Report

  Multicast listeners send Multicast Listener Report messages to either report interest in receiving multicast traffic for a specific multicast address or to respond to a Multicast Listener Query message.

- Multicast Listener Done

  Multicast listeners send Multicast Listener Done messages to report that they are no longer interested in receiving multicast traffic for a specific multicast address.

An MLD message packet consists of an IPv6 header, a Hop-by-Hop Options extension header, and the MLD message. The Hop-by-Hop Options extension header contains the IPv6 Router Alert Option that RFC 2711 describes. This option ensures that routers process MLD messages sent to multicast addresses on which the routers are not listening.

**IPv6 Application Interfaces**

As in IPv4, applications can use the services of IPv6 by using the Windows Sockets application programming interface (API). A socket is defined by a protocol and an address on the host. The format of the address is specific to each protocol. For TCP and UDP traffic over IPv6, the address is the combination of the IPv6 address and port. Two sockets, one for each end of the connection, form a bi-directional communications path.

To communicate with IPv6, an application can use Windows Sockets to specify the protocol (IPv6), the IPv6 address of the destination host, and the port of the destination application. After the application is connected, information can be sent and received.

Until IPv6 is broadly adopted, most hosts will be IPv6/IPv4 hosts, using implementations of both the IPv6 and IPv4 protocols. Developers could modify current applications to test for and then selectively use either IPv4 or IPv6 as their transport for data. However, it makes more sense to modify the applications to use a single Windows Sockets function to perform network operations regardless of whether IPv4, IPv6, or both are installed.

A good example of making applications IP version-independent is to replace all instances of the Windows Sockets function **gethostbyname( )** with the Windows Sockets function **getaddrinfo( )**. The **gethostbyname( )** function is commonly used to resolve a specified name to an IPv4 address and never returns an IPv6 address. The function **getaddrinfo( )** resolves names to both IPv4 and IPv6 addresses, depending on whether IPv4 and IPv6 is installed and which types of addresses the Domain Name System (DNS) name query returns. The application need not test for the existence of both protocols or both types of addresses in the response. By replacing **gethostbyname( )** with **getaddrinfo( )**, the developer makes the application IP version-independent for name resolution.

Windows Sockets has been extended to support IPv6 either directly, using IPv6-specific Windows Sockets functions and structures, or indirectly, using IP version-independent functions. The following figure shows the Windows Sockets architecture for Windows Server 2003.

**Windows Sockets for Both IPv4 and IPv6**

**IPv6 Addressing**

The most obvious distinguishing feature of IPv6 is its use of much larger addresses. The size of an address in IPv6 is 128 bits, which is four times larger than an IPv4 address. A 32-bit address space includes 232 or 4,294,967,296 possible addresses. A 128-bit address space includes $2^{128}$ or 340,282,366,920,938,463,463,374,607,431,768,211,456 (or $3.4\times10^{38}$) possible addresses.

The IPv4 address space was designed in the late 1970s, and it seemed impossible to exhaust. However, addresses were not allocated in a way that anticipated changes in technology and an explosion in the number of hosts on the Internet. The IPv4 address space was consumed to the point that, by 1992, it clearly needed a replacement.

It is even harder to conceive that the IPv6 address space will be consumed. A 128-bit address space provides 655,570,793,348,866,943,898,599 ($6.5\times10^{23}$) addresses for every square meter of the Earth's surface.

It is important to remember that the decision to make the IPv6 address 128 bits long was not so that every square meter of the Earth could have $6.5\times10^{23}$ addresses. Rather, the relatively large size of the IPv6 address is designed to be subdivided into hierarchical routing domains that reflect the topology of the modern Internet. The use of 128 bits allows multiple levels of hierarchy and flexibility in designing hierarchical addressing and routing that is currently lacking in the IPv4-based Internet.

RFC 3513 describes the IPv6 addressing architecture.

**IPv6 Address Syntax**

IPv4 addresses are represented in dotted-decimal format. These 32-bit addresses are divided along 8-bit boundaries. Each set of 8 bits is converted to its decimal equivalent and separated from the other sets by periods. For IPv6, the 128-bit address is divided along 16-bit boundaries. Each 16-bit block is converted to a 4-digit hexadecimal number and separated by colons. The resulting representation is known as colon-hexadecimal.

The following is an IPv6 address in binary form:

```
0010000111011010000000001101001100000000000000000010111100111011
0000001010101010000000001111111111111100010100010011100010110 10
```

The 128-bit address is divided along 16-bit boundaries:

```
0010000111011010   0000000011010011   0000000000000000   0010111100111011
0000001010101010   0000000011111111   1111111000101000   1001110001011010
```

Each 16-bit block is converted to hexadecimal and delimited with colons. The result is:

```
21DA:00D3:0000:2F3B:02AA:00FF:FE28:9C5A
```

IPv6 representation can be further simplified by removing the leading zeros within each 16-bit block. However, each block must have at least a single digit. With leading zero suppression, the address representation becomes:

```
21DA:D3:0:2F3B:2AA:FF:FE28:9C5A
```

**Compressing Zeros**

Some types of addresses contain long sequences of zeros. To further simplify the representation of IPv6 addresses, a contiguous sequence of 16-bit blocks set to 0 in the colon-hexadecimal format can be compressed to "::," known as double-colon.

For example, the link-local address of FE80:0:0:0:2AA:FF:FE9A:4CA2 can be compressed to FE80::2AA:FF:FE9A:4CA2. The multicast address FF02:0:0:0:0:0:0:2 can be compressed to FF02::2.

Zero compression can be used to compress only a single contiguous series of 16-bit blocks expressed in colon-hexadecimal notation. You cannot use zero compression to include part of a 16-bit block. For example, you cannot express FF02:30:0:0:0:0:0:5 as FF02:3::5.

To determine how many 0 bits are represented by the double colon, you can count the number of blocks in the compressed address, subtract this number from 8, and then multiply the result by 16. For example, the address FF02::2 has two blocks (the "FF02" block and the "2" block.) The number of 0 bits expressed by the double colon is 96 (96 = (8 – 2)×16).

Zero compression can be used only once in a given address. Otherwise, you could not determine the number of 0 bits represented by each double colon.

**IPv6 Prefixes**

The prefix is the part of the address that indicates which bits have fixed values or reflect the subnet identifier. Prefixes for IPv6 subnet identifiers and routes are expressed in the same way as Classless Inter-Domain Routing (CIDR) notation for IPv4, that is, in address/prefix-length notation. For example, 21DA:D3::/48 is a route prefix and 21DA:D3:0:2F3B::/64 is a subnet prefix.

### Note

- IPv4 implementations commonly use a dotted decimal representation of the network prefix known as the subnet mask. IPv6 does not support subnet masks. IPv6 supports only the prefix-length notation.

**Types of IPv6 Addresses**

IPv6 supports three types of addresses:

- Unicast

  A unicast address identifies a single interface within the scope of the type of unicast address. With the appropriate unicast routing topology, packets addressed to a unicast address are delivered to a single interface. To accommodate load-balancing systems, RFC 3513 allows multiple interfaces to use the same address as long as they appear as a single interface to the IPv6 implementation on the host.

- Multicast

  A multicast address identifies multiple interfaces. With the appropriate multicast routing topology, packets addressed to a multicast address are delivered to all interfaces that are identified by the address. A multicast address is used for one-to-many communication, with delivery to multiple interfaces.

- Anycast

  An anycast address identifies multiple interfaces. With the appropriate routing topology, packets addressed to an anycast address are delivered to a single interface, the nearest interface that is identified by the address. The nearest interface is defined as being closest in terms of routing distance. An anycast address is used for one-to-one-of-many communication, with delivery to a single interface.

IPv6 addresses always identify interfaces, not nodes. A node is identified by any unicast address that is assigned to one of its interfaces.

**Note**

- RFC 3513 does not define a broadcast address. All types of IPv4 broadcast addressing are performed in IPv6 using multicast addresses. For example, the subnet and limited broadcast addresses from IPv4 are replaced with the link-local scope all-nodes multicast address of FF02::1.

**Unicast IPv6 Addresses**

Unicast IPv6 addresses fall into one of five types:

- Global unicast addresses
- Link-local addresses
- Site-local addresses
- Special addresses
- Compatibility addresses

**Global unicast addresses**

Global unicast addresses are equivalent to public IPv4 addresses. They are globally routable and reachable on the IPv6 Internet.

Unlike the current IPv4-based Internet, which is a mixture of both flat and hierarchical routing, the IPv6-based Internet has been designed from its foundation to support efficient, hierarchical addressing and routing. The scope (that is, the region of the IPv6 internetwork over which the address is unique) of a global unicast address is the entire IPv6 Internet.

The following figure shows the structure of a global unicast address as defined in RFC 3587.

**The Global Unicast Address**

Global unicast addresses contain four fields.

- The three high-order bits are set to 001. The address prefix for currently assigned global addresses is 2000::/3.
- The Global Routing Prefix indicates the global routing prefix for a specific organization's site. The combination of the three fixed bits and the 45-bit Global Routing Prefix creates a 48-bit site prefix, which is assigned to an individual site of an organization. After this prefix is assigned, routers on the IPv6 Internet forward IPv6 traffic matching the 48-bit prefix to the routers of the organization's site.
- The Subnet ID is used within an organization's site to identify subnets. This field is 16 bits long. The organization's site can use these 16 bits within its site to create 65,536 subnets or multiple levels of addressing hierarchy and an efficient routing infrastructure.
- The Interface ID indicates the interface on a specific subnet within the site. This field is 64 bits long.

The following figure shows how fields within the global unicast address create a three-level structure.

**The Three-level Structure of the Global Unicast Address**

The public topology is the collection of larger and smaller ISPs that provide access to the IPv6 Internet. The site topology is the collection of subnets within an organization's site. The interface identifier identifies a specific interface on a subnet within an organization's site. For more information about global unicast addresses, see RFC 3587 in the IETF RFC Database.

**Local-use unicast addresses**
Local-use unicast addresses fall into one of two types:

- Link-local addresses are used between on-link neighbors and for Neighbor Discovery processes.
- Site-local addresses are used between nodes in the same site.

**Link-local addresses**
Nodes use link-local addresses when communicating with neighboring nodes on the same link. For example, on a single-link IPv6 network with no router, hosts use link-local addresses to communicate with other hosts on the link. Link-local addresses are equivalent to Automatic Private IP Addressing (APIPA) IPv4 addresses autoconfigured on computers that are running Windows. APIPA addresses use the 169.254.0.0/16 prefix. The scope of a link-local address is the local link.

A link-local address is required for Neighbor Discovery processes and is always automatically configured, even in the absence of all other unicast addresses. For more information about how link-local addresses are configured, see "Address Autoconfiguration" later in this section.

The following figure shows the structure of the link-local address.

### The Link-Local Address

Link-local addresses always begin with FE80. With the 64-bit interface identifier, the prefix for link-local addresses is always FE80::/64. An IPv6 router never forwards link-local traffic beyond the link.

**Site-local addresses**
Site-local addresses are equivalent to the IPv4 private address space (10.0.0.0/8, 172.16.0.0/12, and 192.168.0.0/16). For example, private intranets that do not have a direct, routed connection to the IPv6 Internet can use site-local addresses without conflicting with global addresses. Site-local addresses are not reachable from other sites, and routers must not forward site-local traffic outside the site. Site-local addresses can be used in addition to global addresses. The scope of a site-local address is the site (the organization internetwork).

Unlike link-local addresses, site-local addresses are not automatically configured and must be assigned through either stateless or stateful address configuration.

The following figure shows the structure of the site-local address.

### The Site-Local Address

The first 10 bits are always fixed for site-local addresses, beginning with FEC0::/10. After the 10 fixed bits is a 54-bit subnet identifier (Subnet ID field) that provides 54 bits with which you can create a hierarchical and summarizable routing infrastructure within the site. After the Subnet ID field is a 64-bit Interface ID field that identifies a specific interface on a subnet.

**Special IPv6 addresses**
The following are special IPv6 addresses:

- Unspecified address

  The unspecified address (0:0:0:0:0:0:0:0 or ::) indicates the absence of an address. It is equivalent to the IPv4 unspecified address of 0.0.0.0. The unspecified address is typically used as a source address for packets attempting to verify the uniqueness of a tentative address. The unspecified address is never assigned to an interface or used as a destination address.

- Loopback address

  The loopback address (0:0:0:0:0:0:0:1 or ::1) is used to identify a loopback interface, enabling a node to send packets to itself. It is equivalent to the IPv4 loopback address of 127.0.0.1. Packets addressed to the loopback address must never be sent on a link or forwarded by a router.

**Compatibility addresses**
To aid in the migration from IPv4 to IPv6 and the coexistence of both types of hosts, the following addresses are defined:

- IPv4-compatible address

  The IPv4-compatible address, 0:0:0:0:0:0:*w.x.y.z* or ::*w.x.y.z* (where *w.x.y.z* is the dotted decimal representation of a public IPv4 address), is used by IPv6/IPv4 nodes that are communicating using IPv6. IPv6/IPv4 nodes support both IPv4 and IPv6 protocols. When an IPv4-compatible address is used as an IPv6 destination, the IPv6 traffic is automatically encapsulated with an IPv4 header and sent to the destination using the IPv4 infrastructure.

- IPv4-mapped address

  The IPv4-mapped address, 0:0:0:0:0:FFFF:*w.x.y.z* or ::FFFF:*w.x.y.z*, is used to represent an IPv4-only node to an IPv6 node. It is used only for internal representation. The IPv4-mapped address is never used as a source or destination address of an IPv6 packet.

- 6to4 address

  The 6to4 address is used for communicating between two nodes running both IPv4 and IPv6 over an IPv4 routing infrastructure. The 6to4 address is formed by combining the prefix 2002::/16 with the 32 bits of a public IPv4 address of the node, forming a 48-bit prefix. 6to4 is a tunneling technique described in RFC 3056.

- ISATAP address

  The Internet draft titled "Intra-Site Automatic Tunnel Addressing Protocol (ISATAP)" defines ISATAP addresses used between two nodes running both IPv4 and IPv6 over an IPv4 routing infrastructure. ISATAP addresses use the locally administered interface ID ::0:5EFE:*w.x.y.z* where *w.x.y.z* is any unicast IPv4 address, which includes both public and private addresses.

  The ISATAP interface ID can be combined with any 64-bit prefix that is valid for IPv6 unicast addresses. This includes the link-local address prefix (FE80::/64), site-local prefixes, and global prefixes.

- Teredo address

  Teredo addresses use the prefix 3FFE:831F::/32. Beyond the first 32 bits, Teredo addresses are used to encode the IPv4 address of a Teredo server, flags, and the encoded version of the external address and port of a Teredo client. An example of a Teredo address is 3FFE:831F:CE49:7601:8000:EFFF:62C3:FFFE. Teredo addresses are used to represent a host when using the automatic tunneling mechanism defined in the Internet draft titled "Teredo: Tunneling IPv6 over UDP through NATs." For more information, see "Teredo" later in this section.

**Multicast IPv6 Addresses**
In IPv6, multicast traffic operates in the same way that it does in IPv4. Arbitrarily located IPv6 nodes can listen for multicast traffic on arbitrary IPv6 multicast addresses. IPv6 nodes can listen to multiple multicast addresses at the same time. Nodes can join or leave a multicast group at any time.

IPv6 multicast addresses have the first 8 bits set to 1111 1111. An IPv6 address is easy to classify as multicast because it always begins with "FF." Multicast addresses cannot be used as source addresses or as intermediate destinations in a Routing header.

Beyond the first 8 bits, multicast addresses include additional structure to identify their flags, scope, and multicast group. The following figure shows the structure of the IPv6 multicast address.

**The IPv6 Multicast Address**

The fields in the multicast address are:

- Flags

Indicates flags set on the multicast address. The size of this field is 4 bits. As of RFC 3513, the only flag defined is the Transient (T) flag. The T flag uses the low-order bit of the Flags field. When set to 0, the T flag indicates that the multicast address is a well-known multicast address that has been permanently assigned by the Internet Assigned Numbers Authority (IANA). When set to 1, the T flag indicates that the multicast address is a transient multicast address that IANA has not permanently assigned.

- Scope

  Indicates the scope of the IPv6 internetwork for which the multicast traffic is intended. The size of this field is 4 bits. In addition to using information provided by multicast routing protocols, routers use the multicast scope to determine whether they can forward multicast traffic. The most prevalent values for the Scope field are 1 (interface-local scope), 2 (link-local scope), and 5 (site-local scope).

  For example, traffic with the multicast address of FF02::2 has a link-local scope. An IPv6 router never forwards this traffic beyond the local link.

- Group ID

  Identifies the multicast group and is unique within the scope. The size of this field is 112 bits. Permanently assigned group IDs are independent of the scope. Transient group IDs are relevant only to a specific scope. Multicast addresses from FF01:: through FF0F:: are reserved, well-known addresses.

To identify all nodes for the interface-local and link-local scopes, the following addresses are defined:

- FF01::1 (interface-local scope all-nodes multicast address)
- FF02::1 (link-local scope all-nodes multicast address)

To identify all routers for the interface-local, link-local, and site-local scopes, the following addresses are defined:

- FF01::2 (interface-local scope all-routers multicast address)
- FF02::2 (link-local scope all-routers multicast address)
- FF05::2 (site-local scope all-routers multicast address)

With 112 bits for the group ID, it is possible to have $2^{112}$ group IDs. However, because of the way in which IPv6 multicast addresses are mapped to Ethernet multicast media access control (MAC) addresses, RFC 3513 recommends assigning the group ID from the low-order 32 bits of the IPv6 multicast address and setting the remaining original group ID bits to 0. By using only the low-order 32 bits, each group ID maps to a unique Ethernet multicast MAC address. The following figure shows the recommended IPv6 multicast address.

**The Recommended IPv6 Multicast Address Using a 32-bit Group ID**

**Solicited-node Address**

The solicited-node address facilitates the efficient querying of network nodes during address resolution. In IPv4, the ARP Request frame is sent to the MAC-level broadcast, disturbing all nodes on the network segment, including those that are not running IPv4. IPv6 uses the Neighbor Solicitation message to perform address resolution. However, instead of using the local-link scope all-nodes multicast address as the Neighbor Solicitation message destination, which would disturb all IPv6 nodes on the local link, the solicited-node multicast address is used. The following figure shows how the solicited-node multicast address comprises the prefix FF02::1:FF00:0/104 and the last 24-bits of the IPv6 address that is being resolved.

**Mapping Unicast IPv6 Addresses to Solicited Node IPv6 Addresses**

For example, for the node with the link-local IPv6 address of FE80::2AA:FF:FE28:9C5A, the corresponding solicited-node address is FF02::1:FF28:9C5A. This node is listening for multicast traffic at the solicited-node address of FF02::1:FF28:9C5A and, for interfaces that correspond to a physical network adapter, has registered the corresponding multicast address with the network adapter. To resolve the address of FE80::2AA:FF:FE28:9C5A to its link-layer address, a neighboring node sends a Neighbor Solicitation to the solicited-node address of FF02::1:FF28:9C5A.

The result of using the solicited-node multicast address is that address resolutions, a common occurrence on a link, are not required to use a mechanism that disturbs all network nodes. By using the solicited-node address, address resolution disturbs very few nodes. In practice, due to the relationship between the Ethernet MAC address, the IPv6 interface ID, and the solicited-node address, the solicited-node address acts as a pseudo-unicast address for very efficient address resolution.

**Anycast IPv6 Addresses**

An anycast address is assigned to multiple interfaces. The routing infrastructure forwards packets that are addressed to an anycast address to the nearest interface to which the anycast address is assigned. To facilitate delivery, the routing infrastructure must track the interfaces that have been assigned anycast addresses and their distance in terms of routing metrics. At present, anycast addresses are used only as destination addresses and are assigned only to routers. Anycast addresses are assigned out of the unicast address space, and the scope of an anycast address is the scope of the type of unicast address from which the anycast address is assigned.

The Subnet-Router anycast address is predefined and required. It is created from the subnet prefix for a given interface. To construct the Subnet-Router anycast address, the bits in the subnet prefix are fixed at their appropriate values, and the remaining bits are set to 0. All router interfaces attached to a subnet are assigned the Subnet-Router anycast address for that subnet. The Subnet-Router anycast address is used to communicate with one of multiple routers attached to a remote subnet.

**IPv6 Addresses for a Host**

An IPv4 host with a single network adapter typically has a single IPv4 address assigned to that adapter. An IPv6 host, however, usually has multiple IPv6 addresses — even with a single interface. An IPv6 host is assigned the following unicast addresses:

- A link-local address for each interface.
- Unicast addresses for each interface (which could be a site-local address and one or multiple global unicast addresses).
- The loopback address (::1) for the loopback interface.

Typical IPv6 hosts are logically multi-homed because they have at least two addresses with which they can receive packets — a link-local address for local link traffic and a routable site-local or global address.

Additionally, each host is listening for traffic on the following multicast addresses:

- The interface-local scope all-nodes multicast address (FF01::1).
- The link-local scope all-nodes multicast address (FF02::1).
- The solicited-node address for each unicast address on each interface.
- The multicast addresses of joined groups on each interface.

**IPv6 Addresses for a Router**

An IPv6 router is assigned the following unicast addresses:

- A link-local address for each interface.
- Unicast addresses for each interface (which could be a site-local address and one or multiple global unicast addresses).

- A Subnet-Router anycast address.
- Additional anycast addresses (optional).
- The loopback address (::1) for the loopback interface.

Additionally, each router is listening for traffic on the following multicast addresses:

- The interface-local scope all-nodes multicast address (FF01::1).
- The interface-local scope all-routers multicast address (FF01::2).
- The link-local scope all-nodes multicast address (FF02::1).
- The link-local scope all-routers multicast address (FF02::2).
- The site-local scope all-routers multicast address (FF05::2).
- The solicited-node address for each unicast address on each interface.
- The multicast addresses of joined groups on each interface.

**IPv6 Interface Identifiers**
The last 64 bits of an IPv6 address are the interface identifier that is unique to the 64-bit prefix of the IPv6 address. IPv6 interface identifiers are determined as follows:

- Derived from the Extended Unique Identifier (EUI)-64 address.
- Generated randomly and changed over time to provide a level of anonymity.
- Assigned during stateful address autoconfiguration (for example, through DHCPv6).

**EUI-64 Address-based Interface Identifiers**
RFC 3513 states that all unicast addresses that use the prefixes 001 through 111 must also use a 64-bit interface identifier derived from the EUI-64 address. EUI-64 addresses have 64-bits and are defined by the Institute of Electrical and Electronic Engineers (IEEE). EUI-64 addresses are either assigned to network adapters or derived from IEEE 802 addresses.

**IEEE 802 addresses**
Traditional interface identifiers for network adapters use a 48-bit address called an IEEE 802 address. It consists of a 24-bit company ID (also called the manufacturer ID) and a 24-bit extension ID (also called the board ID). The combination of the company ID, which is uniquely assigned to each manufacturer of network adapters, and the board ID, which is uniquely assigned to each network adapter at the time of assembly, produces a globally unique 48-bit address. This 48-bit address is also called the physical, hardware, or media access control (MAC) address.

The following figure shows the structure of the 48-bit IEEE 802 address.

### 48-bit IEEE 802 Address

The IEEE 802 address includes the following defined bits:

- Universal/Local (U/L)

  The next-to-the-low order bit in the first byte indicates whether the address is universally or locally administered. If the U/L bit is set to 0, the IEEE (through the designation of a unique company ID) has administered the address. If the U/L bit

is set to 1, the address is locally administered, which means that the network administrator has overridden the manufactured address and specified a different address.

- Individual/Group (I/G)

  The low-order bit of the first byte indicates whether the address is an individual address (unicast) or a group address (multicast). If the I/G bit is set to 0, the address is a unicast address. If the I/G bit is set to 1, the address is a multicast address.

For a typical IEEE 802 network adapter address, both the U/L and I/G bits are set to 0, indicating a universally administered, unicast MAC address.

**IEEE EUI-64 addresses**
The IEEE Extended Unique Identifier (EUI)-64 address represents a newer standard for network interface addressing. The company ID is still 24 bits, but the extension ID is 40 bits, creating a much larger address space for each network adapter manufacturer. The EUI-64 address uses the U/L and I/G bits in the same way as the IEEE 802 address.

The following figure shows the structure of the EUI-64 address.

**EUI-64 Address**

**Mapping IEEE 802 addresses to EUI-64 addresses**
To create an EUI-64 address from an IEEE 802 address, the 16 bits of 11111111 11111110 (0xFFFE) are inserted into the IEEE 802 address between the company ID and the extension ID. The following figure shows an example of such a conversion.

**Conversion of an IEEE 802 Address to an EUI-64 Address**

**Mapping EUI-64 addresses to IPv6 interface identifiers**
To obtain the 64-bit interface identifier for an IPv6 unicast address, the U/L bit in the EUI-64 address is complemented. (If it is set to 1, it is changed to 0, and if it is set to 0, it is changed to 1.) The following figure shows the conversion for a universally administered, unicast EUI-64 address.

**Conversion of a Universally Administered, Unicast EUI-64 Address to an IPv6 Interface Identifier**

To obtain an IPv6 interface identifier from an IEEE 802 address, you must first map the IEEE 802 address to an EUI-64 address, and then complement the U/L bit. The following figure shows this conversion process for a universally administered, unicast IEEE 802 address.

**Conversion of a Universally Administered, Unicast IEEE 802 Address to an IPv6 Interface Identifier**

**IEEE 802 address conversion example**

Host A has the Ethernet MAC address of 00-AA-00-3F-2A-1C. First, it is converted to EUI-64 format by inserting FF-FE between the third and fourth bytes, yielding 00-AA-00-FF-FE-3F-2A-1C. The U/L bit, which is the seventh bit in the first byte, is then complemented. Before the conversion, the first byte in binary form is 00000000. When the seventh bit is complemented, it becomes 00000010 (0x02). The final result is 02-AA-00-FF-FE-3F-2A-1C which, when converted to colon-hexadecimal notation, becomes the interface identifier 2AA:FF:FE3F:2A1C. As a result, the link-local address that corresponds to the network adapter with the MAC address of 00-AA-00-2A-1C is FE80::2AA:FF:FE3F:2A1C.

### Note

- When complementing the U/L bit, add 0x2 to the first byte if the address is universally administered, and subtract 0x2 from the first byte if the address is locally administered.

**Temporary Address Interface Identifiers**

In today's Internet, a typical Internet user connects to an Internet service provider (ISP) and obtains an IPv4 address using the Point-to-Point Protocol (PPP) and the Internet Protocol Control Protocol (IPCP). Each time the user connects, a different IPv4 address might be obtained. Because of this, it is difficult to track a dial-up user's traffic on the Internet on the basis of IP address.

For dial-up connections that are based on IPv6, the user is assigned a 64-bit prefix through router discovery and stateless address autoconfiguration after the connection is made. If the interface identifier is always based on the EUI-64 address (as derived from the static IEEE 802 address), it is possible to identify the traffic of a specific node regardless of the prefix, making it easy to track a specific user and their use of the Internet. To address this concern and provide a level of anonymity, RFC 3041 describes an alternative IPv6 interface identifier that is randomly generated and changes over time.

The initial interface identifier is generated by using random numbers. For computers that cannot store any historical information for generating future interface identifier values, a different random interface identifier is generated each time the IPv6 protocol is initialized. For IPv6 systems that have storage capabilities, a history value is stored. When the IPv6 protocol is initialized, a new interface identifier is generated through the following process:

1. Retrieve the history value from storage, and append the interface identifier based on the EUI-64 address of the adapter.

2. Compute a Message Digest-5 (MD5) one-way encryption hash over the quantity in step 1.

3. Save the last 64 bits of the MD5 hash computed in step 2 as the history value for the next interface identifier computation.

4. Take the first 64 bits of the MD5 hash computed in Step 2, and set the seventh bit to 0. The seventh bit corresponds to the U/L bit which, when set to 0, indicates a locally administered IPv6 interface identifier. The result is the IPv6 interface identifier.

The resulting IPv6 address, based on this random interface identifier, is known as a temporary or anonymous address. Temporary addresses are generated for public address prefixes that use stateless address autoconfiguration. Temporary addresses are used for the shorter of the valid and preferred lifetimes:

- The lifetimes included in the Prefix Information option in the received Router Advertisement message.

- Local default values of one week for valid lifetime and one day for preferred lifetime.

After the valid lifetime of the temporary address expires, a new interface identifier and temporary address is generated.

**Subnetting Global Address Prefixes**
For most users of IPv6, subnetting the IPv6 address space consists of using subnetting techniques to divide the Subnet ID portion of the global address. This approach allows for route summarization and delegation of the remaining address space to different portions of an IPv6 intranet.

For the global address, the first 48 bits are fixed and allocated by an ISP.

Subnetting the subnet ID portion of a global address space requires two steps:

1. Determine the number of bits to be used for the subnetting.

2. Enumerate the new subnetted network prefixes.

You are not required to subnet in any specific fashion. The subnetting technique described here assumes that subnetting is done by dividing the 16-bit address space of the subnet ID using the high-order bits in the subnet ID. Although this method promotes hierarchical addressing and routing, it is not required. For example, in a small organization with a small number of subnets, you can also create a flat addressing space for the subnet ID by numbering the subnets from 0 to 65,535.

**Step 1: Determining the Number of Subnetting Bits**
The number of bits being used for subnetting determines the possible number of new subnetted network prefixes that can be allocated to portions of your network based on geographical or departmental divisions. In a hierarchical routing infrastructure, you need to determine how many network prefixes, and therefore how many bits, are needed at each level in the hierarchy. The more bits you choose for the various levels of the hierarchy, the fewer bits you have to enumerate individual subnets in the last level of the hierarchy.

For example, a network administrator can decide to implement a two-level hierarchy reflecting a geographical/departmental structure, use 4 bits for the geographical level, and use 6 bits for the departmental level. With this approach, each department in each geographical location has only 6 bits of subnetting space left (16 - 6 - 4) or only 64 (=$2^6$) subnets per department.

On any given level in the hierarchy, some number of bits is already fixed by the next level up in the hierarchy (*f*), some number of bits is used for subnetting at the current level in the hierarchy (*s*), and some number of bits remain for the next level down in the hierarchy (*r*). At all times, $f+s+r = 16$. The following figure shows this relationship.

**Subnetting a Subnet ID**

**Step 2: Enumerating Subnetted Network Prefixes**
Based on the number of bits used for subnetting, you must list the new subnetted network prefixes. There are two main approaches:

- Hexadecimal — Enumerate new subnetted network prefixes by using hexadecimal representations of the subnet ID and increment.

- Decimal — Enumerate new subnetted network prefixes by using decimal representations of the subnet ID and increment.

Either method produces the same result: an enumerated list of subnetted network prefixes.

**To create the enumerated list of subnetted network prefixes using the hexadecimal method**

1. Based on *s*, the number of bits chosen for subnetting, and *m*, the length of the network prefix being subnetted, calculate the following:

$f = m - 48$

$f$ is the number of bits within the global address prefix that are already fixed.

$n = 2^s$

$n$ is the number of network prefixes that are obtained.

$i = 2^{16-(f+s)}$

$i$ is the incremental value between each successive subnet ID expressed in hexadecimal.

$l = 48+f+s$

$l$ is the length of the new subnetted network prefixes.

2. Create a two-column table with *n* entries. The first column is the network prefix number (starting with 1), and the second column is the new subnetted network prefix.

3. In the first table entry, the subnetted network prefix is the original network prefix with the new prefix length. For example, based on *F*, the hexadecimal value of the subnet ID being subnetted, the subnetted network prefix is [*48-bit prefix*]:*F*::/*l*.

4. In the next table entry, increase the value within the subnet ID portion of the site-local or global address by *i*. For example, in the second table entry, the subnetted prefix is [*48-bit prefix*]:*F*+*i*::/*l*.

5. Repeat step 4 until the table is complete.

For example, to perform a 3-bit subnetting of the site-local network prefix 3FFE:FFFF:0:C000::/51, first calculate the values of the number of prefixes, the increment, and the new prefix length. The starting values are $F$=0xC000, $s$=3, and $f$=51-48=3. The number of prefixes is 8 ($n=2^3$). The increment is 0x400 ($i=2^{16-(3+3)}$=1024=0x400). The new prefix length is 54 ($l$=48+3+3).

Next, construct a table with 8 entries. The entry for the network prefix 1 is 3FFE:FFFF:0:C000::/54. Additional entries in the table are successive increments of *i* in the subnet ID portion of the network prefix, as shown in the following table.

**Hexadecimal Subnetting Technique for Network Prefix 3FFE:FFFF:0:C000::/51**

| Network Prefix | Subnetted Network Prefix |
|---|---|
| 1 | 3FFE:FFFF:0:C000::/54 |
| 2 | 3FFE:FFFF:0:C400::/54 |
| 3 | 3FFE:FFFF:0:C800::/54 |
| 4 | 3FFE:FFFF:0:CC00::/54 |
| 5 | 3FFE:FFFF:0:D000::/54 |
| 6 | 3FFE:FFFF:0:D400::/54 |
| 7 | 3FFE:FFFF:0:D800::/54 |
| 8 | 3FFE:FFFF:0:DC00::/54 |

**To create the enumerated list of subnetted network prefixes using the decimal method**

1. Based on *s*, the number of bits chosen for subnetting, *m*, the length of the network prefix being subnetted, and *F*, the hexadecimal value of the subnet ID being subnetted, calculate the following:

$f = m - 48$

*f* is the number of bits within the prefix that are already fixed.

$n = 2^s$

*n* is the number of network prefixes that are obtained.

$i = 2^{16-(f+s)}$

*i* is the incremental value between each successive subnet ID.

$l = 48+f+s$

*l* is the length of the new subnetted network prefixes.

*D* = decimal representation of *F*

2. Create a three-column table with *n* entries. The first column is the network prefix number (starting with 1), the second column is the decimal representation of the subnet ID portion of the new subnetted network prefix, and the third column is the new subnetted network prefix.

3. In the first column of the first row, the decimal representation of the subnet ID is *D* and the subnetted prefix is [*48-bit prefix*]:*F*::/*l*.

4. In the second column of the first row, increase the value of the decimal representation of the subnet ID by *i*. For example, in the second table entry, the decimal representation of the subnet ID is *D*+*i*.

5. In the third column of the first row, convert the decimal representation of the subnet ID to hexadecimal, and construct the prefix from [*48-bit prefix*]:[*subnet ID*]::/*l*. For example, in the second table entry, the subnetted network prefix is [*48-bit prefix*]:[*D*+*i (converted to hexadecimal)*]::/*l*.

6. Repeat steps 4 and 5 until the table is complete.

For example, to perform a 3-bit subnetting of the site-local network prefix 3FFE:FFFF:0:C000::/51, first calculate the values of the number of prefixes, the increment, the new prefix length, and the decimal representation of the starting subnet ID. The starting values are *F*=0xC000, *s*=3, and *f*=51-48=3. The number of prefixes is 8 ($n=2^3$). The increment is 1024 ($i=^{216-(3+3)}$). The new prefix length is 54 (*l*=48+3+3). The decimal representation of the starting subnet ID is 49152 (*D*=0xC000=49152).

Next, construct a table with 8 entries. The entry for the network prefix 1 is 49192 and 3FFE:FFFF:0:C000::/54. Additional entries in the table are successive increments of *i* in the subnet ID portion of the network prefix, as shown in the following table.

**Decimal Subnetting for Network Prefix 3FFE:FFFF:0:C000::/51**

| Network Prefix | Decimal Representation of Subnet ID | Subnetted Network Prefix |
|---|---|---|
| 1 | 49192 | 3FFE:FFFF:0:C000::/54 |
| 2 | 50176 | 3FFE:FFFF:0:C400::/54 |
| 3 | 51200 | 3FFE:FFFF:0:C800::/54 |
| 4 | 52224 | 3FFE:FFFF:0:CC00::/54 |
| 5 | 53248 | 3FFE:FFFF:0:D000::/54 |
| 6 | 54272 | 3FFE:FFFF:0:D400::/54 |
| 7 | 55296 | 3FFE:FFFF:0:D800::/54 |

| | | |
|---|---|---|
| 8 | 56320 | 3FFE:FFFF:0:DC00::/54 |

**Note**

- RFC 3513 allows the use of subnetted network prefixes where the bits being used for subnetting are set to all 0s (the all-zeros subnetted network prefix) and all 1s (the all-ones subnetted network prefix).

#### IPv6 and Name Resolution

Resolving names to IPv6 addresses is supported if either the local Hosts file (stored in *systemroot*\System32\Drivers\Etc) contains entries for IPv6 addresses or the Domain Name System (DNS) infrastructure contains resource records for IPv6 addresses. RFC 1886 describes enhancements to DNS for IPv6, and the DNS name resolver and DNS Server service in Windows Server 2003 support them.

**Note**

- NetBIOS over IPv6 is not supported. Therefore, NetBIOS name resolution techniques cannot be used to resolve names to IPv6 addresses.

In RFC 1886, a new DNS resource record type, AAAA (called quad A), is used for resolving a fully qualified domain name to an IPv6 address. It is comparable to the host address (A) resource record used with IPv4. The resource record type is named AAAA (Type value of 28) because IPv6 addresses are four times as large as IPv4 addresses. The following is an example of a AAAA resource record:

```
host1.microsoft.com    IN    AAAA   FEC0::2AA:FF:FE3F:2A1C
```

A host must specify either a AAAA query or a general query for a specific host name to receive IPv6 address resolution data in the DNS query answer sections.

RFC 1886 also describes the IP6.INT domain created for IPv6 reverse queries. However, according to RFC 3152, Internet Engineering Task Force (IETF) consensus has been reached that the IP6.ARPA domain be used instead of IP6.INT. Also called pointer queries, reverse queries determine a host name based on the IP address. To create the namespace for reverse queries, each hexadecimal digit in the fully expressed 32-digit IPv6 address becomes a separate level in inverse order in the reverse domain hierarchy.

For example, the reverse lookup domain name for the address FEC0::2AA:FF:FE3F:2A1C (fully expressed as FEC0:0000:0000:0000:02AA: 00FF:FE3F:2A1C) is:

C.1.A.2.F.3.E.F.F.F.0.0.A.A.2.0.0.0.0.0.0.0.0.0.0.0.0.0.0.C.E.F.IP6.ARPA.

The DNS support that RFC 1886 describes represents a simple way to both map host names to IPv6 addresses and to provide reverse name resolution.

#### IPv4 Addresses and IPv6 Equivalents

The following table lists IPv4 addresses and concepts next to their IPv6 equivalents.

**IPv4 Addresses and their IPv6 Equivalents**

| IPv4 Address | IPv6 Address |
|---|---|
| Internet address classes | Not applicable in IPv6 |
| Multicast addresses (224.0.0.0/4) | IPv6 multicast addresses (FF00::/8) |
| Broadcast addresses | Not applicable in IPv6 |
| Unspecified address is 0.0.0.0 | Unspecified address is :: |
| Loopback address is 127.0.0.1 | Loopback address is ::1 |
| Public IP addresses | Global unicast addresses |
| Private IP addresses (10.0.0.0/8, 172.16.0.0/12, and 192.168.0.0/16) | Site-local addresses (FEC0::/10) |

| | |
|---|---|
| Autoconfigured addresses (169.254.0.0/16) | Link-local addresses (FE80::/64) |
| Text representation: Dotted decimal notation | Text representation: Colon-hexadecimal format with suppression of leading zeros and zero compression. IPv4-compatible addresses are expressed in dotted decimal notation. |
| Network bits representation: Subnet mask in dotted decimal notation or prefix length notation | Network bits representation: Prefix length notation only |
| DNS name resolution: IPv4 host address (A) resource record | DNS name resolution: IPv6 host address AAAA resource records (RFC 1886) or A6 records (RFC 2874) |
| DNS reverse resolution: IN-ADDR.ARPA domain | DNS reverse resolution: IP6.INT domain (RFC 1886) or IP6.ARPA domain (RFC 2874) |

**Neighbor Discovery**
Neighbor Discovery uses ICMPv6 messages to manage neighboring node interaction. Neighbor Discovery replaces ARP, ICMP Router Discovery, and ICMP Redirect and provides additional functionality.

**Neighbor Discovery Messages**
All functions of Neighbor Discovery are performed with the following messages:

- Router Solicitation

  IPv6 hosts send Router Solicitation messages to discover IPv6 routers present on the link. To prompt IPv6 routers to respond immediately, hosts send multicast Router Solicitation messages rather than waiting for a periodic Router Advertisement message.

- Router Advertisement

  IPv6 routers send Router Advertisement messages either periodically or in response to the receipt of Router Solicitation messages. Router Advertisement messages contain the information required by hosts to determine what the link prefixes are, what the link MTU is, whether or not to use address autoconfiguration, and the duration for which addresses created through address autoconfiguration are both valid and preferred.

- Neighbor Solicitation

  IPv6 hosts send Neighbor Solicitation messages to discover the link-layer addresses of on-link IPv6 nodes. Neighbor Solicitation messages include the link-layer address of the sender. Hosts send Neighbor Solicitation messages to multicast addresses to resolve addresses and to unicast addresses to verify the reachability of a neighboring node.

- Neighbor Advertisement

  IPv6 nodes send Neighbor Advertisement messages in response to the receipt of Neighbor Solicitation messages. Nodes also send unsolicited Neighbor Advertisements to inform neighboring nodes of changes in link-layer addresses. Neighbor Advertisement messages contain information that nodes require to determine the type of Neighbor Advertisement message, the link-layer address of the sender, and the sender's role on the network.

- Redirect

  IPv6 routers send Redirect messages to inform an originating host of a better first-hop address for a specific destination. Routers send Redirect messages for unicast traffic only and only to originating hosts. Only hosts process Redirect messages.

To ensure that all Neighbor Discovery messages were sent by a node on the local link, all Neighbor Discovery messages are sent with a hop limit of 255. When a Neighbor Discovery message is received, the Hop Limit field in the IPv6 header is checked. If the field is not set to 255, the message is silently discarded. Verifying that the Neighbor Discovery message has a hop limit of 255 provides protection from network attacks that are based on Neighbor Discovery and launched from off-link nodes. If a

message has a hop limit of 255, a router could not have forwarded the message from an off-link node.

**Neighbor Discovery Options**
RFC 2461 defines the following Neighbor Discovery options:

- Source Link-Layer Address Option

  The Source Link-Layer Address option indicates the link-layer address of the Neighbor Discovery message sender. Neighbor Solicitation, Router Solicitation, and Router Advertisement messages include this option. This option is not included when the source address of the Neighbor Discovery message is the unspecified address (::).

- Target Link-Layer Address Option

  The Target Link-Layer Address option indicates the link-layer address of the neighboring node to which IPv6 packets should be directed. Neighbor Advertisement and Redirect messages include this option.

- Prefix Information Option

  The Prefix Information option is sent in Router Advertisement messages to indicate both address prefixes and information about address autoconfiguration. Each Router Advertisement message can include multiple Prefix Information options, indicating multiple address prefixes.

- Redirected Header Option

  The Redirected Header option is sent in Redirect messages to specify the IPv6 packet that caused the router to send a Redirect message. This option can contain all or part of the redirected IPv6 packet, depending on the size of the IPv6 packet that was initially sent.

- MTU Option

  The MTU option is sent in Router Advertisement messages to indicate the IPv6 MTU of the link. This option can be used when the IPv6 MTU for a link is not well known or must reflect a translational or mixed-media bridging configuration. The MTU option overrides the IPv6 MTU that the interface hardware reports.

  In bridged or Layer-2 switched environments, different link-layer technologies with different link-layer MTUs can exist on the same network segment. In this case, differences in IPv6 MTUs between nodes on the same network are not discovered through Path MTU Discovery. The MTU option indicates the highest IPv6 MTU supported by all link-layer technologies on the network segment.

**Host Data Structures**
To facilitate interactions between neighboring nodes, RFC 2461 defines the following host data structures as examples of how to store information for Neighbor Discovery processes:

- Neighbor cache

  Stores the on-link address of a neighbor, its corresponding link-layer address, and an indication of the neighbor's reachability state. The neighbor cache is equivalent to the ARP cache in IPv4.

- Destination cache

  Stores information about forwarding or next-hop addresses for destinations to which traffic has recently been sent. Entries in the destination cache contain the destination IP address (either local or remote), the previously resolved next-hop address, and the Path MTU for the destination.

- Prefix list

  Lists on-link prefixes. Each entry defines a range of IP addresses for destinations that are directly reachable (neighbors). This list is populated from prefixes that routers advertise in Router Advertisement messages.

- Default router list

  Lists IP addresses corresponding to on-link routers that send Router Advertisement messages and that are eligible to be default routers.

RFC 2461 defines these structures as an example of an IPv6 host conceptual model. An IPv6 implementation is not required to create these exact data structures as long as the external behavior of the host is consistent with RFC 2461. For example, the IPv6 protocol for Windows Server 2003 uses a routing table rather than a prefix list and default router list. The routing table contains sufficient information to determine how to forward IPv6 packets. For more information, see "IPv6 Routing" later in this section.

**Neighbor Discovery Message Exchanges**
The Neighbor Discovery protocol provides message exchanges for the following processes:

- Address resolution
- Duplicate address detection
- Router discovery
- Redirect function

**Address Resolution**
To resolve addresses, IPv6 nodes exchange Neighbor Solicitation and Neighbor Advertisement messages to resolve the link-layer address of the on-link next-hop address for a given destination. The sending host sends a multicast Neighbor Solicitation message on the appropriate interface. The multicast address of the Neighbor Solicitation message is the solicited-node multicast address derived from the target IP address. The Neighbor Solicitation message includes the link-layer address of the sending host in the Source Link-Layer Address option.

When the target host receives the Neighbor Solicitation message, it updates its own neighbor cache based on the source address of the Neighbor Solicitation message and the link-layer address in the Source Link-Layer Address option. Next, the target host sends a unicast Neighbor Advertisement to the Neighbor Solicitation sender. The Neighbor Advertisement includes the Target Link-Layer Address option.

After receiving the Neighbor Advertisement from the target host, the sending host updates its neighbor cache with an entry for the target host based on the information in the Target Link-Layer Address option. At this point, the sending host and the target host can send unicast IPv6 traffic to each other.

As an example of this process, Host A has an Ethernet MAC address of 00-AA-00-11-11-11 and a corresponding link-local address of FE80::2AA:FF:FE11:1111. Host B has an Ethernet MAC address of 00-AA-00-22-22-22 and a corresponding link-local address of FE80::2AA:FF:FE22:2222. To send a packet to Host B, Host A must resolve Host B's link-layer address.

The following figure shows Host A sending a solicited-node multicast Neighbor Solicitation message (based on Host B's IP address) to the address of FF02::1:FF22:2222.

**Multicast Neighbor Solicitation Message for Address Resolution**

Host B, having registered the solicited-node multicast address of 33-33-FF-22-22-22 with its Ethernet adapter, receives and

processes the Neighbor Solicitation. The following figure shows Host B responding with a unicast Neighbor Advertisement message.

**Unicast Neighbor Advertisement Message for Address Resolution**

**Duplicate Address Detection**

IPv4 nodes use ARP Request messages and a method called gratuitous ARP to detect duplicate IP addresses on their local links. Similarly, IPv6 nodes use the Neighbor Solicitation message to detect duplicate address use on their local links.

With gratuitous ARP, the Source Protocol Address and Target Protocol Address fields in the ARP Request message header are set to the IPv4 address for which duplication is being detected. In IPv6 duplicate address detection, the Target Address field in the Neighbor Solicitation message is set to the IPv6 address for which duplication is being detected.

Duplicate address detection differs from address resolution in these ways:

- In a Neighbor Solicitation message for duplicate address detection, the Source Address field in the IPv6 header is set to the unspecified address (::). The address being queried for duplication cannot be used until it is determined that the address is not already in use.

- In the Neighbor Advertisement reply to a Neighbor Solicitation message for duplicate address detection, the Destination Address in the IPv6 header is set to the link-local scope all-nodes multicast address (FF02::1). Because the sender of the Neighbor Solicitation message for duplicate address detection is not using the desired address, it cannot receive unicast Neighbor Advertisement messages. Therefore, the Neighbor Advertisement message is multicast.

Upon receipt of the multicast Neighbor Advertisement message sent in response to the Neighbor Solicitation message, the node disables the use of the duplicate address on the interface. If the node does not receive a Neighbor Advertisement message that defends the use of the IPv6 address, it initializes the address on the interface.

**Router Discovery**

Router discovery is the process through which nodes attempt to discover the set of routers on the local link. Router discovery in IPv6 is similar to ICMP Router Discovery for IPv4 described in RFC 1256.

An important difference between ICMPv4 Router Discovery and IPv6 router discovery is the mechanism through which the default router is changed when the current one becomes unavailable. In ICMPv4 Router Discovery, the Router Advertisement message includes an Advertisement Lifetime field. Advertisement Lifetime is the time after which the router, upon sending its last Router Advertisement message, can be considered unavailable. In the worst case, a router can become unavailable and hosts will not attempt to discover a new default router until the Advertisement Lifetime has elapsed.

IPv6 has a Router Lifetime field in the Router Advertisement message. This field indicates the length of time that the router can be considered a default router. However, if the current default router becomes unavailable, the condition is detected through neighbor unreachability detection instead of the Router Lifetime field in the Router Advertisement message. Because neighbor unreachability detection determines that the router is no longer reachable, a new router is chosen immediately from the default router list. For more information, see "Neighbor Unreachability Detection" later in this section.

In addition to configuring a default router, IPv6 router discovery also configures the following:

- The default setting for the Hop Limit field in the IPv6 header.

- A determination of whether the node should use a stateful address protocol, such as Dynamic Host Configuration Protocol for IPv6 (DHCPv6), for addresses and other configuration parameters.

- The timers used in reachability detection and the retransmission of Neighbor Solicitation messages.

- The list of network prefixes defined for the link. Each network prefix contains both the IPv6 network prefix and its valid and preferred lifetimes. If indicated, a network prefix combined with the interface identifier creates a stateless IP address configuration for the receiving interface. A network prefix also defines the range of addresses for nodes on the local link.

- The MTU of the local link.

The IPv6 router discovery processes are the following:

- IPv6 routers periodically send Router Advertisement messages on the local link advertising their existence as routers. They also provide configuration parameters such as default hop limit, MTU, and prefixes.

- Active IPv6 hosts on the local link receive the Router Advertisement messages and use the contents to maintain their default router lists, prefix lists, and other configuration parameters.

- A host that is starting up sends a Router Solicitation message to the link-local scope all-routers multicast address (FF02::2). Upon receipt of a Router Solicitation message, each router on the local link send a unicast Router Advertisement message to the node that sent the Router Solicitation message. The node receives the Router Advertisement messages and uses their contents to build the default router and prefix lists and to set other configuration parameters.

**Redirect Function**

Routers use the redirect function to inform originating hosts of a better first-hop neighbor to which traffic should be forwarded for a specific destination. Routers use the redirect function for two purposes:

- A router informs an originating host of the IP address of a router available on the local link that is closer to the destination. The term closer is a routing metric function used to reach the destination network segment. This condition can occur when multiple routers are on a network segment, the originating host chooses a default router, and it is not the best one to use to reach the destination.

- A router informs an originating host that the destination is a neighbor (it is on the same link as the originating host). This condition can occur when the prefix list of a host does not include the prefix of the destination. Because the destination does not match a prefix in the list, the originating host forwards the packet to its default router.

The following steps occur in the IPv6 redirect process:

1. The originating host sends a unicast packet to its default router.

2. The router processes the packet and notes that the address of the originating host is a neighbor. Additionally, the router notes that both the originating host and the next-hop are on the same link.

3. The router forwards the packet to the appropriate next-hop address.

4. The router sends the originating host a Redirect message. In the Target Address field of the Redirect message is the next-hop address of the node to which the originating host should send packets addressed to the destination.

   For packets redirected to a router, the Target Address field is set to the link-local address of the router. For packets redirected to a host, the Target Address field is set to the destination address of the packet originally sent.

   The Redirect message includes the Redirected Header option. The message might also include the Target Link-Layer Address option.

5. Upon receiving the Redirect message, the originating host updates the destination address entry in the destination cache with the address in the Target Address field. If the Redirect message includes the Target Link-Layer Address option, its contents are used to create or update the corresponding entry in the neighbor cache.

Only the first router in the path between the originating host and the destination sends redirect messages, and (like ICMPv6 error messages) they are rate limited. Hosts never send Redirect messages, and routers never update routing tables based on the receipt of a Redirect message.

**Neighbor Unreachability Detection**

Reachability is defined as the ability to send an IPv6 packet to a neighboring node and have the IPv6 layer of the neighbor receive and process that packet. When a node sends a packet to a router, the packet is delivered to the router's IPv6 layer and then forwarded to the next hop. When a node sends a packet to a neighboring node, the packet is delivered to the node's IPv6 layer. It is important to note that the definition of reachability does not require delivery to a remote node across a router — only to the neighboring router.

When a neighbor becomes unreachable, IPv6 detects this condition and attempts to correct it. To determine whether a neighbor is reachable, IPv6 relies on either upper layer protocols that indicate communication progress or receipt of a Neighbor Advertisement message that has been sent in response to a unicast Neighbor Solicitation message.

For TCP traffic, communication progress is indicated when new data or acknowledgement segments for sent data are received. For UDP traffic, a progress indication might not be present. In this case, the node sends unicast Neighbor Solicitation messages to the next-hop neighbor to monitor its ongoing reachability.

Only the receipt of a solicited Neighbor Advertisement message is considered proof of reachability. A solicited Neighbor Advertisement message, which has its Solicited flag set to 1, is sent only in response to a Neighbor Solicitation message. Unsolicited Neighbor Advertisement or Router Advertisement messages are not considered proof of reachability.

Neighbor unreachability detection detects symmetric reachability. In this instance, packets must be able to travel to and from the desired neighboring node. When a Neighbor Solicitation message is sent and a solicited Neighbor Advertisement message is received, the path between the nodes is confirmed. For an unsolicited Neighbor Advertisement or Router Advertisement message, only the path from the node sending the message is confirmed. This is called asymmetric reachability.

For a specific local node, reachability is confirmed only by the node that sends the Neighbor Solicitation message and receives the Neighbor Advertisement message. The node sending the Neighbor Advertisement message receives no confirmation that the message reached the intended node. For two neighboring nodes to both determine reachability, each node must exchange Neighbor Solicitation and Neighbor Advertisement messages with the other.

The reachability of a neighboring node is determined by monitoring the state of the neighboring node's entry in the neighbor cache. RFC 2461 defines the following states for a neighbor cache entry:

- INCOMPLETE

  IPv6 address resolution, which is using a solicited-node multicast Neighbor Solicitation message, is in progress. The INCOMPLETE state is entered when a neighbor cache entry is created but does not yet have the node's corresponding link-layer address. RFC 2461 recommends that three successive multicast Neighbor Solicitation messages be sent.

- REACHABLE

  Reachability has been confirmed by receipt of a solicited unicast Neighbor Advertisement message. The neighbor cache entry stays in the REACHABLE state until the number of milliseconds indicated in the Reachable Time field in the Router Advertisement message elapses. The entry stays in the REACHABLE state as long as upper layer protocols such as TCP indicate that communication is progressing. Each time that progress is indicated, the reachable time for the entry is refreshed.

- STALE

  Reachable time (the duration since the last reachability confirmation was received) has elapsed. The neighbor cache entry enters the STALE state after the number of milliseconds in the Reachable Time field in the Router Advertisement message (or a host default value) elapses, and the entry remains in this state until a packet is sent to the neighbor. The entry also enters the STALE state when the host receives an unsolicited Neighbor Advertisement message that is advertising the link-layer address.

- DELAY

  To allow time for upper layer protocols to provide reachability confirmation before sending Neighbor Solicitation

messages, the neighbor cache entry enters the DELAY state and waits a configurable period of time after sending a packet. RFC 2461 recommends a value of 5 seconds. If reachability is not confirmed by the delay time, then the entry enters the PROBE state, and a unicast Neighbor Solicitation message is sent.

- PROBE

  Reachability confirmation is in progress for a neighbor cache entry that was in the STALE or DELAY state. Unicast Neighbor Solicitation messages are sent at intervals corresponding to a retransmission timer field in the Router Advertisement message that this host received. A configurable variable determines the number of Neighbor Solicitation messages sent before the reachability detection process is abandoned and the neighbor cache entry is removed. RFC 2461 recommends sending three successive unicast Neighbor Solicitation messages.

The following figure shows the state diagram of an entry in the neighbor cache.

**States of a Neighbor Cache Entry**

If the unreachable neighbor is a router, the host chooses another router from the default router list and performs both address resolution and unreachability detection on it.

**Address Autoconfiguration**

A highly useful aspect of IPv6 is its ability to automatically configure itself without the use of a stateful configuration protocol, such as Dynamic Host Configuration Protocol for IPv6 (DHCPv6). By default, an IPv6 host can configure a link-local address for each interface. By using router discovery, a host can also determine the addresses of routers, additional addresses, and other configuration parameters. The Router Advertisement message indicates whether a stateful address configuration protocol should be used.

Address autoconfiguration can be performed only on multicast-capable interfaces. RFC 2462 describes address autoconfiguration.

**Autoconfigured Address States**

Autoconfigured addresses are in one or more of the following states:

- Tentative

  The address is in the process of being verified as unique. Verification occurs through duplicate address detection.

- Preferred

  An address for which uniqueness has been verified. A node can send and receive unicast traffic to and from a preferred address. Router Advertisement messages include the period of time that an address can remain in the tentative and preferred states.

- Deprecated

  An address that is still valid but whose use is discouraged for new communication. Existing communication sessions can continue to use a deprecated address. Nodes can send and receive unicast traffic to and from deprecated addresses.

- Valid

  An address from which unicast traffic can be sent and received. The valid state covers both the preferred and deprecated states. Router Advertisement messages include the amount of time that an address remains in the valid state. The valid lifetime must be longer than or equal to the preferred lifetime.

- Invalid

  An address for which a node can no longer send or receive unicast traffic. An address enters the invalid state after the valid lifetime expires.

The following figure shows the relationship between the states of an autoconfigured address and the preferred and valid lifetimes.

**States of an Autoconfigured Address**

With the exception of link-local addresses, address autoconfiguration is specified only for hosts. Routers must obtain address and configuration parameters through another means (for example, manual configuration).

**Types of Autoconfiguration**

Autoconfiguration falls into three types:

1. Stateless

   Configuration is based on Router Advertisement messages. These messages include stateless address prefixes and require that hosts not use a stateful address configuration protocol.

2. Stateful

   Configuration is based on a stateful address configuration protocol, such as DHCPv6, to obtain addresses and other configuration options. Hosts use stateful address configuration when they receive Router Advertisement messages that do not include address prefixes and that require the hosts to use a stateful address configuration protocol. A host will also use a stateful address configuration protocol when no routers are present on the local link.

3. Both

   Configuration is based on Router Advertisement messages. These messages include stateless address prefixes but require hosts to use a stateful address configuration protocol.

For all autoconfiguration types, a link-local address is always configured.

**Autoconfiguration Process**

Address autoconfiguration for an IPv6 node occurs as follows:

1. A tentative link-local address is derived, based on the link-local prefix of FE80::/64 and the 64-bit interface identifier.

2. Duplicate address detection is performed to verify the uniqueness of the tentative link-local address.

   If the address is already in use, the node must be configured manually.

   If the address is not already in use, the tentative link-local address is assumed to be unique and valid. The link-local address is initialized for the interface. The corresponding solicited-node multicast link-layer address is registered with the

network adapter.

3. The host sends a Router Solicitation message.

4. If the host receives no Router Advertisement messages, then it uses a stateful address configuration protocol to obtain addresses and other configuration parameters. Windows Server 2003 does not support the use of a stateful address configuration protocol for IPv6.

5. If the host receives a Router Advertisement message, the host is configured based on the information in the message

6. For each stateless address prefix that the message includes:

   A tentative address is derived from the address prefix and the appropriate 64-bit interface identifier.

   The uniqueness of the tentative address is verified.

   If the tentative address is in use, the address is not initialized for the interface.

   If the tentative address is not in use, the address is initialized. Initialization includes setting the valid and preferred lifetimes based on information in the Router Advertisement message. Initialization also includes registering the corresponding solicited-node multicast link-layer address with the network adapter.

7. If specified in the Router Advertisement message, the host uses a stateful address configuration protocol to obtain additional addresses or configuration parameters.

**IPv6 Routing**

Similar to IPv4, IPv6 nodes use local routing tables to determine how to forward packets. IPv6 routing table entries are created by default when IPv6 initializes, and either a system administrator adds entries manually or communication with routers adds them automatically.

A routing table is present on each IPv6 node that is running Windows Server 2003. The routing table stores information about IPv6 network prefixes and how they can be reached (either directly or indirectly). Routing tables are not exclusive to IPv6 routers. IPv6 hosts that are running Windows Server 2003 also have IPv6 routing tables. Before a routing table is used, the destination cache is checked for an entry matching the destination address in the packet being forwarded. If the destination cache does not contain an entry for the destination address, the routing table is used to determine:

1. The next-hop address

   For a direct delivery (in which the destination is on a local link), the next-hop address is the destination address in the packet. For an indirect delivery (in which the destination is not on a local link), the next-hop address is the address of a router.

2. The next-hop interface

   The interface identifies the physical or logical interface that is used to forward the packet either to its destination or to the next router.

After the next-hop address and interface are determined, the destination cache is updated. Subsequent packets forwarded to the destination use the destination cache entry, rather than the routing table.

**Entry Types in IPv6 Routing Tables**

Entries in IPv6 routing tables store the following types of routes:

- Directly attached network routes

  Routes for network prefixes that are directly attached and typically have prefixes that are 64 bits long.

- Remote network routes

Routes for network prefixes that are not directly attached but are available across other routers. Remote network routes can be subnet network prefixes or prefixes for address spaces.

- Host routes

  Routes to specific IPv6 addresses. Host routes allow routing to occur for each IPv6 address. For host routes, the route prefix is a specific IPv6 address with a prefix length of 128 bits. Prefixes for both types of network routes are shorter than 128 bits.

- Default route

  The default route is used when a more specific network route or host route is not found. The default route prefix is ::/0.

**Route Determination Process**

IPv6 uses the following process to determine which routing table entry is used for the forwarding decision:

- For each entry in a routing table, IPv6 compares the bits in the network prefix to the same bits in the destination IPv6 address for the number of bits in the prefix length in the route. If all the bits in the network prefix match all the bits in the destination IPv6 address for the number of bits in the prefix length for the route, the route is a match for the destination.

- The list of matching routes is compiled. The route that has the largest prefix length (the route that matched the most high-order bits with the destination IPv6 address) is chosen. The longest matching route is the most specific route to the destination. If multiple entries with the longest match are found (multiple routes to the same network prefix, for example), the router uses the lowest metric to identify the best route. If multiple entries exist that are the longest match and the lowest metric, IPv6 can choose which routing table entry to use.

The match for any given destination finds routes in the following order:

1. A route that matches the entire destination IPv6 address (a host route with a 128-bit prefix length).

2. A route with the longest prefix length that matches the destination.

3. The default route (the network prefix ::/0).

The end result of the route determination process is the selection of a single route in the routing table. The selected route yields a next-hop address and an interface. If the route determination process on the sending host fails to find a route, IPv6 assumes that the destination is locally reachable. If the route determination process on a router fails to find a route, IPv6 sends an ICMPv6 Destination Unreachable-No Route Found message to the sending host and discards the packet.

**End-to-End IPv6 Delivery Process**

The following sections describe the process of forwarding an IPv6 packet from the sending host across one or more IPv6 routers to the final destination. These sections assume that the Hop-by-Hop Options, Destination Options, and Routing extension headers are not present.

**IPv6 on the Sending Host**

The process by which hosts send IPv6 packets combines the local host's data structures with the Neighbor Discovery protocol. IPv6 hosts use the following algorithm when sending a packet to an arbitrary destination:

1. Set the Hop Limit value to either a default or application-specified value.

2. Check the destination cache for an entry that matches the destination address.

3. If the destination cache contains an entry that matches the destination address, obtain the next-hop address and interface index from the destination cache entry. If the destination is a mobile IPv6 node and the sending host is a mobile correspondent node, the destination cache entry might contain a pointer to care-of destination cache. If so, obtain the next-hop address from the corresponding entry in the care-of destination cache. For more information about IPv6 mobility support, see the Internet draft titled "Mobility Support in IPv6." Go to step 7.

4. If the destination cache does not contain an entry that matches the destination address, check the local IPv6 routing table for the longest matching route to the destination address.

5. Based on the longest matching route, determine the next-hop address and the interface index used for forwarding the packet.

   If no route is found, IPv6 assumes that the destination is directly reachable. The next-hop address is set to the destination address, and an interface index is chosen.

6. Update the destination cache.

7. Check the neighbor cache for an entry that matches the next-hop address.

8. If the neighbor cache contains an entry that matches the next-hop address, obtain the link-layer address.

9. If the neighbor cache does not contain an entry that matches the next-hop address, use address resolution to obtain the link-layer address for the next-hop address.

   If address resolution is not successful, indicate an error.

10. Send the packet using the link-layer address of the entry in the neighbor cache.

The following figure shows this sending host process.

**Sending Host Process**

**IPv6 on the Router**

IPv6 routers use the following algorithm when they receive and forward a packet to an arbitrary destination:

1. Verify whether the destination address in the IPv6 packet corresponds to an address assigned to a router interface.

   If so, the router processes the IPv6 packet as the destination host. (For more information, see step 2 in the following subsection, "IPv6 on the Destination Host.")

2. Decrement the value of the Hop Limit field by 1.

   If the value of the Hop Limit field is 0, send an ICMPv6 Time Exceeded message to the sender, and discard the packet.

3. If the value of the Hop Limit field is 1 or greater, update the Hop Limit field in the IPv6 header of the packet.

4. Check the destination cache for an entry that matches the destination address.

5. If the destination cache contains an entry that matches the destination address, obtain the next-hop address and interface index in the entry, and go to step 9.

6. Check the local IPv6 routing table for the longest matching route to the destination address.

7. Based on the longest matching route, determine the next-hop IPv6 address and the interface index used for forwarding the packet.

   If no route is found, send an ICMPv6 Destination Unreachable-No Route Found message to the sending host, and discard the packet.

8. Update the destination cache.

9. If the interface on which the packet was received is the same as the interface on which the packet is being forwarded, the interface is a point-to-point link, and the Destination Address field matches a prefix assigned to the interface, send an ICMPv6 Destination Unreachable-Address Unreachable message to the sending host, and discard the packet. This prevents the needless "ping-pong" forwarding of IPv6 packets between the two interfaces on a point-to-point link for a packet whose destination matches the prefix of the point-to-point link but does not match the address of either interface. This condition and its solution is described in the Internet draft titled "Avoiding ping-pong packets on point-to-point links."

10. If the interface on which the packet was received is the same as the interface on which the packet is being forwarded and the Source Address field matches a prefix assigned to the interface, send a Redirect message to the sending host (subject to rate limiting).

11. Compare the link MTU of the next-hop interface to the size of the IPv6 packet being forwarded.

12. If the link MTU is smaller than the packet, send an ICMPv6 Packet Too Big message.

13. Check the neighbor cache of the next-hop interface for an entry that matches the next-hop address.

14. If the neighbor cache of the next-hop interface contains an entry that matches the next-hop address, obtain the link-layer address.

15. If the neighbor cache of the next-hop interface does not contain an entry that matches the next-hop address, use address resolution to obtain the link-layer address for the next-hop address.

    If address resolution is not successful, send an ICMPv6 Destination Unreachable-Destination Address Unreachable message, and discard the packet.

16. Send the packet using the link-layer address of the neighbor cache entry.

The following figures show this router forwarding process.

**Router Forwarding Process**

**Router Forwarding Process**

This entire process is repeated at each router in the path between the source and destination host.

**IPv6 on the Destination Host**

IPv6 hosts use the following algorithm when they receive IPv6 packets:

1. Verify whether the destination address in the packet corresponds to an IPv6 address that is assigned to a host interface.

   If the destination address is not assigned to a host interface, silently discard the packet.

2. Based on the Next Header field, process extension headers (if present), and pass the upper-layer PDU to the appropriate upper-layer protocol.

   If the protocol does not exist, send an ICMPv6 Parameter Problem message back to the sender, and discard the packet.

3. For TCP and UDP packets, check the destination port.

   If no application exists for the UDP port number, send an ICMPv6 Destination Unreachable-Destination Port Unreachable message back to the sender, and discard the packet. If no application exists for the TCP port number, send a TCP Connection Reset segment back to the sender, and discard the packet.

4. For TCP and UDP packets, pass the TCP segment or UDP message to the appropriate application.

**IPv6 Internet Connection Firewall**

A firewall provides security by creating a protective boundary between a computer or network and the Internet. When you install the Advanced Networking Pack for Windows XP, IPv6 Internet Connection Firewall (ICF) is provided and enabled by default to dynamically restrict traffic from the Internet. IPv6 ICF is different from the existing ICF in Windows XP, which restricts IPv4 traffic.

IPv6 ICF:

- Runs automatically and provides filters for all network connections on which IPv6 is enabled.
- Monitors all outbound traffic and dynamically creates inbound packet filters for response traffic. This is known as stateful filtering. IPv6 ICF silently discards all unsolicited inbound traffic.
- Logs IPv6 traffic events to a log file (separate from IPv4 ICF). By default, this log file is located at: *systemroot*\Pfirewall-v6.log.

IPv6 ICF protects your computer by silently dropping all packets that are initiated from a source outside the IPv6 ICF computer, such as the Internet. IPv6 ICF stops common attempts to illegally gain access to your computer or network by malicious Internet users using techniques such as port scanning. Instead of notifying you of inbound discarded traffic, IPv6 ICF creates entries in a security log from which you can view the activity that the firewall tracks.

IPv6 ICF is configured using commands in the **netsh firewall** context. You can use netsh commands to configure IPv6 ICF to allow specific types of ICMPv6 traffic or traffic to specific TCP or UDP ports.

**Note**

- Windows XP shows only the IPv4 ICF configuration in Network Connections. IPv6 ICF might appear disabled, but it is actually enabled and filtering IPv6 traffic.

**IPv6 Transition Technologies**

Protocol transitions are not easy, and the transition from IPv4 to IPv6 is no exception. Protocol transitions are typically deployed by installing and configuring the new protocol on all nodes within the network and verifying that all node and router operations work. Although this might be possible in a small- or medium-sized organization, the challenge of making a rapid protocol transition in a large organization is very difficult. Additionally, given the scope of the Internet, rapid protocol transition becomes an impossible task.

The transition from IPv4 to IPv6 will take years, and organizations or hosts within organizations might continue to use IPv4 indefinitely. Therefore, although migration is the long-term goal, equal consideration must be given to the interim coexistence of IPv4 and IPv6 nodes.

RFC 1752 defines the following transition criteria:

- Existing IPv4 hosts can be upgraded at any time, independent of the upgrade of other hosts or routers.
- Hosts that use only IPv6 can be added at any time, without dependencies on other hosts or routing infrastructure.
- IPv4 hosts on which IPv6 is installed can continue to use their IPv4 addresses and do not need additional addresses.
- Little preparation is required to either upgrade IPv4 nodes to IPv6 or deploy new IPv6 nodes.

The inherent lack of dependencies between IPv4 and IPv6 hosts, IPv4 routing infrastructure, and IPv6 routing infrastructure requires several mechanisms that allow seamless coexistence.

**Node Types**
RFC 2893 defines the following node types:

**IPv4-only Node**
A node that implements only IPv4 (and has only IPv4 addresses). This node does not support IPv6. Most hosts and routers installed today are IPv4-only nodes.

**IPv6-only Node**
A node that implements only IPv6 (and has only IPv6 addresses). This node is able to communicate only with IPv6 nodes and applications. This type of node is not common today, but it might become more prevalent as smaller devices such as cellular phones and handheld computing devices include the IPv6 protocol.

**IPv6/IPv4 Node**
A node that implements both IPv4 and IPv6. This node is IPv6-enabled if it has an IPv6 interface configured.

**IPv4 Node**
A node that implements IPv4 (it can send and receive IPv4 packets). An IPv4 node can be an IPv4-only node or an IPv6/IPv4 node.

**IPv6 Node**
A node that implements IPv6 (it can send and receive IPv6 packets). An IPv6 node can be an IPv6-only node or an IPv6/IPv4 node.

For coexistence to occur, the largest number of nodes (IPv4 or IPv6 nodes) can communicate using an IPv4 infrastructure, an IPv6 infrastructure, or an infrastructure that is a combination of IPv4 and IPv6. True migration is achieved when all IPv4 nodes are converted to IPv6-only nodes. However, for the foreseeable future, practical migration is achieved when as many IPv4-only nodes as possible are converted to IPv6/IPv4 nodes. IPv4-only nodes can communicate with IPv6-only nodes only through an IPv4-to-IPv6 proxy or translation gateway.

**Address Compatibility**
The following addresses are defined to help IPv4 and IPv6 nodes coexist:

**IPv4-compatible Addresses**
IPv6/IPv4 nodes that are communicating with IPv6 over an IPv4 infrastructure use IPv4-compatible addresses, 0:0:0:0:0:0:w.x.y.z or ::w.x.y.z (where w.x.y.z is the dotted decimal representation of a public IPv4 address). When an IPv4-compatible address is used as an IPv6 destination, IPv6 traffic is automatically encapsulated with IPv4 headers and sent to their destinations using the IPv4 infrastructure.

**IPv4-mapped Addresses**
The IPv4-mapped address, 0:0:0:0:0:FFFF:w.x.y.z or ::FFFF:w.x.y.z, is used to represent an IPv4-only node to an IPv6 node. It is used only for internal representation. The IPv4-mapped address is never used as a source or destination address of an IPv6 packet. The IPv6 protocol for Windows Server 2003 does not support IPv4-mapped addresses. Some IPv6 implementations use IPv4-mapped addresses when translating traffic between IPv4-only and IPv6-only nodes.

**6over4 Addresses**
Each 6over4 address comprises a valid 64-bit unicast address prefix and the interface identifier ::WWXX:YYZZ (where WWXX:YYZZ is the colon-hexadecimal representation of w.x.y.z, a unicast IPv4 address assigned to an interface). An example of a link-local 6over4 address based on the IPv4 address of 131.107.4.92 is FE80::836B:45C. 6over4 addresses represent a host that use the automatic tunneling mechanism defined in RFC 2529.

**6to4 Addresses**
6to4 addresses are based on the prefix 2002:WWXX:YYZZ::/48 (where WWXX:YYZZ is the colon-hexadecimal representation of w.x.y.z, a public IPv4 address assigned to an interface). 6to4 addresses represent sites that use the automatic tunneling mechanism defined in RFC 3056, also known as 6to4. For more information, see “6to4” later in this section.

**ISATAP Addresses**
Each Intra-site Automatic Tunnel Addressing Protocol (ISATAP) addresses comprise a valid 64-bit unicast address prefix and the interface identifier ::0:5EFE:w.x.y.z (where w.x.y.z is a unicast IPv4 address assigned to an interface). An example of a link-local ISATAP address is FE80::5EFE:131.107.4.92. ISATAP addresses represent hosts that use the automatic tunneling mechanism defined in the Internet draft titled “Intra-Site Automatic Tunnel Addressing Protocol (ISATAP).” For more information, see “ISATAP” later in this section.

**Teredo Addresses**
Teredo addresses use the prefix 3FFE:831F::/32. An example of a Teredo address is 3FFE:831F:CE49:7601:8000:EFFF:62C3:FFFE.

Beyond the first 32 bits, Teredo addresses encode the IPv4 address of a Teredo server, flags, and the encoded version of the external address and port of a Teredo client. Teredo addresses represent hosts that use the automatic tunneling mechanism defined in the Internet draft titled "Teredo: Tunneling IPv6 over UDP through NATs." For more information, see "Teredo" later in this section.

**Transition Mechanisms**

The following mechanisms are used to help IPv6 coexist with an IPv4 infrastructure and to provide an eventual transition to an IPv6-only infrastructure:

- Dual IP layer
- IPv6 over IPv4 tunneling
- DNS infrastructure

**Dual IP Layer**

The dual IP layer is an implementation of the TCP/IP suite of protocols that includes both an IPv4 Internet layer and an IPv6 Internet layer. IPv6/IPv4 nodes use this mechanism to communicate with both IPv4 and IPv6 nodes. A dual IP layer contains a single implementation of Host-to-Host Transport layer protocols such as TCP and UDP. All upper layer protocols in an implementation of dual IP layer can communicate over IPv4, IPv6, or IPv6 tunneled in IPv4.

The following figure shows a dual IP layer architecture.

**A Dual IP Layer Architecture**

The IPv6 protocol for Windows Server 2003 is not a dual IP layer. The IPv6 protocol driver, Tcpip6.sys, contains a separate implementation of TCP and UDP and is sometimes referred to as a dual-stack implementation. The following figure shows the dual stack architecture of the IPv6 protocol for Windows Server 2003.

**The Dual Stack Architecture of the IPv6 Protocol for Windows Server 2003**

Although the IPv6 protocol for Windows Server 2003 is not a dual IP layer, it functions in the same way as a dual IP layer in terms of providing functionality for IPv6 transition.

**IPv6 over IPv4 Tunneling**

IPv6 over IPv4 tunneling is the encapsulation of IPv6 packets with an IPv4 header so that IPv6 packets can be sent over an IPv4 infrastructure. Within the IPv4 header:

- The IPv4 Protocol field is set to 41 to indicate an encapsulated IPv6 packet.
- The Source and Destination fields are set to IPv4 addresses of the tunnel endpoints. The tunnel endpoints are either manually configured as part of the tunnel interface or are automatically derived from the sending interface, the next-hop address of the matching route, or the source and destination IPv6 addresses in the IPv6 header.

The following figure shows IPv6 over IPv4 tunneling.

**IPv6 over IPv4 Tunneling**

For IPv6 over IPv4 tunneling, the IPv6 path MTU is typically 20 less than the IPv4 path MTU However, if the IPv4 path MTU is not stored for each tunnel, an intermediate IPv4 router might need to fragment the IPv4 packet. In this case, the Don't Fragment flag in the IPv4 header must be set to 0 when IPv6 over IPv4 tunneled packets are sent.

**DNS Infrastructure**

Because most users refer to network resources by name rather than by address, successful coexistence requires upgrading the DNS infrastructure. Upgrading the DNS infrastructure consists of populating the DNS servers with records to support IPv6 name-to-address and address-to-name resolution. After the sending host obtains addresses using a DNS name query, the node must select which addresses to use for communication.

**Address Records**

The DNS infrastructure must contain the following resource records (populated either manually or dynamically) for the successful resolution of domain names to addresses:

- A records for IPv4-only and IPv6/IPv4 nodes
- AAAA records for IPv6-only and IPv6/IPv4 nodes

**Pointer Records**

The DNS infrastructure must contain the following resource records (populated either manually or dynamically) for the successful resolution of address to domain names (reverse queries):

- PTR records in the IN-ADDR.ARPA domain for IPv4-only and IPv6/IPv4 nodes
- PTR records in the IP6.ARPA domain for IPv6-only and IPv6/IPv4 nodes (optional)

**Address Selection Rules**

For name-to-address resolution, after the querying node obtains the set of addresses corresponding to the name, the node must determine the set of addresses to choose as source and destination for outbound packets.

This choice is not an issue in today's environment, in which IPv4-only nodes prevail. However, in an environment in which IPv4 and IPv6 coexist, the set of addresses returned in a DNS query might contain multiple IPv4 and IPv6 addresses. The querying host is configured with at least one IPv4 address and (typically) multiple IPv6 addresses. It is not an easy task to decide which type of address (IPv4 versus IPv6) and then which scope (public versus private for IPv4 and link-local versus global versus compatible for IPv6) to use for both the source and the destination addresses.

Default address selection rules are currently under discussion and are described in RFC 3484.

You can view the default address selection rules for the IPv6 protocol for Windows Server 2003 using the **netsh interface ipv6 show prefixpolicy** command to display the prefix policy table. You can modify the entries in the prefix policy table using the **netsh interface ipv6 add|set|delete prefixpolicy** commands. By default, IPv6 addresses in DNS query responses are preferred over IPv4 addresses.

**Tunneling Configurations**

RFC 2893 defines the following configurations with which to tunnel IPv6 traffic between IPv6/IPv4 nodes over an IPv4 infrastructure:

- Router-to-Router
- Host-to-Router or Router-to-Host
- Host-to-Host

**Note**

- IPv6 over IPv4 tunneling describes only an encapsulation of IPv6 packets with an IPv4 header so that IPv6 nodes are reachable across an IPv4 infrastructure. Unlike tunneling for Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP), no messages are exchanged for tunnel setup, maintenance, or termination. Additionally, IPv6 over IPv4 tunneling does not provide security for tunneled IPv6 packets.

#### Router-to-Router

In the tunneling configuration between routers, two IPv6/IPv4 routers connect two IPv4 or IPv6 infrastructures over an IPv4 infrastructure. The tunnel spans a logical link in the path between the source and destination. The IPv6 over IPv4 tunnel between the two routers acts as a single hop. Routes within each IPv4 or IPv6 infrastructure point to the IPv6/IPv4 router on the edge. For each IPv6/IPv4 router, an interface represents the IPv6 over IPv4 tunnel and routes that use the tunnel interface.

The following figure shows tunneling between two routers.

**Router-to-Router Tunneling**

Examples of this tunneling configuration include:

- An IPv6-only test lab that tunnels across an organization's IPv4 infrastructure to reach the IPv6 Internet.
- Two IPv6-only routing domains that tunnel across the IPv4 Internet.
- A 6to4 router that tunnels across the IPv4 Internet to reach another 6to4 router or a 6to4 relay router. For more information about "6to4", see "6to4" later in this section.

#### Host-to-Router and Router-to-Host

In the host-to-router tunneling configuration, an IPv6/IPv4 node that resides within an IPv4 infrastructure creates an IPv6 over IPv4 tunnel to reach an IPv6/IPv4 router. The tunnel spans the first segment of the path between the source and destination nodes. The IPv6 over IPv4 tunnel between the IPv6/IPv4 node and the IPv6/IPv4 router acts as a single hop.

On the IPv6/IPv4 node, a tunnel interface representing the IPv6 over IPv4 tunnel is created, and a route (typically a default route) is added using the tunnel interface. The IPv6/IPv4 node tunnels the IPv6 packet based on the matching route, the tunnel interface, and the next-hop address of the IPv6/IPv4 router.

In the router-to-host tunneling configuration, an IPv6/IPv4 router creates an IPv6 over IPv4 tunnel across an IPv4 infrastructure to reach an IPv6/IPv4 node. The tunnel endpoints span the last segment of the path between the source node and destination node. The IPv6 over IPv4 tunnel between the IPv6/IPv4 router and the IPv6/IPv4 node acts as a single hop.

On the IPv6/IPv4 router, a tunnel interface representing the IPv6 over IPv4 tunnel is created, and a route (typically a subnet route) is added using the tunnel interface. The IPv6/IPv4 router tunnels the IPv6 packet based on the matching subnet route, the tunnel interface, and the destination address of the IPv6/IPv4 node.

The following figure shows host-to-router (for traffic traveling from Node A to Node B) and router-to-host (for traffic traveling from Node B to Node A) tunneling.

**Host-to-Router and Router-to-Host Tunneling**

Examples of host-to-router and router-to-host tunneling include:

- An IPv6/IPv4 host that tunnels across an organization's IPv4 infrastructure to reach the IPv6 Internet.

- An ISATAP host that tunnels across an IPv4 network to an ISATAP router to reach the IPv4 Internet, another IPv4 network, or an IPv6 network. For more information about "ISATAP", see "ISATAP" later in this section.

- An ISATAP router that tunnels across an IPv4 network to reach an ISATAP host.

**Host-to-Host**
In the tunneling configuration between hosts, an IPv6/IPv4 node that resides within an IPv4 infrastructure creates an IPv6 over IPv4 tunnel to reach another IPv6/IPv4 node that resides within the same IPv4 infrastructure. The tunnel spans the entire path between the source and destination nodes. The IPv6 over IPv4 tunnel between the IPv6/IPv4 nodes acts as a single hop.

On each IPv6/IPv4 node, an interface representing the IPv6 over IPv4 tunnel is created. Routes might indicate that the destination node is on the same logical subnet defined by the IPv4 infrastructure. Based on the sending interface, the optional route, and the destination address, the sending host tunnels the IPv6 traffic to the destination.

The following figure shows tunneling between hosts.

**Host-to-Host Tunneling**

Examples of this tunneling configuration include:

- IPv6/IPv4 hosts that use ISATAP addresses to tunnel across an organization's IPv4 infrastructure.

- IPv6/IPv4 hosts that use IPv4-compatible addresses to tunnel across an organization's IPv4 infrastructure.

**Types of Tunnels**
RFC 2893 defines the following types of tunnels:

- Configured

- Automatic

**Configured Tunnels**
A configured tunnel is one whose endpoints must be configured manually. In a configured tunnel, the endpoints have IPv4 addresses that are not derived from the IPv6 source or destination addresses or the next-hop address of the matching route.

Tunnels between routers are typically configured manually. To configure the tunnel interface, the IPv4 addresses of the tunnel endpoints must be manually specified along with static routes that use the tunnel interface.

To manually configure tunnels for the IPv6 protocol for Windows Server 2003, use the **netsh interface ipv6 add v6v4tunnel** command.

**Automatic Tunnels**
An automatic tunnel is one whose endpoints do not need to be configured manually. Tunnel endpoints are determined from logical tunnel interfaces, routes, and source and destination IPv6 addresses.

The IPv6 protocol for Windows Server 2003 supports the following automatic tunneling technologies:

- 6to4, which is enabled by default.

- ISATAP, which is enabled by default. For more information, see "ISATAP" later in this section.

- IPv6 Automatic Tunneling, which is disabled by default.

- 6over4, which is disabled by default.

Additionally, the IPv6 protocol for Windows XP with Service Pack 1 also supports Teredo when the Advanced Networking Pack

for Windows XP is installed. Teredo is enabled by default. For more information, see "Teredo" later in this section.

**6to4**

6to4 is a technology that assigns addresses and automatically configures tunnels between routers to provide unicast IPv6 connectivity between IPv6 sites and hosts across the IPv4 Internet. 6to4 uses the global address prefix:

```
2002:WWXX:YYZZ::/48
```

in which *WWXX*:*YYZZ* is the colon-hexadecimal representation of a public IPv4 address (*w.x.y.z*) assigned to a site or host. The full 6to4 address is:

```
2002:WWXX:YYZZ:[Subnet ID]:[Interface ID]
```

RFC 3056 describes 6to4 in the following terms:

- 6to4 host

Any IPv6 host that is configured with at least one 6to4 address (a global address with the 2002::/16 prefix). 6to4 hosts do not require any manual configuration, and they create 6to4 addresses using standard address autoconfiguration mechanisms.

- 6to4 router

An IPv6/IPv4 router that supports the use of a 6to4 tunnel interface and that is typically used to forward 6to4-addressed traffic between the 6to4 hosts within a site and other 6to4 routers or 6to4 relay routers on an IPv4 internetwork, such as the Internet. 6to4 routers require additional processing logic for proper encapsulation and decapsulation, and they might require manual configuration.

- 6to4 relay router

An IPv6/IPv4 router that forwards 6to4-addressed traffic between 6to4 routers on the Internet and hosts on the IPv6 Internet.

The following figure shows 6to4 components.

**6to4 Components**

Within a site, IPv6 routers advertise 2002:*WWXX*:*YYZZ*:[*Subnet ID*]::/64 prefixes so that hosts can create an autoconfigured 6to4 address and 64-bit prefix routes are used to deliver traffic between 6to4 hosts within the site. Hosts on individual subnets are automatically configured with a 64-bit subnet route for direct delivery to neighbors and a default route with the next-hop address of the advertising router. All IPv6 traffic that does not match a 64-bit prefix used by one of the subnets within the site is forwarded to a 6to4 router on the site border.

The 6to4 router on the site border has a 2002::/16 route that is used to forward traffic to other 6to4 sites and a default route (::/0) that is used to forward traffic to a 6to4 relay router.

In the example network shown in the previous figure, Host A and Host B can communicate with each other because of a default route using the next-hop address of the 6to4 router in Site 1. When Host A communicates with Host C in another site, Host A sends the traffic to the 6to4 router in Site 1 as IPv6 packets. The 6to4 router in Site 1, using the 6to4 tunnel interface and the 2002::/16 route in its routing table, encapsulates the packet with an IPv4 header and tunnels the packet to the 6to4 router in

Site 2. When the 6to4 router in Site 2 receives the packet, the router removes the IPv4 header and, using the 64-bit prefix route in its routing table, forwards the IPv6 packet to Host C.

In this example, Host A (with the interface ID ID_A) resides on subnet 1 within Site 1, which uses the public IPv4 address of 157.60.91.123. Host C (with the interface ID ID_C) resides on subnet 2 within Site 2, which uses the public IPv4 address of 131.107.210.49. When the 6to4 router in Site 1 sends the IPv4-encapsulated IPv6 packet to the 6to4 router in Site 2, the addresses in the IPv4 and IPv6 headers are as listed in the following table.

**Example 6to4 Addresses**

| Field | Value |
|---|---|
| IPv6 Source Address | 2002:9D3C:5B7B:1:[ID_A] |
| IPv6 Destination Address | 2002:836B:D231:2:[ID_C] |
| IPv4 Source Address | 157.60.91.123 |
| IPv4 Destination Address | 131.107.210.49 |

For a more detailed example of 6to4 traffic using ISATAP-derived interface identifiers, see "ISATAP" later in this section.

The following types of communication are possible when 6to4 hosts, an IPv6 routing infrastructure within a site, a 6to4 router at the site boundary, and a 6to4 relay router are used:

- A 6to4 host can communicate with another 6to4 host within the same site.

  This type of communication is available with the IPv6 routing infrastructure, which provides reachability to all hosts within the site. The previous figure shows this type of communication between Host A and Host B.

- A 6to4 host can communicate with 6to4 hosts in other sites across the IPv4 Internet.

  This type of communication occurs when a 6to4 host forwards IPv6 traffic that is destined to a 6to4 host in another site to the 6to4 router for the local site. The 6to4 router for the local site tunnels the IPv6 traffic through the IPv4 Internet to the 6to4 router at the destination site. The 6to4 router at the destination site removes the IPv4 header and forwards the IPv6 packet to the appropriate 6to4 host by using the IPv6 routing infrastructure of the destination site. The previous figure shows this type of communication between Host A and Host C.

- A 6to4 host can communicate with hosts on the IPv6 Internet.

  This type of communication occurs when a 6to4 host forwards IPv6 traffic that is destined for an IPv6 Internet host to the 6to4 router for the local site. The 6to4 router for the local site tunnels the IPv6 traffic to a 6to4 relay router that is connected to both the IPv4 Internet and the IPv6 Internet. The 6to4 relay router removes the IPv4 header and forwards the IPv6 packet to the appropriate IPv6 Internet host by using the routing infrastructure of the IPv6 Internet. The previous figure shows this type of communication between Host A and Host D.

All of these types of communication use IPv6 traffic without having to obtain either a direct connection to the IPv6 Internet or an IPv6 global address prefix from an ISP.

**Communicating Using a 6to4 Address**

The IPv6 protocol for Windows Server 2003 contains a 6to4 component that supports 6to4 hosts and 6to4 routers. If a public IPv4 address is assigned to an interface on the host and a global prefix is not received in a router advertisement, the 6to4 component:

- Configures 6to4 addresses on the 6to4 Tunneling Pseudo-Interface for all public IPv4 addresses that are assigned to interfaces on the computer.

- Creates a 2002::/16 route that forwards all 6to4 traffic with the 6to4 Tunneling Pseudo-Interface (interface index 3). All traffic forwarded by this host to 6to4 destinations is encapsulated with an IPv4 header.

- Performs a DNS query to obtain the IPv4 address of a 6to4 relay router on the Internet. You can also use the **netsh interface ipv6 6to4 set relay** command to specify the DNS name to query. If the query is successful, a default route is

added using the 6to4 Tunneling Pseudo-Interface, and the next-hop address is set to the 6to4 address of the 6to4 relay router.

The results of 6to4 component autoconfiguration vary depending on the configuration of the host. The following figure shows how 6to4 is configured for different types of hosts running Windows Server 2003 (except IPv6 host D).

**6to4 for Hosts Running Windows**

For a host that is assigned a private IPv4 address or receives a router advertisement for a global prefix, no 6to4 addresses are assigned to the 6to4 Tunneling Pseudo-Interface. Addresses are autoconfigured based on the global prefix, and the routing table contains a 64-bit global prefix route and default route. This configuration corresponds to Host A, Host B, and Host C in the previous figure.

For a host that is assigned a public IPv4 address and does not receive a router advertisement for a global prefix, a 6to4 address of the form 2002:*WWXX*:*YYZZ*::*WWXX*:*YYZZ* is automatically assigned to the 6to4 Tunneling Pseudo-Interface. A 2002::/16 route using the 6to4 Tunneling Pseudo-Interface is added, and, if the DNS query for the 6to4 relay router is successful, a default route using the 6to4 address of the 6to4 relay router as the next hop is added. This configuration corresponds to Host E in the previous figure, a host that is directly connected to the IPv4 Internet. In this case, the host is acting as its own site and its own 6to4 router.

The 6to4 component can also enable a computer running Windows Server 2003 as a 6to4 router by utilizing the configuration of the Internet Connection Sharing (ICS) feature. This configuration corresponds to 6to4 router 1 and 6to4 router 2 in the previous figure.

If ICS is enabled on an interface that is assigned a public IPv4 address, the 6to4 component automatically:

- Enables IPv6 forwarding on both the public and private interfaces.

  The public interface is connected to the Internet. The private interface is connected to a single-subnet intranet and uses private IPv4 addresses from the 192.168.0.0/24 prefix.

- Sends Router Advertisement messages on the private interface.

  The router advertisements advertise the ICS computer as a default router and contain a global 6to4 address prefix that is based on the public IPv4 address assigned to the public interface. The Subnet ID in the 6to4 address prefix is set to the interface index of the interface on which the advertisements are sent.

For example, for an ICS computer using the public IPv4 address of 131.107.23.89 and interface 5 as the private interface, the advertised prefix would be 2002:836B:1759:5::/64. Private hosts that receive this router advertisement would create global addresses through normal address autoconfiguration. The hosts would also add a 2002:836B:1759:5::/64 route for the local subnet and a default route with a next-hop address of the link-local address of the ICS computer's private interface. Private hosts can communicate with each other on the same subnet using the 2002:836B:1759:5::/64 route. For all other 6to4 sites or the IPv6 Internet, the IPv6 packets are forwarded to the ICS computer using the default route.

For traffic to other 6to4 sites, the ICS computer uses its 2002::/16 route and encapsulates the IPv6 traffic with IPv4 headers and

sends the packets across the IPv4 Internet to another 6to4 router. For all other IPv6 traffic, the ICS computer uses its default route and encapsulates the IPv6 traffic with IPv4 headers and sends the packets across the IPv4 Internet to a 6to4 relay router.

**Note**

- The 6to4 component does not perform network address translation on the IPv6 packets that it forwards. ICS translates network addresses for IPv4 packets being forwarded to and from private hosts. The 6to4 component uses the ICS configuration to determine the public IPv4 address and public interface.

**ISATAP**

ISATAP is a technology that assigns addresses, configures tunnels between hosts and between routers and hosts, and provides unicast IPv6 connectivity between IPv6 hosts across an IPv4 intranet. ISATAP is described in the Internet draft titled "Intra-Site Automatic Tunnel Addressing Protocol (ISATAP)." ISATAP hosts do not require any manual configuration, and they create ISATAP addresses using standard mechanisms for address autoconfiguration.

IPv6/IPv4 nodes can use ISATAP to communicate on an IPv4 network. ISATAP addresses use the locally administered interface identifier ::0:5EFE:*w.x.y.z* where the *w.x.y.z* portion is any public or private unicast IPv4 address.

The ISATAP interface identifier can be combined with any 64-bit prefix that is valid for IPv6 unicast addresses. This includes the link-local address prefix (FE80::/64) and global prefixes (including 6to4 prefixes).

Like IPv4-compatible addresses, 6over4 addresses, and 6to4 addresses, ISATAP addresses contain embedded IPv4 addresses that are used to determine either the source or destination IPv4 addresses within the IPv4 header when ISATAP-addressed IPv6 traffic is tunneled across an IPv4 network.

By default, the IPv6 protocol for Windows Server 2003 automatically configures the link-local ISATAP address of FE80::5EFE:*w.x.y.z* on the Automatic Tunneling Pseudo-Interface (interface index 2) for each IPv4 address that is assigned to the node. This link-local ISATAP address allows two hosts to communicate over an IPv4 network by using each other's link-local ISATAP addresses.

For example, Host A is configured with the IPv4 address of 10.40.1.29, and Host B is configured with the IPv4 address of 192.168.41.30. When the IPv6 protocol for Windows Server 2003 is started, Host A is automatically configured with the ISATAP address of FE80::5EFE:10.40.1.29, and Host B is automatically configured with the ISATAP address of FE80::5EFE:192.168.41.30. The following figure shows this configuration.

**An Example ISATAP Configuration**

When Host A sends IPv6 traffic to Host B by using Host B's link-local ISATAP address, the source and destination addresses for the IPv6 and IPv4 headers are as listed in the following table.

**Example Link-Local ISATAP Addresses**

| Field | Value |
|---|---|
| IPv6 Source Address | FE80::5EFE:10.40.1.29 |
| IPv6 Destination Address | FE80::5EFE:192.168.41.30 |
| IPv4 Source Address | 10.40.1.29 |
| IPv4 Destination Address | 192.168.41.30 |

To test connectivity, use the ping command. For example, Host A would use the following command to ping Host B by using its link-local ISATAP address:

```
ping FE80::5EFE:192.168.41.30%2
```

Because the destination of the ping command is a link-local address, the *%ZoneID* portion of the command specifies the interface index of the interface from which traffic is sent. In this case, %2 specifies interface 2, which is the interface index assigned to the Automatic Tunneling Pseudo-Interface on Host A. The Automatic Tunneling Pseudo-Interface uses the link-local ISATAP address assigned to the interface as a source. The Automatic Tunneling Pseudo-Interface also uses the last 32 bits in the source and destination IPv6 addresses (corresponding to the embedded IPv4 addresses) as the source and destination IPv4 addresses.

**ISATAP Router**

The use of link-local ISATAP addresses allows IPv6/IPv4 hosts on the same logical subnet (an IPv4 network) to communicate with each other, but not with other IPv6 addresses on other subnets. To communicate outside the logical subnet using ISATAP-derived global addresses, IPv6 hosts using ISATAP addresses must tunnel their packets to an ISATAP router. The following figure shows this configuration.

**An ISATAP Router**

An ISATAP router is an IPv6 router that:

- Forwards packets between ISATAP hosts on a logical subnet (an IPv4 network) and hosts on other subnets.

  The other subnets can be other IPv4 networks (such as a portion of an organization network or the IPv4 Internet) or subnets in a native IPv6 routing domain (such as an organization's IPv6 network or the IPv6 Internet).

- Acts as a default router for ISATAP hosts.

- Advertises address prefixes to identify the logical subnet on which ISATAP hosts are located. ISATAP hosts use the advertised address prefixes to configure global ISATAP addresses.

When an ISATAP host receives a Router Advertisement message from an ISATAP router, a default route (::/0) is added using the Automatic Tunneling Pseudo-Interface with next-hop address set to the link-local ISATAP address that corresponds to the logical subnet interface of the ISATAP router. When packets destined to locations outside the logical subnet are sent, they are tunneled to the IPv4 address that corresponds to the ISATAP router's interface on the logical subnet defined by the IPv4 network containing the ISATAP router and ISATAP host. The ISATAP router then forwards the IPv6 packet.

For the IPv6 protocol for Windows Server 2003, the configuration of the intranet IPv4 address of the ISATAP router is obtained through one of the following:

- The resolution of the name ISATAP to an IPv4 address.

- The **netsh interface ipv6 isatap set router** command.

**Resolving the ISATAP Name**

When the IPv6 protocol for Windows Server 2003 starts, it attempts to resolve the name "ISATAP" to an IPv4 address using normal TCP/IP name resolution techniques. These techniques include the following:

1. Checking the local host name.

2. Checking the DNS client resolver cache, which includes the entries in the Hosts file. This file is located in the *systemroot*\system32\drivers\etc folder.

3. Forming a fully qualified domain name and sending a DNS name query. For example, if the computer running Windows Server 2003 is a member of the example.microsoft.com domain (and example.microsoft.com is the only domain name in the search list), the computer sends a DNS query to resolve the name isatap.example.microsoft.com.

4. Converting the ISATAP name into the NetBIOS name "ISATAP <00>" and checking the NetBIOS name cache.

5. Sending a NetBIOS name query to the configured Windows Internet Name Service (WINS) servers.

6. Sending NetBIOS broadcasts.

7. Checking the Lmhosts file. This file is located in the *systemroot*\system32\drivers\etc folder.

If the name is resolved, the host sends an IPv4-encapsulated Router Solicitation message to the ISATAP router. The ISATAP router responds with an IPv4-encapsulated unicast Router Advertisement message that contains prefixes to use for autoconfiguring ISATAP-based addresses and, optionally, advertising itself as a default router.

To ensure that at least one of these attempts is successful, you can do one of the following:

- If the ISATAP router is a computer running Windows Server 2003, name the computer ISATAP, and it will automatically register the appropriate records in DNS and WINS.

- Manually create an ISATAP address (A) record in the appropriate domain in DNS. For example, create an A record for isatap.example.microsoft.com.

- Manually create a static WINS record in WINS for the NetBIOS name "ISATAP <00>."

- Add the following entry to the Hosts file of the computers that need to resolve the name ISATAP:

  IPv4Address ISATAP

- Add the following entry to the Lmhosts file of the computers that need to resolve the name ISATAP:

  IPv4Address ISATAP

**Resolving the _ISATAP Name for Windows XP (without SP1)**
When the IPv6 protocol for Windows XP (without SP1) starts, it attempts to resolve the name "_ISATAP," rather than "ISATAP." To ensure that a computer running Windows XP (without SP1) can resolve the name _ISATAP, you can do one of the following:

- Manually create _ISATAP canonical name (CNAME) records in the appropriate domains in DNS. A CNAME record maps a name that is an alias to another name. For example, assuming that an A record already exists for the name isatap.example.microsoft.com, create a CNAME record that maps _isatap.example.microsoft.com to isatap.example.microsoft.com.

- Manually create a static WINS record for the NetBIOS name "_ISATAP <00>."

- Add the following entry to the Hosts file of the computers running Windows XP:

  *IPv4Address* _ISATAP

- Add the following entry to the Lmhosts file of the computers running Windows XP:

  *IPv4Address* _ISATAP

### Note

- Windows XP with SP1 attempts to resolve the name "ISATAP" to determine the IPv4 address of the ISATAP router. The methods described here are not needed if all your computers are running either Windows Server 2003 or Windows XP with SP1.

**Using the Netsh Interface Ipv6 Isatap Set Router Command**
Although the automatic resolution of the ISATAP name is the recommended method for configuring the IPv4 address of the ISATAP router, you can configure this address manually by using the **netsh interface ipv6 isatap set router** command. The syntax of this command is:

**netsh interface ipv6 isatap set router** *AddressOrName*

where *AddressOrName* is the name or IPv4 address of the ISATAP router's intranet interface. For example, if the ISATAP router's IPv4 address is 192.168.39.1, the command is:

**netsh interface ipv6 isatap set router 192.168.39.1**

After a host has been configured, it sends an IPv4-encapsulated Router Solicitation message to the ISATAP router. The ISATAP router responds with an IPv4-encapsulated unicast Router Advertisement message that contains prefixes to use for autoconfiguring ISATAP-based addresses. This additional configuration is needed only when no IPv6 router is on the host's subnet.

**ISATAP and 6to4 Example**
The following figure shows two ISATAP hosts that are using 6to4 prefixes to communicate across the Internet even though each site is using the 192.168.0.0/16 private address space internally.

**Communication Between ISATAP Hosts in Different 6to4 Sites**

In this configuration:

- ISATAP Host A automatically configures a link-local ISATAP address of FE80::5EFE:192.168.12.9 on its Automatic Tunneling Pseudo-Interface.
- 6to4 Router A automatically configures a link-local ISATAP address of FE80::5EFE:192.168.204.1 on its Automatic Tunneling Pseudo-Interface.
- 6to4 Router B automatically configures a link-local ISATAP address of FE80::5EFE:192.168.39.1 on its Automatic Tunneling Pseudo-Interface.
- ISATAP Host B automatically configures a link-local ISATAP address of FE80::5EFE:192.168.141.30 on its Automatic Tunneling Pseudo-Interface.

ISATAP Host A can reach 6to4 Router A and all other hosts within Site A using link-local ISATAP addresses. However, ISATAP Host A cannot reach any addresses outside Site A. 6to4 Router A constructs the global prefix 2002:9D36:1:5::/64. (9D36:1 is the colon-hexadecimal notation for 157.54.0.1 and 5 is the interface index of 6to4 Router A's intranet interface.) 6to4 Router A also advertises the prefix using a Router Advertisement message on its intranet interface. However, ISATAP Host A is not on 6to4

Router A's subnet and will never create a global address based on this 6to4 prefix.

To configure ISATAP Host A to receive the router advertisement from 6to4 Router A, the network administrator for Site A has configured 6to4 Router A as an ISATAP router. The administrator has also added an A record to Site A's DNS infrastructure so that the name ISATAP is resolved to the IPv4 address of 192.168.204.1. Upon startup, the IPv6 protocol on Host A resolves the ISATAP name and sends a Router Solicitation message to the addresses listed in the following table.

**Addresses in the Router Solicitation Message**

| Field | Value |
|---|---|
| IPv6 Source Address | FE80::5EFE:192.168.12.9 |
| IPv6 Destination Address | FF02::2 |
| IPv4 Source Address | 192.168.12.9 |
| IPv4 Destination Address | 192.168.204.1 |

6to4 Router A receives the Router Solicitation message from ISATAP Host A and sends back a unicast Router Advertisement message advertising itself as a default router with a Prefix Information option to automatically configure IPv6 addresses using the prefix 2002:9D36:1:2::/64. (9D36:1 is the colon-hexadecimal notation for 157.54.0.1, and 2 is the interface index of 6to4 Router A's Automatic Tunneling Pseudo-Interface.)

The Router Advertisement message is sent to the addresses listed in the following table.

**Addresses in the Router Advertisement Message**

| Field | Value |
|---|---|
| IPv6 Source Address | FE80::5EFE:192.168.204.1 |
| IPv6 Destination Address | FE80::5EFE:192.168.12.9 |
| IPv4 Source Address | 192.168.204.1 |
| IPv4 Destination Address | 192.168.12.9 |

ISATAP Host A receives the Router Advertisement message and autoconfigures the address 2002:9D36:1:2:0:5EFE:192.168.12.9. The host also configures a default route (::/0) using the Automatic Tunneling Pseudo-Interface (interface index 2) with the next-hop address of FE80::5EFE:192.168.204.1 and a 2002:9D36:1:2::/64 route using the Automatic Tunneling Pseudo-Interface.

Similarly, 6to4 Router B is configured as an ISATAP router, and Site B has an appropriate A record in its DNS infrastructure so that ISATAP Host B autoconfigures the address 2002:836B:1:2:0:5EFE:192.168.141.30. (836B:1 is the colon-hexadecimal notation for 131.107.0.1.) ISATAP Host B also configures a default route (::/0) using the Automatic Tunneling Pseudo-Interface (interface index 2) with the next-hop address of FE80::5EFE:192.168.39.1 and a 2002:836B:1:2::/64 route using the Automatic Tunneling Pseudo-Interface.

ISATAP Host A can now send a packet to ISATAP B. Packet addressing comprises three parts (as shown in the previous figure during the packet's trip from ISATAP Host A to ISATAP Host B).

**Part 1: from ISATAP Host A to 6to4 Router A**

ISATAP Host A sends the IPv6 packet with the ::/0 route that uses the Automatic Tunneling Pseudo-Interface to the next-hop address of FE80::5EFE:192.168.204.1. By using this route, the next-hop address for this packet is set to the link-local ISATAP address of 6to4 Router A (FE80::5EFE:192.168.204.1).

Using the Automatic Tunneling Pseudo-Interface, the packet is tunneled using IPv4 from the address assigned to its intranet interface (192.168.12.9) to the embedded address in the ISATAP interface ID of the next-hop address (192.168.204.1). The resulting addresses are listed in the following table.

**Addresses in Part 1**

| Field | Value |
|---|---|

| | |
|---|---|
| IPv6 Source Address | 2002:9D36:1:2:0:5EFE:192.168.12.9 |
| IPv6 Destination Address | 2002:836B:1:2:0:5EFE:192.168.141.30 |
| IPv4 Source Address | 192.168.12.9 |
| IPv4 Destination Address | 192.168.204.1 |

**Part 2: from 6to4 Router A to 6to4 Router B**

6to4 Router A receives the IPv4 packet and removes the IPv4 header. 6to4 Router A then forwards the IPv6 packet with the 2002::/16 route that uses the 6to4 Tunneling Pseudo-Interface. The router, by using this route, ensures that the next-hop address for this packet is set to the destination address (2002:836B:1:2:0:5EFE:192.168.141.30).

The packet is tunneled using IPv4 and the 6to4 Tunneling Pseudo-Interface from the address assigned to its Internet interface (157.54.0.1) to the embedded address in the 6to4 prefix (836B:1) of the next-hop address (131.107.0.1). The resulting addresses are listed in the following table.

**Addresses in Part 2**

| Field | Value |
|---|---|
| IPv6 Source Address | 2002:9D36:1:2:0:5EFE:192.168.12.9 |
| IPv6 Destination Address | 2002:836B:1:2:0:5EFE:192.168.141.30 |
| IPv4 Source Address | 157.54.0.1 |
| IPv4 Destination Address | 131.107.0.1 |

**Part 3: from 6to4 Router B to ISATAP Host B**

6to4 Router B receives the IPv4 packet and removes the IPv4 header. 6to4 Router B then forwards the IPv6 packet with the 2002:836B:1:2::/64 route that uses the ISATAP Automatic Tunneling Pseudo-Interface. The router, by using this route, ensures that the next-hop address for this packet is set to the destination address (2002:836B:1:2:0:5EFE:192.168.141.30).

Because the packet is forwarded using Automatic Tunneling Pseudo-Interface, the packet is tunneled using IPv4 from the address assigned to its intranet interface (192.168.39.1) to the embedded address in the ISATAP interface ID of the next-hop IPv6 address (192.168.141.30). 6to4 Router B sets the addresses in the forwarded packet as listed in the following table.

**Addresses in Part 3**

| Field | Value |
|---|---|
| IPv6 Source Address | 2002:9D36:1:2:0:5EFE:192.168.12.9 |
| IPv6 Destination Address | 2002:836B:1:2:0:5EFE:192.168.141.30 |
| IPv4 Source Address | 192.168.39.1 |
| IPv4 Destination Address | 192.168.141.30 |

**PortProxy**

To facilitate communication between nodes or applications that cannot connect using a common Internet layer protocol (IPv4 or IPv6), the IPv6 protocol for Windows Server 2003 provides PortProxy, a component that allows the following traffic to be proxied:

- IPv4 to IPv4

  TCP traffic to an IPv4 address is proxied to TCP traffic to another IPv4 address.

- IPv4 to IPv6

  TCP traffic to an IPv4 address is proxied to TCP traffic to an IPv6 address.

- IPv6 to IPv6

TCP traffic to an IPv6 address is proxied to TCP traffic to another IPv6 address.

- IPv6 to IPv4

  TCP traffic to an IPv6 address is proxied to TCP traffic to an IPv4 address.

  The most interesting and useful proxying for IPv6/IPv4 coexistence and migration is from IPv4 to IPv6 and from IPv6 to IPv4. For coexistence and migration, PortProxy enables the following scenarios:

- An IPv4-only node can access an IPv6-only node.

  In the IPv4 DNS infrastructure of the IPv4-only node, the name of the IPv6-only node resolves to an IPv4 address assigned to an interface of the PortProxy computer. (Resolving this name might require an A record to be configured manually in DNS.) The PortProxy computer is configured to proxy IPv4 to IPv6. All TCP traffic sent by the IPv4-only node is proxied in a manner similar to Internet proxy servers: the IPv4-only node establishes a TCP connection with the PortProxy computer, and the PortProxy computer establishes a separate TCP connection with the IPv6-only node. The TCP connection data is transferred between the IPv4-only node and the IPv6-only node by the PortProxy component.

- An IPv6-only node can access an IPv4-only node.

  In the IPv6 DNS infrastructure of the IPv6-only node, the name of the IPv4-only node resolves to an IPv6 address assigned to an interface of the PortProxy computer. (Resolving this name might require AAAA records to be manually configured in DNS.) The PortProxy computer is configured to proxy IPv6 to IPv4. TCP traffic sent by the IPv6-only node to the PortProxy computer is proxied to the IPv4-only node.

- An IPv6 node can access an IPv4-only service running on a PortProxy computer.

  In the IPv6 DNS infrastructure of the IPv6-only node, the name of the IPv6/IPv4 node resolves to an IPv6 address assigned to an interface of the PortProxy computer. The PortProxy computer is configured to proxy from IPv6 to IPv4 on itself. TCP traffic sent by the IPv6 node to the PortProxy computer is proxied to an IPv4-only service or application running on the PortProxy computer.

The last scenario allows IPv6 nodes to access services that are running on a server that does not support IPv6. For example, Windows Server 2003 includes Telnet Client, which supports IPv6, and Telnet Server, which does not. However, you can allow IPv6 nodes to access the Telnet service by running PortProxy on the computer that is running Telnet Server.

To configure the PortProxy component, use the **netsh interface portproxy add|set|delete v4tov4|v4tov6|v6tov4|v6tov6** commands. For example, use the **netsh interface portproxy add v6tov4 23** command to enable IPv6 on the Telnet service (using TCP port 23) on a computer that is running Windows Server 2003.

By default, the IPv6/IPv4 node that is running Telnet Server dynamically registers both its IPv6 and IPv4 addresses in DNS. By default, a computer that is running Windows Server 2003 queries DNS for all record types, preferring IPv6 addresses to IPv4 addresses. When the Telnet client is a computer that is running Windows Server 2003, it attempts to connect using IPv6 first. With PortProxy properly configured, the first attempt to connect using an IPv6 address of the computer that is running Telnet Server should succeed without manual configuration of DNS records.

**Note**

- The PortProxy component is provided only with the IPv6 protocol for Windows Server 2003.

- The PortProxy component works only for TCP traffic and for application-layer protocols that do not embed address or port information inside the upper-layer PDU. PortProxy has no facilities to check for and change embedded address or port information in upper layer PDUs that are being proxied. For example, PortProxy cannot enable the FTP server service for IPv6 because the FTP PORT command embeds IPv4 address information inside the FTP PDU.

**IPv6 Automatic Tunneling**

RFC 2893 defines IPv6 Automatic Tunneling as the tunneling that occurs when IPv4-compatible addresses (::*w.x.y.z* where *w.x.y.z* is a public IPv4 address) are used. IPv6 Automatic Tunneling is a host-to-host tunnel between two IPv6/IPv4 hosts using IPv4-compatible addresses.

For example, when Host1 (with the public IPv4 address of 157.60.91.123 and corresponding IPv4-compatible address of ::157.60.91.123) sends traffic to Host2 (with the IPv4 address of 131.107.210.49 and corresponding IPv4-compatible address of ::131.107.210.49), the addresses in the IPv4 and IPv6 headers are as listed in the following table.

**Example IPv6 Automatic Tunneling Addresses**

| Field | Value |
|---|---|
| IPv6 Source Address | ::157.60.91.123 |
| IPv6 Destination Address | ::131.107.210.49 |
| IPv4 Source Address | 157.60.91.123 |
| IPv4 Destination Address | 131.107.210.49 |

To test connectivity, use the ping command. For example, Host A would use the following command to ping Host B by using its IPv4-compatible address:

```
ping ::131.107.210.49
```

The IPv6 protocol for Windows Server 2003 does not use IPv4-compatible addresses by default. To enable IPv4-compatible addresses, use the **netsh interface ipv6 set state v4compat=enabled** command. When the IPv6 protocol for Windows Server 2003 is enabled, communication to IPv4-compatible addresses is facilitated by a ::/96 route in the IPv6 routing table that uses the Automatic Tunneling Pseudo-Interface (interface index 2). This route indicates that all packets with destination addresses in which the first 96 bits are set to 0 are forwarded to their destination addresses with the Automatic Tunneling Pseudo-Interface. The Automatic Tunneling Pseudo-Interface uses the last 32 bits in the source and destination IPv6 addresses (corresponding to the embedded IPv4 addresses) as the source and destination IPv4 addresses for the outgoing IPv4 packet.

**Note**

- In this section, the term "IPv6 Automatic Tunneling" refers to the use of IPv4-compatible addresses. The term "automatic tunneling" is tunneling that occurs without manual configuration, independent of the type of addressing being used.

- IPv4-compatible addresses are not widely used because they are defined only for public IPv4 addresses, and their functionality has been replaced with ISATAP for IPv4 intranets and 6to4 for the IPv4 Internet. For more information, see "ISATAP" and "6to4" earlier in this section.

#### 6over4

6over4, also known as IPv4 multicast tunneling, is a technology that automatically configures tunnels between hosts, between routers, and between hosts and routers. 6over4 provides unicast and multicast connectivity between IPv6 nodes across an IPv4 intranet. RFC 2529 describes 6over4. 6over4 hosts use a valid 64-bit prefix for unicast addresses and the interface identifier ::*WWXX*:*YYZZ*, where *WWXX*:*YYZZ* is the colon-hexadecimal representation of the IPv4 address (*w.x.y.z*) that is assigned to the host. By default, 6over4 hosts automatically configure the link-local address FE80::*WWXX*:*YYZZ* on each 6over4 interface.

6over4 treats an IPv4 infrastructure as a single link with multicast capabilities. Neighbor Discovery processes (such as address resolution and router discovery) work over a physical link with multicast capabilities. To emulate a multicast-capable link, the IPv4 infrastructure must be enabled for IPv4 multicast traffic. The following figure shows a 6over4 configuration.

**A 6over4 Configuration**

To facilitate IPv6 multicast communication over an infrastructure that is enabled for IPv4 multicast traffic, RFC 2529 defines the following mapping to translate an IPv6 multicast address to an IPv4 multicast address:

239.192.[*second to last byte of IPv6 address*].[*last byte of IPv6 address*]

The following are example mappings for IPv6 multicast addresses:

- FF02::1 (link-local scope all-hosts multicast address) is mapped to 239.192.0.1.
- FF02::2 (link-local scope all-routers multicast address) is mapped to 239.192.0.2.
- FF02::1:FF28:9C5A (example solicited-node multicast address) is mapped to 239.192.156.90.

When 6over4 is enabled, the IPv4 layer uses Internet Group Membership Protocol (IGMP) messages to inform local IPv4 routers that it will receive IPv4 multicast traffic that is sent to the mapped IPv4 multicast addresses. Hosts that are enabled for 6over4 also register additional multicast MAC addresses with their network adapters that correspond to the mapped IPv4 multicast addresses. For example, for an Ethernet adapter:

- The corresponding multicast MAC address for 239.192.0.1 is 01-00-5E-40-00-01.
- The corresponding multicast MAC address for 239.192.0.2 is 01-00-5E-40-00-02.
- The corresponding multicast MAC address for 239.192.156.90 is 01-00-5E-40-9C-5A.

Because the IPv4 infrastructure acts as a multicast-capable link, hosts can use Neighbor Solicitation and Neighbor Advertisement messages to resolve each other's link-layer addresses. The 6over4 link-layer addresses are the tunnel endpoints. Hosts and routers can use Router Solicitation and Router Advertisement messages for router, prefix, and parameter discovery. The following figure shows the format for the Source and Target Link-Layer Address options that, as defined in RFC 2529, facilitate Neighbor Discovery.

**Source and Target Link-Layer Address Options for 6over4**

For example, Host1 has the public IPv4 address of 157.60.91.123 and corresponding link-local 6over4 address of FE80::9D3C:5B7B. Host2 has the public IPv4 address of 131.107.210.49 and corresponding link-local 6over4 address of FE80::836B:D231. When Host 1 sends traffic to Host 2, the addresses in the IPv4 and IPv6 headers are as listed in the following table.

**Example 6over4 Addresses**

| Field | Value |
|---|---|

| | |
|---|---|
| IPv6 Source Address | FE80::9D3C:5B7B |
| IPv6 Destination Address | FE80::836B:D231 |
| IPv4 Source Address | 157.60.91.123 |
| IPv4 Destination Address | 131.107.210.49 |

The use of 6over4 for the IPv6 protocol for Windows Server 2003 is disabled by default. To enable the use of 6over4, use the **netsh interface ipv6 set state 6over4=enabled** command. This command creates a 6over4 tunneling interface for each IPv4 address assigned to the computer. If the computer receives Router Advertisement messages over any of these interfaces (through the multicast mapping mechanism described earlier), appropriate addresses for this interface and routes that use this interface are automatically configured.

Routes and the 6over4 tunneling interface facilitate communication to 6over4 addresses. For example, the interface index for the 6over4 tunneling interface of a host is 5. (The actual interface index for the 6over4 tunneling interface varies depending on the configuration of the computer.) A Router Advertisement message from a router with the link-local 6over4 address of FE80::C0A8:1501 is received. The router is advertised as a default router, and the message contains the auto-configuration prefix FEC0:0:0:21A8::/64. The host configures a default route with the next-hop address of FE80::C0A8:1501 and a subnet route for prefix FEC0:0:0:21A8::/64 that uses interface index 5.

When packets are sent using the default or FEC0:0:0:21A8::/64 routes, the sending host uses the appropriate locally assigned 6over4 address as a source. The node also uses the last 32 bits in the source and destination IPv6 addresses (corresponding to the embedded IPv4 addresses) as the source and destination IPv4 addresses for the outgoing IPv4 packet.

A packet to a destination that matches the prefix FEC0:0:0:21A8::/64 is sent to the next-hop address of the destination using the 6over4 tunneling interface. The 6over4 tunneling interface uses address resolution for the destination address to determine the source and destination link-layer addresses (and corresponding IPv4 addresses) to use when sending the IPv4-encapsulated IPv6 packet.

A packet to a destination that matches the default route is sent to the next-hop address of FE80::C0A8:1501 using the 6over4 tunneling interface. The 6over4 tunneling interface uses address resolution for the next-hop address to determine the source and destination link-layer addresses (and corresponding IPv4 addresses) to use when sending the IPv4-encapsulated IPv6 packet.

**Note**

- 6over4 is not widely used because it requires an IPv4 multicast infrastructure.
- The difference between using ISATAP versus 6over4 on an IPv4 intranet is that 6over4 supports IPv6 multicast, and ISATAP currently does not.
- When you enable 6over4 with the **netsh interface ipv6 set state 6over4=enabled** command, it creates a 6over4 tunneling interface with a name that is based on a globally unique identifier (GUID). To create a 6over4 tunneling interface with a friendlier name, use the **netsh interface ipv6 add 6over4tunnel** command instead.

**Teredo**

Teredo, also known as IPv4 network address translation (NAT) traversal for IPv6, is an IPv6/IPv4 transition technology. Teredo provides address assignment and host-to-host automatic tunneling for unicast IPv6 connectivity when IPv6/IPv4 hosts are located behind one or multiple IPv4 NATs. To traverse IPv4 NATs, IPv6 packets are sent as IPv4-based User Datagram Protocol (UDP) messages. This section provides an overview of Teredo — including Teredo addresses and packet structures — and detailed explanations of how communication is initiated between Teredo clients, Teredo host-specific relays, and IPv6-only hosts that use the IPv4 Internet, the IPv6 Internet, Teredo servers, and Teredo relays.

Teredo is an address assignment and automatic tunneling technology that provides unicast IPv6 connectivity across the IPv4 Internet. 6to4 is a well-defined automatic tunneling technology that provides unicast IPv6 connectivity across the IPv4 Internet. However 6to4 works best when a 6to4 router exists at the edge of the site. The 6to4 router uses a public IPv4 address to construct the 6to4 prefix and acts as an IPv6 advertising and forwarding router. The 6to4 router encapsulates and decapsulates IPv6 traffic sent to and from site nodes.

6to4 relies on the configuration of a public IPv4 address and the implementation of 6to4 routing functionality in the edge device. Many small office/home office (SOHO) configurations include an IPv4 network address translator (NAT). For more

information about how network address translation works, see "Overview of Network Address Translators (NATs)" later in this section. In most NAT configurations, the device providing NAT functionality is not capable of being a 6to4 router. Even if all NAT devices could support 6to4, some configurations contain multiple levels of NATs. In these configurations, a 6to4-capable NAT device will not work because it does not have a public IPv4 address.

Teredo fills the need for 6to4 functionality in modern-day NATs and multi-layered NAT configurations by tunneling IPv6 packets between the hosts within the sites. In contrast, 6to4 uses tunneling from the edge device. Tunneling between hosts presents another issue for NATs: IPv4-encapsulated IPv6 packets are sent with the Protocol field in the IPv4 header set to 41. Most NATs translate only TCP or UDP traffic, and they must either be manually configured to translate other protocols or have installed NAT editors that handle the translation. Because Protocol 41 translation is not a common feature of NATs, IPv4-encapsulated IPv6 traffic will not traverse typical NATs. Therefore, to allow IPv6 traffic to traverse one or multiple NATs, the IPv6 packet is encapsulated as an IPv4 UDP message, containing both an IPv4 and a UDP header. UDP messages can be translated universally by NATs and can traverse multiple layers of NATs.

To summarize, Teredo is an IPv6/IPv4 transition technology that allows automatic IPv6 tunneling between hosts that are located across one or more IPv4 NATs. IPv6 traffic from Teredo hosts can traverse NATs because it is sent as IPv4 UDP messages. If a NAT supports UDP port translation, then the NAT supports Teredo. The exception is a symmetric NAT. For more information, see "Types of NATs" later in this section.

Teredo is designed as a last-resort transition technology for IPv6 connectivity. If native IPv6, 6to4, or ISATAP connectivity is present, the host does not act as a Teredo client. As more IPv4 NATs are upgraded to support 6to4 and IPv6 connectivity becomes ubiquitous, Teredo will be used less and less and eventually eliminated.

**Network Address Translators**

As defined in RFC 1631, a network address translator (NAT) is an IPv4 router that can translate the IP addresses and TCP/UDP port numbers of packets as it forwards them. For example, consider a small business network with multiple computers that connect to the Internet. Without a NAT, this business would need to obtain a public IP address for each computer on the network. With a NAT, however, the small business can use private addressing (as described in RFC 1918) and have the NAT map its private addresses to a single or to multiple public IP addresses.

NAT is a common solution for the following combination of requirements:

- The administrator wants to leverage a single connection over multiple computers, rather than connecting each one to the Internet.
- The administrator wants to use private addressing.
- The administrator wants to allow access to Internet resources without having to deploy a proxy server.

**How network address translation works**

When a private user on the small business intranet connects to an Internet resource, the user's TCP/IP protocol creates an IP packet with the following values set in the IP and TCP or UDP headers (bold text indicates the fields that are affected by the NAT):

- Destination IP Address: IP address of the Internet resource
- Source IP Address: **Private IP address**
- Destination Port: TCP or UDP port of the Internet resource
- Source Port: **Source application TCP or UDP port**

The source host or another router forwards this IP packet to the NAT, which translates the addresses of the outgoing packet as follows:

- Destination IP Address: IP address of the Internet resource
- Source IP Address: **ISP-allocated public address**
- Destination Port: TCP or UDP port of the Internet resource

- Source Port: **Remapped source application TCP or UDP port**

The NAT sends the remapped IP packet over the Internet. The responding computer sends back a response to the NAT. The response contains the following addressing information:

- Destination IP Address: ISP-allocated public address
- Source IP Address: IP address of the Internet resource
- Destination Port: Remapped source application TCP or UDP port
- Source Port: TCP or UDP port of the Internet resource

When the NAT maps and translates the addresses and forwards the packet to the intranet client, the packet contains the following addressing information:

- Destination IP Address: **Private IP address**
- Source IP Address: IP address of the Internet resource
- Destination Port: **Source application TCP or UDP port**
- Source Port: TCP or UDP port of the Internet resource

For outgoing packets, the source IP address and TCP/UDP port numbers are mapped to a public source IP address and a possibly changed TCP/UDP port number. For incoming packets, the destination IP address and TCP/UDP port numbers are mapped to the private IP address and original TCP/UDP port numbers.

For example, a small business is using the 192.168.0.0/24 private network ID for its intranet and has been allocated a single public IP address of 131.107.0.1 by its ISP. When a user with the private address 192.168.0.99 on the small business intranet connects to a Web server at the IP address 157.60.0.1, the user's TCP/IP protocol creates an IP packet with the following values set in the IP and TCP or UDP headers:

- Destination IP Address: 157.60.0.1
- Source IP Address: **192.168.0.99**
- Destination Port: 80
- Source Port: **1025**

The source host forwards this packet to the NAT device, which translates the addresses of the outgoing packet as follows:

- Destination IP Address: 157.60.0.1
- Source IP Address: **131.107.0.1**
- Destination Port: 80
- Source Port: **5000**

The NAT sends the remapped packet over the Internet. The Web server sends back a response to the NAT. The response contains the following addressing information:

- Destination IP Address: **131.107.0.1**

- Source IP Address: 157.60.0.1
- Destination Port: **5000**
- Source Port: 80

When the NAT maps and translates the addresses and forwards the packet to the intranet client, the packet contains the following addressing information:

- Destination IP Address: **192.168.0.99**
- Source IP Address: 157.60.0.1
- Destination Port: **1025**
- Source Port: 80

The following figure shows the configuration for this example.

**NAT example**

The mappings for private to public traffic are stored in a NAT translation table, which can contain two types of entries:

- Dynamic mappings

  Created when private network clients initiate communication. Dynamic mappings are removed from the NAT translation table after a specified amount of time, unless traffic that corresponds to the mapping refreshes it.

- Static mappings

  Configured manually so that communication that Internet clients initiate can be mapped to specific private network addresses and ports. Static mappings are needed when you want to make servers (for example, Web servers) or applications (for example, games) on the private network available to computers that are connected to the Internet. Static mappings are not automatically removed from the NAT translation table.

The NAT forwards traffic from the Internet to the private network only if the NAT translation table contains an appropriate mapping. In this way, the NAT provides a level of protection for computers that are connected to private network segments. However, a NAT should not be used in place of a fully featured firewall when Internet security is a concern.

**Types of NATs**

NATs fall into the following types:

- Cone NATs

  A NAT in which the NAT translation table entry stores a mapping between an internal address and port number and an external address and port number. When the NAT translation table entry is in place, inbound traffic to the external address and port number from any source address and port number is translated.

- Restricted NATs

  A NAT in which the NAT translation table entry stores a mapping between an internal address and port number and an external address and port number, for either specific source addresses or specific source address and port numbers. An inbound packet from an unknown external address or port number is silently discarded.

- Symmetric NATs

  A NAT that maps the same internal address and port number to different external addresses and ports, depending on the external destination address (for outbound traffic).

Teredo can work over only cone and restricted NATs. Teredo cannot work over symmetric NATs.

**Teredo Components**
The following figure shows the components of the Teredo infrastructure:

- Teredo clients
- Teredo servers
- Teredo relays
- Teredo host-specific relays

**Components of the Teredo infrastructure**

**Teredo client**
A Teredo client is an IPv6/IPv4 node that supports a Teredo tunneling interface through which packets are tunneled to either other Teredo clients or nodes on the IPv6 Internet (through a Teredo relay). A Teredo client communicates with a Teredo server to obtain an address prefix from which a Teredo-based IPv6 address is configured or to help initiate communication with other Teredo clients or hosts on the IPv6 Internet.

The Advanced Networking Pack for Windows XP includes a Teredo client.

**Teredo server**
A Teredo server is an IPv6/IPv4 node that is connected to both the IPv4 Internet and the IPv6 Internet, supports a Teredo tunneling interface over which packets are received. The general role of the Teredo server is to help configure addresses for Teredo clients and to facilitate the initial communication between Teredo clients and other Teredo clients or between Teredo clients and IPv6-only hosts. The Teredo server listens on UDP port 3544 for Teredo traffic.

The Advanced Networking Pack for Windows XP does not include Teredo server functionality. To facilitate communication between computers using the Advanced Networking Pack for Windows XP, Microsoft has deployed Teredo servers on the IPv4 Internet.

**Teredo relay**
A Teredo relay is an IPv6/IPv4 router that can forward packets between Teredo clients on the IPv4 Internet (using a Teredo tunneling interface) and IPv6-only hosts. In some cases, the Teredo relay interacts with a Teredo server to help it facilitate initial communication between Teredo clients and IPv6-only hosts. The Teredo relay listens on UDP port 3544 for Teredo traffic.

The Advanced Networking Pack for Windows XP does not include Teredo relay functionality. Microsoft does not plan to deploy

any Teredo relays on the IPv4 Internet. Individual Internet service providers (ISPs) could deploy their own Teredo relays. The implementation of the Teredo client in the Advanced Networking Pack for Windows XP will work with a Teredo relay when sending traffic to an IPv6-only host on the IPv6 Internet. Teredo relays are not needed to communicate with Teredo host-specific relays.

**Teredo host-specific relay**

Communication between Teredo clients and IPv6 hosts that are configured with global addresses must go through a Teredo relay. This is required for IPv6-only hosts connected to the IPv6 Internet. However, when the IPv6 host enabled for both IPv6 and IPv4 and connected to both the IPv4 Internet and IPv6 Internet, then communication should occur between the Teredo client and the IPv6 host over the IPv4 Internet, rather than having to traverse the IPv6 Internet and go through a Teredo relay.

A Teredo host-specific relay is an IPv6/IPv4 node that has an interface and connectivity to both the IPv4 Internet and the IPv6 Internet and that can communicate directly with Teredo clients over the IPv4 Internet, without the need for an intermediate Teredo relay. The connectivity to the IPv4 Internet can be through a public IPv4 address or through a private IPv4 address and a neighboring NAT. The connectivity to the IPv6 Internet can be through a direct connection to the IPv6 Internet or through an IPv6 transition technology such as 6to4, where IPv6 packets are tunneled across the IPv4 Internet. The Teredo host-specific relay listens on UDP port 3544 for Teredo traffic.

The implementation of the Teredo client in the Advanced Networking Pack for Windows XP includes Teredo host-specific relay functionality. When the Advanced Networking Pack for Windows XP is installed, the Teredo host-specific relay functionality is automatically enabled if the computer running Windows XP SP1 has a global address assigned. A global address can be assigned from a Router Advertisement message from a native IPv6 router, an ISATAP router, or a 6to4 router. If the computer running Windows XP SP1 does not have a global address, Teredo client functionality is enabled.

The Teredo host-specific relay allows Teredo clients to efficiently communicate with 6to4 hosts, IPv6 hosts with a non-6to4 global prefix, or ISATAP or 6over4 hosts within organizations that use a global prefix for their addresses, provided both hosts are using the Advanced Networking Pack for Windows XP.

**Teredo Addresses**

The following figure shows the format of Teredo addresses.

### Teredo Address Format

A Teredo address consists of the following:

- Teredo prefix (Prefix)

  The first 32 bits are for the Teredo prefix, which is the same for all Teredo addresses. The Internet Assigned Numbers Authority (IANA) has not yet defined this prefix, although the prefix 3FFE:831F::/32 is used for initial deployment.

- Teredo server IPv4 address

  The next 32 bits contain the IPv4 public address of the Teredo server that helped configure this Teredo address.

- Flags

  The next 16 bits for are reserved for Teredo flags. The only defined flag is the high-order bit known as the Cone flag. The Cone flag is set when the NAT that is connected to the Internet is a cone NAT. The determination of whether the NAT that is connected to the Internet is a cone NAT occurs during the initial configuration of a Teredo client.

- Obscured external port

  The next 16 bits store an obscured version of the external UDP port that corresponds to all Teredo traffic for this Teredo client. When the Teredo client sends its initial packet to a Teredo server, the source UDP port of the packet is mapped by the NAT to a different, external UDP port. The Teredo client maintains this port mapping so that it remains in the NAT's translation table. Therefore, all Teredo traffic for the host uses the same external, mapped UDP port. The Teredo server determines the external UDP port from the source UDP port of the incoming initial packet that the Teredo client sent, and the Teredo server sends the port information back to the Teredo client.

  The external port is obscured by XORing the external port with 0xFFFF. For example, the obscured version of external port

5000 in hexadecimal format is EC77 (5000 = 0x1388, 0x1388 XOR 0xFFFF = 0xEC77). Obscuring the external port prevents NATs from translating the external port within the payload of the packets that they are forwarding.

- Obscured external address

  The last 32 bits store an obscured version of the external IPv4 address that corresponds to all Teredo traffic for this Teredo client. Just like the external port, when the Teredo client sends its initial packet to a Teredo server, the source IP address of the packet is mapped by the NAT to a different, external (public) address. The Teredo client maintains this address mapping so that it remains in the NAT's translation table. Therefore, all Teredo traffic for the host uses the same external, mapped, public IPv4 address. The Teredo server determines the external IPv4 address from the source IPv4 address of the incoming initial packet that the Teredo client sent, and the Teredo server sends the address information back to the Teredo client.

  The external address is obscured by XORing the external address with 0xFFFFFFFF. For example, the obscured version of the public IPv4 address 131.107.0.1 in colon-hexadecimal format is 7C94:FFFE (131.107.0.1 = 0x836B0001, 0x836B0001 XOR 0xFFFFFFFF = 0x7C94FFFE). Obscuring the external address prevents NATs from translating the external address within the payload of the packets that they are forwarding.

The following figure shows an example of two Teredo clients and their addressing.

**Teredo Addressing Example**

For Teredo client A, the following are used to construct its Teredo address:

- Its external address and port for its Teredo traffic is 157.60.0.1, UDP port 4096.
- Its Teredo server is at the public IPv4 address of 206.73.118.1.
- It has determined that it is behind a cone NAT.

Therefore, using the Teredo address format of Prefix:*ServerAddr*:Flags:*ObscExtPort*:*ObscExtAddr*, the address for Teredo client A is 3FFE:831F:CE49:7601:8000:EFFF:62C3:FFFE. This address is based on the following:

- CE49:7601 is the colon-hexadecimal version of 206.73.118.1.
- 8000 is the Flags field in which the Cone flag is set to 1, indicating that Teredo client A's

NAT is a cone NAT.

- EFFF is the obscured version of 4096 (0x1000).
- 62C3:FFFE is the obscured version of 157.60.0.1.

For Teredo client B, the following are used to construct its Teredo address:

- Its external address and port for its Teredo traffic is 131.107.0.1, UDP port 8192.
- Its Teredo server is at the public IPv4 address of 206.73.118.1.
- It has determined that it is behind a restricted NAT.

Therefore, using the Teredo address format of Prefix:*ServerAddr*:Flags:*ObscExtPort*:*ObscExtAddr*, the address for Teredo client B is 3FFE:831F:CE49:7601:0:DFFF:7C94:FFFE. This address is based on the following:

- CE49:7601 is the colon-hexadecimal version of 206.73.118.1.
- 0 is the Flags field in which the Cone flag is set to 0, indicating that Teredo client B's NAT is a restricted NAT.
- DFFF is the obscured version of 8192 (0x2000).
- 7C94:FFFE is the obscured version of 131.107.0.1.

Teredo addresses are assigned to Teredo clients only. Teredo servers, relays, and host-specific relays are not assigned Teredo addresses.

**Communicating Using a Teredo Address**
Initial configuration for Teredo clients is accomplished by sending a series of Router Solicitation messages to Teredo servers. The clients use the responses to derive a Teredo address and determine whether they are behind cone, restricted, or symmetric NATs. If a Teredo client is behind a symmetric NAT, then it cannot function. You can see what type of NAT a Teredo client has discovered from the display of the **netsh interface ipv6 show teredo** command.

Based on the Router Advertisement messages that the Teredo client receives, the Teredo client constructs its Teredo address from the following:

- The first 64 bits are set to the value that the Prefix Information option of the Router Advertisement message includes. The 64-bit prefix that the Teredo server advertises consists of the Teredo prefix (32 bits) and the public IPv4 address of the Teredo server (32 bits).
- The next 16 bits are either 0x8000 (cone NAT) or 0x0 (restricted NAT).
- The next 16 bits are set to the obscured external UDP port number that a special Teredo header in the Router Advertisement message includes.
- The last 32 bits are set to the obscured external IP address that a special Teredo header in the Router Advertisement message includes.

The success of initial communication between Teredo clients that are located in different sites depends on whether those sites are using cone NATs or restricted NATs.

When both Teredo clients are located behind cone NATs, the NAT translation table entries for Teredo traffic for each Teredo client allow traffic from any source IP address or source UDP port. Therefore, a Teredo client in one site can send packets directly to a Teredo client in another site without the use of additional packets to establish NAT translation table entries.

When both Teredo clients are located behind restricted NATs, the clients must establish additional NAT translation table entries before they can exchange unicast packets. The following figure shows the initial communication process between Teredo clients that are located in different sites when both sites are using restricted NATs.

**Initial Communication Process Between Teredo Clients that Are Located in Different Sites when Both Sites Are Using Restricted NATs**

To send an initial communication packet from Teredo Client A to Teredo Client B, the following process is used:

1. Teredo Client A sends a bubble packet directly to Teredo Client B. A bubble packet contains no data and is used to create or maintain NAT mappings. Because Teredo Client B is behind a restricted NAT, Teredo traffic from an arbitrary source IPv4 address and UDP port number is not allowed unless the NAT translation table contains a source-specific entry. Assuming that no such entry exists, the restricted NAT silently discards the bubble packet. However, when the restricted NAT for Teredo Client A forwarded the bubble packet, it created a source-specific NAT translation table entry that will allow future packets sent from Teredo Client B to be forwarded to Teredo Client A.

2. Teredo Client A sends a bubble packet to Teredo Client B through Teredo Server 2 (Teredo Client B's Teredo server). The IPv4 destination address in the bubble packet is set to the IPv4 address of Teredo Server 2, which Teredo Client A determines from the third and fourth blocks of Teredo Client B's Teredo address.

3. Teredo Server 2 forwards the bubble packet to Teredo Client B. The restricted NAT for Teredo Client B forwards the packet because a source-specific mapping exists for Teredo traffic from Teredo Server 2 (established by the initial configuration of Teredo Client B).

4. Teredo Client B responds to the bubble packet received from Teredo Client A with its own bubble packet, which is sent directly to Teredo Client A. Because Teredo Client A's restricted NAT has a source-specific mapping for Teredo traffic from Teredo Client B (as established by the initial bubble packet sent from Teredo Client A in step 1), it forwards the bubble packet to Teredo Client A.

5. When Teredo Client A receives the bubble packet from Teredo Client B, Teredo Client A determines that source-specific NAT mappings exist for both NATs. Teredo Client A sends an initial communication packet directly to Teredo Client B.

This process occurs transparently to the user at Teredo Client A.

**Related Information**

For more information about TCP/IP, see "TCP/IP Technical Reference."

The standards for IPv6 are published in a series of documents called Requests for Comments (RFCs). RFCs are an evolving series of reports, proposals for protocols, and protocol standards that describe the internal workings of IPv6 and the Internet.

Although IPv6 standards are always published as RFCs, not all RFCs specify standards. RFCs are authored by individuals who voluntarily write and submit draft proposals for new protocols or specifications to the Internet Engineering Task Force (IETF) and other working groups. Submitted Internet drafts are first reviewed by a technical expert, a task force, or an RFC editor, and then the drafts are assigned a status.

If an Internet draft passes this initial review stage, the IETF circulates it to the larger Internet community for a period of time for further comment and review, and the IETF assigns an RFC number to the draft. This RFC number remains constant.

If the proposed specification changes, the IETF assigns a higher RFC number to the updated draft and circulates it. Higher RFC numbers identify more recent documents.

For more information, see the IETF RFC Database.

**Table of RFCs and Internet Drafts**

The following table lists the RFCs and Internet drafts that relate to the implementation of the IPv6 protocol in Windows Server 2003 and Windows XP.

**Table of IPv6-Related RFCs and Internet Drafts**

| RFC Number or Internet Draft | Title |
|---|---|
| 1752 | The recommendation for the IP next generation protocol |
| 1828 | IP authentication using keyed MD5 |
| 1886 | DNS extensions to support IP version 6 |
| 1993 | Transition mechanisms for IPv6 hosts and routers |
| 1981 | Path MTU discovery for IP version 6 |
| 2185 | Routing aspects of IPv6 transition |
| 2373 | IP version 6 addressing architecture |
| 2374 | An IPv6 aggregatable global unicast address format |
| 2401 | Security architecture for the Internet protocol |
| 2402 | IP authentication header |
| 2403 | The use of HMAC-MD5-96 within ESP and AH (implemented for AH only) |
| 2404 | The use of HMAC-SHA-1-96 within ESP and AH (implemented for AH only) |
| 2406 | IP encapsulating security payload (ESP) |
| 2428 | FTP extensions for IPv6 and NATs |
| 2460 | Internet protocol, version 6 (IPv6) specification |
| 2461 | Neighbor discovery for IP version 6 (IPv6) |
| 2462 | IPv6 stateless address autoconfiguration |
| 2463 | Internet Control Message Protocol (ICMPv6) for the Internet protocol version 6 (IPv6) specification |
| 2464 | Transmission of IPv6 packets over Ethernet networks |
| 2465 | Management Information Base for IP Version 6: Textual Conventions and General Group (for Windows Server 2003 only) |
| 2467 | Transmission of IPv6 packets over FDDI networks |
| 2526 | Reserved IPv6 subnet anycast addresses |
| 2529 | Transmission of IPv6 over IPv4 domains without explicit tunnels |
| 2553 | Basic socket interface extensions for IPv6 |
| 2710 | Multicast listener discovery (MLD) for IPv6 (implemented for host only) |
| 2711 | IPv6 router alert option (implemented for host only) |
| 3041 | Privacy extensions for stateless address autoconfiguration in IPv6 |

| | |
|---|---|
| 3056 | Connection of IPv6 domains via IPv4 clouds |
| 3484 | Default Address Selection for Internet Protocol version 6 (IPv6) |
| Internet draft | An extension of format for IPv6 scoped addresses |
| Internet draft | Intra-site Automatic Tunnel Addressing Protocol (ISATAP) |
| 3513 | IP version 6 addressing architecture |
| Internet draft | IP version 6 scoped address architecture |
| Internet draft | Mobility support in IPv6 (host only) |
| Internet draft | Routing of scoped addresses in the Internet protocol version 6 (IPv6) |
| Internet draft | Site prefixes in neighbor discovery |
| Internet draft | The UDP lite protocol |
| Internet draft | IPv6 Near-Unique Site-Local Addresses |
| Internet draft | Management Information Base for the User Datagram Protocol (UDP) |
| Internet draft | Internet Control Message Protocol (ICMPv6) for the Internet Protocol Version 6 (IPv6) |
| Internet draft | Default Router Preferences and More-Specific Routes |

# IPv6 Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 Tools and Settings**

**In this section**

- IPv6 Tools
- Related Information

**IPv6 Tools**

The following tools are associated with Internet Protocol version 6 (IPv6).

**IPv6-aware TCP/IP Tools**

| Tool | Description |
|---|---|
| Ftp | Use to communicate with remote computers. |
| Ipconfig | Display current TCP/IP and IPv6 network configuration values, update or release Dynamic Host Configuration Protocol (DHCP) allocated leases, and display, register, or flush Domain Name System (DNS) names. |
| Ipsec6.exe | Use to configure Internet Protocol security (IPSec) policies and security associations between two IPv6 hosts. |
| Netsh | Provides 13 sets of commands for performing network configuration tasks. Windows Server 2003 adds a new context for managing IPv6 to the **netsh** command set. |
| Netstat | Display statistics for current TCP/IP connections. Windows Server 2003 adds IPv6 parameters to the **netstat** command. |
| Pathping | Trace a path to a remote system and report packet losses at each router along the way. Windows Server 2003 adds IPv6 parameters to the **pathping** command. |
| Ping | Send Internet Control Message Protocol (ICMP) Echo Requests to verify that TCP/IP is configured correctly and that a remote TCP/IP computer is available. Windows Server 2003 adds IPv6 parameters to the **ping** command. |
| Route | Display the IP routing table, and add or delete IPv6 routes. |
| Tracert | Trace a path to a remote system. Windows Server 2003 adds IPv6 parameters to the **tracert** command. |

**FTP**

The FTP connectivity tool included with Microsoft TCP/IP can be used to communicate with remote computers.

**Category**

The IPv6-aware version of this tool is included on the Windows Server 2003 product CD.

**Version compatibility**

You can run this command on computers running Windows XP or Windows Server 2003.

You can use the FTP tool to transfer files to and from a host running an FTP server service, such as the FTP component of Internet Information Services (IIS). The File Transfer Protocol (FTP) is a protocol that defines how to transfer files from one computer to another over a TCP/IP network, such as the Internet or a company intranet.

**Note**

- The FTP service is a component of IIS. However, when you enable IIS on a server, FTP is not enabled unless you explicitly enable it. If you install IIS without FTP, you can use **Add or Remove Windows Components** in **Add or Remove Programs** in the **Control Panel** to install FTP later.

For more information about TCP/IP, see "TCP/IP Technical Reference."

**Ipconfig**
**Category**
The IPv6-aware version of this tool is included on the Windows Server 2003 product CD.

**Version compatibility**
You can run this command on computers running Windows XP or Windows Server 2003.

You can use the Ipconfig command-line tool to display the current configuration of the installed IP stack on a networked computer and to refresh DCHP and DNS settings. The **ipconfig** command is often one of the first commands you use to check the status of the connection when you experience communication problems on a TCP/IP network. Ipconfig is most useful for managing computers that obtain an IP address automatically, such as by using DHCP or Automatic Private IP Addressing (APIPA).

When called with no parameters, Ipconfig displays the Internet Protocol version 4 (IPv4) address, subnet mask, and default gateway for all adapters on a computer. If the computer has an IPv6 address, Ipconfig also displays the IPv6 address information.

**Ipsec6.exe**
**Category**
The Ipsec6.exe tool is included on the Windows Server 2003 product CD.

**Version compatibility**
You can run Ipsec6.exe on computers running Windows Server 2003 and use Ipsec6.exe to target computers running versions of Windows that support IPv6 (Windows XP Service Pack 1 [SP1] and later and Windows Server 2003).

You can use Ipsec6.exe to configure IPSec policies and security associations between two IPv6 hosts. This configuration creates an IPSec security association (SA) between two hosts on the same subnet. The SA performs authentication by using the Authentication Header (AH) and either the Message Digest 5 (MD5) or Secure Hash Algorithm 1 (SHA1) hashed message authentication code (HMAC) algorithms. This configuration provides data origin authentication and data integrity for all traffic between two IPv6 hosts. Ipsec6.exe has multiple commands, each with its own set of parameters:

**ipsec6 sp** [*Interface*]

Displays the active security policies. Alternatively, displays the active security policies for a specific interface.

**ipsec6 sa**

Displays the active security associations.

**ipsec6 |** *FileNameWithNoExtension*

Loads the security policies from FileName.spd and the security associations from FileName.sad.

**ipsec6 s |** *FileNameWithNoExtension*

Saves the current security policies to FileName.spd and the current security associations to FileName.sad. You can use this command to create files that are used to configure security policy and security associations. When there are no security policies or security associations, this command creates FileName.spd for security policies and FileName.sad for security associations. You can use these files as templates to configure the desired security policies or security associations by modifying them with a text editor.

**ipsec6 d** [{**sp** | **sa**}] [*Index*]

Deletes the security policies (using the **sp** parameter) or security associations (using the **sa** parameter) from the list of active security policies and security associations, as specified by index number. You can use **ipsec6 sp** or **ipsec6 sa** to display the index number.

**ipsec6 m** [{**on** | **off**}]

Specifies whether binding updates that are used for mobile IPv6 are protected by IPSec. This is enabled by default.

**Note**

- This implementation of IPSec for IPv6 is not recommended for use in a production environment because it relies on static keying and has no provisions for updating keys upon sequence number reuse.

- When you manually configure Security Parameters Indexes (SPIs), always use random numbers. Do not use sequential numbers for SPIs, or you will compromise the security of your IPSec for IPv6 policies.

- The IPv6 protocol for the Windows Server 2003 family supports the use of IPSec Encapsulating Security Payload (ESP) with NULL encryption.

**Netsh Commands for Interface IPv6**
**Category**
Netsh commands for Interface IPv6 are included on the Windows Server 2003 product CD.

**Version compatibility**
You can run Netsh commands for Interface IPv6 on computers running Windows Server 2003 and use Netsh commands for Interface IPv6 to target computers running versions of Windows that support IPv6 (Windows XP SP1 and later and Windows Server 2003).

The Netsh commands for Interface IPv6 provide a command-line tool that you can use to query and configure IPv6 interfaces, address, caches, and routes.

The Interface IPv6 context of **netsh** has a subcontext for 6to4, a transition technology described in the *HowIPv6 Works* section of this Technical Reference, that allows communication between IPv6/IPv4 nodes across the IPv4 Internet. You can use the commands in the **netsh interface IPv6 6to4** context to configure or display the configuration of the IPv6 Helper service on either a 6to4 host or a 6to4 router. In addition, the Interface IPv6 context of **netsh** has a subcontext for Intra-Site Automatic Tunnel Addressing Protocol (ISATAP). ISATAP is an address assignment and tunneling mechanism for communication between IPv6/IPv4 nodes within an IPv4 intranet. You can use the commands in the **nesth interface ipv6 isatap** context to configure the IPv4 address of the ISATAP router.

You can run these commands from the command prompt in the Windows Server 2003 family of products, or from the command prompt for the **netsh interface IPv6** context. For these commands to work at the Windows Server 2003 family command prompt, you must type **netsh interface ipv6** before typing commands and parameters as they appear in the following reference.

**6to4**
Specifies that the **6to4** context of **netsh interface IPv6 6to4** is used.

**Syntax**

```
6to4
```

**add6over4tunnel**
Creates a 6over4 interface using the specified IPv4 address.

**Syntax**

```
add 6over4tunnel [[interface=]String] [localaddress=]IPv4Address
[[store=]{active | persistent}]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[**localaddress=**]*IPv4Address*

Required. Specifies the IPv4 address that is encapsulated.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command creates a 6over4 interface using the IPv4 address 10.1.1.1 on the interface named “Private.”

**add 6over4tunnel “Private” 10.1.1.1**

**add address**
Adds an IPv6 address to a specified interface. Time values can be expressed in days (d), hours (h), minutes (m), and seconds (s).

For example, 2d represents two days.

**Syntax**

```
add address [[interface=]String] [address=]IPv6Address [[type=]{unicast | anycast}] [[validlifetime=]{Integer | infinite}] [[preferredlifetime=]{Integer | infinite}] [[store=]{active | persistent}]
```

**Parameters**

[[**interface=**]*String*]

Specifies an interface name or index.

[**address=**]*IPv6Address*

Required. Specifies the IPv6 address to add.

[[**type=**]{**unicast** | **anycast**}]

Specifies whether a unicast address (**unicast**) or an anycast address (**anycast**) is added. The default selection is **unicast**.

[[**validlifetime=**]{*Integer* | **infinite**}]

Specifies the lifetime over which the address is valid. The default value is **infinite**.

[[**preferredlifetime=**]{*Integer* | **infinite**}]

Specifies the lifetime over which the address is preferred. The default value is **infinite**.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**

This example command adds the IPv6 address FE80::2 to the interface named "Private."

**add address "Private" FE80::2**

**add dns**

Adds a new DNS server IP address to the statically-configured list of DNS servers for the specified interface.

**Syntax**

```
add dns [interface=]String [address=]IPAddress [[index=]Integer]
```

**Parameters**

[**interface=**]*String*

Required. Specifies, by name, which interface will have a DNS server IP address added to its list of DNS server IP addresses.

[**address=**]*IPAddress*

Required. Specifies the IPv6 address of the DNS server to add to the list.

[[**index=**]*Integer*]

Specifies the position on the statically-configured list in which to place the DNS server IP address specified in **address**. By default, the DNS server IP address is added to the end of the list.

**Remarks**

If an index is specified, the DNS server is placed in that position in the list.

**Examples**

In the first example command, a DNS server with the IPv6 address FEC0:0:0:FFFF::1 is added to the list of DNS server IP addresses for the interface named "Local Area Connection." In the second example, a DNS server with the IPv6 address FEC0:0:0:FFFF::2 is added at index 2 as the second server on the list of servers for the interface named "Local Area Connection."

**add dns "Local Area Connection" FEC0:0:0:FFFF::1**

**add dns "Local Area Connection" FEC0:0:0:FFFF::2 index=2**

**add prefixpolicy**
Adds a source and destination address selection policy for a specified prefix.

**Syntax**

```
                add prefixpolicy [prefix=]IPv6Address/Integer [precedence=]Integer
[label=]Integer [[store=]{active | persistent}]
```

**Parameters**
[**prefix=**]*IPv6Address***/***Integer*

Required. Specifies the prefix for which to add a policy in the policy table. *Integer* specifies the prefix length.

[**precedence=**]*Integer*

Required. Specifies the precedence value used for sorting destination addresses in the policy table.

[**label=**]*Integer*

Required. Specifies the label value that allows for policies that require a specific source address prefix for use with a destination address prefix.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command adds a prefix policy for prefix ::/96, with a precedence value of 3 and a label value of 4.

**add prefixpolicy ::/96 3 4**

**add route**
Adds a route for a specified prefix. Time values can be expressed in days (d), hours (h), minutes (m), and seconds (s). For example, 2d represents two days.

**Syntax**

```
                add route [prefix=]IPv6Address/Integer [[interface=]String]
[[nexthop=]IPv6Address] [[siteprefixlength=]Integer] [[metric=]Integer] [[publish=]{no
| yes | immortal}] [[validlifetime=]{Integer | infinite}] [[preferredlifetime=]{Integer
| infinite}] [[store=]{active | persistent}]
```

**Parameters**
[**prefix=**]*IPv6Address***/***Integer*

Required. Specifies the prefix for which to add a route. *Integer* specifies the prefix length.

[[**interface=**]*String*]

Specifies an interface name or index.

[[**nexthop=**]*IPv6Address*]

Specifies the gateway address, if the prefix is not on-link.

[[**siteprefixlength=**]*Integer*]

Specifies the prefix length for the entire site, if the prefix is not on-link.

[[**metric=**]*Integer*]

Specifies the route metric.

[[**publish=**]{**no** | **yes** | **immortal**}]

Specifies whether routes are advertised (**yes**), advertised with an infinite lifetime (**immortal**), or not advertised (**no**) in Route

Advertisements. The default selection is **no**.

[[**validlifetime=**]{*Integer* | **infinite**}]

Specifies the lifetime over which the route is valid. The default value is **infinite**.

[[**preferredlifetime=**]{*Integer* | **infinite**}]

Specifies the lifetime over which the route is preferred. The default value is **infinite**.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command adds a route on the interface named "Internet" with a prefix of 3FFE:: and a prefix length of 16 bits (3FFE::/16). The **nexthop** value is FE80::1.

**add route 3FFE::/16 "Internet" FE80::1**

**add v6v4tunnel**
Creates an IPv6-in-IPv4 tunnel.

**Syntax**

```
                add v6v4tunnel [[interface=]String] [localaddress=]IPv4Address
[remoteaddress=]IPv4Address [[neighbordiscovery=]{enabled | disabled}] [[store=]{active
| persistent}]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[**localaddress=**]*IPv4Address*

Required. Specifies the IPv4 address of the local tunnel endpoint.

[**remoteaddress=**]*IPv4Address*

Required. Specifies the IPv4 address of the remote tunnel endpoint.

[[**neighbordiscovery=**]{**enabled** | **disabled**}]

Specifies whether Neighbor Discovery is enabled (**enabled**) or disabled (**disabled**) on the interface. The default selection is **disabled**.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command creates an IPv6-in-IPv4 tunnel between the local address 10.0.0.1 and the remote address 192.168.1.1 on the interface "Private."

**add v6v4tunnel "Private" 10.0.0.1 192.168.1.1**

**delete address**
Modifies an IPv6 address on a specified interface.

**Syntax**

```
                delete address [[interface=]String] [address=]IPv6Address [[store=]
{active | persistent}]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[**address=**]*IPv6Address*

Required. Specifies the IPv6 address to delete.

[[**store=**]{**active** | **persistent**}]

Specifies whether the deletion lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command deletes the address FE80::2 from the interface named "Private."

**delete address "Private" FE80::2**

**delete destinationcache**
Clears the destination cache. If an interface is specified, clears the cache only on that interface. If an address is also specified, deletes only that destination cache entry.

**Syntax**

```
delete destinationcache [[interface=]String] [[address=]IPv6Address]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[[**address=**]*IPv6Address*]

Specifies the address of the destination.

**Remarks**
When no parameters are specified, all entries in the destination caches for all interfaces are deleted.

**Example**
This example command deletes the destination cache for the interface named "Private."

**delete destinationcache "Private"**

**delete dns**
Deletes statically-configured DNS server IPv6 addresses for a specific interface.

**Syntax**

```
delete dns [interface=]String [[address=]{IPv6Address | all}]
```

**Parameters**
[**interface=**]*String*

Required. Specifies the interface, by name, for which you want to remove a DNS server from the list of DNS servers.

[[**address=**]{*IPv6Address* | **all**}]

Specifies the DNS server IPv6 address to delete. If **all** is specified, all DNS server IPv6 addresses on the list for the interface are deleted.

**Examples**
In the first example command, the DNS server IPv6 address FEC0:0:0:FFFF::1 is deleted from the list of addresses for the connection named "Local Area Connection." In the second example command, all DNS server IPv6 addresses are deleted for the connection named "Local Area Connection."

**delete dns "Local Area Connection" FEC0:0:0:FFFF::1**

**delete dns "Local Area Connection" all**

**delete interface**
Deletes a specified interface from the IPv6 stack.

**Syntax**

```
delete interface [[interface=]String] [[store=]{active | persistent}]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[[**store=**]{**active** | **persistent**}]

Specifies whether the deletion lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Examples**
This example command deletes the interface named "Private."

**delete interface "Private"**

**delete neighbors**
Specifies that all entries in the neighbor cache are deleted. If an interface is specified, clears the cache only on that interface. If an address is also specified, deletes only that neighbor cache entry.

**Syntax**

```
delete neighbors [[interface=]String] [[address=]IPv6Address]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[[**address=**]*IPv6Address*]

Specifies the address of the neighbor.

**Example**
This example command removes all entries from the neighbor cache on the interface named "Private."

**delete neighbors "Private"**

**delete prefixpolicy**
Deletes the source and destination address selection policy for a specified prefix.

**Syntax**

```
delete prefixpolicy [prefix=]IPv6Address/Integer [[store=]{active |
persistent}]
```

**Parameters**
[**prefix=**]*IPv6Address***/***Integer*

Required. Specifies the prefix (*IPv6Address*) and prefix length (*Integer*) to delete from the policy table.

[[**store=**]{**active** | **persistent**}]

Specifies whether the deletion lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command deletes the prefix ::/96 from the policy table.

**delete prefixpolicy ::/96**

**delete route**
Deletes an IPv6 route.

**Syntax**

```
delete route [prefix=]IPv6Address/Integer [[interface=]String]
[[nexthop=]IPv6Address] [[store=]{active | persistent}]
```

**Parameters**

[**prefix=**]*IPv6Address***/***Integer*

Required. Specifies the prefix of the route to delete.

[[**interface=**]*String*]

Specifies an interface name or index.

[[**nexthop=**]*IPv6Address*]

Specifies the gateway address, if the prefix is not on-link.

[[**store=**]{**active** | **persistent**}]

Specifies whether the deletion lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**

This example command deletes the route with the prefix 3FFE::/16 and the gateway FE80::1 from the interface named "Internet."

**delete route 3FFE::/16 "Internet" FE80::1**

**dump**

Dumps the network adapter IPv6 configuration to the command prompt window when run within the **netsh** context. When used in a batch file or script, output can be saved in a text file.

**Syntax**

```
netsh interface ipv6 dump > [
PathAndFileName
]
```

**Parameters**

[*PathAndFileName*]

Specifies both the location to which to save the file and the name of the destination file to which the configuration is saved.

**Remarks**

After file output is obtained, you can use the **netsh exec** command to either configure another computer with the same IPv6 configuration or to restore the original configuration on the same computer.

All IPv6 configuration information is saved with the **dump** command. For example, if an ISATAP or a 6to4 configuration is defined on an interface, the **dump** command saves these settings in the text file.

**Examples**

In the first example, the command is run manually at the **netsh interface ipv6** context of a command prompt. The IPv6 configuration is displayed in the command prompt window, and can be copied and pasted into a text file. In the second example, the **dump** command is run in a batch file, and the configuration is saved to a text file named Ipv6_conf.txt at the location C:\Temp.

**dump**

**netsh interface ipv6 dump > C:\temp\ipv6_conf.txt**

**install**

Installs IPv6.

**Syntax**

```
install
```

**isatap**
Specifies that the **isatap** context of **netsh interface IPv6 isatap** is used.

**Syntax**

```
isatap
```

**Remarks**
ISATAP is used for communication between IPv6 and IPv4 nodes within an IPv4 site. It is described in the Internet draft titled "Intra-Site Automatic Tunnel Addressing Protocol (ISATAP)."

**renew**
Restarts IPv6 interfaces.

**Syntax**

```
renew [[interface=]String]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

**Example**
**renew "Private"**

**reset**
Resets the IPv6 configuration state.

**Syntax**

```
reset
```

**set address**
Modifies an IPv6 address on a specified interface. Time values can be expressed in days (d), hours (h), minutes (m), and seconds (s). For example, 2d represents two days.

**Syntax**

```
set address [[interface=]String] [address=]IPv6Address [[type=]{unicast
| anycast}] [[validlifetime=]{Integer | infinite}] [[preferredlifetime=]{Integer |
infinite}] [[store=]{active | persistent}]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[**address=**]*IPv6Address*

Required. Specifies the IPv6 address to modify.

[[**type=**]{**unicast** | **anycast**}]

Specifies whether the address is marked as a unicast address (**unicast**) or as an anycast address (**anycast**). The default selection is **unicast**.

[[**validlifetime=**]{*Integer* | **infinite**}]

Specifies the lifetime over which the address is valid. The default value is **infinite**.

[[**preferredlifetime=**]{*Integer* | **infinite**}]

Specifies the lifetime over which the address is preferred. The default value is **infinite**.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command sets the address FE80::2 on the interface named “Private” as an anycast address.

**set address "Private" FE80::2 anycast**

**set global**
Modifies global configuration parameters.

**Syntax**

```
                set global [[defaultcurhoplimit=]Integer] [neighborcachelimit=]Integer
[[routecachelimit=]Integer] [[reassemblylimit=]Integer] [[store=]{active | persistent}]
```

**Parameters**
[[**defaultcurhoplimit=**]*Integer*]

Specifies the default hop limit of packets sent.

[**neighborcachelimit=**]*Integer*

Required. Specifies the maximum number of neighbor cache entries.

[[**routecachelimit=**]*Integer*]

Specifies the maximum number of route cache entries.

[[**reassemblylimit=**]*Integer*]

Specifies the maximum size of the reassembly buffer.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command sets global parameters for all IPv6-enabled interfaces on the computer. The default hop limit is set to 32, the maximum number of neighbor cache entries is set to 100, and the maximum number of route cache entries is 100,000.

**set global 32 100 100000**

**set interface**
Modifies interface configuration parameters.

**Syntax**

```
                set interface [[interface=]String] [[forwarding=]{enabled | disabled}]
[[advertise=]{enabled | disabled}] [[mtu=]Integer] [[siteid=]Integer]
[[metric=]Integer] [[firewall=]{enabled | disabled}] [[siteprefixlength=]Integer]
[[store=]{active | persistent}]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[[**forwarding=**]{**enabled** | **disabled**}]

Specifies whether packets arriving on this interface can be forwarded to other interfaces. The default selection is **disabled**.

[[**advertise=**]{**enabled** | **disabled**}]

Specifies whether Router Advertisements are sent on this interface. The default selection is **disabled**.

[[**mtu=**]*Integer*]

Specifies the MTU of this interface. The default MTU is the natural MTU of the link.

[[**siteid=**]*Integer*]

Specifies the site scope zone identifier.

[[**metric=**]*Integer*]

Specifies the interface metric, which is added to route metrics for all routes over the interface.

[[**firewall=**]{**enabled** | **disabled**}]

Specifies whether to operate in firewall mode.

[[**siteprefixlength=**]*Integer*]

Specifies the default length of the global prefix for the entire site.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command sets the interface with the name "Private," with a **siteid** of 2 and a **metric** of 2. All other parameter values are left at the default values.

**set interface "Private" siteid=2 metric=2**

**set mobility**
Modifies mobility configuration parameters.

**Syntax**

```
                set mobility [[security=]{enabled | disabled}]
[[bindingcachelimit=]Integer] [[correspondentnode=]enabled | disabled] [[store=]{active
| persistent}]
```

**Parameters**
[[**security=**]{**enabled** | **disabled**}]

Specifies whether binding updates must be secured.

[[**bindingcachelimit=**]*Integer*]

Specifies the maximum number of binding cache entries.

[[**correspondentnode=**]**enabled** | **disabled**]

Specifies whether Correspondent Node functionality is set to **enabled** or the default of **disabled**.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
**set mobility security=disabled bindingcachelimit=1000 corr=enabled**

**set prefixpolicy**
Modifies a source and destination address selection policy for a specified prefix.

**Syntax**

```
                set prefixpolicy [prefix=]IPv6Address/Integer [precedence=]Integer
[label=]Integer [[store=]{active | persistent}]
```

**Parameters**
[**prefix=**]*IPv6Address***/***Integer*

Required. Specifies the prefix for which to add a policy in the policy table. *Integer* specifies the prefix length.

[**precedence=**]*Integer*

Required. Specifies the precedence value used for sorting destination addresses in the policy table.

[**label=**]*Integer*

Required. Specifies the label value that allows for policies that require a specific source address prefix for use with a destination address prefix.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**
This example command sets a policy in the policy table for the prefix ::/96, with a precedence value of 3 and a label value of 4.

**set prefixpolicy ::/96 3 4**

**set privacy**
Modifies parameters related to temporary address generation. If **randomtime=** is specified, **maxrandomtime=** is not used. Time values can be expressed in days (d), hours (h), minutes (m), and seconds (s). For example, 2d represents two days.

**Syntax**

```
                set privacy [[state=]{enabled | disabled}] [[maxdadattempts=]Integer]
[[maxvalidlifetime=]Integer] [[maxpreferredlifetime=]Integer]
[[regeneratetime=]Integer] [[maxrandomtime=]Integer] [[randomtime=]Integer] [[store=]
{active | persistent}]
```

**Parameters**
[[**state=**]{**enabled** | **disabled**}]

Specifies whether temporary addresses are enabled.

[[**maxdadattempts=**]*Integer*]

Specifies the number of duplicate address detection attempts made. The default value is 5.

[[**maxvalidlifetime=**]*Integer*]

Specifies the maximum lifetime over which a temporary address is valid. The default value is 7d (seven days).

[[**maxpreferredlifetime=**]*Integer*]

Specifies the maximum lifetime over which an anonymous address is preferred. The default value is 1d (one day).

[[**regeneratetime=**]*Integer*]

Specifies the duration of time that elapses when a new address is generated prior to deprecating a temporary address. The default value is 5s (five seconds).

[[**maxrandomtime=**]*Integer*]

Specifies the upper limit to use when computing a random delay at boot. The default value is 10m (ten minutes).

[[**randomtime=**]*Integer*]

Specifies a time value to use, instead of a value generated at boot.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**set route**
Modifies route parameters. Time values can be expressed in days (d), hours (h), minutes (m), and seconds (s). For example, 2d represents two days.

**Syntax**

```
set route [prefix=]IPv6Address/Integer [[interface=]String]
[[nexthop=]IPv6Address] [[siteprefixlength=]Integer] [[metric=]Integer] [publish=]{no |
yes | immortal}] [[validlifetime=]{Integer | infinite}] [[preferredlifetime=]{Integer |
infinite}] [[store=]{active | persistent}]
```

**Parameters**

[**prefix=**]*IPv6Address***/***Integer*

Required. Specifies the prefix (*IPv6Address*) and prefix length (*Integer*) of the route to modify.

[[**interface=**]*String*]

Specifies an interface name or index.

[[**nexthop=**]*IPv6Address*]

Specifies the gateway address, if the prefix is not on-link.

[[**siteprefixlength=**]*Integer*]

Specifies the prefix length for the entire site, if the prefix is not on-link.

[[**metric=**]*Integer*]

Specifies the route metric.

[[**publish=**]{**no** | **yes** | **immortal**}]

Specifies whether routes are advertised (**yes**), advertised with an infinite lifetime (**immortal**), or not advertised (**no**) in Route Advertisements. The default selection is **no**.

[[**validlifetime=**]{*Integer* | **infinite**}]

Specifies the lifetime over which the route is valid. The default value is **infinite**.

[[**preferredlifetime=**]{*Integer* | **infinite**}]

Specifies the lifetime over which the route is preferred. The default value is **infinite**.

[[**store=**]{**active** | **persistent**}]

Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Example**

This example command sets a route on the interface named “Internet.” The route prefix is 3FFE::, and has a length of 16 bits. The gateway address, defined by the **nexthop** parameter, is FE80::1.

**set route 3FFE::/16 "Internet" FE80::1**

**set state**

Enables or disables IPv4 compatibility. The default value for all parameters is **disabled**.

**Syntax**

```
set state [[v4compat=](enabled | disabled | default)]
```

**Parameters**

[[**v4compat=**](**enabled** | **disabled** | **default**)]

Specifies whether IPv4 compatible interfaces are created. To both disable and delete IPv4 compatible interfaces, specify **default**. To disable IPv4 compatible interfaces without deleting them, specify **disabled**.

**Examples**

In the first example command, IPv4-compatible addresses are disabled, and any previously existing interfaces are deleted. In the second example command, IPv4-compatible addresses are enabled.

**set state default**

**set state v4compat=enabled**

**show address**
Displays all IPv6 addresses, or all addresses on a specified interface.

**Syntax**

```
show address [[interface=]String] [[level=]{normal | verbose}]
[[store=]{active | persistent}]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[[**level=**]{**normal** | **verbose**}]

Specifies whether one line per interface is displayed (**normal**) or additional information is displayed for each interface (**verbose**). When no interface is specified, the default selection is **normal**. When an interface is specified, the default selection is **verbose**.

[[**store=**]{**active** | **persistent**}]

Specifies whether active (**active**) or persistent (**persistent**) addresses are displayed. The default selection is **active**.

**show bindingcacheentries**
Displays all binding cache entries.

**Syntax**

```
show bindingcacheentries
```

**show destinationcache**
Displays destination cache entries. If an interface is specified, displays the cache only on that interface. If an address is also specified, displays only that destination cache entry.

**Syntax**

```
show destinationcache [[interface=]String] [[address=]IPv6Address]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[[**address=**]*IPv6Address*]

Specifies the address of the destination.

**show dns**
Displays the DNS server configuration for a specific interface or interfaces.

**Syntax**

```
show dns [[interface=]String]
```

**Parameters**
[[**interface=**]*String*]

Specifies the interface, by name, for which you want to display configured DNS server IPv6 addresses. If no interface is specified, servers for all interfaces are displayed.

**Example**
In this example command, DNS server IPv6 addresses configured on the “Local Area Connection” interface are displayed.

**show dns "Local Area Connection"**

**show global**
Displays global configuration parameters.

**Syntax**

```
show global [[store=]{active | persistent}]
```

**Parameters**
[[**store=**]{**active** | **persistent**}]

Specifies whether active (**active**) or persistent (**persistent**) information is displayed. The default selection is **active**.

**show interface**
Displays information about all interfaces, or about a specified interface.

**Syntax**

```
show interface [[interface=]String] [[level=]{normal | verbose}]
[[store=]{active | persistent}]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[[**level=**]{**normal** | **verbose**}]

Specifies whether one line per interface is displayed (**normal**) or additional information is displayed for each interface (**verbose**). When no interface is specified, the default selection is **normal**. When an interface is specified, the default selection is **verbose**.

[[**store=**]{**active** | **persistent**}]

Specifies whether active (**active**) or persistent (**persistent**) interfaces are displayed. The default selection is **active**.

**show joins**
Displays all IPv6 multicast addresses, or all multicast addresses on a specified interface.

**Syntax**

```
show joins [[interface=]String] [[level=]{normal | verbose}]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[[**level=**]{**normal** | **verbose**}]

Specifies whether one line per interface is displayed (**normal**) or additional information is displayed for each interface (**verbose**). When no interface is specified, the default selection is **normal**. When an interface is specified, the default selection is **verbose**.

**show mobility**
Displays mobility configuration parameters.

**Syntax**

```
show mobility [[store=]{active | persistent}]
```

**Parameters**
[[**store=**]{**active** | **persistent**}]

Specifies whether active (**active**) or persistent (**persistent**) information is displayed. The default selection is **active**.

**show neighbors**
Displays neighbor cache entries. If an interface is specified, displays only the cache on that interface. If an address is also

specified, displays only that neighbor cache entry.

**Syntax**

```
show neighbors [[interface=]String] [[address=]IPv6Address]
```

**Parameters**
[[**interface=**]*String*]

Specifies an interface name or index.

[[**address=**]*IPv6Address*]

Specifies the address of the neighbor.

**show prefixpolicy**
Displays prefix policy table entries used in source and destination address selection.

**Syntax**

```
show prefixpolicy [[store=]{active | persistent}]
```

**Parameters**
[[**store=**]{**active** | **persistent**}]

Specifies whether active (**active**) or persistent (**persistent**) information is displayed. The default selection is **active**.

**show privacy**
Displays privacy configuration parameters.

**Syntax**

```
show privacy [[store=]{active | persistent}]
```

**Parameters**
[[**store=**]{**active** | **persistent**}]

Specifies whether active (**active**) or persistent (**persistent**) information is displayed. The default selection is **active**.

**show routes**
Displays route table entries.

**Syntax**

```
show routes [[level=]{normal | verbose}] [[store=]{active |
persistent}]
```

**Parameters**
[[**level=**]{**normal** | **verbose**}]

Specifies whether only normal routes (**normal**) or routes used for loopback (**verbose**) are displayed. The default selection is **normal**.

[[store=]{active | persistent}]

Specifies whether active (**active**) or persistent (**persistent**) routes are displayed. The default selection is **active**.

**show siteprefixes**
Displays the site prefix table.

**Syntax**

```
show siteprefixes
```

**uninstall**
Uninstalls IPv6.

**Syntax**

```
uninstall
```

**Netsh Interface IPv6 6to4**

You can use the following commands in the **netsh interface IPv6 6to4** context to display the configuration of or configure the 6to4 service on either a 6to4 host or a 6to4 router.

**set interface**

Configures the 6to4 service on an interface.

**Syntax**

```
set interface [name=] InterfaceName [[routing=] {enabled | disabled | default}]
```

**Parameters**

[**name=**] *InterfaceName*

Required. Specifies the name of the interface for which you want to set 6to4 service configuration. *InterfaceName* must match the name of the interface specified in Network Connections. If *InterfaceName* contains any spaces, it must be enclosed in quotes.

[[**routing=**] {**enabled** | **disabled** | **default**}]

Specifies whether the forwarding of 6to4 packets received on the interface is enabled, disabled, or set to its default value.

**Remarks**

This command enables, disables, or sets to default the routing behavior of the 6to4 service on a specified interface.

The default setting for the **routing** parameter is **enabled**, which enables routing on private interfaces if Internet Connection Sharing (ICS) is used.

**show interface**

Displays the 6to4 service routing configuration on all interfaces, or on a specified interface.

**Syntax**

```
show interface [[name=] InterfaceName]
```

**Parameters**

[[**name=**] *InterfaceName*]

Specifies the name of the interface for which you want to display the 6to4 service configuration. *InterfaceName* must match the name of the interface specified in Network Connections. If *InterfaceName* contains any spaces, it must be enclosed in quotes.

**Remarks**

If an interface name is not specified, the 6to4 configuration for all interfaces is displayed.

**set relay**

Configures the name of the 6to4 relay router for the 6to4 service. Additionally, specifies how often the name is resolved and the state of the relay component for the 6to4 service.

**Syntax**

```
set relay [[name=] {RelayDNSName | default}] [[state=] {enabled | disabled | automatic | default}] [[interval=] {ResInterval | default}]
```

**Parameters**

[[**name=**] {*RelayDNSName* | **default**}]

Specifies either the fully qualified domain name (FQDN) of a 6to4 relay router on the IPv4 Internet (*RelayDNSName*), or sets the relay name to its default value of 6to4.ipv6.microsoft.com (**default**).

[[**state=**] {**enabled** | **disabled** | **automatic** | **default**}]

Specifies whether the state of the relay component for the 6to4 service is enabled, disabled, automatically enabled if a public IPv4 address is configured, or set to its default value.

[[**interval=**] {*ResInterval* | **default**}]

Specifies how often the name of the relay router is resolved in minutes (*ResInterval*) or sets the resolution interval to its default value of 1440 minutes (**default**).

**Remarks**
The 6to4 relay router is a router that provides an access point between the IPv4 Internet and the 6bone (the native IPv6 portion of the Internet). To access 6bone resources from a 6to4 router, the 6to4 router encapsulates 6to4 traffic with an IPv4 header and sends it to the IPv4 address of the 6to4 relay router. The 6to4 relay router removes the IPv4 header and forwards the traffic to the 6bone. For return traffic, the 6to4 relay router encapsulates IPv6 traffic and sends it to the 6to4 router at the 6to4 host's site.

The default name of the 6to4 relay router is 6to4.ipv6.microsoft.com.

The default state is **automatic**, which enables the forwarding of native IPv6 traffic to a relay router when a public IPv4 address is assigned to any interface.

The default resolution interval is 1440 minutes (once each day).

**show relay**
Displays the relay router configuration for the 6to4 service.

**Syntax**

```
show relay
```

**set routing**
Sets both the state of routing and the inclusion of site-local address prefixes in Router Advertisements that are sent by the 6to4 router.

**Syntax**

```
set routing [[routing=] {enabled | disabled | automatic | default}]
[[sitelocals=] {enabled | disabled | default}]
```

**Parameters**
[[**routing=**] {**enabled** | **disabled** | **automatic** | **default**}]

Specifies whether the state of routing on a 6to4 router is enabled, disabled, automatically enabled if ICS is enabled, or set to its default value.

[[**sitelocals=**] {**enabled** | **disabled** | **default**}]

Specifies whether the advertising of site-local address prefixes, in addition to 6to4 address prefixes, is enabled, disabled, or set to its default value.

**Remarks**
The default setting for the **routing** parameter is **automatic**, which enables routing on private interfaces when ICS is used.

The default setting for the **sitelocals** parameter is **enabled**, which enables the advertising of site-local prefixes when site-local addresses are configured on private interfaces.

**show routing**
Displays the routing configuration of the 6to4 service.

**Syntax**

```
show routing
```

**set state**
Configures the state of the 6to4 service.

**Syntax**

```
set state [[state=] {enabled | disabled | default}] [[undoonstop=] {enabled | disabled | default}] [[6over4=] {enabled | disabled | default}]
```

**Parameters**

[[**state=**] {**enabled** | **disabled** | **default**}]

Specifies whether the state of the 6to4 service is enabled, disabled, or set to its default value.

[[**undoonstop=**] {**enabled** | **disabled** | **default**}]

Specifies whether the reversal of all automatic configuration that has been performed by the 6to4 service occurs when the service stops is enabled, disabled, or set to its default value.

**Remarks**

The default setting for the **state** parameter is **enabled**, which enables the 6to4 service.

The default setting for the **undoonstop** parameter is **enabled**, which reverses all automatic configuration performed by the 6to4 service when the service is stopped.

**show state**

Displays the state of the 6to4 service.

**Syntax**

```
show state
```

**reset**

Resets the 6to4 service.

**Syntax**

```
reset
```

**Netsh Interface IPv6 ISATAP**

You can use the following commands to configure the ISATAP router.

**set router**

Specifies the ISATAP router information, including router name, state, and resolution interval.

**Syntax**

```
set router [[name=]{String | default}] [[state=]{Enabled | Disabled | Default}] [[interval]=Integer]
```

**Parameters**

[[**name=**]{*String* | **default**}]

Specifies whether the router is named with a string. If **default** is specified, the system reverts to using the default name.

[[**state=**]{**Enabled** | **Disabled** | **Default**}]

Specifies whether the ISATAP router relays packets between subnets.

[[**interval**]=*Integer*]

Specifies the router resolution interval, in minutes. The default interval is 1440 (24 hours).

**Example**

The following example command sets the router name to isatap, enables the router, and sets the resolution interval to 120 minutes:

**set router isatap enabled 120**

**show router**

Displays configuration information for the ISATAP router.

**Syntax**

```
show router
```

**Remarks**
This command displays the router name, the relay state, and the resolution interval.

**Netstat**
**Category**
The IPv6-aware version of this tool is included on the Windows Server 2003 product CD.

**Version compatibility**
You can run this command on computers running Windows XP or Windows Server 2003.

You can use the Netstat command-line tool to display active TCP/IP connections, ports on which the computer is listening, Ethernet statistics, the IP routing table, IPv4 statistics (for the IP, ICMP, TCP, and User Datagram Protocol [UDP]), and IPv6 statistics (for the IPv6, ICMPv6, TCP over IPv6, and UDP over IPv6 protocols).

**Pathping**
**Category**
The IPv6-aware version of this tool is included on the Windows Server 2003 product CD.

**Version compatibility**
You can run this command on computers running Windows XP or Windows Server 2003.

You can use Pathping, an IP packet route-tracing command-line tool that combines features of Ping and Tracert, to obtain additional information that neither of those tools provides. Specifically, you can use Pathping to discover the route to a remote host; it then pings the remote host for a period of time and collects and reports statistics. Pathping path information includes information about the intermediate routers visited on the path, the Round-Trip Time (RTT) value, and link-loss information.

**Ping**
**Category**
The IPv6-aware version of this tool is included on the Windows Server 2003 product CD.

**Version compatibility**
You can run this command on computers running Windows XP or Windows Server 2003.

You can use the Ping command-line tool as your primary tool for troubleshooting IP-level connectivity between two TCP/IP computers. Ping sends ICMP Echo Request or ICMPv6 messages to perform network diagnostics and to test reachability for a specific destination. By default, Ping queries for both IPv4 and IPv6 addresses and uses the addresses returned by the operating system.

Ping lets you specify the size of packets to use (the default is 32 bytes), how many to send, whether to record the route used, which Time-To-Live (TTL) value to use, and so on.

**Route**
**Category**
The IPv6-aware version of this tool is included on the Windows Server 2003 product CD.

**Version compatibility**
You can run this command on computers running Windows XP or Windows Server 2003.

You can use the Route command-line tool to view and modify the local IP routing table.

For two hosts to exchange IP datagrams, they must both have a route to each other, or they must use a default gateway that knows a route between the two. Typically, routers exchange information using a protocol such as Routing Information Protocol (RIP) or Open Shortest Path First (OSPF). RIP Listening service is available for Microsoft Windows XP Professional, and full routing protocols are supported by Windows Server 2003 in the Routing and Remote Access service.

**Tracert**
**Category**
The IPv6-aware version of this tool is included on the Windows Server 2003 product CD.

**Version compatibility**
You can run this command on computers running Windows XP or Windows Server 2003.

You can use the Tracert command-line route-tracing tool to display the path between the sending host and a destination.

The path that Tracert displays is a list of near-side router interfaces of the routers in the path between the source host and destination. Tracert uses the IP TTL field in ICMP Echo Requests and ICMP Time Exceeded messages to determine the path from a source to a destination through an IP internetwork.

Some routers silently drop packets with expired TTLs. These routers do not appear in the Tracert display.

Tracert works by incrementing the TTL value by one for each ICMP Echo Request it sends, and then waiting for an ICMP Time Exceeded message. The TTL values of the Tracert packets start with an initial value of one; the TTL of each trace after the first is incremented by one. A packet sent out by Tracert travels one hop further on each successive trip.

**Note**

- The UNIX version of Tracert performs the same function as the Windows version, except that the IP payload is a UDP packet addressed to a (presumably) unknown destination UDP port. Intermediate routers send back ICMP Time Expired messages recording the route taken, and the final destination sends back an ICMP Destination Unreachable-Port Unreachable message.

- The UDP payload from the UNIX Tracert tool can cross routers and firewalls, whereas the ICMP Echo Request messages might not due to ICMP filtering. To avoid this problem in Windows Sever 2003, turn off packet filtering and then try using Tracert again.

# Routing Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing Technologies**
Routing technologies manage the flow of data between network segments, which are also known as *subnets*. Windows Server 2003 includes several routing technologies, including demanddial routing, unicast Internet Protocol (IP) routing, IP multicasting, and network address translation (NAT) functionality, which are discussed in this subcollection.

**Routing Components**
This subcollection contains information about the following routing technologies:

- Demand-dial routing
- Unicast IP routing
- IP multicasting
- NAT

**Demand-Dial Routing**
Demand-dial routing (also known as dial-on-demand routing) is the forwarding of packets over Point-to-Point Protocol (PPP) links within a wide-area network (WAN) infrastructure of dial-up telecommunications technologies, including Public Switched Telephone Network (PSTN), Integrated Services Digital Network (ISDN), X.25, and Asynchronous Transfer Mode (ATM) over asymmetric digital subscriber line (ADSL). Demand-dial routing allows you to connect branch offices through the Internet and to implement dial-up site-to-site virtual private network (VPN) connections.

Because demand-dial routing is an implementation of Routing and Remote Access technologies, including unicast routing and multicasting, it is integrated within the Routing and Remote Access architecture. For information about the architecture of Routing and Remote Access, see Unicast IPv4 Routing Technical Reference and IPv4 Multicasting Technical Reference.

**Unicast IP Routing**
Unicast routing forwards packets from one host to another host using the unicast destination IP address.

The Unicast IP Routing subject describes Internet Protocol version 4 (IPv4) unicast routing technologies included in the Routing and Remote Access service. The IP networking protocol is fundamental to the unicast routing that occurs on any Windows-based IPv4 network. This includes networks that use hardware routers, software-based routers, or a combination of both.

In addition to supporting IP routing, Windows Server 2003 also supports Appletalk routing; however, Windows Server 2003 does not support Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX) routing. Although, at some time in the future, IPv4 might be replaced by the next generation of IP, IP version 6 (IPv6), at present most unicast IP routing takes place over IPv4 networks. Windows Server 2003 supports both IPv4 and IPv6. This subject describes unicast IP routing in an IPv4 environment. For more information about Windows Server 2003 and IPv6, see "IPv6 Technical Reference."

**IP Multicasting**
Internet Protocol (IP) multicasting is the delivery of a single IP datagram to a group of hosts on a TCP/IP-based network. IP multicasting is the most practical method for point-to-multipoint data transmission because unicast IP routing requires multiple copies of the datagrams, and broadcast does not work across routers.

The IP Multicasting subject describes the IPv4 multicast forwarding functionalities included in the TCP/IP (IPv4) protocol and the Routing and Remote access service.

**NAT**
Windows Server 2003 provides network address translation (NAT) functionality as part of the Routing and Remote Access service. NAT provides a method for translating the IPv4 addresses of computers on one network into IPv4 addresses of computers on a different network. A NAT-enabled IP router deployed at the boundary where a private network meets a public network allows computers on the private network to access computers on the public network by providing this translation service.

**Routing Scenarios**

The ability for people to communicate by sending messages from one computer to another, whether the computers are located on the same network or on networks at opposite sides of the globe, has become commonplace. These communications are supported by routing methods described in the following scenarios.

**Demand-dial routing scenario**
Organizations looking to reduce the telephone costs incurred by their dial-in users may want to consider implementing demand-dial routing. Demand-dial routing reduces dial-in costs because the connection becomes active only when data is sent to the remote site. When no data has been sent over the link for a specified amount of time, the link is disconnected. By making a demand-dial connection, you can use existing dial-up telephone lines instead of leased lines for low-traffic situations. Demand-dial routing also provides organizations the ability to specify the hours that a router is allowed to dial out to make demand-dial connections. Demand-dial routing can significantly reduce connection costs.

**Unicast routing scenario**
Unicast routing over IP internetworks is a major part of the technology that makes such communication possible.

Today, the majority of internetwork traffic worldwide is over IPv4 networks, and most user-initiated traffic across IPv4 internetworks is unicast traffic. Any Windows-based network supports unicast IP routing, including networks that use only hardware routers, networks that use software-based routers such as that provided by the Windows Server 2003 Routing and Remote Access service, or a combination of hardware and software routers.

**IP multicasting scenario**
Recent trends in multimedia transmission across intranets and the Internet, such as video conferencing, live event broadcasting, and distance learning, require a bandwidth-conserving method of delivering data to multiple interested hosts. Of the delivery methods supported by IP, multicasting is the method that best addresses this need.

**NAT scenario**
The impetus initiating the development of NAT technology was the need to provide a temporary solution to the IPv4 address-depletion problem faced by the Internet community. The number of available globally unique (public) IPv4 addresses is far too few to accommodate the rapidly increasing number of computers that need access to the Internet. Although the long-term solution — the development of Internet Protocol version 6 (IPv6) addresses — exists, IPv6 is not yet widely adopted. NAT technology lets computers on any network use reusable private addresses to connect to computers with globally unique public addresses on the Internet.

NAT enables computers on small- to medium-sized organizations with private networks to access resources on the Internet or other public network. The computers on a private network are configured with reusable private IPv4 addresses; the computers on a public network are configured with globally unique IPv4 (or rarely, at present, IPv6) addresses. A typical deployment is a small office or home office (SOHO) or a medium-sized business that uses Routing and Remote Access NAT technology to enable computers on the internal corporate network to connect to resources on the Internet without having to deploy a proxy server.

# Demand Dial Routing Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Demand-Dial Routing Technical Reference**
Demand-dial routing is the forwarding of packets between networks and over Point-to-Point Protocol (PPP) links, such as analog phone lines and Integrated Services Digital Network (ISDN). Microsoft Windows Server 2003 provides extensive support for demand-dial routing, which is available as part of Routing and Remote Access.

# What Is Demand Dial Routing?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Types of Demand-Dial Connections
- Components of a Demand-Dial Connection
- Demand-Dial Routing vs. Remote Access
- Components of Secure Demand-Dial Connections
- Related Information

Demand-dial routing is available as part of Routing and Remote Access that is included in Microsoft Windows Server 2003.

Demand-dial routing is the forwarding of packets over Point-to-Point Protocol (PPP) links within a wide-area network (WAN) infrastructure of dial-up telecommunications technologies, including Public Switched Telephone Network (PSTN), Integrated Services Digital Network (ISDN), X.25, and Asynchronous Transfer Mode (ATM) over asymmetric digital subscriber line (ADSL). Demand-dial routing allows you to connect branch offices through the Internet and to implement dial-up site-to-site virtual private network (VPN) connections.

For more information about dial-up telecommunications technologies, see "Dial-up Remote Access Technical Reference."

**Types of Demand-Dial Connections**
Demand-dial connections are characterized as either on-demand or persistent and as either two-way initiated or one-way initiated.

These characteristics determine the configuration of the demand-dial interface.

**On-Demand and Persistent Connections**
Demand-dial connections are either on-demand or persistent.

**On-Demand Connections**
On-demand connections are used when the cost of using the communications link is time-sensitive. For example, the charges for long distance analog phone calls are on a per-minute basis. On-demand connections make the connection when traffic is forwarded and terminate the connection after a configured amount of idle time.

Idle disconnect behavior is configured on the calling router and the answering router.

- On the calling router, the idle disconnect time is set on the **General** tab of the properties of the demand-dial interface.
- On the answering router, the idle disconnect time is set on the **Dial-In Constraints** tab of the profile properties of the remote access policy being used by the demand-dial connection.

**Persistent Connections**
Persistent connections use a dial-up WAN technology when the cost of the link is fixed and the connection can be active 24 hours a day. Examples of WAN technologies for persistent demand-dial connections include local calls that use analog phone lines, leased analog lines, and flat-rate ISDN. If a persistent connection is lost, the calling router immediately attempts to reestablish the connection.

Persistent connection behavior must be configured on the calling router and the answering router.

**Two-Way and One-Way Initiated Connections**
Demand-dial connections are either two-way initiated or one-way initiated.

**Two-Way Initiated Connections**
With two-way initiated connections, either router can be the answering router or the calling router, depending on which router

initiates the connection. Both routers must be configured to initiate and accept a demand-dial connection. You use two-way initiated connections when traffic from either router can create the demand-dial connection. Two-way initiated demand-dial connections require that:

- Both routers are configured as local area network (LAN) and WAN routers.
- User accounts are added for both routers so that the authentication credentials of the calling router are accessed and validated by the answering router.
- Demand-dial interfaces are fully configured on both routers and include the phone number of the answering router and user account credentials to authenticate the calling router.
- Static routes are configured on both routers.

For two-way initiated demand-dial routing to work properly, the user account names of the calling routers on both sides of the connection must match the name of a demand-dial interface. The following table shows an example of this configuration.

**Example of Two-Way Initiated Connection Configuration**

| Router | User Account Name | Demand-Dial Interface Name |
|---|---|---|
| Corporate office router | CorpHub | NewYorkRouter |
| Branch office router | NewYorkRouter | CorpHub |

For a description of the two-way connection process, see "How Demand Dial Routing Works."

**One-Way Initiated Connections**

With one-way initiated connections, one router is always the answering router and the other router is always the calling router. In one-way initiated connections, the routing configuration is simplified because user accounts, demand-dial interfaces, and static IP routes do not need to be fully configured on both sides of the connection. Instead of configuring a demand-dial interface and static routes on the answering router, static routes are added to the dial-in properties of the user account of the calling router.

If your answering router is in a Windows Server 2003 or Windows 2000 Server mixed-mode domain or in a Microsoft Windows NT version 4.0 domain, static routes on the user account are not available. In this case, one-way initiated connections require that:

- Both routers are configured as LAN and WAN routers.
- A user account is added for the authentication credentials of the calling router.
- A demand-dial interface is configured at the calling router with the user credentials of the user account. A demand-dial interface is configured at the answering router with the same name as the user account that is used by the calling router. Because the demand-dial interface of the answering router is not used to dial out, it is not configured with the phone number of the calling router or with valid user credentials.

For a description of the one-way connection process, see "How Demand Dial Routing Works."

**Components of a Demand-Dial Connection**

A demand-dial connection contains the following components:

- Calling router, which initiates the demand-dial connection.
- Answering router, which accepts the demand-dial connection initiated by the calling router.
- Connection medium, which is either a physical medium or a tunnel medium. For more information about connection media, see "Connection Medium" later in this section.

**Components of a Demand-Dial Connection**

**Common Components for Routers**

The following components are common to both the calling router and the answering router:

- Routing and Remote Access
- Port

**Routing and Remote Access**

Routing and Remote Access on the calling router must be configured as a LAN and WAN router and configured for IP address allocation and authentication methods. IP addresses can be allocated either by using Dynamic Host Configuration Protocol (DHCP) or a static address pool.

**Port**

A port is a logical or physical communications channel that can support a single PPP connection. Physical ports are based on equipment installed in the calling router. VPN ports are logical ports.

**Calling Router Components**

In addition to Routing and Remote Access and a port, the calling router contains the following components:

- Demand-dial interface
- Route

**Demand-Dial Interface**

A demand-dial interface configured on the calling router represents the PPP connection and contains configuration information such as the port to use, the addressing used to create the connection (such as a phone number), authentication and encryption methods, and authentication credentials.

**Route**

An IP route in the routing tables of the calling router is configured to use a demand-dial interface to forward traffic.

**Answering Router Components**

In addition to Routing and Remote Access and a port, the answering router contains the following components:

- User account
- Demand-dial interface
- Route
- Remote access policy

### Note

- Two-way initiated and one-way initiated connections require different configurations for the answering router. For more information about two-way initiated and one-way initiated connections, see "Types of Demand-Dial Connections" in this section.

**User Account**

To authenticate the calling router, the credentials of the calling router must be verified by the properties of a corresponding user account. A user account for the calling router must be either locally present or available through Windows Server 2003

security. If the answering router is configured for RADIUS authentication, then the RADIUS server must have access to the user account of the calling router.

The user account must have the following settings:

- On the **Dial-in** tab, remote access permission is set to either **Allow access** or **Control access through Remote Access Policy**.
- On the **General** or **Account** tab, **User must change password at next logon** is disabled and **Password never expires** is enabled.

For a one-way initiated connection, configure static IP routes that are added to the answering router's routing table when the demand-dial connection is made.

**Demand-Dial Interface**
For two-way initiated connections, a demand-dial interface configured on the answering router represents the PPP connection to the calling router. For a one-way initiated connection using static routes on the user account of the calling router, a demand-dial interface on the answering router does not need to be configured.

**Route**
For two-way initiated connections, an IP route in the routing tables of the calling router is configured to use a demand-dial interface to forward traffic.

For one-way initiated connections, you can configure the user account of the calling router with static IP routes.

**Remote Access Policy**
To specify connection parameters that are specific to demand-dial connections, create a separate remote access policy that uses the **Windows-Groups** attribute set to the group, which has all of the user accounts for calling routers as members. A separate remote access policy for demand-dial connections is not required.

**Connection Medium**
The PPP link is established over either a physical medium or a tunnel medium. Physical media includes PSTN, ISDN, X.25, and ATM over ADSL. Tunnel media includes Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol (L2TP). For more information about PPP, see "Dial-up Remote Access Technical Reference."

**PPPoE**
PPPoE is a method of encapsulating PPP frames so that they can be sent over an Ethernet network. Using PPPoE and a broadband modem, LAN clients can gain individual authenticated access to high-speed data networks. For more information about PPPoE, see "Dial-up Remote Access Technical Reference."

**Demand-Dial Routing vs. Remote Access**
Remote access is not the same as demand-dial routing. Remote access connects a single user to a network. Demand-dial routing connects networks together. However, both remote access and demand-dial routing use PPP to negotiate and authenticate the connection and encapsulate data sent on the connection. As implemented in Routing and Remote Access for Windows Server 2003, both remote access and demand-dial connections can be enabled separately but share the same:

- Behavior of the dial-in properties of user accounts.
- Security, including authentication protocols and encryption.
- Use of remote access policies.
- Use of Windows or Remote Authentication Dial-In User Service (RADIUS) as authentication providers.
- IP address allocation configuration.
- Use of PPP features, such as Microsoft Point-to-Point Compression (MPPC), Multilink Protocol (MP), and Bandwidth Allocation Protocol (BAP).
- Troubleshooting facilities, including event logging, Windows or RADIUS authentication and accounting, logging, and tracing.

**Remote Access Clients and Routers**
Because the routing service and the remote access service coexist on a server running Routing and Remote Access, both routers and remote access clients can call the same phone number. The server running Routing and Remote Access that answers the call must be able to distinguish a remote access client from a router that is calling to create a demand-dial connection. To differentiate a remote access client from a demand-dial router, the user name in the authentication credentials sent by the calling router must exactly match the name of a demand-dial interface on the answering router. Otherwise, the incoming connection is assumed to be a remote access connection.

**Components of Secure Demand-Dial Connections**
Security for demand-dial connections uses the following security methods:

- Remote access permission
- User-level and computer-level authentication
- One-way and mutual authentication
- Encryption
- Packet filtering

For information about callback and caller ID, see "Dial-up Remote Access Technical Reference." For information about remote access account lockout, see "IAS Technical Reference."

**Remote Access Permission**
The user account of the calling router must be a valid account in the security database of the answering router or RADIUS server (if RADIUS authentication is being used); it must be granted remote access permission either explicitly in the user account (remote access permission of the dial-in properties of the user account is set to **Allow access**) or implicitly through the remote access permission setting on a remote access policy (the remote access permission of the dial-in properties of the user account is set to **Control access through Remote Access Policy** and a matching remote access policy remote access permission is set to **Grant remote access**).

**User-Level and Computer-Level Authentication**
The calling router can be authenticated at the user level and the computer level.

**User-Level Authentication**
As part of the PPP connection establishment process, the calling router's credentials must be authenticated. User-level authentication occurs through one of the following PPP authentication methods:

- Password Authentication Protocol (PAP)
- Shiva Password Authentication Protocol (SPAP)
- Challenge Handshake Authentication Protocol (CHAP)
- Microsoft Challenge Handshake Authentication Protocol version 1 (MS-CHAP)
- Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAP v2)
- Extensible Authentication Protocol-Message Digest 5 Challenge (EAP-MD5)
- Extensible Authentication Protocol-Transport Layer Security (EAP-TLS)

For all of the authentication methods except EAP-TLS, the calling router's credentials consist of a user name, a domain, and a password. For all of the authentication methods except PAP, the password is sent over the connection in an encrypted or hashed form.

In the case of EAP-TLS, the calling router's credentials consist of a user certificate that is validated by the answering router. EAP-TLS requires a public key infrastructure (PKI) to issue and validate certificates.

For more information about PPP authentication protocols, see "Dial-up Remote Access Technical Reference."

**Computer-Level Authentication**
Computer-level authentication for demand-dial routing occurs in the following cases:

- When Internet Protocol security (IPSec) is used for a L2TP over IPSec demand-dial connection, computer-level authentication is performed through the exchange of computer certificates (also known as machine certificates) during the establishment of the IPSec security association.

- When EAP-TLS is used for user-level authentication, the answering router authenticates itself to the calling router by sending its computer certificate.

Computer certificates require a PKI to issue and validate certificates.

**One-Way and Mutual Authentication**
Authentication of the demand-dial routing connection can be one-way or mutual.

**One-Way Authentication**
With one-way authentication, the calling router authenticates itself to the answering router. PAP, SPAP, CHAP, MS-CHAP v1, and EAP-MD5 authentication methods provide for the passing of credentials from the calling router to the answering router only. With one-way authentication, the calling router does not receive any verification that the answering router is the authorized router. One-way authentication does not provide protection from unauthorized or masquerading answering routers.

**Mutual Authentication**
With mutual authentication, the calling router authenticates itself to the answering router and the answering router authenticates itself to the calling router. Both ends of the connection verify the identity of the other end of the connection. MS-CHAP v2 and EAP-TLS authentication methods provide mutual authentication.

With MS-CHAP v2, both sides of the connection send a hash of a challenge string and the user password. If successful, both ends of the connection receive verification that the other end of the connection has access to the user account's password.

With EAP-TLS, the calling router sends a user certificate that is validated by the answering router and the answering router sends a computer certificate that is validated by the calling router. EAP-TLS is the most secure form of mutual authentication; however, it requires a PKI.

Windows NT 4.0 with the Routing and Remote Access Service (RRAS) supports a feature called two-way authentication. Two-way authentication uses one-way authentication methods to perform mutual authentication. When two-way authentication is enabled on a demand-dial interface, the calling router forces the answering router to authenticate itself after the calling router authenticates itself to the answering router. A Windows 2000 calling router never requests to authenticate a Windows NT 4.0 RRAS answering router. However, a Windows 2000 answering router authenticates itself when requested by a Windows NT 4.0 RRAS calling router.

**Encryption**
There are two forms of encryption available for demand-dial connections: Microsoft Point-to-Point Encryption (MPPE) and IPSec.

**MPPE**
All PPP connections, including PPTP but not including L2TP, can use MPPE. MPPE uses the Rivest-Shamir-Adleman (RSA) RC4 stream cipher and is used only when the EAP-TLS, MS-CHAP, or MS-CHAP v2 authentication methods are used.

MPPE can use 40-bit, 56-bit, or 128-bit encryption keys — the higher the number of bits, the higher the key strength. The 40-bit key is designed for backward compatibility and international use. The 56-bit key is designed for international use and adheres to United States encryption export laws. The 128-bit key is designed for North American use. By default, the highest key strength supported by the calling router and answering router is negotiated during the connection-establishment process. If the answering router requires a higher key strength than is supported by the calling router, the connection attempt is rejected.

**IPSec**
For demand-dial connections using L2TP over IPSec, encryption is determined by the establishment of the IPSec security association (SA). The available encryption algorithms include:

- Data Encryption Standard (DES) with a 56-bit key.

- Triple DES (3DES), which uses three 56-bit keys and is designed for high-security environments.

The initial encryption keys are derived from the IPSec authentication process. For more information, see "VPN Technical Reference."

**Packet Filtering**
Routing and Remote Access supports IP packet filtering, which prevents certain types of network packets from either being sent or received. IP packet filtering specifies the type of traffic that is allowed into (input filters) and out of (output filters) the router.

**Demand-Dial Interface Packet Filtering**
You can set packet filters for each demand-dial interface and configure the filters to do one of the following:

- Pass through all traffic except packets prohibited by the filters.
- Discard all traffic except packets allowed by the filters.

IP packet filtering only occurs when the demand-dial interface is in a connected state.

Packet filtering is especially useful for an extranet, a portion of your private intranet that is accessible to business partners over demand-dial connections. For example, when a business partner makes a demand-dial connection, packet filters on the demand-dial interface can restrict the TCP/IP traffic to specific network segments or specific resources, as identified by IP address and TCP or UDP port number.

**Remote Access Policy Profile Packet Filtering**
In addition to demand-dial interface packet filtering, IP packet filters can be configured on the profile of the remote access policy configured for calling routers. While primarily designed to restrict the traffic of remote access connections, remote access policy profile-based IP packet filters can be used for demand-dial routing. Rather than configure the same IP packet filters on many demand-dial interfaces, if all the demand-dial connections share the same IP packet filters and remote access policy, then remote access policy profile packet filters allow you to configure the IP packet filters once for all of the demand-dial connections.

# How Demand Dial Routing Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Demand-Dial Routing and Routing Protocols
- Demand-Dial Routing Processes and Interactions
- Related Information

Microsoft Windows Server 2003 provides extensive support for demand-dial routing, which is available as part of Routing and Remote Access.

With demand-dial routing, packets are forwarded between networks and over Point-to-Point Protocol (PPP) links. The PPP link is represented inside the Windows Server 2003 router as a demand-dial interface. Demand-dial interfaces are used to connect networks (for example, between branch offices and the corporate office) through the Internet or through dial-up site-to-site virtual private networks (VPNs).

For more information about dial-up site-to-site VPNs, see "Dial-up Site-to-Site VPN" later in this section.

With local area network (LAN) and permanent wide area network (WAN) links, the interface that is used to forward the packets is always in an active or connected state. The packets can be forwarded without having to create the physical or logical connection. However, the demand-dial interface can be either in a connected state or a disconnected state, depending on the type of connection. The demand-dial interface must be changed to a connected state before the packet can be forwarded.

For information about the types of demand-dial connections, see "What Is Demand Dial Routing?."

**Note**

- Because demand-dial routing is an implementation of Routing and Remote Access technologies, including unicast routing and multicasting, it is integrated within the Routing and Remote Access architecture. For information about the architecture of Routing and Remote Access, see "Unicast IPv4 Routing Technical Reference" and "IPv4 Multicasting Technical Reference."

**Demand-Dial Routing and Routing Protocols**

The method for updating the routing tables of demand-dial routers depends on the type of demand-dial connection. For on-demand connections, use static routing. For persistent connections, use dynamic routing with routing protocols.

For more information about on-demand and persistent connections, see "What Is Demand Dial Routing?"

**Routing with On-Demand Connections**

Static routing is recommended for on-demand connections for the following reasons:

- The routing protocols that are provided with Routing and Remote Access—Open Shortest Path First (OSPF) and Routing Information Protocol (RIP) for Internet Protocol (IP)—can either cause the connection to be made each time routing tables are advertised or keep the connection open permanently if the advertising interval is less than the idle time-out.

- To trigger an on-demand connection, it is necessary to add static routes to the route table. RIP and OSPF do not require static routes to operate. Rather, RIP and OSPF are designed to prevent an administrator from having to add static routes to a route table. RIP and OSPF simply listen for dynamic route updates and add new routes to the route table as appropriate.

- RIP for IP and OSPF detect unsuccessful network connections and, through time-out mechanisms, report these problems to neighboring routers. This means that these protocols assume that network connections are permanent unless they are disconnected. This assumption is inaccurate for on-demand connections, which are connected only when needed and are disconnected when no traffic is being routed.

Because of the time, distance, and cost-sensitive nature of typical dial-up WAN links, the use of routing protocols for on-demand connections is not recommended.

For more information about OSPF and RIP for IP, see "Unicast IPv4 Routing Technical Reference."

**Manual Configuration of Static Routes**
Manual configuration of static routes is the adding of static routes (for TCP/IP traffic, static IP routes) that are available across the demand-dial interface through the use of Routing and Remote Access.

**Using a Default IP Route for an On-Demand Connection**
The default IP route (0.0.0.0/0) summarizes all IP destinations and becomes the route used to forward IP packets when a more specific route is not found. Although the default IP route can be used to simplify static routing for on-demand connections, be sure to use the default IP route carefully.

Using the default IP route assumes that all other destinations are in the direction of the default route. The assumption is valid if you are using a demand-dial interface to connect to the Internet. However, if you are using a demand-dial interface to connect a branch office to a corporate office in a private intranet, using the default IP route can produce undesirable results for unreachable traffic.

If a default IP route is configured to use a demand-dial interface, then it is possible that a demand-dial connection can be initiated for IP traffic that is unreachable. For example, if an organization is using the private IP network 10.0.0.0/8 for its address space and a branch office uses 10.1.1.0/24 for the hosts of the branch office, then the static routing of the branch office router can be configured as follows:

**Example 1: Configure a static route for 10.0.0.0/8 using the on-demand demand-dial interface.**
If someone in the branch office attempts to send traffic to the destination IP address of 192.168.0.1, the router at the branch office does not have a route in its routing table for the packet. The packet is discarded and an ICMP (Internet Control Message Protocol) Destination Unreachable-Host Unreachable message is sent to the sending host.

**Example 2: Configure a default route for 0.0.0.0/0 using the on-demand demand-dial interface.**
If someone in the branch office attempts to send traffic to the destination IP address of 192.168.0.1, the router at the branch office initiates the connection and forwards the packet across the demand-dial connection to the corporate router. Neither the corporate router nor another router on the corporate intranet has a route in its routing table for the packet. The packet is discarded and an ICMP Destination Unreachable-Host Unreachable message is sent to the sending host.

In Example 1, the branch office immediately determines that the IP traffic destination is unreachable and does not initiate a connection to the corporate office.

In Example 2, the IP traffic destination is determined to be unreachable only after the branch office initiates the connection and the IP traffic reaches the corporate office.

For more information about default IP routes and routing tables, see "Unicast IPv4 Routing Technical Reference."

**Auto-Static Updates**
When the number of routes is large or when routes change, manual configuration of static routes is no longer a viable administrative option. For this reason, Routing and Remote Access supports auto-static updates, the process of automatically adding static routes to the routing table.

When you configure an interface to use auto-static update mode, the router sends a request to other routers and inherits routes. The routes are saved in the routing table as auto-static routes and are kept even if the router is restarted or the interface becomes unavailable. Auto-static updates are supported in RIP for IP, but are not available for use with OSPF.

### Note

- The "auto" in "auto"-static refers to the automatic adding of the requested routes as static routes in the routing table. The sending of the request for routes is performed through an explicit action while the demand-dial interface is in a connected state. Auto-static updates are not automatically performed every time a demand-dial connection is made.

An auto-static update requests all known routes or services from the router on the other side of the connection and adds them to the routing tables of the requesting router. An auto-static update is a one-time, one-way exchange of routing information. After the routes are sent, the two routers do not periodically advertise even though the connection remains in a connected state.

To use auto static updates for IP routes, the demand-dial interface must be added to the RIP routing protocol. The default operation mode for demand-dial interfaces for RIP is Autostatic update mode. The default outgoing packet protocol is RIP version 2 multicast. The default settings are correct when initiating a connection with another Windows Server 2003 router.

**Note**

- When an auto-static update is requested, the existing routes that were obtained through a previous auto-static update are deleted before the request for routes is sent. If there is no response to the request, then the router cannot replace the routes it has deleted. This might lead to a loss of connectivity to remote networks.

Auto-static updates can be scheduled or made manually.

**Scheduled Auto-Static Updates**
You can schedule auto-static updates to occur periodically by using a combination of Netsh utility scripts and Task Scheduler. For more information, see "Demand Dial Tools and Settings."

**Manual Auto-Static Updates**
In the Routing and Remote Access snap-in, you can manually update static IP routes.

The transfer of IP routing information occurs through RIP for IP. The router on which the update was initiated sends a General RIP Request. The router on the other end of the connection responds with a RIP Response containing all of the appropriate routes in its IP routing table. The RIP routes received by the requesting router are automatically added as static routes to the requesting router's IP routing table. For more information about RIP messages, see "Unicast IPv4 Routing Technical Reference."

**Routing with Persistent Connections**
For persistent demand-dial connections, you can enable routing protocols to operate the same way as LAN interfaces to provide dynamic updates of routing tables. The following table describes the configuration of the routing protocol for a persistent demand-dial interface.

**Routing Protocol Configuration for a Persistent Demand-Dial Connection**

| Routing Protocol | Configuration Change |
|---|---|
| RIP for IP | Default operation mode is Periodic update mode and triggered updates are enabled. |
| OSPF | On the **General** tab on the properties of an OSPF interface, select the Point-to-Point network type. This is the default network type for demand-dial interfaces. For a persistent site-to-site VPN connection, on the **Advanced** tab on the properties of an OSPF interface, you might want to increase the values of the transit delay, the re-transmit interval, the hello interval, and the dead interval to account for the delay of forwarding OSPF packets across the Internet. |

Routing protocols provided by Windows Server 2003 Routing and Remote Access must run over numbered connections. Although unnumbered connections are supported by Routing and Remote Access, routing protocols cannot operate over them. For unnumbered connections, you must use static routing.

For more information about numbered and unnumbered connections, see "Address Allocation for TCP/IP-Based Connections" later in this section.

**Using MP and BAP**
Multilink Protocol (MP) and Bandwidth Allocation Protocol (BAP) can be used with demand-dial routing to automatically add physical connections to a Multilink PPP connection when network traffic increases and remove physical connections when the network traffic decreases.

**Note**

- If one of the physical links of the Multilink logical link is dropped, and BAP is not being used for the connection, then the dropped link will not be redialed.

For more information about Multilink PPP, see "Dial-up Remote Access Technical Reference."

**Demand-Dial Routing Processes and Interactions**
This section describes the following processes that take place when establishing demand-dial-routing connections.

- Connection establishment delay
- Address allocation for TCP/IP-based connections
- Two-way initiated and one-way initiated connections

- Dial-up site-to-site VPN connection

**Connection Establishment Delay**
The connection establishment process, which consists of creating a physical or a logical connection and a PPP connection, introduces a delay in the forwarding of the packet called the connection establishment delay. The length of the connection establishment delay varies, depending on the type of physical or logical connection being established. For example, the connection establishment delay for analog phone lines or X.25 dialing in to a packet assembler-disassembler (PAD) can be 10 to 20 seconds or more. For Integrated Services Digital Network (ISDN) lines, the connection establishment delay can be as short as 3 to 5 seconds.

Because the connection establishment delay affects applications that are being used across a demand-dial connection, the following factors must be considered:

- How long it takes for the application to abandon the attempt to establish network communications, also known as application time-out. If the application time-out is longer than the connection establishment delay, then the application fails to establish communications and presents an error message to the user.

- How many times the application attempts to establish network communications. On the first attempt, network traffic is forwarded to the demand-dial router, which begins the connection establishment process. Due to the limited size of a buffer in the router, additional packets that arrive during the connection establishment process to be forwarded across the demand-dial connection might overwrite the initial application connection attempt packet. If the application tries to establish communications multiple times, then there is a better chance of forwarding an application connection attempt packet after the connection is established.

Applications that have long time-outs or multiple retries might not fail while waiting for the link to become available. Interactive applications, such as Web browsers and Telnet, might fail when first connecting. However, when the user retries, the connection attempt succeeds because the first connection attempt created the demand-dial connection.

After the connection is established, packets are forwarded across the demand-dial connection. Because the costs of demand-dial connections are typically time-sensitive, after a configured amount of idle time, the demand-dial link is terminated.

**Address Allocation for TCP/IP-Based Connections**
For a TCP/IP-based demand-dial connection, TCP/IP connection settings are negotiated. An important element of a TCP/IP-based PPP connection is the allocation of an IP address.

**Numbered Connections**
When a call is initiated between demand-dial routers (either servers running Windows Server 2003 Routing and Remote Access or servers running Windows NT 4.0 Routing and Remote Access Service [RRAS]), the calling router requests an IP address from the answering router; the answering router requests an IP address from the calling router. If both routers have an IP address to give each other, the logical interface on the PPP connection for each router is assigned an IP address from the other router. This is known as a numbered connection.

**Windows NT 4.0 Connections**
Windows NT 4.0 RRAS demand-dial connections require a numbered connection. If either the calling or the answering router does not have an IP address to assign to the other router, the connection establishment process fails. For both routers to assign IP addresses to each other, you must configure both routers for the proper IP address assignment behavior through the properties of RRAS.

### Note

- With RRAS, the default configuration for IP address assignment is to obtain an IP address through DHCP and no DHCP server is available on the network. Because no IP address is allocated to the other router, the connection establishment process fails.

- This common configuration problem is resolved by the following features in Windows Server 2003 Routing and Remote Access:

- Use of Automatic Private IP Addressing (APIPA) addresses.

- Support for unnumbered connections.

**APIPA Addresses**
In Routing and Remote Access, the default IP address assignment configuration is still to obtain an IP address from a DHCP server. However, if a DHCP server is not available, APIPA addresses in the range 169.254.0.0 through 169.254.255.255 with subnet mask 255.255.0.0 are used. Therefore, the default configuration does not prevent two routers from establishing a numbered connection. For more information about APIPA, see "DHCP Technical Reference."

**Unnumbered Connections**
By default, demand-dial connections do not require a numbered connection. The calling and answering routers request an IP address from each other during the connection establishment process. However, if one of the routers rejects the request, both routers continue the connection establishment process. The logical interface on the point-to-point connection does not have an assigned IP address. This is known as an unnumbered connection.

With unnumbered connections, servers running Routing and Remote Access can connect to other routers that do not assign an IP address during the connection establishment process. For example, some Internet service providers (ISPs) prefer to use an unnumbered connection to conserve IP addresses. The Internet connection can be unnumbered because you would typically configure a default static IP route rather than run a routing protocol.

**Two-Way and One-Way Initiated Connections**
This section illustrates the complexity and elegance of demand-dial routing through examples of the two-way initiated and the one-way initiated connections.

The following figure shows the basic configuration between two offices that use demand-dial IP routing.

### Demand-Dial IPv4 Routing Between Two Offices

The Seattle office has a server running Routing and Remote Access that acts as a remote access server and demand-dial router. All computers in the Seattle office are connected to the 172.16.1.0 network (subnet mask 255.255.255.0). The Seattle router (hereafter referred to as Router 1) has a modem connected to its COM1 port; the phone number of the modem is 555-0111.

The New York office has a server running Routing and Remote Access that acts as a remote access server and demand-dial router. All computers in the New York office are connected to the 172.16.2.0 network (subnet mask 255.255.255.0). The New York router (hereafter referred to as Router 2) has a modem connected to its COM2 port; the phone number of the modem is 555-0122.

The user on the computer with the IP address of 172.16.1.10 must be able to connect to the user on the computer with the IP address of 172.16.2.20, and vice versa.

This section describes the process by which Router 1 and Router 2 are configured; it also provides examples of two-way and one way initiated connections that use those router configurations.

**Router Configuration**
The following describes the configuration of Router 1 and Router 2.

**Configuring Router 1**
The configuration for demand-dial routing on Router 1 consists of the following three steps:

1. Create a demand-dial interface.

2. Create a static route.

3. Create an account that Router 2 uses when calling Router 1.

**Create a demand-dial interface**
By using Routing and Remote Access with the Demand-Dial Interface Wizard, the administrator at Router 1 creates a demand-

dial interface called DD_NewYork with the configuration shown in the following table.

**Demand-Dial Interface Configuration for Router 1**

| Configuration Information | Description |
|---|---|
| Equipment | Modem on COM1 |
| Phone number | 555-0122 |
| Protocols | TCP/IP |
| Authentication credentials | DD_Seattle with a password |

**Create a static route**

By using Routing and Remote Access, the Demand-Dial Interface Wizard will already have the name and destination of the static route with the configuration shown in the following table.

**Static Route Configuration for Router 1**

| Static Route Information | Description |
|---|---|
| Interface | DD_NewYork |
| Destination | 172.16.2.0 |
| Network mask | 255.255.255.0 |
| Metric | 1 |

**Note**

- Because the demand-dial connection is a point-to-point connection, the gateway IP address cannot be configured.

**Create a user account with dial-in permissions**

By using Active Directory Users and Computers or Local Users and Groups, the administrator at Router 1 creates a user account with the settings in the following table.

**User Account with Dial-In Permissions for Router 1**

| Account Information | Description |
|---|---|
| Account name | DD_NewYork with a password |
| Account settings | Clear the **User must change password at next logon** check box and select the **Password never expires** check box |

The DD_NewYork account is granted dial-in permissions either through the dial-in properties of the user account or through remote access policies. For more information about remote access policies, see "Dial-up Remote Access Technical Reference" and "IAS Technical Reference."

**Configuring Router 2**

The configuration for demand-dial routing on Router 2 consists of the following three steps:

1. Create a demand-dial interface.
2. Create a static route.
3. Create an account that Router 2 uses when calling Router 1.

**Create a demand-dial interface**

By using Routing and Remote Access with the Demand-Dial Interface Wizard, the administrator at Router 2 creates a demand-dial interface called DD_Seattle with the configuration shown in the following table.

**Demand-Dial Interface Configuration for Router 2**

| Configuration Information | Description |
|---|---|
| Equipment | Modem on COM2 |
| Phone number | 555-0111 |
| Protocols | TCP/IP |
| Authentication credentials | DD_NewYork with a password |

**Create a static route**

By using Routing and Remote Access, the Demand-Dial Interface Wizard will already have the name and destination of the static route with the configuration shown in the following table.

**Static Route Configuration for Router 2**

| Static Route Information | Description |
|---|---|
| Interface | DD_Seattle |
| Destination | 172.16.1.0 |
| Network mask | 255.255.255.0 |
| Metric | 1 |

**Note**

- Because the demand-dial connection is a point-to-point connection, the gateway IP address cannot be configured.

**Create a user account with dial-in permissions**

By using Active Directory Users and Computers or Local Users and Groups, the administrator at Router 2 creates a user account with the settings in the following table.

**User Account with Dial-In Permissions for Router 2**

| Account Information | Description |
|---|---|
| Account name | DD_Seattle with a password |
| Account settings | Clear the **User must change password at next logon** check box and select the **Password never expires** check box |

The DD_Seattle account is granted dial-in permissions either through the dial-in properties of the user account or through remote access policies. For more information about remote access policies, see "Dial-up Remote Access Technical Reference" and "IAS Technical Reference."

**Resulting Configuration**

The following figure shows the demand-dial routing configuration in terms of the demand-dial interfaces, static routes, and user accounts for the routers for the Seattle and New York offices.

**Resulting Configuration for the Seattle and New York Offices**

**Example of a Two-Way Initiated Demand-Dial Connection**

For two-way initiated demand-dial routing to work properly, authentication credentials (such as user account name) for the demand-dial interface must be created on both servers running Routing and Remote Access. This example shows a proper configuration and is summarized in the following table.

**Resulting Demand-Dial Routing Configuration**

| Router | Demand-Dial Interface Name | User Account Name |
|---|---|---|
| Router 1 | DD_NewYork | DD_Seattle |
| Router 2 | DD_Seattle | DD_NewYork |

The following is an example of the process by which a two-way initiated connection takes place. For more information about two-way initiated connections, see "What Is Demand Dial Routing?."

When the user at 172.16.1.10 tries to connect to a resource at 172.16.2.20, the following events occur:

1. Packets from 172.16.1.10 destined for 172.16.2.20 are forwarded to Router 1.
2. Router 1 receives the packet from 172.16.1.10 and checks its routing table. It finds a route to 172.16.2.20 that uses the DD_NewYork interface.
3. Router 1 checks the state of the DD_NewYork interface and finds it is in a disconnected state.
4. Router 1 retrieves the configuration of the DD_NewYork demand-dial interface.
5. Based on the DD_NewYork configuration, Router 1 uses the modem on COM1 to dial the number 555-0122.
6. Router 2 answers the incoming call.
7. Router 2 requests authentication credentials from the incoming caller.
8. Router 1 sends the user name, DD_Seattle, with its associated password.
9. Upon receiving the authentication credentials, Router 2 checks the user name and password against the security features of Windows Server 2003 and verifies that Router 1 has dial-in permission through the dial-in properties of the DD_Seattle user account and the configured remote access policies.
10. Router 2 must now determine whether the incoming caller is a dial-up networking client or a router that is creating a demand-dial connection. Router 2 looks in its list of demand-dial interfaces to find one that matches the user name sent by Router 1 as part of the authentication credentials. Router 2 finds a demand-dial interface, DD_Seattle, that matches the user name credential.
11. Router 2 changes the state of the DD_Seattle demand-dial interface to a connected state.

12. Router 1 forwards the packet from the computer at 172.16.1.10 across the demand-dial connection to Router 2.

13. Router 2 receives the packet and forwards it to the computer at 172.16.2.20.

14. The response to the connection request by the computer at 172.16.1.10 is forwarded to Router 2 by the computer at 172.16.2.20.

15. Router 2 receives the packet destined for 172.16.1.10 and checks its routing table. It finds a route to 172.16.1.10 by using the DD_Seattle interface.

16. Router 2 checks the state of the DD_Seattle interface and finds it is in a connected state.

17. Router 2 forwards the packet to Router 1.

18. Router 1 forwards the packet to the computer at 172.16.1.10.

**Router vs. Remote Access Client**

If the user name credential does not match the name of an appropriate demand-dial interface, the calling entity is identified as a remote access client, which can result in routing problems.

For example, if Router 1 uses DialUpRouter1 as its user name credential, then Router 1 is identified as a remote access client rather than a router (assuming DialUpRouter1 is a valid account with dial-in permissions). Packets are routed from the user at 172.16.1.10 to the user at 172.16.2.20, as described earlier.

However, response packets from 172.16.2.20 to 172.16.1.10 are forwarded to Router 2 which, upon inspecting its routing table, determines that the interface to use is DD_Seattle. DD_Seattle is in a disconnected state. Based on the configuration for DD_Seattle, COM2 should be used. However, COM2 is currently being used for a remote access client (Router 2). Router 2 then tries to locate a modem that is not being used. If found, Router 2 dials Router 1 and forwards the packet after the connection has been established. If another modem cannot be found, the response packets from 172.16.2.20 to 172.16.1.10 are dropped.

**Example of a One-Way Initiated Demand-Dial Connection**

The following is an example of the process by which a one-way initiated connection takes place. For more information about one-way initiated connections, see "What Is Demand Dial Routing?"

When the user at 172.16.1.10 tries to connect to a resource at 172.16.2.20, the following events occur:

1. Packets from 172.16.1.10 destined for 172.16.2.20 are forwarded to Router 1.

2. Router 1 receives the packet from 172.16.1.10 and checks its routing table. It finds a route to 172.16.2.20 by using the DD_NewYork interface.

3. Router 1 checks the state of the DD_NewYork interface and finds it is in a disconnected state.

4. Router 1 retrieves the configuration of the DD_NewYork demand-dial interface.

5. Based on the DD_NewYork configuration, Router 1 uses the modem on COM1 to dial the number 555-0122.

6. Router 2 answers the incoming call.

7. Router 2 requests authentication credentials from the incoming caller.

8. Router 1 sends the user name, DD_Seattle, with its associated password.

9. Upon receiving the authentication credentials, Router 2 checks the user name and password against the security features of Windows Server 2003 and verifies that Router 1 has dial-in permission through the dial-in properties of the DD_Seattle user account and the configured remote access policies.

10. Router 2 retrieves the static route (172.16.1.0 with the subnet mask of 255.255.255.0) that is configured on the

DD_Seattle user account and creates a corresponding static route in its routing table. If Router 2 is configured with routing protocols, Router 2 uses routing protocols to communicate with neighboring routers so that the route to the Seattle network is propagated to all of the routers in the New York office.

11. Router 2 must now determine whether the incoming caller is a dial-up networking client or a router creating a demand-dial connection. Router 2 looks in its list of demand-dial interfaces and does not find one called DD_Seattle. Therefore, Router 2 considers the connection to the Seattle office to be a remote access connection.

12. Router 1 forwards the packet from the computer at 172.16.1.10 across the demand-dial connection to Router 2.

13. Router 2 receives the packet and forwards it to the computer at 172.16.2.20.

14. The response to the connection request by the computer at 172.16.1.10 is forwarded to Router 2 by the computer at 172.16.2.20.

15. Router 2 receives the packet destined for 172.16.1.10 and checks its routing table. A route to 172.16.1.10 is found by using the connection to Router 1.

16. Router 2 forwards the packet to Router 1.

17. Router 1 forwards the packet to the computer at 172.16.1.10.

**Note**

- When the connection is made, the static routes on the user account of the calling router are added to the routing table of the answering router. If routing protocols are used to propagate the new static route, then there is a delay between the time the connection is made and the time when all of the routers on the intranet of the answering router are aware of the new route. Therefore, hosts on the intranet of the calling router might experience a delay between the time that the connection is made and the time when they begin to receive traffic from hosts on the intranet of the answering router.

**Dial-up Site-to-Site VPN**

A site-to-site VPN connection (also known as a router-to-router VPN connection) is typically used to connect remote offices together when both routers are connected to the Internet through permanent WAN links, such as T1 or Frame Relay. In this configuration, the VPN connection is always available. However, when a permanent WAN link is not possible or practical, you can configure a dial-up site-to-site VPN connection.

The following figure shows a dial-up site-to-site VPN connection.

**Dial-up Site-to-Site VPN Connection**

A dial-up site-to-site VPN connection consists of two demand-dial interfaces and two static routes that are configured on the VPN client (the calling router) as follows. In this discussion, the VPN client is the branch office router.

- A demand-dial interface to dial in to a local ISP.

- A demand-dial interface for the site-to-site VPN connection.

- A static host route to dynamically connect to the Internet.

- A static route to reach the locations of the corporate office.

A dial-up site-to-site VPN connection is automatically established when you route traffic. For example, in a branch office configuration, upon receipt of a packet to be routed to the corporate office, the branch office router uses a dial-up link to connect to a local ISP and then creates a site-to-site VPN connection with the corporate office router located on the Internet.

**Note**

- This discussion assumes that the corporate office router (the answering router) is connected to the Internet by using a permanent WAN link. It is possible to have both routers connected to the Internet by using a dial-up WAN link. However, this is feasible only if the ISP supports demand-dialing routing to customers; the ISP calls the customer router when an IP datagram is to be delivered to the customer. Demand-dial routing to customers is not widely supported by ISPs.

**Router Configuration**

The branch office router and the corporate office router must be configured for the site-to-site VPN connection.

A dial-up site-to-site VPN connection at the branch office router is configured as follows:

1. A demand-dial interface for the Internet connection is configured for the appropriate equipment (a modem or ISDN device), the phone number of the local ISP, and the user name and password to gain Internet access.

2. A demand-dial interface for the VPN connection with the corporate office router is configured for a VPN port (a Point-to-Point Tunneling Protocol [PPTP] or Layer Two Tunneling Protocol [L2TP] port), the IP address of the interface on the Internet for the corporate office router, and a user name and password that can be verified by the VPN server. The user name must match the name of a demand-dial interface on the corporate office router.

3. A static host route to the corporate office router is created that uses the ISP demand-dial interface.

4. A static route (or routes) for the IP network IDs of the corporate intranet is created that uses the VPN demand-dial interface.

The corporate office router is configured as follows:

1. A demand-dial interface for the VPN connection with the branch office router is configured for a VPN port (a PPTP or L2TP port). The demand-dial interface must have the same name as the user name in the authentication credential that is used by the branch office router to create the VPN connection.

2. A static route (or routes) for the IP network IDs of the branch office is created that uses the VPN demand-dial interface.

**Dial-up Site-to-Site VPN Connection**

The dial-up site-to-site VPN connection is automatically initiated by the branch office router through the following process:

1. Packets sent to a corporate hub network location from a computer in the branch office are forwarded to the branch office router.

2. The branch office router checks its routing table and finds a route to the corporate intranet network ID, which uses the VPN demand-dial interface.

3. The branch office router checks the state of the VPN demand-dial interface and finds that the demand-dial interface is in a disconnected state.

4. The branch office router retrieves the configuration of the VPN demand-dial interface.

5. Based on the VPN demand-dial interface configuration, the branch office router attempts to initialize a site-to-site VPN connection at the IP address of the corporate office router on the Internet.

6. To establish a VPN, either a Transmission Control Protocol (TCP) (by using PPTP) or User Datagram Protocol (UDP) (by using L2TP/Internet Protocol security [IPSec]) packet must be sent to the corporate office router that acts as the VPN

server. The VPN establishment packet is created.

7. To forward the VPN establishment packet to the corporate office router, the branch office router checks its routing table and finds the host route that is using the ISP demand-dial interface.

8. The branch office router checks the state of the ISP demand-dial interface and finds that the demand-dial interface is in a disconnected state.

9. The branch office router retrieves the configuration of the ISP demand-dial interface.

10. Based on the ISP demand-dial interface configuration, the branch office router uses its modem to dial and establish a connection with its local ISP.

11. Immediately after the ISP connection is made, the VPN establishment packet is sent to the corporate office router.

12. A site-to-site VPN connection is negotiated between the branch office router and the corporate office router. As part of the negotiation, the branch office router sends authentication credentials that are verified by the corporate office router.

13. The corporate office router checks its demand-dial interfaces and finds one that matches the user name sent during authentication and changes the interface to a connected state.

14. The branch office router forwards the routed packet across the VPN and the corporate office router forwards the packet to the appropriate intranet location.

15. When the intranet location responds to the packet sent to it by the user in the branch office, the packet is forwarded to the corporate office router.

16. The corporate office router checks its routing table and finds a route to the branch office network that uses the VPN demand-dial interface.

17. The corporate office router checks the state of the VPN demand-dial interface and finds that the interface it is in a connected state.

18. The response packet is forwarded across the Internet by using the VPN connection.

19. The response packet is received by the branch office router and is forwarded to the original user.

# Demand Dial Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Demand-Dial Routing Tools
- Demand-Dial Routing Registry Entries

The "Demand-Dial Routing Tools" section describes tools that are useful for auditing, customizing, and troubleshooting demand-dial routing connections.

The "Demand-Dial Routing Registry Entries" section describes registry entries that:

- Enable negotiation of the Point-to-Point Protocol (PPP) connection with the endpoint.
- Indicate the router managers installed in the system.
- Indicate the types of router interfaces in the system.

**Demand-Dial Routing Tools**
The following tools are associated with demand-dial routing.

**Iprtrmgr.dll**
**Category**
Iprtrmgr.dll, also known as the IP router manager, is a dynamic-link library (DLL) available as part of the operating system.

**Version compatibility**
Iprtrmgr.dll is available on all platforms that support Routing and Remote Access, including Windows Server 2003, Windows 2000 Server, and Windows XP.

Iprtrmgr.dll manages the routing protocols. Acting as liaison between the routing protocols and the dynamic interface manager (DIM), Iprtrmgr.dll does the following:

- Obtains configuration information from the DIM.
- Communicates IP packet-filtering configuration to the IP filtering driver.
- Communicates IP routing configuration information to the IP forwarder in the TCP/IP protocol.
- Maintains an interface database of all IP routing interfaces.
- Loads and communicates configuration information to IP routing protocols that are supplied with Windows Server 2003, such as Routing Information Protocol (RIP) for IP and Open Shortest Path First (OSPF).
- Initiates demand-dial connections for routing protocols by communicating with the DIM.

In addition, Iprtrmgr.dll updates the route information for the Route Table Manager (RTM) and keeps the RTM synchronized with the stack forwarding table.

For more information about Iprtrmgr.dll, see "Windows Support Tools" in the Tools and Settings Collection.

**Mprdim.dll**
**Category**
Mprdim.dll, also known as the DIM, is a dynamic-link library available as part of the operating system.

**Version compatibility**

Mprdim.dll is available in all platforms that support Routing and Remote Access, including Windows Server 2003, Windows 2000 Server, and Windows XP.

The primary responsibility of Mprdim.dll is the administration of the Routing and Remote Access server computer and to relay information to other routing components, such as the IP router manager.

Mprdim.dll does the following:

- Supports a remote procedure call (RPC) interface for Simple Network Management Protocol (SNMP)-based management functions used by management utilities, such as the Routing and Remote Access snap-in.
- Loads configuration information from the Windows registry under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess.
- Reads the router phone book file: *systemroot*\system32\RAS\Router.pbk.
- Communicates with the Connection Manager for demand-dial connections.
- Communicates configuration information to the router managers (for example, the IP router manager).
- Passes information about static routes and filters to the appropriate router manager.
- Manages all routing interfaces, including local area network (LAN), persistent demand-dial, and IP-in-IP interfaces.
- Sends information to the Active Directory Service if the computer is configured as a member of a domain.

For more information about Mprdim.dll, see "Windows Support Tools" in the Tools and Settings Collection.

**Rtm.dll**
**Category**
Rtm.dll, also known as the RTM, is a dynamic-link library available as part of the operating system.

**Version compatibility**
Rtm.dll is available in all platforms that support Routing and Remote Access, including Windows Server 2003, Windows 2000 Server, and Windows XP.

Rtm.dll is the central repository of routing information for all routing protocols and components, such as router managers.

Rtm.dll does the following:

- Maintains a user-mode route table for all routes from all possible route sources.
- Provides application programming interfaces (APIs) to accomplish the following tasks:
    - Adding, deleting, and enumerating routes that are used by the routing protocols.
    - Querying and modifying routing information (other than adding, deleting, and enumerating routes) stored in the RTM.
    - Registering routes.
    - Registering to receive notifications of changes to RTM information.
- Ages learned routes. The age of a route is the time, in seconds, since the route was created or last updated.
- Provides routing information to routing protocols, management programs, and monitoring programs.
- Communicates only the best routes to the appropriate IP forwarder driver. For IP routes, the best route is the route with the lowest cost based on specified criteria, such as the number of networks crossed, the type of network crossed (for example, private or public), or a monetary or bandwidth limit. The best routes become the routes in the IP forwarding

table.

For more information about Rtm.dll, see "Windows Support Tools" in the Tools and Settings Collection.

**Netsh**
**Category**
Netsh is a command-line scripting tool used to configure multiple networking components and is available as part of the operating system.

**Version compatibility**
Netsh is available in Windows Server 2003, Windows 2000 Server, and all versions of Windows that include TCP/IP.

The Netsh command-line syntax is as follows:

```
netsh [-a AliasFile] [-c Context] [-r RemoteMachine]
       [Command | -f ScriptFile]
```

Netsh enables you to display or modify the network configuration of a local or remote computer. You can schedule auto-static updates to occur periodically by using a combination of Netsh utility scripts and Task Scheduler. The transfer of routing information occurs by using RIP for IP. To perform a scheduled automated auto-static update, use the following Netsh commands:

```
netsh interface set interface name=DemandDialInterfaceName connect=CONNECTED
netsh routing ip rip update DemandDialInterfaceName
netsh interface set interface name=DemandDialInterfaceName connect=DISCONNECTED
```

For example, to automatically update the RIP-for-IP routes by using a demand-dial connection called CorpHub, you type the following Netsh commands:

```
netsh interface set interface name=CorpHub connect=CONNECTED
netsh routing ip rip update CorpHub
netsh interface set interface name=CorpHub connect=DISCONNECTED
```

You can run these commands from a batch file or you can place them in a Netsh script file. For example, the script file, Corphub.scp, runs the following commands for CorpHub:

```
interface set interface name=CorpHub connect=CONNECTED
routing ip rip update CorpHub
interface set interface name=CorpHub connect=DISCONNECTED
```

To run the Corphub.scp script, type the following at a command prompt:

```
netsh -f corphub.scp
```

After the batch file or Netsh script file is created, you can execute the batch file or Netsh script on a scheduled basis by using Task Scheduler.

For more information about Netsh, see "Command-Line References" in the Tools and Settings Collection.

**Demand-Dial Routing Registry Settings**
The following registry settings are associated with demand-dial routing.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_LOCAL_MACHINE\SYSTEM**
The following registry key is located under
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RasMan\PPP\ControlProtocols\BuiltIn

**BuiltIn**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Rasman\PPP\ControlProtocols\

**Version**
The BuiltIn registry setting is available in Windows Server 2003, Windows 2000 Server, and Windows XP.

After a demand-dial connection (physical or logical) is made, a PPP connection is negotiated with the endpoint. By default, the calling router does not register itself with the DNS or WINS servers of the answering router unless the value of **RegisterRoutersWithNameServers** is set to 1.

**HKEY_LOCAL_MACHINE\SYSTEM**
The following registry key is located under
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Interfaces

**Interfaces**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\

**Version**
The Interfaces registry setting is available in Windows Server 2003, Windows 2000 Server, and Windows XP.

The Interfaces key is populated with the interfaces that have been added to the local system from the Router configuration. Each interface has an associated Type (Internal, Dedicated, or Dynamic) and subkeys, such as Ip, for each router manager.

**HKEY_LOCAL_MACHINE\SOFTWARE**
Every router manager installed in the system has a registry key created under the Router registry key. For the Ip subkey, the DllPath name specifies the location of the DLL that corresponds to the router manager; the ProtocolID name specifies the protocol family identifier for the router manager.

The following registry key is located under
HKEY_LOCAL_MACHINE\Software\Microsoft\Router\CurrentVersion\RouterManagers\Ip\

**OSPF**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Microsoft\Router\CurrentVersion\RouterManagers\Ip\

**Version**
The OSPF registry setting is available in Windows Server 2003 and Windows 2000 Server.

Values for the OSPF registry key are set as shown in the following table.

### OSPF Registry Key Values

| Name | Type | Data |
|---|---|---|
| ConfigDll | REG_SZ | ipadmin.dll |
| DllName | REG_SZ | ospf.dll |
| ProtocolID | REG_DWORD | 0x0000000d |
| Title | REG_SZ | Open Shortest Path First |

The following registry key is located under
HKEY_LOCAL_MACHINE\Software\Microsoft\Router\CurrentVersion\RouterManagers\Ip\

**IPBOOTP**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Microsoft\Router\CurrentVersion\RouterManagers\Ip\

**Version**
The IPBOOTP registry setting is available in Windows Server 2003 and Windows 2000 Server.

Values for the IPBOOTP registry key are set as shown in the following table.

### IPBOOTP Registry Key Values

| Name | Type | Data |
|---|---|---|

| | | |
|---|---|---|
| ConfigDll | REG_SZ | ipadmin.dll |
| DllName | REG_SZ | ipbootp.dll |
| ProtocolID | REG_DWORD | 0x0000270f |
| Title | REG_SZ | DHCP Relay Agent |

The following registry key is located under HKEY_LOCAL_MACHINE\Software\Microsoft\Router\CurrentVersion\RouterManagers\Ip\

**IPRIP**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Microsoft\Router\CurrentVersion\RouterManagers\Ip\

**Version**
The IPRIP registry setting is available in Windows Server 2003 and Windows 2000 Server.

Values for the IPRIP registry key are set as shown in the following table.

### IPRIP Registry Key Values

| Name | Type | Data |
|---|---|---|
| ConfigDll | REG_SZ | ipadmin.dll |
| DllName | REG_SZ | iprip2.dll |
| ProtocolID | REG_DWORD | 0x00000008 |
| Title | REG_SZ | RIP Version 2 for Internet Protocol |

**HKEY_LOCAL_MACHINE\SOFTWARE**
The following registry key is located under HKEY_LOCAL_MACHINE\Software\Microsoft\Router\CurrentVersion\UiConfigDlls\

**UiConfigDlls**
Under the Router registry key, in addition to registry keys for the router manager, there is the UiConfigDlls registry key.

**Registry path**
HKEY_LOCAL_MACHINE\Software\Microsoft\Router\CurrentVersion\UiConfigDlls\

**Version**
The UiConfigDlls registry setting is available in Windows Server 2003, Windows 2000 Server, and Windows XP.

The UiConfigDlls registry key requires that globally unique identifier (GUID) values are set as shown in the following table.

### UiConfigDlls Registry Key Values

| Name | Type | Data |
|---|---|---|
| <guid1> | REG_SZ | ifadmin.dll |
| <guid2> | REG_SZ | ipadmin.dll |
| <guid3> | REG_SZ | ddadmin.dll |

# IPv4 Multicasting Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv4 Multicasting Technical Reference**
Internet Protocol (IP) multicasting is the delivery of a single IP datagram to a group of hosts, regardless of their location, on a TCP/IP-based network. Of the three delivery methods supported by IP — multicasting, unicasting, and broadcasting — multicasting is the most practical method for point-to-multipoint data transmission, because unicasting requires multiple copies of datagrams and broadcasting does not work across routers.

Multicasting in an IP version 4 (IPv4) network is different from multicasting in an IP version 6 (IPv6) network. This document describes multicasting with IPv4. IPv4 is frequently referred to as IP and that convention is used in this document. For information about multicasting with IPv6, see "IPv6 Technical Reference."

Although Windows Server 2003 does not provide any multicast routing protocols, the Routing and Remote Access service provides a platform that supports these multicast routing protocols. In addition, you can configure Routing and Remote Access as a multicast forwarder for limited network configurations.

# What Is IPv4 Multicasting?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP Multicasting Overview**

The concept of group membership is central to IP multicasting. IP multicast datagrams are sent to a group, and only members of the group receive the datagrams. A group is identified by a single IP multicast address, which is an IP address in the Class D range of 224.0.0.0 to 239.255.255.255 (designated as 224.0.0.0/4 in classless interdomain routing (CIDR) notation). These Class D addresses are known as group addresses. A source host sends multicast datagrams to a group address. Destination hosts inform a local router that they need to join the group.

In an IP multicast-enabled intranet, any host can send IP multicast datagrams to any group address, and any host can receive IP multicast datagrams from any group address regardless of its location. To facilitate this capability, the hosts and routers on the intranet must support IP multicasting. Hosts use the Internet Group Management Protocol (IGMP) for establishing group membership. Routers use multicast routing protocols for forwarding multicast data.

The following figure illustrates a multicast-enabled intranet.

**Multicast-Enabled Network**

In this illustration, the hosts and routers are multicast-enabled so that the following can occur:

- The sending host sends multicast datagrams to a designated group address.
- The routers forward the multicast datagrams to any network segments that include group members. Routers can forward multicast traffic across a network, between networks, and across the Internet.
- The receiving hosts inform a local router to join the group, and then they receive all subsequent datagrams sent to the group address.
- If a receiving host leaves the group and detects that it might be the last group member on the subnet, it can contact the local router to leave the group, informing the router to stop forwarding the multicast datagrams to that subnet.

**Benefits of IP Multicasting**

Multicasting provides an efficient way to support high-bandwidth, one-to-many applications on a network:

- Multicasting can dramatically reduce network traffic by sending a single copy of the data.
- Hosts can be configured for multicasting without hardware upgrades.
- Because newer routers already support multicast forwarding and multicast routing protocols, enabling multicasting on a network is practical and cost-effective.

Multicasting is useful for many types of one-to-many applications, such as the following:

- Multimedia, such as video conferencing and collaborative computing.
- Automatic discovery of resources in an internetwork (in Windows Server 2003 for example, TCP/IP router discovery uses multicasting by default, and WINS uses multicasting during automatic discovery of replication partners).
- Datacasting such as file distribution or database synchronization.
- Mobile computer support such as remote address book updating.
- Distribution of organizational publications.

**IP Multicasting with Routing and Remote Access**

Windows Server 2003 does not provide multicast routing protocols, such as Distance Vector Multicast Routing Protocol (DVMRP), Multicast Extensions to Open Shortest Path First (MOSPF), and Protocol Independent Multicast (PIM), although Routing and Remote Access does support multicast routing protocols developed by independent software vendors (ISVs).

As an alternative, you can use the Routing and Remote Access service to forward multicast traffic. In this case, the Routing and Remote Access service uses IGMP as an IP routing protocol component. Router interfaces are configured in one of two operating modes: IGMP router mode or IGMP proxy mode. The purpose of IGMP router mode is to forward multicast traffic in a single-router intranet. The purpose of IGMP proxy mode is to connect a single-router intranet to a multicast-capable intranet or the Internet.

Although Routing and Remote Access uses IGMP in a limited way to enable multicast forwarding on an intranet, it is not the equivalent of a true multicast routing protocol. The Routing and Remote Access IGMP routing protocol component supports multicast forwarding for several specific internetwork topologies. For more information about the supported topologies, see "How IPv4 Multicasting Works."

# How IPv4 Multicasting Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- IP Multicasting Architecture
- IP Multicasting Protocols
- IP Multicasting Processes and Interactions
- IP Multicasting with Routing and Remote Access
- IP Multicasting Interfaces
- Related Information

Internet Protocol (IP) multicasting is the sending of a single datagram to multiple hosts on a network or internetwork. Of the three delivery methods supported by IP, multicasting is the method that is most practical for one-to-many delivery. Unlike IP multicasting, IP unicasting sends a separate datagram to each recipient host. IP broadcasting sends a single datagram to all hosts on a single network segment (also known as subnet), even to those not interested in receiving it. Recent trends toward multimedia applications such as video conferencing necessitate the use of multicasting to efficiently send traffic to multiple hosts.

Before sending or receiving IP multicast data, a network must be enabled for multicasting, as follows:

- Hosts must be configured to send and receive multicast data..
- Routers must support the Internet Group Membership Protocol (IGMP), multicast forwarding, and multicast routing protocols.

Windows Server 2003 supports IP multicasting in the following ways:

- All computers running Windows Server 2003 can both send and receive multicast data.
- Windows Server 2003 TCP/IP (IPv4) can forward multicast IP traffic.
- Windows Server 2003 Routing and Remote Access supports IGMP for forwarding multicast traffic in a single-router intranet and for passing group membership information from a single-router intranet to a multicast-enabled intranet or the Internet.
- Routing and Remote Access provides a platform for true IP multicast routing protocols for forwarding multicast traffic across an intranet.

This section covers the following:

- The components of IP multicasting and the role of each
- The protocols that support multicasting
- How multicasting works
- How Routing and Remote Access supports multicasting

- The interfaces available for developing multicast-enabled applications and multicast routing protocols

This document describes how multicasting works in an IPv4 network. In addition to IPv4, the Windows Server 2003 family includes the latest version of IP, known as IP version 6 (IPv6). For information about how multicasting works with IPv6, see "IPv6 Technical Reference."

**IP Multicasting Architecture**

To support multicasting in an internetwork, the hosts and routers must be multicast-enabled. In an IP multicast-enabled intranet, any host can send IP multicast datagrams, and any host can receive IP multicast datagrams, including sending and receiving across the Internet.

The source host sends multicast datagrams to a single Class D IP address, known as the group address. Any host that is interested in receiving the datagrams contacts a local router to join the multicast group and then receives all subsequent datagrams sent to that address.

Routers use a multicast routing protocol to determine which subnets include at least one interested multicast group member and to forward multicast datagrams only to those subnets that have group members or a router that has downstream group members. The IP header of a multicast datagram includes a Time-to-Live (TTL) value that determines how far routers can forward a multicast datagram.

The following figure shows how multicasting components fit in an internetwork.

**IP Multicasting Architecture**

In this illustration, the following is occurring:

1. Host A in Subnet 1 is the multicasting source and is sending multicast data to the multicast group address.

2. Host B in Subnet 1 has requested group membership from its local router. Because Host B has joined the multicast group, its network adapter is listening for datagrams sent to the multicast group address. The remaining host in Subnet 1 has not requested group membership, so its network adapter is filtering out traffic sent to the multicast group address.

3. Routers forward multicast data to any subnet that has group members or a router that has downstream group members. In this example, the routers are forwarding multicast data from Subnet 1 to Subnet 3. The data is also sent across Subnet 2, although it has no group members, because there are downstream group members.

4. Host C in Subnet 3 has requested group membership and is also receiving the multicast data.

5. Host D in Subnet 3 is sending a request to its local router to join the group. After Host D joins the group, its network adapter will also listen for traffic sent to the multicast group address.

Alternatively, multicast data might come from the multicast-enabled portion of the Internet, known as the MBone.

The following table introduces the multicasting components, which are described later in this section.

**IP Multicasting Components**

| Component | Description |
|---|---|
| Host (source or receiver) | A host is any client or server on the network. A multicast-enabled host is configured to send and receive (or only send) multicast data. |
| Router | A multicast router is capable of handling host requests to join or leave a group and of forwarding multicast data to subnets that contain group members. A multicast router can be either a non-Microsoft router that uses a multicast routing protocol or a Windows Server 2003-based server running the Routing and Remote Access service. |
| Multicast address | A Class D IP address used for sending IP multicast data. An IP multicast source sends the data to a single multicast address, as described later in this section. A specific IP multicast address is also known as a group address. |
| Multicast group | A multicast group is the set of hosts that listen for a specific IP multicast address. A multicast group is also known as a host group. |
| MBone | The Internet multicast backbone, or the portion of the Internet that supports multicast routing. |

**Host**

On a multicast-enabled network, a host that is configured to send multicast data can send datagrams to a single designated Class D IP address so that multiple hosts can receive the data. A host that is configured to receive multicast data can use IGMP to join a multicast group and then listen for datagrams sent to the multicast address. Hosts can send and receive multicast data from anywhere on an intranet or the Internet.

A host supports IP multicasting at one of the following levels:

- Level 0 - No support for sending or receiving IP multicast datagrams.
- Level 1 - Supports sending but not receiving IP multicast datagrams.
- Level 2 - Supports both sending and receiving IP multicast datagrams.

TCP/IP for Windows Server 2003 (as well as Windows XP) supports all levels of IP multicasting and, by default, is configured for Level 2 support. You can modify the level of support by changing the **IGMPLevel** subkey under HKLM\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\ in the registry.

**Note**

- It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**Router**

The role of a multicast router is to:

- Manage multicast group membership by processing IGMP requests to join or leave groups.
- Forward multicast traffic to subnets of the internetwork that contain multicast group members.

Multicast routing is more complex than unicast routing. The following table compares the characteristics of unicast routing and multicast routing.

**Unicast Routing and Multicast Routing Comparison**

| Unicast Routing Characteristics | Multicast Routing Characteristics |
|---|---|

| | |
|---|---|
| Unicast traffic is sent to a globally unique destination. | Multicast traffic is sent to an ambiguous group destination. |
| Unicast routes in the routing table summarize ranges of globally unique destinations. | Because group addresses represent different groups with different members, group addresses generally cannot be summarized in the IP multicast forwarding table. |
| Unicast routes are comparatively consistent, so the routing table needs to be updated only when the topology of the internetwork changes. Unicast routing protocols update the unicast routing table. | The location of group members is not consistent, so the IP multicast forwarding table might need to be updated whenever a group member joins or leaves a multicast group. Multicast routing protocols update the IP multicast forwarding table. |

Multicast routers can be hardware or software routers. Non-Microsoft routers that are multicast-enabled run a multicast routing protocol, such as one of the following:

- Distance Vector Multicast Routing Protocol (DVMRP)
- Multicast Extensions to Open Shortest Path First (MOSPF)
- Protocol Independent Multicast (PIM)

These protocols are briefly described later in this document. These protocols are not included with Windows Server 2003.

Windows Server 2003 Routing and Remote Access can be used for multicast forwarding. The Routing and Remote Access service includes an IGMP routing protocol component that uses two modes, router mode and proxy mode, to add entries to the TCP/IP multicast forwarding table. Because Routing and Remote Access is not designed to replace a true multicast routing protocol, it supports several specific configurations, which are described later in this document.

**Multicast Addresses**

IP addresses in the Class D range are reserved for IP multicasting. Class D addresses are in the range of 224.0.0.0 to 239.255.255.255, with the four high-order bits always set to 1110. In network prefix or classless interdomain routing (CIDR) notation, IP multicast addresses are summarized as 224.0.0.0/4.

Within the Class D range of addresses, certain ranges of multicast addresses have special meaning, as follows:

- Addresses in the range of 224.0.0.0 to 224.0.0.255 (224.0.0.0/24) are reserved for local subnet multicast traffic. Datagrams sent to addresses in this range are not forwarded by IP routers.
- Addresses in the range of 224.0.1.0 to 238.255.255.255 are known as globally scoped addresses, which means they can be used for multicasting across an intranet or the Internet. Some addresses within this range are reserved by the Internet Assigned Numbers Authority (IANA) for special purposes.
- Addresses in the range of 239.0.0.0 to 239.255.255.255 (239.0.0.0/8) are reserved for administratively scoped addresses. Administratively scoped addresses as defined by RFC 2365 are used to prevent the forwarding of multicast traffic across boundaries configured for the address. Multicast boundaries are described in more detail later in this document.

The following are examples of reserved IP multicast addresses:

- 224.0.0.1 - All hosts on this subnet
- 224.0.0.2 - All routers on this subnet
- 224.0.0.5 - Open Shortest Path First (OSPF) version 2, designed to reach all OSPF routers
- 224.0.0.6 - OSPF version 2, designed to reach all OSPF-designated routers and designated backup routers
- 224.0.0.9 - Routing Information Protocol (RIP) version 2
- 224.0.1.1 - Network Time Protocol

For the latest list of reserved multicast addresses, see the IANA link.

#### MAC-Level Multicast Addresses

As described previously, a multicast datagram is sent to a single group address, and only members of the group receive the datagram. For a network adapter to receive a multicast datagram, the IP multicast address must be mapped to a hardware, or media access control (MAC), multicast address. The network adapter then listens for any datagrams that are addressed to this MAC-level address and passes the datagrams up to the operating system.

The Internet Assigned Numbers Authority (IANA) has reserved a range of multicast addresses for Ethernet and Fiber Distributed Data Interface (FDDI) networks. The following table lists the MAC-level multicast addresses used for different types of networks.

### MAC-Level Multicast Addresses

| Network Type | Multicast Addresses | Related RFC |
|---|---|---|
| Ethernet and FDDI | 0x01-00-5E-00-00-00 to 0x01-00-5E-7F-FF-FF | 1112 |
| Token Ring | 0xC0-00-00-04-00-00 | 1469 |

Token Ring can use the same method of MAC-level multicast addressing as Ethernet and FDDI, but many Token Ring network adapters do not support it. By default, therefore, all IP multicast addresses on Token Ring networks are mapped to the single functional address specified in the preceding table. You can modify the use of this functional address by editing the **TrFunctionalMcastAddress** subkey under HKLM\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\ in the registry. IP multicasting on Token Ring network adapters is supported for Windows 2000, Windows XP, and the Windows Server 2003 family.

### Note

- It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

#### IP Multicast to MAC-Level Multicast Address Mapping

To map an IP multicast address to a MAC-level multicast address, the 23 low-order bits of the IP multicast address are mapped directly to the 23 low-order bits of the MAC-level multicast address. The 25 high-order bits in the MAC-level multicast address are fixed. The following figure illustrates how the IP multicast address is mapped to the MAC-level multicast address.

### IP Multicast Address Mapped to Ethernet or FDDI MAC Address

This figure also illustrates the following:

- The 4 high-order bits of the IP multicast address are fixed according to the Class D address definition.

- The 5 remaining bits (bits 5 to 9) in the IP multicast address are not mapped to the MAC-level multicast address, so the resulting MAC address is not unique. This means that it is possible for a host to receive MAC-level multicast datagrams for up to 32 groups to which it does not belong. However, IP drops datagrams that do not match a multicast address that is registered by an application or another protocol.

- The low-order bit of the first octet in a MAC-level destination address is the Individual/Group bit. This bit is set to 0 for a unicast or individual address and to 1 for a multicast address or a broadcast address.

**Example of MAC-level address mapping**
If the IP multicast address is 224.192.16.1, the MAC-level multicast address becomes 0x01-00-5E-40-10-01, as illustrated in the following figure.

### Sample Address Mapping

The 23 low-order bits in the IP multicast address map directly to the MAC-level multicast address. Because the entire third and fourth octets are included in the mapping, they can be converted directly to hexadecimal. The high-order bit of the second octet is dropped from the mapping, so that octet must be converted to binary first. In this example, dropping the high-order bit results in a value of 1000000, which converts to decimal 64 and hexadecimal 0x40. The shading in the figure shows that the 25 high-order bits of the MAC-level multicast address are fixed values.

**Multicast Groups**
The set of hosts listening for a specific IP multicast address is called a multicast group or a host group. Multicast groups have the following attributes:

- Group membership is dynamic; hosts can join and leave the group at any time.
- Members of a group can be located anywhere on a multicast-enabled network.
- A host need not be a member of a multicast group to send data to the group's IP multicast address.
- Group members can receive both unicast and multicast traffic.
- A host can be a member of any number of multicast groups.
- A multicast group has no size limits.
- Multicast groups can be either transient or permanent. Permanent groups are assigned a well-known multicast address. For example, multicast address 224.0.0.1 is a permanent address for the all-hosts multicast group. Membership in a permanent group is transient; only the address is permanent.

**MBone**
The MBone, or Internet multicast backbone, is the portion of the Internet that supports the forwarding of Internet-based IP multicast traffic. The MBone, used in conjunction with tunneling, provides a way for multicast traffic to travel across portions of the Internet that do not support multicasting.

Tunneling is the encapsulation of a datagram within another datagram. For multicast traffic to traverse the Internet, each IP multicast datagram must be encapsulated within an IP unicast datagram, which is known as IP-in-IP tunneling. An IP-in-IP tunnel is used to forward information between endpoints in an IP internetwork that have differing capabilities, thus acting as a logical link between the endpoints. The encapsulating IP header includes the addresses of the endpoints as the source and destination addresses. The following figure illustrates an encapsulated IP datagram.

### IP-in-IP Datagram Structure

The MBone consists of a series of multicast-enabled islands. These islands are collections of contiguous networks that use

routers that support multicast routing. IP-in-IP tunneling allows the multicast traffic to travel from one island to another. The IP header of the unicast datagram is addressed from a router in one multicast-enabled island to a router in another multicast-enabled island.

The MBone is used for audio and video multicasts of Internet Engineering Task Force (IETF), the National Aeronautics and Space Administration, and the United States House of Representatives and Senate meetings, among other uses. Support for the MBone can vary among Internet service providers (ISPs).

**IP Multicasting Protocols**

A variety of protocols are used for various aspects of IP multicasting. The following table briefly identifies the protocols described in this section.

**Protocols Used for IP Multicasting**

| Protocol | Description | RFC |
|---|---|---|
| IGMP | Internet Group Management Protocol. Hosts use this protocol to make group membership requests. Routers use this protocol to query for active group members in a subnet. (Note: IPv6 uses Multicast Listener Discovery (MLD) instead of IGMP to manage group membership.) | 1112 |
| DVMRP | Distance Vector Multicast Routing Protocol. This is a multicast routing protocol. | 1075 |
| MOSPF | Multicast Extensions to Open Shortest Path First. This is a multicast routing protocol. | 1584 |
| PIM | Protocol-Independent Multicast. This is a multicast routing protocol. | 2117 |
| MADCAP | Multicast Address Dynamic Client Allocation Protocol. This protocol enables a host to request an IP multicast address from a multicast address allocation server. | 2730 |
| PGM | Pragmatic General Multicast. PGM is a reliable multicast transport protocol. Typically, multicast datagrams are delivered by using UDP, which is an inherently unreliable transport protocol. Hosts and routers that are PGM-enabled can recover lost multicast datagrams. | 3208 |

**IGMP**

Internet Group Management Protocol (IGMP) maintains host group membership on a local subnet. Hosts use IGMP to communicate multicast group membership requests with their local multicast router. Routers receive the group membership requests and periodically send out queries to determine which host groups are active or inactive on the local subnet. This protocol is required to support Level 2 multicasting.

IGMP messages are encapsulated in IP datagrams and use IP protocol number 0x02. The following illustrates the resulting datagram.

**Encapsulated IGMP Message**

There are three versions of IGMP:

- IGMP version 1 is provided by TCP/IP for Microsoft Windows NT Server 4.0 Service Pack 3 and earlier.
- IGMP version 2 is provided by TCP/IP for Microsoft Windows NT Server 4.0 Service Pack 4 and later and Windows 2000. Routers using this version are backward-compatible with hosts using IGMP version 1.
- IGMP version 3 is provided by TCP/IP for Windows XP and Windows Server 2003. Routers using this version are backward-compatible with hosts using IGMP version 2 or IGMP version 1. Hosts running Windows XP or Windows Server 2003 use IGMP version 3 by default. To configure a host running Windows XP SP2 or later to use IGMP version 1 or IGMP version 2, use the **IGMPVersion** subkey under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\ in the registry.

  **Note**

- It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

This section describes the differences between the three versions of IGMP.

**IGMP Version 1**
IGMP version 1 consists of the following two types of messages:

- Host Membership Report
- Host Membership Query

The following table describes the fields in IGMP version 1 messages.

**Fields in IGMP Version 1 Messages**

| IGMP Version 1 Field | Length | Description |
|---|---|---|
| Version | 4 bits | Identifies the IGMP version. It is set to 1. |
| Type | 4 bits | Identifies the type of message:<br>• 0x1 for Host Membership Query<br>• 0x2 for Host Membership Report |
| Unused | 1 octet | Set to 0 by sender, ignored by receiver. |
| Checksum | 2 octets | Used to test for data transmission errors. |
| Group Address | 4 octets | Specifies the group address for the type of message:<br>• 0.0.0.0 for Host Membership Query<br>• The multicast group address to be joined for Host Membership Report |

**Host Membership Report**
To join a multicast group, a host sends an IGMP Host Membership Report message to the specific group address, regardless of whether other hosts on the subnet are already multicast group members. Unlike a multicast router, a host does not keep track of the multicast group membership of other hosts on its subnet. A multicast router uses a special listening mode called multicast promiscuous mode so that it can receive all IP multicast traffic. Because it listens in multicast promiscuous mode, a multicast router receives and processes IGMP Host Membership Report messages that are sent to any multicast address.

**Host Membership Query**
An IGMP version 1 multicast router (known as a multicast query router) periodically sends an IGMP Host Membership Query message to IP address 224.0.0.1 (the all-hosts group) to obtain updated information about multicast group membership on the subnet. The multicast routing protocols determine which router is to send the query messages.

Multicast routers do not need to track the specific hosts that belong to a group, but only that at least one host in a subnet belongs to the group. For each multicast group that has members on the subnet, one multicast group member responds with an IGMP Host Membership Report message. To keep multiple hosts on a particular subnet from sending IGMP Host Membership Report messages for the same group, a random response timer on the hosts delays the transmission of the IGMP Host Membership Report message. If another host on the same subnet sends a message before the response timer expires, a host does not send its own message.

**Addresses and TTLs used for IGMP version 1 messages**
The following table summarizes the values of the source and destination IP addresses in the IP header, the TTL in the IP header,

and the Group Address in the IGMP header for the two types of IGMP version 1 messages.

**Addresses and TTLs Used for IGMP Version 1 Messages**

| Address | IGMP Host Membership Report | IGMP Host Membership Query |
|---|---|---|
| Source IP address (IP header) | *<HostInterfaceIPAddress>* | *<RouterInterfaceIPAddress>* |
| Destination IP address (IP header) | *<GroupAddress>* | 224.0.0.1 |
| TTL | 1 | 1 |
| Group address | *<GroupAddress>* | 0.0.0.0 |

IGMP version 1 has no explicit mechanism for hosts to notify a router that it is ready to leave a multicast group.

For more information about IGMP version 1, see Appendix I of RFC 1112 in the IETF RFC Database.

**IGMP Version 2**

IGMP version 2 extends the functionality of IGMP version 1 by including the following:

- A procedure for determining which router in a subnet is to be the multicast query router
- A new message for when hosts leave a multicast group
- A new group-specific query message
- A new version of the Host Membership Report

The following table describes the fields in IGMP version 2 messages.

**Fields in IGMP Version 2 Messages**

| IGMP Version 2 Field | Length | Description |
|---|---|---|
| Type | 1 octet | Identifies the type of message:<br>• 0x11 for Host Membership Query<br>• 0x12 for IGMP version 1 Host Membership Report<br>• 0x16 for IGMP version 2 Host Membership Report<br>• 0x17 for Leave Group Message |
| Maximum Response Time | 1 octet | Specifies the maximum allowable time (in tenths of a second) for a host to respond to a router query. Used only in query messages.<br>For Routing and Remote Access routers, this value is configured with the **Query response interval** from either of the following sources:<br>• Routing and Remote Access Microsoft Management Console (MMC) snap-in **Router** tab for the IGMP interface properties<br>• **Netsh routing ip igmp set interface** command |
| Checksum | 2 octets | Used to test for data transmission errors. |

| | | |
|---|---|---|
| Group Address | 4 octets | Specifies the group address for the type of message:<br>• 0.0.0.0 for general Host Membership Query message<br>• The specific multicast group address for Group-Specific Host Membership Query, Host Membership Report, and Leave Group messages |

**Note**

- The Version field is eliminated and the Type field is 8 bits in IGMP version 2. The hexadecimal value of the Type field in version 2 messages is the result of concatenating the version 1 hexadecimal values of the Version field (0x1) and the Type field (0x1 for Host Membership Query and 0x2 for Host Membership Report).

**Query router election**

In contrast to IGMP version 1, in which the multicast routing protocols determine the multicast query router, IGMP version 2 uses a simple election process to choose one router on each subnet to send the periodic IGMP Host Membership Query messages. The elected router is the one with the numerically lowest IP address. During the election process, each router listens for IGMP queries from other routers. If a router receives a query with a lower source IP address, that router does not send multicast queries. If a router does not receive a query with a lower source IP address, it becomes the multicast query router for the subnet.

**Leave Group message**

The Leave Group message reduces leave latency, which is the time it takes for a multicast router to stop forwarding multicast traffic to a subnet that no longer contains multicast group members. If a host responds to the last IGMP query, it might be the last or only member of the multicast group. When this host leaves the group, it sends an IGMP Leave Group message to the all-routers multicast group (224.0.0.2). Upon receipt of the Leave Group message, the router sends a series of group-specific queries to the multicast group. If no host responds to the group-specific queries, the router determines that the multicast group on that subnet contains no members.

**IGMP group-specific query**

An IGMP Host Membership Query is sent to 224.0.0.1 (the all-hosts group) to find out which multicast groups have members on the subnet. IGMP version 2 routers can also send a group-specific query to a specific group address to find out if that group has any members on the subnet.

**IGMP version 2 Host Membership Report**

The IGMP version 2 Host Membership Report has the same function as the IGMP version 1 Host Membership Report, except that it is used by IGMP version 2 routers.

**Addresses and TTLs used for IGMP version 2 messages**

The following table summarizes the values of the source IP address, the destination IP address and the TTL in the IP header, as well as the value of the Group Address in the IGMP header for the two additional types of IGMP version 2 messages.

### Addresses and TTLs Used for IGMP Version 2 Messages

| Address | IGMP Leave Group Message | IGMP Group-Specific Query |
|---|---|---|
| Source IP address (IP header) | *<HostInterfaceIPAddress>* | *<RouterInterfaceIPAddress>* |
| Destination IP address (IP header) | 224.0.0.2 | *<GroupBeingQueried>* |
| TTL | 1 | 1 |
| Group address | *<GroupBeingLeft>* | *<GroupBeingQueried>* |

For more information about IGMP version 2, see RFC 2236 in the IETF RFC Database.

**IGMP Version 3**

IGMP version 3 extends the functionality of IGMP version 2 by adding support for source filtering, also known as source-specific multicasting. With IGMP version 3, it is possible to have multiple sources for a multicast data stream so that hosts can join the group and receive the data from the nearest source. For example, you might use this feature for an organization-wide video conference. You can have multiple sources multicast the video conference and place the sources in different regions so that hosts can join the group and specify the source topologically nearest them.

IGMP version 3 has a modified version of the Host Membership Query message and includes a new version of the Host

Membership Report.

**Source filtering**
Source filtering is the ability of a host to specify that it receive multicast traffic only from specific source addresses. With IGMP version 1 and IGMP version 2, a host reports group membership regardless of the source of the multicast traffic sent to its group. If multicast traffic is sent to a group from multiple sources, a subnet with a group member receives one multicast datagram from each source.

IGMP version 3 allows a host to specify either of the following for a particular multicast group:

- The sources from which it is to receive messages pertaining to the group (a list of included sources).
- The sources from which it is not to receive messages pertaining to the group (a list of excluded sources).

Multicast routers and multicast routing protocols use the source-specific information in the IGMP version 3 Host Membership Report message to prevent forwarding and delivering multicast messages from specific sources to subnets that have no interested group members.

**IGMP version 3 Host Membership Query**
The IGMP version 3 Host Membership Query message has the same Type value and the same format as the IGMP version 2 Host Membership Query message, except that it includes additional fields after the Group Address field. The additional fields provide query parameters for routers and specify the included or excluded sources for the multicast group being queried. The list of included or excluded sources is used only for queries to a specific group that uses source filtering.

The first 8 octets of the IGMP version 3 Host Membership Query message are the same as IGMP version 2. The Type value for the modified Host Membership Query remains 0x11. The following table describes the fields in IGMP version 3 Host Membership Query messages.

**Fields in IGMP Version 3 Host Membership Query Messages**

| IGMP Version 3 Field | Length | Description |
|---|---|---|
| Type | 1 octet | Identifies the type of message:<br>• 0x11 for Host Membership Query |
| Maximum Response Time | 1 octet | Specifies the maximum allowable time (in tenths of a second) for a host to respond to a general (not group-specific) router query.<br>For Routing and Remote Access routers, this value is configured with the **Query response interval** from either of the following sources:<br>• Routing and Remote Access snap-in **Router** tab for the IGMP interface properties<br>• **Netsh routing ip igmp set interface** command |
| Checksum | 2 octets | Used to test for data transmission errors. |
| Group Address | 4 octets | Specifies the group address for the query message:<br>• 0.0.0.0 for general Host Membership Query<br>• The specific multicast group address for Group-Specific Host Membership Query, Host Membership Report, and Leave Group |
| Reserved | 4 bits | Set to 0 by sender, ignored by receiver. |
| Suppress Router-Side Processing | 1 bit | Set to 1 to specify that receiving routers are to suppress normal timer updates when they receive a query. |

| | | |
|---|---|---|
| Querier's Robustness Variable (QRV) | 3 bits | Allows tuning for expected datagram loss on the network. IGMP can recover QRV-1 lost datagrams.<br><br>For Routing and Remote Access routers, this value is configured with the **Robustness variable** from either of the following sources:<br><br>• Routing and Remote Access snap-in **Router** tab for the IGMP interface properties<br><br>• **Netsh routing ip igmp set interface** command |
| Querier's Query Interval Code | 1 octet | Specifies how many seconds the router waits between general queries.<br><br>For Routing and Remote Access routers, this value is configured with the **Query interval** from either of the following sources:<br><br>• Routing and Remote Access snap-in **Router** tab for the IGMP interface properties<br><br>• **Netsh routing ip igmp set interface** command |
| Number of Sources | 2 octets | Specifies the number of source addresses included in the query message. |
| Source Addresses | 4 octets per address | Specifies the IP addresses of multicast sources. |

**IGMP version 3 Host Membership Report**

A host uses the IGMP version 3 Host Membership Report message to specify all the multicast groups it wants to join, and for each group address, either the sources from which it is to receive multicast data (the list of included sources) or the sources from which it is not to receive multicast data (the list of excluded sources).

The IGMP version 3 Host Membership Report message contains a series of group records. Each record contains the multicast group address and the associated list of sources. The Host Membership Report message is sent to the multicast address 224.0.0.22, which is a reserved multicast address for all IGMP version 3-capable multicast routers.

The following table describes the fields in IGMP version 3 Host Membership Report messages.

**Fields in IGMP Version 3 Host Membership Report Messages**

| IGMP Version 3 Field | Length | Description |
|---|---|---|
| Type | 1 octet | Identifies the type of message:<br><br>• 0x12 for IGMP version 1 Host Membership Report<br><br>• 0x16 for IGMP version 2 Host Membership Report<br><br>• 0x22 for IGMP version 3 Host Membership Report |
| Reserved | 1 octet | Set to 0 by sender, ignored by receiver. |
| Checksum | 2 octets | Used to test for data transmission errors. |
| Reserved | 2 octets | Set to 0 by sender, ignored by receiver. |
| Number of Records | 2 octets | Specifies the number of group records in the message. |
| Group Records | Variable | Each record specifies the IP address for a multicast group being joined or left and a list of included or excluded sources. |

**Addresses and TTLs used for IGMP version 3 messages**

The following table summarizes the values of the source and destination IP addresses, the TTL in the IP header, and the value of the Group Address in the IGMP header for the two additional types of IGMP version 3 messages.

**Addresses and TTLs Used for IGMP Version 3 Messages**

| Address | IGMP Host Membership Query for Specific Groups and Sources | IGMP Host Membership Report |
|---|---|---|
| Source IP address (IP header) | <*RouterInterfaceIPAddress*> | <*HostInterfaceIPAddress*> |
| Destination IP address (IP header) | <*GroupBeingQueried*> | 224.0.0.22 |
| TTL (IP header) | 1 | 1 |
| Group address (IGMP header) | <*GroupBeingQueried*> | <*GroupAddress*> in individual group address records |

For more information about IGMP version 3, see RFC 3376 in the IETF RFC Database.

**Multicast Routing Protocols: DVMRP, MOSPF, and PIM**

The goals of multicast routing protocols include the following:

- Forward traffic away from the source to prevent loops.
- Minimize or eliminate multicast traffic to subnets that do not need to receive it.
- Minimize CPU and memory load on the router for scalability.
- Minimize the traffic overhead of a routing protocol.
- Minimize the join latency, which is the time it takes for the first group member on a subnet to begin receiving group traffic.

Multicast routing protocols use a variety of algorithms to create efficient multicast delivery paths through the internetwork. Unicast routers use the IP destination address to forward traffic toward the destination. Because multicast traffic is sent to a group address, multicast routers use the source address to forward traffic away from the source to avoid looping the traffic back to the source.

This section provides a brief introduction to the most common multicasting routing protocols. These protocols are not provided with Windows Server 2003.

**Distance Vector Multicast Routing Protocol (DVMRP)**

DVMRP is a multicast routing protocol that grew from Routing Information Protocol (RIP), a unicast routing protocol that forwards datagrams based on information about the next hop toward the destination. In contrast to RIP, DVMRP forwards datagrams based on information about the previous hop back toward the source.

DVMRP builds a delivery tree for determining where to forward datagrams. It floods the first multicast datagrams to a multicast group across the internetwork and then prunes the branches of the tree that lead to subnets that do not include group members.

DVMRP is most efficient in environments where multicast group members are densely distributed over the internetwork. DVMRP runs on internetworks with multicast routers and also supports tunneling (encapsulating multicast datagrams within a unicast datagram for forwarding through non-multicast routers). DVMRP does not scale well.

**Multicast Extensions to OSPF (MOSPF)**

MOSPF is a multicast routing protocol that is an extension to Open Shortest Path First (OSPF). This protocol builds a delivery tree for determining where to forward datagrams by using group membership information from IGMP and the OSPF link-state database. The trees are built on demand for each source-group pair.

MOSPF is intended for use on a single organization’s network and does not scale well. MOSPF requires OSPF as its accompanying unicast routing protocol. It can sometimes put a heavy load on router CPU bandwidth.

MOSPF is most efficient in environments where multicast group members are densely distributed over the internetwork. It does not support tunneling but can work in multicast environments with non-MOSPF routers.

**Protocol-Independent Multicast (PIM)**
PIM consists of two protocols: PIM Dense Mode (PIM-DM) and PIM Sparse Mode (PIM-SM). PIM-DM is most efficient in environments where multicast group members are densely distributed over the internetwork. PIM-SM is most efficient in environments where group members are sparsely distributed. A multicast group that uses PIM can declare itself sparse or dense.

The PIM protocol establishes routes to multicast groups whose members span wide-area and interdomain internetworks. PIM functions independently of any specific unicast routing protocol, although it does use the existing unicast routing table.

**PIM-DM**
This protocol is designed for multicast groups whose members are distributed densely over an area where bandwidth is plentiful. Like DVMRP, PIM-DM first floods multicast traffic across the internetwork and then prunes the subnets that have no group members.

PIM-DM is interoperable with PIM-SM. PIM-DM does not scale well.

**PIM-SM**
PIM-SM is the most widely used multicast routing protocol. It is designed for multicast groups with members distributed sparsely across a large region and is most efficient in a WAN environment. The flood-and-prune method used by PIM-DM can cause unnecessary traffic. In contrast, PIM-SM forwards multicast traffic only to routers that explicitly request it. With PIM-SM, routers must explicitly join and leave multicast groups to receive or stop receiving multicast traffic.

**MADCAP**
Multicast Address Dynamic Client Allocation Protocol (MADCAP) is a method for hosts to request a multicast address from a multicast address allocation server. If multiple hosts use the same IP multicast address for different applications, multicast traffic can be forwarded to the incorrect group members. MADCAP prevents this problem by allocating unique multicast addresses. It supports dynamic assignment and configuration of IP multicast addresses on TCP/IP-based networks.

MADCAP is an extension of the Dynamic Host Configuration Protocol (DHCP) standard, but is separate from DHCP. The Windows Server 2003 DHCP service supports both DHCP and MADCAP, but the functions are independent.

Multicast administrative scopes configured on the DHCP server define ranges of IP multicast addresses. Unique IP multicast addresses are allocated to a single DHCP client, similar to how unique unicast IP addresses are assigned to clients.

For more information about MADCAP and its support in Windows Server 2003, see "DHCP Technical Reference." For more information about the IETF definition of MADCAP, see RFC 2730 in the IETF RFC Database.

**PGM**
Pragmatic General Multicast (PGM) is a reliable multicast transport protocol for multicast-enabled applications that require properly sequenced, duplicate-free delivery of datagrams. Typically, multicast datagrams are sent as UDP datagrams, but UDP is inherently unreliable because it does not guarantee packet delivery or retransmit lost packets. PGM ensures that a host that is a member of a multicast group either receives all the transmitted datagrams or detects unrecoverable lost datagrams. It is implemented on both source and destination hosts.

PGM is a transport-layer protocol that runs directly over IP and uses IP protocol number 113. It is the type of reliable multicast protocol known as router assist. With this type of protocol, PGM-enabled receiving hosts use negative acknowledgement (NAK) packets to request the retransmission of lost multicast datagrams, and PGM-enabled routers on the network can retransmit lost packets on behalf of the sender. The PGM-enabled routers define a logical PGM topology that overlays the physical IP internetwork topology. This topology defines the series of hops used for PGM packets between the sending host and the receiving hosts. Routers are not required for PGM: the PGM topology can consist of a single logical hop between the sending host and its receiving hosts.

PGM is currently the only reliable multicast protocol supported by Windows Server 2003. To use PGM with Windows Server 2003, you must add the Reliable Multicast Protocol component in Network Connections to sending and receiving hosts and create PGM-enabled applications. For more information about creating PGM-enabled applications, see "Reliable Multicast Programming (PGM)" on MSDN.

With PGM, a session is established during multicast datagram transmission. The source host caches transmission for retransmission in the event of an error. If a receiving host detects an error, it sends a unicast NAK to the next upstream PGM router. The PGM router confirms receipt of the NAK packet and forwards the NAK packet upstream until it reaches the source host. The source host then retransmits the datagram and routers forward it only to the subnets that require it.

**IP Multicasting Processes and Interactions**

In a multicast-enabled intranet, hosts send and receive multicast datagrams and routers manage group membership and forward multicast datagrams. The Windows Server 2003 implementation of TCP/IP supports all levels of multicasting.

**Host Processes**

In a Level 2 multicast-enabled intranet, any host can send IP multicast datagrams to any group address, and any host can receive IP multicast datagrams from any group address. In a Level 1 multicast-enabled intranet, any host can send multicast datagrams but cannot receive them. This section describes what happens when hosts send and receive multicast datagrams.

**Sending IP Multicast Datagrams**

To send IP multicast datagrams, a host determines the IP multicast address to use, constructs the multicast datagram, and then places the multicast datagram on the medium.

An IP multicast address can be obtained in any of the following ways:

- Assigned by the application
- Selected from well-known (reserved) IP multicast addresses defined by the IANA
- Allocated by an address allocation protocol, such as MADCAP

The sending host constructs the IP datagram by using its own IP address as the source address, the obtained IP multicast address as the destination address, and an appropriate TTL value.

The TTL value for an IP multicast datagram determines how many subnets the datagram can travel. As specified earlier, IP multicast addresses in the range 224.0.0.0 to 224.0.0.255 (224.0.0.0/24) are reserved for local subnet multicast traffic. By convention, the TTL value is 1 for a datagram sent to an address in this range, but routers do not forward multicast traffic sent to an address in this range even if the TTL is greater than 1. For multicast datagrams that are to be forwarded across an intranet or the Internet, the TTL value must be high enough to reach all members of the multicast group. The following table describes the conventional definitions for TTL values.

**TTL Value Conventional Definitions**

| TTL Value | Definition |
|---|---|
| 0 | Restricted to the same host |
| 1 | Restricted to the local subnet, no router hops |
| 32 | Restricted to the site |
| 64 | Restricted to the region |
| 128 | Restricted to the continent |
| 255 | Worldwide (unrestricted) |

After the host constructs the IP multicast datagram, the datagram passes through the IP routing process and is sent to Address Resolution Protocol (ARP), which maps the IP address to the hardware address. An ARP extension processes IP multicast addresses. If the IP address is in the multicast range, ARP does not check the ARP cache or broadcast a request datagram to locate the corresponding MAC address. Instead, for Ethernet and FDDI networks, ARP maps the IP destination address to the MAC-level address, as described in "IP Multicast Architecture." For Token Ring networks, ARP assigns a single functional address, as described in "IP Multicasting Architecture" earlier in this document. For more information about how ARP works, see "How TCP/IP Works." For more information about the IP routing process, see "Unicast IPv4 Routing Technical Reference."

**Receiving IP Multicast Datagrams**

To receive IP multicast datagrams, a host notifies IP to process multicast datagrams for a specific group address, registers the appropriate multicast MAC address with the network adapter, and notifies the local router to join the multicast group.

To determine the specific group address to use, the host can obtain an address from the application or derive the address from a universal resource locator (URL). On the MBone, multicasts are typically announced with the Session Description Protocol (SDP). SDP provides all the information needed to receive a multicast, including the multicast name and description, the times it is active, the type of media it uses, as well as the IP addresses, ports, and protocol it uses. The information is sent to a well-known IP address and port where a host running the session directory tool receives it.

After determining the group address, the host informs IP to process multicast datagrams with that destination address. For shared access technologies such as Ethernet, FDDI, and Token Ring (in which all attached nodes use a common wire), IP contacts the Network Interface layer to have the MAC-level multicast address that corresponds to the group address added to the table of interesting destination MAC addresses, which identifies the datagrams to be received and passed up to the operating system. To accomplish this task in the Windows Server 2003 family, IP uses the **NDISRequest()** function.

If the group address of interest is outside the range of 224.0.0.0 through 224.0.0.255 or 224.0.0.0/24 (the group address is non-local), the host sends an IGMP Host Membership Report message to the local router to inform it to forward datagrams for that group address to the host's subnet.

If the host has multiple applications that use the same IP multicast address, IP keeps track of group membership for each application and passes a copy of the multicast datagram to each application. If a host is multihomed, IP keeps track of group membership for each subnet.

A host stops receiving datagrams for a specific multicast group address when the corresponding MAC-level address is removed from the table of interesting destination MAC addresses. This occurs when a multicast-enabled application notifies Windows Sockets to stop receiving datagrams for a specific group address, such as at application shutdown.

**Router Processes**
Multicast routers handle multicast group membership and forward IP multicast datagrams to the subnets that have at least one group member. Multicast routers do the following:

- Send and receive IGMP group membership messages.
- Communicate group membership to other multicast routers.
- Receive all IP multicast traffic.
- Forward IP multicast traffic.

**Send and Receive IGMP Group Membership Messages**
**Receive and process IGMP Host Membership Report and Leave Group messages**
Multicast routers receive IGMP Host Membership Report messages from any hosts on local subnets and process these messages by placing entries that track group membership in the IP multicast forwarding table. Because multicast routers listen in multicast promiscuous mode, they receive all IGMP Host Membership Report messages sent to any group address.

An IGMP version 2 host that might be the last group member on a subnet sends a Leave Group message. Multicast routers process these messages by sending group-specific queries to the multicast group. If no host responds to the queries, the multicast router removes the entry for the subnet from the IP multicast forwarding table.

**Query local subnets for host membership status**
Any single subnet can support any combination of IGMP version 1, IGMP version 2, and IGMP version 3 hosts. Because IGMP version 1 does not support Leave Group messages, an IGMP version 1 host cannot notify the local router when it leaves a multicast group. In addition, because UDP is used to send multicast datagrams, it is possible for IGMP Host Membership Report and Leave Group messages to be lost. In cases such as these, multicast routers can continue to forward multicast traffic to a subnet that no longer has any group members.

To improve leave latency, multicast routers periodically send IGMP Host Membership Query messages to the local subnet to obtain updated host membership information. For each multicast group that has members on the subnet, one multicast group member responds to the query with an IGMP Host Membership Report message. Multicast routers then process these messages to update the IP multicast forwarding table.

**Communicate Group Membership to Other Multicast Routers**
In a multicast-enabled internetwork that contains multiple routers, each router communicates group membership information with its neighboring routers so that group members located anywhere on the internetwork receive the group traffic.

Multicast routers communicate group membership information either explicitly, by exchanging group address and subnet information, or implicitly by informing upstream routers whether group members exist downstream from the source host. The routers use a multicast routing protocol such as DVMRP, MOSPF, or PIM to exchange the group membership information.

**Receive All IP Multicast Traffic**
To receive all multicast traffic, a multicast router must put its network adapter in a special listening mode. A listening mode is the way a network adapter analyzes the destination MAC address of incoming datagrams to determine whether to process them further.

For shared access technologies such as Ethernet, FDDI, and Token Ring, the normal listening mode for network adapters is unicast listening mode. In unicast listening mode, the only datagrams that are considered for further processing are in a table of interesting destination MAC addresses on the network adapter. Typically, the only interesting addresses are the broadcast address (0xFF-FF-FF-FF-FF-FF) and the MAC address of the network adapter.

The special listening mode needed to receive all multicast traffic is called multicast promiscuous mode. Multicast promiscuous mode analyzes the Individual/Group bit in the destination MAC address to determine whether the datagram requires further processing. The Individual/Group bit for Ethernet and FDDI addresses is the low-order bit of the first octet in the destination MAC address. This bit is set to 1 for multicast addresses. When the network adapter is placed in multicast promiscuous mode, any datagrams with the Individual/Group bit set to 1 are passed up to the operating system for further processing.

Multicast promiscuous mode is different from promiscuous mode. In promiscuous mode, all datagrams — regardless of the destination MAC address — are passed up to the operating system for processing. Promiscuous mode is used by protocol analyzers, also known as network sniffers, such as the full version of Network Monitor that is part of the Microsoft Systems Management Server.

A network adapter that supports promiscuous mode might not support multicast promiscuous mode. However, multicast promiscuous mode is supported by most network adapters.

**Forward IP Multicast Traffic**

Multicast routers forward multicast traffic downstream, away from the source host and toward subnets that have at least one group member. The Windows Server 2003 implementation of TCP/IP supports multicast forwarding.

At each hop in the multicast forwarding process, the router decrements the TTL in the IP header. If the resulting TTL is greater than zero, the router compares the source address and destination group address to entries in the local IP multicast forwarding table and then forwards the datagram over the appropriate interfaces. If the TTL equals 0 after decrementing, the router silently discards the multicast datagram. Destination addresses in the range of 224.0.0.0 to 224.0.0.255 (224.0.0.0/24) designate multicast traffic on the local subnet. Multicast routers do not forward datagrams sent to addresses in this range, regardless of the TTL value.

Entries in an IP multicast forwarding table do not identify which, or how many, hosts are group members, but only that at least one host is a member. An entry in an IP multicast forwarding table identifies a subnet that has either a group member or a router that has downstream group members. A multicast router, therefore, can forward multicast datagrams to a subnet that has no group members because the subnet is on the path to other subnets that do have group members.

**Multicast boundaries**

Multicast boundaries are configurable administrative barriers that limit how far routers can forward multicast traffic across an internetwork. Without boundaries, a multicast router forwards all appropriate multicast traffic throughout the internetwork. With boundaries, a multicast router forwards appropriate multicast traffic only over a limited area of the internetwork. There are two types of multicast boundaries, as follows:

- **Scope-based boundaries.** A scope is a range of IP multicast addresses and is defined by specifying the address range as an IP address and mask. Multicast addresses in the range of 239.0.0.0 to 239.255.255.255 (239.0.0.0/8) are used to specify administrative scopes, as defined in RFC 2365. However, the range of 239.255.0.0/16 is defined as a local scope and cannot be divided further.

  An administrative scope becomes a boundary, beyond which multicast datagrams are not forwarded. Routers that support administratively scoped multicasts can have each interface configured with a scoped boundary. Such a router is called a boundary router. Datagrams that match the interface boundary definition of a boundary router do not get forwarded in either direction.

- **TTL-based boundaries.** TTL-based boundaries prevent the forwarding of multicast datagrams beyond a specified number of router hops, as described earlier in this section. TTL-based boundaries apply to all multicast datagrams regardless of the group address. TTL-based boundaries are less precise than scope-based boundaries because of interactions with multicast routing protocols.

**IP Multicasting with Routing and Remote Access**

Routing and Remote Access can forward multicast traffic in limited network configurations. The primary use of Routing and Remote Access as a multicast router is to connect a subnet to a multicast-enabled intranet that contains routers running multicast routing protocols. To fully support efficient multicast forwarding on a multiple-router intranet, it is necessary to install multicast routers that run one or more multicast routing protocols.

Windows Server 2003 Routing and Remote Access supports IGMP version 1, version 2, and version 3 and also supports

multicast boundaries and multicast heartbeat. This section describes how Routing and Remote Access supports multicast traffic.

**Routing and Remote Access Architecture**

The following figure illustrates the components of Windows Server 2003 Routing and Remote Access. The components in clear boxes are unique to multicasting and are discussed in this document. For information about components that pertain to unicasting or to both unicasting and multicasting, see "Unicast IPv4 Routing Technical Reference."

### IP Multicast Components in Routing and Remote Access

The following table describes the multicast components of Routing and Remote Access.

**Multicast Components in Routing and Remote Access**

| Component | Description |
|---|---|
| IGMP | In Routing and Remote Access, IGMP is implemented as a routing protocol component. This implementation of IGMP has two modes: router mode and proxy mode. This component does the following:<br>• Communicates multicast group membership information to the Multicast Group Manager.<br>• Uses Windows Sockets to send and receive IGMP traffic. |
| Multicast Group Manager | The Multicast Group Manager component does the following:<br>• Maintains multicast group membership.<br>• Coordinates operations between all multicast routing protocols when multiple multicast routing protocols are enabled on a router.<br>• Communicates IP multicast forwarding table entries from multicast routing protocols to the IP Multicast Forwarder. |
| IP Multicast Forwarder | The IP Multicast Forwarder component does the following:<br>• Stores the multicast forwarding entries received from Multicast Group Manager.<br>• Communicates source and group information from received multicast traffic to Multicast Group Manager.<br>• Forwards multicast datagrams. |

**Routing and Remote Access Support for Multicast Forwarding**

In Routing and Remote Access, IGMP is implemented as a routing protocol component. The IGMP routing protocol component has two modes: IGMP router mode and IGMP proxy mode.

The Routing and Remote Access Server Setup Wizard adds the IGMP routing protocol component. You can then use the Routing and Remote Access snap-in to accomplish the following:

- Add router interfaces to the IGMP routing protocol.
- Configure each interface for one of the two operating modes and for the IGMP version.
- Remove IGMP as a routing protocol component.

You can configure IGMP router interfaces by using the **Router** tab on the properties of an IGMP interface in the Routing and Remote Access snap-in or by using the **netsh routing ip igmp set interface** command.

**IGMP Router Mode**

An interface that is configured for IGMP router mode supports the following functions:

- **Listens in multicast promiscuous mode.** If the network technology supports it, such as with Ethernet and FDDI, the router-mode interface is placed in multicast promiscuous mode. If the network technology does not support multicast promiscuous mode, an IP Router Manager event is logged in the system event log.

- **Receives and processes IGMP group membership messages.** The IGMP router-mode interface receives and processes IGMP Host Membership Report messages and Leave Group messages that are sent by hosts on the subnet as they join and leave groups.

- **Sends IGMP Host Membership queries.** The IGMP router-mode interface sends periodic general (all-hosts) queries and group-specific queries to obtain updated group membership information from the subnet.

- **Elects an IGMP query router.** Only one router on a subnet sends the IGMP queries. As an IGMP multicast router, the IGMP router-mode interface elects an IGMP query router for the subnet.

- **Maintains the IP multicast forwarding table.** The IP multicast forwarding table for the TCP/IP protocol is updated based on IGMP group membership messages and multicast datagrams received on the router-mode interface. An IP multicast forwarding table entry contains the multicast group address, the source IP address, a list of interfaces that receive forwarded traffic (next-hop interfaces), and the single interface on which traffic must be received to be forwarded (the previous-hop interface). The multicast group and source IP addresses are obtained from the multicast datagram. The next-hop interfaces are determined by the registration of multicast group members using IGMP (and any multicast routing protocols, if present). The previous-hop interface is the interface that is closest — in terms of routing metrics — to the source of the IP traffic. The previous-hop interface is determined by checking the multicast routing table and identifying a single interface that is the best route back to the source of the IP multicast datagram. The best route is the closest matching multicast route based on the routing metrics.

You can configure IGMP router mode on multiple interfaces. For each interface, any version of IGMP can be configured. The default version is IGMP version 3.

**IGMP Proxy Mode**

The purpose of IGMP proxy mode is to act as a proxy for multicast hosts on IGMP router-mode interfaces. As a proxy, the IGMP proxy-mode interface forwards IGMP membership messages for the multicast hosts to a router that is running a multicast routing protocol.

IGMP proxy mode is designed to connect a Windows Server 2003-based router to a multicast-enabled IP internetwork that uses a multicast routing protocol, such as DVMRP, MOSPF, or PIM. The IGMP proxy-mode interface acts like a host and joins multicast groups on behalf of hosts on the IGMP router-mode interfaces. Multicast traffic that is sent to host members on IGMP router-mode interfaces is received on the IGMP proxy-mode interface and is forwarded by the IP multicast forwarding process. Multicast traffic that is sent by hosts on IGMP router-mode interfaces is flooded on the IGMP proxy-mode interface where a downstream IP multicast router can either forward the traffic or ignore it.

An interface configured for IGMP proxy mode performs the following functions:

- 2**Forwards IGMP Membership Messages.** The IGMP proxy-mode interface forwards all IGMP Host Membership Report messages and IGMP Leave Group messages received on the IGMP router-mode interfaces. The IGMP proxy-mode interface does not use the IP multicast forwarding table to forward these messages. It forwards the messages with a TTL value of 1.

- **Registers multicast MAC addresses.** For shared-access technologies such as Ethernet, the network adapter remains in unicast listening mode. For each multicast group that is registered by an IGMP Host Membership Report and forwarded on the IGMP proxy-mode interface, the IGMP router-mode interface adds the MAC address mapped from the multicast group address to the table of interesting destination MAC addresses on the network adapter for the proxy-mode interface. The network adapter then listens for any datagrams that are addressed to these addresses and passes them up to the operating system for further processing. The network adapter remains in unicast listening mode, unless there are too many MAC addresses to fit in the network adapter's table of interesting MAC addresses. In this case, the IGMP routing protocol component enables multicast promiscuous listening mode on the network adapter.

- **Maintains the IP multicast forwarding table.** The IP multicast forwarding table for the TCP/IP protocol is updated based on multicast datagrams received on both the IGMP router-mode interface and the IGMP proxy-mode interface. When non-local multicast traffic is received on an IGMP router-mode interface, entries are added to the IP multicast

forwarding table to forward the traffic across the IGMP proxy-mode interface. These entries cause all non-local multicast traffic that is received on an IGMP router-mode interface to be forwarded across the IGMP proxy-mode interface, regardless of whether there are downstream group members.

You can enable IGMP proxy mode only on one IGMP routing protocol component interface. Enable IGMP proxy mode on the interface that is attached to a subnet where there is a multicast router running multicast routing protocols.

**IGMP Router Mode vs. IGMP Proxy Mode**
The following table compares the functions of IGMP router mode and IGMP proxy mode.

### IGMP Router Mode and IGMP Proxy Mode

| Function | IGMP Router Mode | IGMP Proxy Mode |
|---|---|---|
| Listening mode | Multicast promiscuous mode. | Unicast listening mode. |
| IGMP router or host | Acts as an IGMP-based multicast router and listens for IGMP Host Membership Report messages. | Acts as an IGMP-based host by forwarding IGMP Host Membership Reports and responding to IGMP queries. Listens for IGMP Host Membership Report messages as a host, not as a router. |
| Updating the IP multicast forwarding table | Updates the IP multicast forwarding table based on IGMP traffic. | Updates the IP multicast forwarding table to flood (forward throughout the intranet) non-local multicast traffic that is received on IGMP router-mode interfaces. |
| IGMP queries | Sends IGMP queries to maintain an up-to-date forwarding table. | Sends no IGMP queries. |

**IGMP Router-Mode Processes and Interactions**
A Routing and Remote Access router running the IGMP routing protocol component with an interface configured for IGMP router mode maintains group membership information and the IP multicast forwarding table.

**Maintaining group membership information**
The process of managing group membership information for hosts on an IGMP router-mode interface is as follows:

1. When a host joins a multicast group, it sends an IGMP Host Membership Report message to the router on the local subnet.

2. The router updates the IP multicast forwarding table with the group address and the IGMP router-mode interface that received the message.

3. The IGMP routing protocol adds the multicast MAC address (mapped from the multicast group address, as described in "IP Multicasting Architecture") to the table of interesting destination MAC addresses on the network adapter for IGMP proxy-mode interface.

   **Note**

   - The **NDISRequest( )** function adds the multicast MAC address to the table of interesting addresses on the network adapter.

4. The router forwards the IGMP Host Membership Report message using the IGMP proxy-mode interface.

5. The neighboring multicast router receives the IGMP Host Membership Report message, updates its IP multicast forwarding table, and informs downstream multicast routers that a host member exists on the IGMP proxy-mode interface subnet.

6. Periodically (based on the Querier's Query Interval Code), the router elected as querier sends an IGMP Host Membership Query message. If the router receives a response from a multicast group member, the router updates the expiration time for the group and retains the group entry in the IP multicast forwarding table. If the router does not receive a response to the query, the router sets the expiration time for the group to 0 and removes the group entry from the IP multicast

forwarding table.

**Forwarding IP multicast traffic**
The process of forwarding multicasts from hosts on a router-mode interface works as follows:

1. A multicast host sends multicast traffic to a specific group address, and if the address is not local, the IGMP router-mode interface receives the traffic.

2. When the router receives the first datagram for a specific multicast group, the IGMP routing protocol component adds an entry to the IP multicast forwarding table to indicate that group members exist on the IGMP proxy-mode interface.

3. The multicast traffic passes to the multicast forwarding process, and, based on entries in the IP multicast forwarding table, the traffic is forwarded using the IGMP proxy-mode interface.

4. The neighboring multicast router receives the multicast traffic and passes it to the multicast forwarding process. The multicast router either forwards the traffic to group members or silently discards it based on the entries in its IP multicast forwarding table.

**Routing and Remote Access Support for Multicast Boundaries**
Routing and Remote Access supports multicast boundaries, as described earlier in this document. In addition to supporting scope-based boundaries and TTL-based boundaries, Windows Server 2003-based routers support boundaries defined by the rate of multicast traffic. With multicast rate limiting, multicast traffic forwarding can be restricted for traffic beyond a specified rate in kilobytes per second. You can configure multicast boundaries by using the General node under the IP Routing node in the console tree of the Routing and Remote Access snap-in.

**Multicast Heartbeat**
Multicast heartbeat is the ability of a server running Routing and Remote Access to listen for a regular multicast notification to a specified group address to verify that IP multicast connectivity is available on the network. If the heartbeat is not received within a configured amount of time, the server running Routing and Remote Access sets the multicast heartbeat status of the configured interface to inactive.

A polling mechanism can periodically check the multicast heartbeat status to detect when the multicast heartbeat is missing. For example, Simple Network Management Protocol (SNMP) can be used to send a message when the status becomes inactive.

Simple Network Time Protocol (SNTP) is frequently used for the multicast heartbeat. SNTP performs time synchronization and uses the reserved IP multicast address 224.0.1.1. If the SNTP server (the source of the heartbeat traffic) is strategically placed, the loss of the heartbeat indicates a problem with the IP multicast routing infrastructure. Windows Server 2003 includes an SNTP server called the Windows Time service (W32Time) and an SNTP client. For more information about SNTP, see RFC 1769.

You can configure the multicast heartbeat by using the **Multicast Heartbeat** tab of the properties for the General node under the IP Routing node in the console tree of the Routing and Remote Access snap-in.

**Supported Multicast Configurations**
The IGMP routing protocol component of Windows Server 2003 Routing and Remote Access is not designed as a substitute for multicast routing protocols such as DVMRP, MOSPF, or PIM. Therefore, this protocol works best for specific internetwork configurations of limited size. The recommended and supported configurations for a Windows Server 2003-based router using the IGMP routing protocol component are described in the following sections.

**Single-Router Intranet**
A Windows Server 2003-based router can provide full multicasting capabilities in a single-router intranet. The following figure illustrates a single-router intranet.

### Single-Router Intranet

In this configuration, each router interface is added to the IGMP routing protocol component and is configured for IGMP router mode.

Any host on any subnet can send multicast traffic to, and receive multicast traffic from, any other host. The Windows Server 2003-based router forwards all multicast traffic to subnets that contain group members.

**Single-Router Intranet Connected to the Internet**

A Windows Server 2003-based router supports multicasting in a single-router intranet that is connected to the MBone. The following figure illustrates this configuration.

**Single-Router Intranet Connected to the Internet**

In this configuration, all router interfaces are added to the IGMP routing protocol component. All private intranet interfaces are configured for IGMP router mode, and the Internet interface is configured for IGMP proxy mode.

As hosts join and leave multicast groups, they send IGMP membership messages to the local intranet router interface. These messages are then copied to the Internet interface. Multicast traffic from the Internet is sent to the Internet interface. When the Internet interface receives the multicast traffic, it forwards the traffic to the host on the appropriate subnet. Multicast traffic sent by a host on an intranet subnet is copied to the Internet interface. The multicast router at the ISP either ignores or forwards the multicast traffic, depending on whether there are any group members downstream.

If multicast traffic is sent between two hosts on the private intranet, the traffic is nevertheless copied to the Internet interface and is received by the multicast router at the ISP. You can prevent intranet multicast traffic from being copied to the Internet interface if you configure applications and MADCAP servers to use IP multicast addresses from the administratively scoped range (239.0.0.0 to 239.254.255.255) and configure the Internet interface with the appropriate scope-based boundary.

**Peripheral Router in a Multicast-Enabled Intranet**

A peripheral router is a router that is attached to multiple networks, one of which contains another router. In this case, the other router is a multicast router running a multicast routing protocol that is used in a multicast-enabled intranet. A peripheral router in a multicast-enabled intranet is a configuration that is very similar to the single-router intranet connected to the Internet. In this configuration, a Windows Server 2003-based router can act as the peripheral router.

The following figure illustrates a Windows Server 2003-based router acting as a peripheral router in a multicast-enabled intranet.

**Peripheral Router in a Multicast-Enabled Intranet**

In this configuration, all the peripheral router interfaces are added to the IGMP routing protocol component. All interfaces

except the one with the multicast router are configured for IGMP router mode. The interface connected to the subnet that contains the multicast router is configured for IGMP proxy mode.

When a host joins or leaves a multicast group, it sends an IGMP membership message. The message is copied to the interface that is configured for IGMP proxy mode. Multicast traffic from the multicast-enabled intranet is forwarded to the subnet attached to the IGMP proxy-mode interface. When the Windows Server 2003-based router receives the multicast traffic, it forwards the traffic to the host on the appropriate subnet. Multicast traffic that is sent by a host on an attached subnet is copied to the IGMP proxy-mode interface. The multicast router either ignores the multicast traffic or forwards it to downstream group members.

**Multicast Support for Remote Access Clients**
The Windows Server 2003 IGMP routing protocol component is commonly used to provide multicast services for dial-up or virtual private network (VPN) remote access clients. In this situation, the remote access or VPN server acts as a peripheral router to a multicast-enabled IP internetwork.

Two configurations are possible, depending on which of the following types of connectivity is provided to the remote access clients:

- Access to the MBone is provided by an ISP for dial-up clients.
- Access to a private multicast-enabled intranet is provided for dial-up or VPN clients.

**MBone access for ISP dial-up clients**
The following figure illustrates a configuration in which the Windows Server 2003 Routing and Remote Access service acts as an ISP to provide access to the Internet for dial-up clients.

### MBone Access for ISP Dial-Up Clients

In this configuration, the interface named **Internal**, which represents a logical adapter to which all the ISP clients connect, and the interface that is connected to the Internet are added to the IGMP routing protocol component. The **Internal** interface is configured for IGMP router mode, and the Internet interface is configured for IGMP proxy mode.

When a remote access client joins or leaves a multicast group, it sends an IGMP membership message. This message is copied to the interface that is connected to the Internet. Multicast traffic from the Internet is sent to the IGMP proxy-mode interface. When this interface receives the multicast traffic, it forwards the traffic to the connected remote access client. When a connected remote access client sends multicast traffic, the traffic is forwarded to other connected group members and is copied to the IGMP proxy-mode interface. The multicast router on the Internet either ignores the multicast traffic or forwards it to downstream group members.

**Intranet access for dial-up or VPN clients**
The following figure illustrates a configuration in which the Windows Server 2003 Routing and Remote Access service provides access to a private intranet for dial-up or VPN remote access clients.

### Intranet Access for Dial-Up or VPN Clients

In this configuration, the interface named **Internal** and the interface that is connected to the multicast-enabled intranet are added to the IGMP routing protocol component. The **Internal** interface represents all remote access clients. The intranet interface is attached to a subnet that contains a router running a multicast routing protocol, such as DVMRP, MOSPF, or PIM. The **Internal** interface is configured for IGMP router mode, and the intranet interface is configured for IGMP proxy mode.

When a remote access client joins or leaves a multicast group, it sends an IGMP membership message. This message is copied to the interface that is connected to the multicast-enabled intranet. Multicast traffic from the intranet is sent to the IGMP proxy-mode interface. When this interface receives the multicast traffic, it forwards the traffic to connected remote group members. When a remote access client sends multicast traffic, the traffic is forwarded to other connected group members and is copied to the IGMP proxy-mode interface. The multicast router on the intranet either discards the multicast traffic or forwards it to downstream group members.

**Multicast Support for Branch Office Networks**

A Windows Server 2003-based router can provide multicast forwarding capabilities for single-router branch offices connected to a hub office that has a multicast-enabled intranet. This configuration requires proper configuration of both the branch office and hub office router.

The following figure illustrates the use of a Windows Server 2003-based router to support multicasting for a branch office network.

**Multicast Support for Branch Office Networks**

For the branch office router, all the interfaces are added to the IGMP routing protocol component. The interfaces for the branch office subnets are configured for IGMP router mode, and the interface that connects to the hub office router is configured for IGMP proxy mode. The interface that connects to the hub office router can be a LAN interface (such as one that uses a T-carrier or frame relay connection) or a demand-dial interface (such as one that uses dial-up analog phone lines, ISDN, or a router-to-router VPN connection). A demand-dial interface can be either on-demand or persistent.

For the hub office router, all the interfaces are added to the IGMP routing protocol component. The interface that connects to the branch office router is configured for IGMP router mode. This interface can be a LAN interface (such as one that uses a T-carrier or frame relay connection) or a demand-dial interface (such as one that uses dial-up analog phone lines, ISDN, or a router-to-router VPN connection). The interface that connects to the multicast-enabled intranet is configured for IGMP proxy mode.

When a host joins or leaves a multicast group, it sends an IGMP membership message. The message is copied across the branch office link to the multicast-enabled intranet. Multicast traffic from branch office hosts is copied from the branch office subnets across the branch office link to the multicast-enabled intranet.

If multicast traffic is sent between two hosts on the branch office intranet, the traffic is copied to the branch office link, which results in inefficient use of bandwidth over the link to the hub office. You can configure applications and MADCAP servers to use IP multicast addresses from the administratively scoped range (239.0.0.0 to 239.254.255.255) to prevent local branch office multicast traffic from being copied to the branch office link. In this case, the interface to the hub office is configured with the appropriate scope-based boundaries.

**IP Multicasting Interfaces**

Windows Server 2003 provides application programming interfaces (APIs) that support the following types of development for multicasting:

- Multicast applications

- Reliable multicasting for multicast applications
- Multicast routing protocols

**Multicast Applications**
You can write multicast applications by using Windows Sockets, which is an API for developing applications that communicate by using TCP/IP. Windows Sockets 2 supports IGMP versions 2 and 3. For more information about how the Windows Sockets interface relates to TCP/IP, see "How TCP/IP Works."

For more information about developing multicast applications, see the Platform SDK Windows Sockets 2 documentation about Multicast Programming on MSDN.

**Reliable Multicasting for Multicast Applications**
PGM is an API for developing multicast applications that use a reliable multicast transport protocol rather than UDP. PGM, which is also known as reliable multicast, is implemented in Windows through Windows Sockets. You can use PGM to write multicast applications that have reliability requirements.

For more information about how to use reliable multicast in Windows, see the Microsoft Windows Server 2003 Family Platform SDK for Windows Sockets 2 documentation about Reliable Multicast Programming (PGM) on MSDN.

**Multicast Routing Protocols**
Routing and Remote Access is an extensible platform that supports non-Microsoft routing protocols. The Multicast Group Manager (MGM) API enables developers to write multicast routing protocols that work with routers running the MGM component of Routing and Remote Access.

For more information about developing multicast routing protocols with the MGM API, see the Routing and Remote Access Services SDK documentation about MGM Programming Considerations on MSDN.

# IPv4 Multicasting Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- IP Multicasting Tools
- IP Multicasting Registry Entries

This section describes the tools and registry entries used to configure Routing and Remote Access routers for multicasting and to troubleshoot multicast forwarding.

**IP Multicasting Tools**
The following tools are associated with IPv4 multicasting.

**Mcast.exe: Multicast Packet Tool**
**Category**
The Multicast Packet Tool is included with Windows Server 2003 Resource Kit tools.

**Version compatibility**
The Multicast Packet Tool runs on, and targets, Windows XP Professional and the Windows Server 2003 family.

The Multicast Packet Tool is a command-line tool that you can use to send multicast packets or to listen for packets being sent to a multicast group address. This tool is useful for testing multicast connectivity between computers on an internetwork.

To find more information about the Multicast Packet Tool, see "Resource Kit Tools Help" in the Tools and Settings Collection.

**Mrinfo.exe**
**Category**
The **Mrinfo.exe** tool is included with Windows 2000, Windows XP Professional, and Windows Server 2003.

**Version compatibility**
The **Mrinfo.exe** tool runs on Windows 2000, Windows XP Professional, and the Windows Server 2003 family. You can use this tool for troubleshooting multicasting on Windows 2000-based and Windows Server 2003-based routers.

This tool displays the configuration of a multicast router to help troubleshoot multicast forwarding problems. It sends an Internet Group Management Protocol (IGMP) query message to the specified router, which responds to the query with the version number, list of interfaces, list of neighbors on each interface, metrics, Time to Live (TTL) thresholds, and other data.

For more information about **Mrinfo.exe**, see "Command Line References" in the Tools and Settings Collection.

**Mtrace**
**Category**
Like Windows 2000, the Windows Server 2003 family does not provide a version of Mtrace, a multicast tracing tool.

**Version compatibility**
Although the Windows Server 2003 family does not provide a version of Mtrace, the server running Routing and Remote Access does respond to command queries from non-Microsoft Mtrace tools.

You can use an Mtrace tool for troubleshooting multicast forwarding problems. It traces a multicast path from the source to a receiver.

**Netsh Commands for Multicast Routing**
**Category**
The Netsh commands for multicast routing are included with the Windows Server 2003 operating system.

**Version compatibility**
The Netshcommands for multicast routing run on, and can target, the Windows Server 2003 family and Windows 2000 Server.

The Netsh tool provides command-line support for many of the multicast display and configuration options provided by the Routing and Remote Access Microsoft Management Console (MMC) snap-in.

The Netsh commands that support Routing and Remote Access server administration for multicasting are available from the

command prompt for the **netshrouting ip** context.

The command prompt for the **Netsh routing ip show** context provides support for displaying multicast forwarding table entries and statistics for multicast forwarding table entries.

The command prompt for the **Netsh routing ip igmp** context provides support for configuring specific interfaces and for displaying group members on a specific interface or on all-router interfaces.

For more information about **Netsh.exe**, see "Command Line References" in the Tools and Settings Collection.

**Rrasmgmt.msc: Routing and Remote Access Snap-In**
**Category**
The Routing and Remote Access snap-in is included with Windows 2000 Server and the Windows Server 2003 family.

**Version compatibility**
The Routing and Remote Access snap-in runs on Windows 2000, Windows XP Professional, and on the Windows Server 2003 family. You can use this tool to manage Windows 2000-based and Windows Server 2003-based routers.

The Routing and Remote Access snap-in configures and troubleshoots Routing and Remote Access multicast routers. For example, it supports the following:

- Adding interfaces to the router, including demand-dial interfaces
- Adding routing protocols
- Configuring for IGMP router mode or IGMP proxy mode
- Configuring IGMP router-mode settings
- Setting administrative scopes
- Configuring multicast heartbeats
- Setting IGMP event-logging levels

In addition, the snap-in displays the following:

- Multicast statistics (statistics compiled by IP for each multicast group)
- Multicast forwarding table (used by IP to forward IP multicast traffic)
- IGMP group table (group membership information for all groups registered on all IGMP router-mode interfaces)
- IGMP interface group table (group membership information for all groups registered on a specific IGMP router-mode interface)

**IP Multicasting Registry Entries**
The following registry entries are associated with multicasting.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_LOCAL_MACHINE\SYSTEM**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\.

**EnableMulticastForwarding**
**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\

**Version**
The **EnableMulticastForwarding** entry is supported by Windows 2000, Windows XP Professional, and the Windows Server 2003 family.

The **EnableMulticastForwarding** entry enables or disables the forwarding of IP multicast traffic.

**IGMPLevel**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\

**Version**
The **IGMPLevel** entry is supported by Windows 2000, Windows XP Professional, and the Windows Server 2003 family.

The **IGMPLevel** entry specifies the level of IP multicasting support for hosts. The possible levels are no support for the host, the host can only send multicast traffic, or the host can both send and receive multicast traffic.

To find more information about **IGMPLevel**, see "Registry Reference" in the Tools and Settings Collection.

**TrFunctionalMcastAddress**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\

**Version**
The **TrFunctionalMcastAddress** entry is supported by Windows 2000, Windows XP Professional, and the Windows Server 2003 family. IP multicast on Token Ring network adapters is not supported by Microsoft Windows NT Server 4.0 and earlier versions of Microsoft Windows.

The **TrFunctionalMcastAddress** entry controls whether multicast traffic on a Token Ring network is sent to the functional address 0xC0-00-00-04-00-00 or is sent as a MAC-level broadcast.

**HKEY_LOCAL_MACHINE\SOFTWARE**
The following registry entry is located under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing\IGMPV2\.

**EnableFileTracing**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing\IGMPV2\

**Version**
The **EnableFileTracing** entry is supported by Windows 2000, Windows XP Professional, and the Windows Server 2003 family.

The **EnableFileTracing** entry records detailed information about IGMP routing protocol component processes in the *systemroot*\Tracing\IGMPv2.log file. The **netsh ras tracing igmp enabled** command also enables IGMP tracing.

# NAT Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NAT Technical Reference**
Network address translation (NAT) provides a method for translating the Internet Protocol version 4 (IPv4) addresses of computers on one network into IPv4 addresses of computers on a different network. A NAT-enabled IP router deployed at the boundary where a private network, such as a corporate network, meets a public network, such as the Internet, allows computers on the private network to access computers on the public network by providing this translation service.

The impetus initiating the development of NAT technology was the need to provide a temporary solution to the IPv4 address-depletion problem faced by the Internet community. The number of available globally unique (public) IPv4 addresses is far too few to accommodate the rapidly increasing number of computers that need access to the Internet. Although the long-term solution — the development of Internet Protocol version 6 (IPv6) addresses — exists, IPv6 is not yet widely adopted. NAT technology lets computers on any network use reusable private addresses to connect to computers with globally unique public addresses on the Internet.

In the Microsoft Windows Server 2003 and Microsoft Windows 2000 Server operating systems, the Routing and Remote Access service supports a NAT solution by allowing the optional configuration of a routing protocol component that provides network address translation. Computers on a private network can access a public network by means of a NAT-enabled router that runs the Routing and Remote Access service. All traffic leaving, or entering, the private network must travel by way of the NAT-enabled router. The Windows Server 2003 Routing and Remote Access service improves on the NAT routing protocol component provided by Windows 2000 Server by adding support for a basic firewall, which helps protect the public interface of a computer that is configured to provide NAT, and by enabling connected remote access clients to access the Internet.

# What Is NAT?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section:**

- NAT Solutions
- NAT Connection Scenarios
- How NAT Differs from ICS
- Related Information

Windows Server 2003 provides network address translation (NAT) functionality as a part of the Routing and Remote Access service. NAT enables computers on small- to medium-sized organizations with private networks to access resources on the Internet or other public network. The computers on a private network are configured with reusable private Internet Protocol version 4 (IPv4) addresses; the computers on a public network are configured with globally unique IPv4 (or, rarely at present, Internet Protocol version 6 [IPv6]) addresses. A typical deployment is a small office or home office (SOHO), or a medium-sized business, that uses Routing and Remote Access NAT technology to enable computers on the internal corporate network to connect to resources on the Internet without having to deploy a proxy server.

The following figure is a simplified depiction of the Routing and Remote Access NAT service. When a client on the private network sends a request for information to a computer on the public network, the NAT-enabled router, located at the border between the private and the public networks, translates the outgoing packets and then sends them to the destination computer on the public network. The router also translates the response from the public network resource and returns the response to the client on the local network.

**NAT-Enabled Router Translating Request and Response Packets**

**NAT Solutions**

The Windows Server 2003 Routing and Remote Access implementation of NAT provides the following solutions to problems faced by small- or medium-sized networks:

- Reusing IP addresses
- Bundling NAT, DHCP, and DNS functionality for small networks
- Providing firewall protection to the NAT-enabled router
- Providing Internet access to remote access clients
- Providing PPPoE broadband Internet access

**Reusing IP Addresses**

Any computer with a direct (routed) connection to the Internet requires a public IP address from the Internet Assigned Numbers Authority (IANA). IANA allocates public addresses and guarantees them to be globally unique on the Internet. The limited and ever-decreasing availability of public IPv4 addresses is one of the most compelling problems facing the IP Internet. The major long-term solution to the problem of address depletion is the development of IPv6, which introduces a new

addressing model that uses 16-byte addresses expressed in colon-hexadecimal notation rather than the familiar four-byte IPv4 addresses typically expressed in dotted-decimal notation. Until the long-term IPv6 solution is widely in use, however, other methods to ensure that IPv4 addresses remain available are urgently required. One temporary solution that reduces the demand for IPv4 addresses is address reuse.

NAT, originally defined in RFC 1631 and extended in RFC 3022, was developed explicitly to provide a method that enabled an unlimited number of organizations to reuse private IPv4 addresses on their networks, thus substantially decreasing the demand for new public IPv4 addresses. This need to decrease the demand for public IPv4 addresses was the initial impetus for the creation of NAT technology.

Private networks can use any range of IP addresses for computers on their internal network. Prior to RFC 1918, published in February 1996, the typical practice was to assign public addresses to all hosts that use TCP/IP whether or not they needed access to the Internet. RFC 1918 describes the three ranges of IPv4 addresses that it recommends that organizations use for private networks. RFC 3022, published in January 2001, recommends that private networks that implement NAT in order to access the Internet use the private address space described in RFC 1918.

The private address space described in RFC 1918 consists of three sets of addresses reserved by IANA for use by private networks. These are:

- 10.0.0.0 through 10.255.255.255 (or 10.0.0.0/8 in Classless Inter-domain Routing [CDIR] notation)
- 172.16.0.0 through 172.31.255.255 (or 172.16.0.0/12)
- 192.168.0.0 through 192.168.255.255 (or 192.168.0.0/16)

IANA has designated these addresses as nonroutable, that is, networks that use these addresses cannot directly connect to the Internet (or other public network) through an Internet router. Instead, they need to access a router that supports NAT so that these nonroutable addresses can be translated into public addresses for routing over the Internet.

Thus, all interfaces connected to a private network with a Routing and Remote Access NAT-enabled router are assigned private IP addresses, including the NAT-enabled router itself, which has a private address on its private interface (LAN card) and one or more public addresses on at least one public interface (demand-dial connection or LAN card). The NAT-enabled router is the conduit through which a private network computer sends a request out to a public network and through which a response is received.

Network Address Port Translation (NAPT), described in RFC 3022, extends address translation by using many-to-one mapping when, as is typically the case, the number of internal addresses is greater than the number of public addresses available on the NAT-enabled router. The NAT-enabled router might have only one public address configured, or it might have a pool of public addresses. Using NAPT, it is possible to map many connections through a single public address by assigning each connection a different port number.

In addition to the conservation of IPv4 addresses, NAT technology provides the following additional incentives to choose reusable private addresses:

- Using IPv4 private addresses eliminates the need for an organization to obtain public IPv4 addresses from its ISP. This is an advantage because any organization that uses public addresses that then changes to a different ISP must obtain new public addresses for each computer from the new provider and then reconfigure the network accordingly. With NAT, an organization can use the same private addresses regardless of which ISP provides its Internet access. If such an organization decides to change ISPs, the only reconfiguration required is on the public interface of the NAT-enabled router, which will need a new public address from the new ISP.
- Using private IPv4 addresses, for which you incur no cost, is less expensive than buying a block of public IPv4 addresses from an ISP.
- Using private IPv4 addresses lets organizations continue to use IPv4 networks rather than migrate their networks to IPv6, a process that can be costly, especially for larger organizations, and that might require equipment upgrades or replacement as well as retraining for network administrators.

For a discussion of public versus private addressing in TCP/IP networks, see “Choosing Public or Private Addresses” in the chapter Designing a TCP/IP Network of the Windows Server 2003 Deployment Kit. For information about IPv6, including IPv6 addressing, see “Introducing IPv6 on Your Network” in the same chapter.

**Bundling NAT, DHCP, and DNS for Small Networks**
Organizations with small networks often do not need or want to expend resources setting up a full-fledged network infrastructure. For these organizations, the NAT/Basic Firewall component provided by the Windows Server 2003 Routing and Remote Access service supports NAT in conjunction with simplified versions of the Dynamic Host Configuration Protocol (DHCP), and Domain Name System (DNS) services.

| **Note** |
| --- |
| The name "NAT/Basic Firewall" indicates only that NAT is configured; it does not necessarily indicate that the optional Basic Firewall feature is also configured. You can configure Basic Firewall at the same time that you install NAT, or you can configure Basic Firewall later. You can deploy NAT with both Basic Firewall and another firewall technology, or you can use NAT with another firewall technology without configuring Basic Firewall. For more information, see "Providing Firewall Protection to the NAT-enabled Router" later in this section. |

In addition to the translation component, which translates IP addresses and TCP or UDP port numbers for packets sent between a private network and the Internet, the NAT/Basic Firewall component of the Routing and Remote Access service also provides (optionally) automatic addressing and name-resolution proxying:

- **DHCP Allocator.** The NAT/Basic Firewall automatic addressing capability. If enabled, the DHCP allocator feature allows the NAT-enabled router to act as a simplified DHCP server that automatically assigns to the computers on the private network an IP address, a subnet mask, a default gateway, and the IP address of a DNS server. If multiple routed subnets are configured, you must use a DHCP server rather than the DHCP allocator.

- **DNS Proxy.** The NAT/Basic Firewall automatic name-resolution capability. If enabled, the DNS proxy feature allows the NAT-enabled router to act as a DNS server for the computers on the private network. When the DNS proxy receives a DNS name resolution request, the DNS proxy sends a request to the Internet-based DNS server for which the NAT-enabled router is configured and then provides the results of the response to the private network computer from which the request originated.

For more information about the DHCP allocator and DNS proxy, see "Optional NAT Subsystems" in "How NAT Works".

**Providing Firewall Protection to the NAT-Enabled Router**
To computers on a public network, such as the Internet, all requests from a private network that has deployed NAT appear to come from a public IPv4 address on the NAT-enabled router. The private network IPv4 address scheme remains hidden. By using a NAT, the computers on the private network gain some measure of protection because the NAT-enabled router does not forward traffic from the Internet into the private network unless a private network client had requested it or unless specific traffic is explicitly allowed. Although NAT technology lets organizations that implement it hide their private network topology from the Internet behind the NAT-enabled router, the Internet interface (also known as the public interface) of the NAT-enabled router is not hidden from the Internet. Without firewall protection, the Internet interface of the NAT-enabled router is vulnerable to attack.

The Windows Server 2003 Routing and Remote Access NAT component includes a simple stateful firewall called Basic Firewall, which uses technology similar to that used by the Internet Connection Firewall (ICF) feature available in Windows XP, Windows XP SP1, and Windows Server 2003. A stateful firewall uses dynamic packet filtering to examine incoming and outgoing packets. This new integration of Routing and Remote Access NAT with Basic Firewall lets network administrators protect the Internet interface of any computer running a member of the Windows Server 2003 family that is acting as a NAT. By enabling the optional Basic Firewall feature on the Internet interface (or multiple public interfaces) of the NAT-enabled router, an administrator ensures that all packets that are received on the public interface that do not correspond to traffic requested by the NAT computer (either for itself or for private network clients), or that are explicitly allowed, are discarded.

For more information about Basic Firewall, see the "Optional NAT Subsystems" section in "How NAT Works".

**Providing Internet Access to Remote Access Clients**
A computer running a member of the Windows 2000 Server family might be configured to provide remote access to its private network — for traveling employees or employees working from home, for example. The same server might also be configured as a NAT-enabled router to provide access to the Internet for computers within the private network.

Although you cannot configure a computer running Windows 2000 Server to provide Internet access to connected remote access clients by using the Routing and Remote Access snap-in, you can do so by using the command-line Netsh tool. You can use a Netsh command to add the **Internal** interface, which is a logical interface that represents the connection to all remote access clients, as a private interface to the NAT/Basic Firewall component of the Routing and Remote Access service. This configuration allows connected remote access clients to access the Internet.

Computers running a member of the Windows Server 2003 family now allow you to use the Routing and Remote Access snap-in to add the **Internal** interface as a private interface to the NAT/Basic Firewall component to enable connected remote access clients to access the Internet. With Windows Server 2003, you can also still use Netsh to accomplish the same task.

| **Note** |
| --- |
| When you enable the Routing and Remote Access service on a computer running Windows Server 2003, an interface named **Internal** appears under **Routing Interfaces** in the Routing and Remote Access snap-in. Do not delete the **Internal** interface. |

**Providing PPPoE Broadband Internet Access**

The number of multiple-computer households is increasing at a rapid rate. One efficient option for such households, as well as small businesses, is to use Point-to-Point Protocol over Ethernet (PPPoE) to establish a single broadband connection (such as through a DSL line or cable modem) to an ISP. PPPoE makes high-speed Internet access available to all the computers in the home or small office.

The Windows Server 2003 Routing and Remote Access service introduces the use of PPPoE as a connection type for demand-dial connections. This functionality enables a home or small business to use a NAT-enabled router and the PPPoE broadband Internet connection to connect their private network to the Internet.

**NAT Connection Scenarios**

Scenarios in which you might deploy Windows Server 2003 Routing and Remote Access NAT include connecting a business or home to the Internet, or using NAT on one side of two connected geographically remote offices.

**Connecting a Business or Home to the Internet**

In a typical deployment that uses Windows Server 2003 Routing and Remote Access NAT, a small- or medium-sized business (or home office) assigns private IPv4 addresses to its computers and installs a Routing and Remote Access NAT-enabled router. The computers on the private network cannot gain access to the Internet directly because they have reusable private addresses. Instead, they gain access to the Internet through the NAT-enabled router.

The NAT-enabled router has both a private interface and a public interface, the public IPv4 address of the latter provided by a local ISP. When a client computer sends a request out to a resource on the Internet, the request is sent initially to the NAT-enabled router, which translates the request packets, forwards them to the Internet resource, accepts responses from the Internet resource, re-translates the packets, and then returns the response to the client.

Another example in which NAT technology can provide access to the Internet is the case of a small ISP that serves home users who have dial-up connections. In this case, the NAT-enabled router is located at the ISP. Whenever the customer dials in, the ISP assigns a private IPv4 address to the customer's computer. When the customer requests access to a server on the Internet, the NAT-enabled router at the ISP translates the outgoing request and, later, the incoming response.

**Using NAT on One Side of Two Remote Offices**

Another deployment option is to use NAT on one side (typically, the smaller office) of a connection that links offices in different geographical locations. The Windows Server 2003 Routing and Remote Access service provides two types of virtual private network (VPN) site-to-site connections. The following table describes the circumstances in which you can use a NAT in conjunction with a VPN connection.

### Locating a Network Using a VPN Behind a NAT

| Type of VPN Site-to-Site Connection | Can You Use NAT? | Description |
| --- | --- | --- |
| PPTP VPN | Yes | In most cases, you can locate PPTP–based calling routers behind a NAT-enabled router (or configure one computer as both the calling router and the NAT-enabled router) in order to allow computers with private addresses in a SOHO network to share a single connection to the Internet. With a VPN connection, the site-to-site connection from the small office to the main office is "tunneled" through the Internet. Windows Server 2003 Routing and Remote Access NAT includes a NAT editor that can accurately translate PPTP-tunneled data. |

| | | |
|---|---|---|
| L2TP/IPSec VPN | Yes, but only if you use the IPSec NAT Traversal (NAT-T) feature | With Windows Server 2003–based calling or answering routers, you can use the IPSec feature called NAT traversal (NAT-T) to create L2TP/IPSec connections across NATs. Using NAT-T requires running Windows Server 2003 on both the calling and answering routers (or appropriately configured Cisco routers). With NAT-T, computers with private addresses that are hidden behind a NAT can use IPSec to connect to a remote site if these computers have the NAT-T update installed (for computers running Windows XP Professional SP1). No NAT editor exists for L2TP/IPSec, so the only way to use NAT is by implementing IPSec NAT-T. |

For more information about site-to-site VPN connections, see the chapter "Connecting Remote Sites" in the Networking collection of the "Windows Server 2003 Deployment Kit".

For more information about IPSec NAT-T, see "End-to-End Traffic Through an ISA-Secured Network Address Translator" in "What Is IPSec?" in the Security collection of this technical reference.

For more information about NAT editors provided by the Routing and Remote Access service, see "How NAT Works" in the Networking collection of this technical reference.

**How NAT Differs from ICS**

Internet Connection Sharing (ICS) provides a network translation capability that is an alternative option to that provided by Routing and Remote Access NAT. ICS, which is typically used by networks that have two to 10 computers, is provided by Network Connections on Windows XP as well as on Windows Server 2003, Standard Edition, and Windows Server 2003, Enterprise Edition. Because ICS and Routing and Remote Access NAT share common drivers, they cannot coexist on the same network.

With ICS, as with Routing and Remote Access NAT, you can connect computers on a SOHO network to the Internet by using just one connection. Although configuring Routing and Remote Access NAT is simple, configuring ICS is simpler — a single configuration step (selecting a single check box) provides a translated connection to the Internet for all of the computers on a single-subnet private network.

ICS and Routing and Remote Access NAT share the following features:

- **Address translation.** Both ICS and Routing and Remote Access NAT translate inbound and outbound IPv4 traffic by modifying IPv4 addresses and ports.

- **Public and private interfaces on the computer that connects to the network.** Both ICS and Routing and Remote Access NAT require two interfaces on the computer that provides address translation in order to work: one public and one private. The private interface, typically a LAN adapter or the **Internal** interface, connects the ICS or Routing and Remote Access NAT computer to the computers on the private network. The public interface, typically a DSL, cable, or dial-up modem, connects the private network to the Internet.

- **Firewall protecting the Internet interface.** Windows XP, Windows XP SP1, and Windows Server 2003 include ICF and Windows Server 2003 Routing and Remote Access NAT includes Basic Firewall, to protect the public interface of the workstation, server, or NAT router that provides Internet access to the other computers on the private network.

- **DHCP Allocator.** Both ICS and (optionally) Routing and Remote Access NAT can use this simplified DHCP service, which assigns the IP address, subnet mask, default gateway, and DNS server on the private network.

- **DNS Proxy.** Both ICS and (optionally) Routing Remote Access NAT can use this simplified DNS service, which resolves DNS names on behalf of private network clients and forwards queries.

The most significant differences between Routing and Remote Access NAT and ICS NAT are the following:

- **SOHO or larger network.** ICS is designed specifically for SOHO networks. Routing and Remote Access NAT scales from homes or small organizations to medium-sized networks.

- **Computer connection to the Internet.** With ICS, the connection to the Internet is managed most often by a Windows XP workstation, although you can also configure ICS on a computer running Windows 2000 Server or Windows Server 2003. With Routing and Remote Access NAT, the connection to the Internet or other public network is managed by a NAT-enabled router running the Windows Server 2003 or Windows 2000 Server Routing and Remote Access service.

- **Configuration limits.** ICS allocates addresses for internal hosts automatically from an address range that is not configurable (192.168.0.0/24) and supports only one public interface obtained from an ISP through which network computers can access the Internet. Routing and Remote Access NAT lets you access the Internet (or other public network) through multiple interfaces and lets you choose your own addressing scheme.

- **DNS and DHCP configuration.** DNS and DHCP configuration are similar, but not identical, for ICS and Routing and Remote access NAT:

    - **ICS NAT.** Typically, ICS is used in a network with two to 10 computers. Because a network this small might not have DNS servers or DHCP servers, ICS provides the DHCP allocator and the DNS proxy to provide automatic address configuration and name resolution for private network hosts. If, however, a DHCP server is deployed on a network that uses ICS, the ICS DHCP allocator yields to the DHCP server. Similarly, if the Microsoft DNS service is installed on the same computer as the DNS proxy, the ICS DNS proxy yields to the DNS server. On a private network that uses ICS, if a DNS server is deployed on a separate computer than the computer on which ICS is installed, either a DHCP server must also be installed on a different computer than the computer on which ICS is installed, or all clients on the private network must be manually configured with the IP address of the DNS server.

    - **Routing and Remote Access NAT.** Typically, Routing and Remote Access NAT is used in any network from small to medium in size. Routing and Remote Access NAT also provides the DHCP allocator and the DNS proxy for use in smaller networks that do not install a DNS server or a DHCP server. If a network that uses Routing and Remote Access NAT has a DHCP server in place, do not enable (or disable, if necessary) the DHCP allocator on the Routing and Remote Access NAT-enabled router. The DNS proxy can work in conjunction with a DNS server. For more information about how the DHCP allocator and the DNS proxy work in Routing and Remote Access NAT, see "Optional NAT Subsystems" in "How NAT Works."

- **Number of network segments.** ICS supports only a single private subnet. Routing and Remote Access NAT can support multiple private subnets. A network with multiple subnets must use a DHCP server rather than the DHCP allocator.

For more information about ICS and NAT, see Internet Connection Sharing and network address translation in Help and Support Center for Windows Server 2003 and Internet Connection Sharing Overview.

# How NAT Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- NAT Architecture
- NAT Network Structure
- Optional NAT Subsystems
- NAT Processes and Interactions
- Related Information

The network address translation (NAT) functionality provided by the Routing and Remote Access service enables computers on a private network to access computers on a public network, such as the Internet. In Windows Server 2003, the Routing and Remote Access NAT/Basic Firewall component is typically referred to as a routing protocol component. Strictly speaking, NAT is not a routing protocol; it does not send and receive traffic nor does it instigate changes to the routing table. However, the Routing and Remote Access service interfaces with the NAT/Basic Firewall component through the routing protocol interface, and, in this sense, NAT functions just like a routing protocol. Although NAT is not a true routing protocol, it is installed as if it were by using the Routing and Remote Access snap-in.

This document explains how Routing and Remote Access NAT works. It covers the components of Routing and Remote Access NAT architecture, a typical network behind a NAT-enabled router, optional NAT subsystems designed to simplify configuration for smaller networks, and NAT processes and interactions. The latter section explains how NAT works with TCP/IP, how address and port translation work, how dynamic and static mappings and IP reservations work, how NAT editors work, and includes a flowchart showing how inbound and outbound packets are processed.

For an introductory description of the problems Routing and Remote Access NAT is designed to solve and a quick sketch of typical NAT scenarios, see "What Is NAT?." For information about tools used to install, configure, and manage Routing and Remote Access NAT, see "NAT Tools and Settings."

**NAT Architecture**

Understanding the architecture of Routing and Remote Access NAT requires recognizing the relationship of the NAT routing protocol component to other routing components, to the NAT editors and proxies, to TCP/IP, and to the TCP/IP Address Resolution Protocol (ARP) module. The following figure illustrates Routing and Remote Access NAT architecture:

**Routing and Remote Access NAT Architecture**

The following table describes each component depicted in the figure.

**Routing and Remote Access NAT Components**

| Component | Description |
|---|---|
| IP Router Manager | A component of the Routing and Remote Access service. The IP Router Manager uses input/output (I/O) controls to do the following:<br>• Add interfaces to and remove interfaces from NAT.<br>• Provide NAT with its configuration, which is stored as part of the IP global and per-interface information in the registry. |
| NAT | A routing protocol component that, when enabled on a server running the Routing and Remote Access service, translates IPv4 addresses and TCP or UDP port numbers of request packets originating from a client on a private network, forwards the translated packets to a destination computer on the Internet (or other public network), and then performs reverse translation for response packets sent by the destination computer back to the client. NAT can also translate packets for specifically allowed incoming traffic originating from a computer on the Internet to a client computer on the private network.<br>For more information, see "NAT Network Structure" and "NAT Processes and Interactions" later in this document. |
| NAT Editors | Programs that perform translation for the data of certain network protocols that NAT on its own cannot translate. Routing and Remote Access NAT has the following built-in editors:<br>• **Internet Control Message Protocol (ICMP)**, which supports the transmission of error messages across a NAT.<br>• **Point-to-Point Tunneling Protocol (PPTP)**, which supports PPTP VPN traffic across a NAT.<br>For more information, see "How NAT Editors Work" in "NAT Processes and Interactions" later in this document. |
| NAT Proxies | Programs that redirect packets to a module that builds a new packet modified so that the newly modified packet can cross a NAT.<br>Routing and Remote Access NAT includes the File Transfer Protocol (FTP) proxy, which supports FTP traffic across a NAT, and the H.323 proxy, which supports NetMeeting calls across a NAT. |

| | |
|---|---|
| TCP/IP | The industry standard suite of protocols for transmitting data between computers over networks. Routing and Remote Access NAT is implemented as a routing protocol component that the TCP/IP protocol component in Windows calls when a data packet is sent or received. TCP/IP allows NAT to make modifications to a packet's data (translating IP addresses and TCP or UDP port numbers) and to ensure that checksums within a modified packet are correct.<br><br>For more information, see "How NAT Works with TCP/IP" and "How Address and Port Translation Work" in "NAT Processes and Interactions" later in this document. |
| ARP | The TCP/IP network layer protocol that uses broadcast traffic on the local network to resolve a logically assigned IPv4 address to its physical hardware or media access control (MAC) layer address. When mapping between public and private address pools when a pool of public addresses exists, NAT uses TCP/IP's proxy ARP mechanism to respond to ARP queries for addresses in a public address pool. (Proxy ARP refers to the use of a particular machine, such as a NAT-enabled IP router, to respond to ARP requests for computers other than itself.) |

**NAT Network Structure**

In a typical scenario, a Routing and Remote Access NAT-enabled router provides access to the Internet for a small- or medium-sized organization that uses private IPv4 addresses. To support this type of network, in addition to a server running the Routing and Remote Access service with the NAT/Basic Firewall component enabled, the typical network configuration includes, at minimum, client computers running a Web browser, such as Internet Explorer, and a firewall, such as the Basic Firewall option available with Routing and Remote Access NAT. The NAT-enabled router lets the clients on the private network access a computer on the Internet, such as a Web server running Internet Information Services (IIS).

Unless the network contains multiple routed segments, neither a DHCP nor a DNS server is required because NAT functionality in Windows Server 2003 includes the DHCP allocator and the DNS proxy capabilities, which provide automatic addressing and name resolution, respectively. For more information about the DHCP allocator and the DNS proxy, see "DHCP Allocator" and "DNS Proxy" in "Optional NAT Subsystems" later in this document.

If a DHCP server or a DNS server does exist on the network, Routing and Remote Access NAT is also designed to work with those servers. In addition, Routing and Remote Access NAT is designed to work in networks with or without the Active Directory directory service.

The following figure shows an example of a single-subnet private network that uses a Routing and Remote Access NAT-enabled router to provide access to the Internet. Computers on the private network have a private IPv4 address, except for the router, which has both a private and a public address. The Web server, like any computer on the Internet, has a public IPv4 address.

**Client on a Private Network Behind a Routing and Remote Access NAT Accessing a Resource over the Internet**

The following table describes each component shown in the preceding figure.

**Components of a Private Network Behind a NAT-enabled Router**

| Component | Description |
|---|---|
| Client PCs | Each client has a private IPv4 address configured on its network adapter. Clients need only a Web browser and access to a NAT-enabled router to be able to access the Web server across the Internet. |

| | |
|---|---|
| Routing and Remote Access NAT-enabled router | The NAT-enabled router has a private IP v4 address configured on its private interface, and a public IPv4 address configured on its Internet interface (in this example, a dial-up modem). The router has the optional Basic Firewall, DHCP allocator, and DNS proxy NAT components enabled. For more information, see "Optional NAT Subsystems."<br><br>For a larger network, an administrator might also configure a more sophisticated firewall in addition to using Basic Firewall to protect the Internet interface of the NAT-enabled router and might use a DHCP server (required if the network has more than one segment) and a DNS server. |
| Web server | A Web server on the Internet provides resources needed by the client computers on the private network. Like all computers on the Internet, it has a public IPv4 address. |

For information about why NAT was developed to mediate between private and public networks, see "What Is NAT?" in this collection.

**Optional NAT Subsystems**

One major type of organization that deploys Routing and Remote Access NAT is the small office or home office (SOHO) customer. Routing and Remote Access NAT has three optional sub-components — Basic Firewall, DHCP allocator, and DNS proxy — that are designed specifically to provide vital services while simplifying configuration for smaller-sized networks.

**Basic Firewall**

In Windows Server 2003, the Routing and Remote Access NAT routing protocol component is now integrated with Basic Firewall in order to provide protection to the NAT-enabled router's Internet interface. Basic Firewall is a simple stateful packet filter that prevents unsolicited traffic originating from a public network, such as the Internet, from reaching a private network through the public interface of the NAT-enabled router. Although enabling the Basic Firewall feature is optional, enabling it is a recommended practice even if your network has other firewall software installed. Enabling Basic Firewall helps secure the NAT-enabled router and strengthens overall network security by protecting the private network from unwanted Internet traffic.

Basic Firewall, which combines stateful packet filtering of network traffic with a set of static packet filters, monitors traffic that travels through the interface for which Basic Firewall is enabled. For an interface configured for private network traffic and to provide NAT, each packet's source and destination addresses are recorded in a table and all incoming traffic from the public network is compared to the entries in that table. Traffic from a public network can reach the private network only if the table contains an entry that shows that the communication exchange is allowed.

Windows Server 2003 provides two methods to configure the Basic Firewall that is now integrated with Routing and Remote Access NAT:

- If you use the Routing and Remote Access Server Setup Wizard to enable NAT, you can enable the Basic Firewall option during the same setup procedure.

- Alternatively, if the Routing and Remote Access service is already installed with NAT enabled, you can use the Routing and Remote Access snap-in to enable Basic Firewall at any time.

  **Note**

  - In addition to the Basic Firewall included in the Windows Server 2003 Routing and Remote Access service to protect the public interface of a NAT router, Windows XP, Windows XP SP1, and Windows Server 2003 include Internet Connection Firewall (ICF) to protect the public interface of any server or workstation that provides Internet access to computers on a private network. ICF, which provides a firewall technology similar to Basic Firewall, can be configured by using Network Connections.

For more information about installing and configuring Routing and Remote Access NAT and its optional components, see "NAT Tools and Settings" in this collection.

**TCP or UDP Unicast Packets**

If Routing and Remote Access NAT has Basic Firewall configured, an incoming TCP or UDP unicast packet is dropped unless it meets one of the following conditions:

- The packet belongs to a previously established mapping, or meets the UDP loose source port criteria (see "How Dynamic Mapping, Static Mapping, and IP Reservations Work" in "NAT Processes and Interactions" later in this document).

- The packet is a DHCP response packet, that is, UDP with source port 67 and destination port 68.

- The packet matches a static port mapping (see "How Dynamic Mapping, Static Mapping, and IP Reservations Work" in "NAT Processes and Interactions" later in this document).

- The packet matches a ticket (dynamic or editor-created). A ticket, in this context, is a statically defined port exemption that allows inbound packets that match this ticket.

- The packet matches a redirect. A redirect changes the destination address and port of packets that match the redirect to the address or port specified in the redirect. In Routing and Remote Access NAT, a redirect is used either by the NAT FTP editor to enable FTP traffic across a NAT, or it is used by NAT deployed in combination with the Microsoft Internet Security and Acceleration (ISA) Server to provide high-security Internet access.

**Broadcast and Multicast Packets**
If Routing and Remote Access NAT has Basic Firewall configured, the firewall always accepts broadcast and multicast packets and passes them to the NAT component. However, on a computer running the Windows Server 2003, Windows XP SP1, or later operating system, NAT is set by default to drop all inbound broadcast and multicast packets. To change this default behavior, an administrator can add the following registry key and set it to **1** to allow inbound non-unicast traffic, that is, to allow broadcast and multicast packets across Basic Firewall:

**HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\IpNat\Parameters\AllowInboundNonUnicastTraffic**

By default, **AllowInboundNonUnicastTraffic** is set to **0**, which blocks inbound non-unicast traffic.

**Specially Defined Packets**
If Routing and Remote Access NAT has Basic Firewall configured, the firewall always accepts specially defined packets for the following IP protocols, which are already protected by IPSec, and passes them to the NAT component:

- IP protocol 50 (or 0x32 in hexadecimal) for Internet Protocol security Encapsulating Security Payload (IPSec ESP), an IPSec protocol that provides confidentiality in addition to authentication, integrity, and replay.

- IP protocol 51 (or 0x33 in hexadecimal) for IPSec Authentication Header (IPSec AH), a header that provides authentication integrity, and anti-replay.

**ICMP Traffic**
The ICMP protocol, an extension to the Internet Protocol (IP), enables the generation of error messages, test packets, and informational messages related to IP. ICMP is described in RFC 792.

If Routing and Remote Access NAT has Basic Firewall configured, the following firewall behavior for ICMP traffic is defined:

- Inbound echo, timestamp, mask, and router request packets are dropped.

- Inbound echo, timestamp, mask, and router replies are dropped unless there exists a mapping automatically created by a corresponding outbound request.

- Inbound time exceeded, parameter problem, destination unreachable, and source quench are always forwarded.

- Outbound time exceeded, parameter problem, destination unreachable, and source quench are always dropped.

- Redirects are always dropped.

An administrator can configure the ICMP behavior to allow message types that are dropped by default (for example, to allow an echo request).

**DHCP Allocator**
In Windows Server 2003, the DHCP allocator feature of the Routing and Remote Access NAT routing protocol component provides a simplified form of automatic addressing. Windows Server 2003 (as well as Windows 2000 and Windows NT) supports automatic address acquisition by using the DHCP service. On starting up, a DHCP client obtains its addressing information from a DHCP server automatically, including its default gateway and DNS server. However, DHCP server configuration is complex and might be inappropriate for many SOHO networks. In response to this need, Windows, beginning

with Windows 98, also supports Automatic Private IP Addressing (APIPA), in which client computers, when no DHCP server is available, automatically configure themselves with private addresses in the range 169.254.0.1 to 169.254.255.254 with a subnet mask of 255.255.0.0 (or 169.254.0.0/16 in Classless Inter-domain Routing [CDIR] notation). Computers using APIPA addresses can communicate only with other computers that are also using APIPA addresses within a single subnet but cannot connect to computers outside the subnet. This approach works, therefore, only for strictly local networks, but does not cover the case where a local network has a link to the Internet.

The DHCP allocator feature provided by Routing and Remote Access NAT provides a solution that is a combination of the two approaches just described. The DHCP allocator is disabled by default. If you enable it, the Routing and Remote Access NAT-enabled router will function as a simplified DHCP server, that is, it will automatically assign IPv4 addresses to local clients and advertise itself to its DHCP clients as both the default gateway and the DNS server to the Internet. Specifically, the DHCP allocator assigns the following to each client on the private network:

- An IPv4 address and subnet mask.
- The IPv4 address of a default gateway (the private address of the NAT-enabled router).
- The IPv4 address of a DNS server (the private address of the NAT-enabled router; the router will forward a name resolution request that it receives from a client on its private network to the Internet–based DNS server for which the router is configured).

You must configure computers on the private network as DHCP clients in order to automatically receive the IP configuration.

Because the DHCP allocator provided by Routing and Remote Access NAT maintains no database, it does not require additional configuration beyond enabling the DHCP allocator feature. In Routing and Remote Access NAT, the DHCP allocator randomly allocates addresses from the range of configured addresses. For each address generated for a new client, the DHCP allocator uses the TCP/IP ARP module to ascertain whether that address is in use by another client. If a client replies to the ARP message indicating that it is using that address, a new address is generated. Each address assignment has a lease time of 10 minutes to avoid duplicate addresses that might be used by unavailable computers.

**Note**

- Configuring the NAT DHCP allocator feature works well when all computers on the local network are connected to the same subnet. On the same subnet, computers share each other's broadcasts and, therefore, can resolve each other's names by using broadcast NetBIOS name queries. If the network has multiple subnets, you must use a DHCP server rather than the DHCP allocator capability of the NAT/Basic Firewall component.

The DHCP allocator allocates addresses only to clients on permanently connected interfaces (such as LAN media) that are configured as private. You can configure this feature at either of two points:

- If you use the Routing and Remote Access Server Setup Wizard to enable NAT and you choose a network interface with a static IPv4 address as the private interface, you are given the option toenable the DHCP allocator feature for addressing services and the DNS Proxy feature for name resolution services. (For more information about "DNS Proxy," see "DNS Proxy," described next.)
- Alternatively, if the Routing and Remote Access service is already installed with NAT enabled, you can use the Routing and Remote Access snap-in to enable the DHCP allocator at any time.

For more information about installing and configuring Routing and Remote Access NAT and its optional components, see "NAT Tools and Settings" in this collection.

**DNS Proxy**

In Windows Server 2003, the DNS proxy feature of the Routing and Remote Access NAT routing protocol component provides a simplified name resolution service. Windows Server 2003 (as well as Windows 2000 and Windows NT) supports the assignment of DNS server addresses to DHCP clients during DHCP address assignment. This scheme fails in the case of a SOHO where the DNS server resides either with an ISP or on a corporate network because the correct DNS server address cannot be known until after a connection is established. Moreover, the typical SOHO will not have a DHCP server configured.

To solve this problem, a Routing and Remote Access NAT-enabled router that has both the DHCP allocator (described earlier) and the DNS proxy features configured provides its own address as the DNS server address to DHCP clients on the local

network. Then, when the connection to the Internet is established, the NAT-enabled router proxies DNS name resolution requests to the Internet DNS server address assigned to the Internet interface of the router. The DNS proxy makes the name resolution process transparent from the point of view of local computers. Like the DHCP allocator, the DNS proxy is disabled by default.

The following list explains how DNS proxy works:

1. The private computer sends a DNS name query request to the DNS proxy (source: private computer IP address, destination: DNS proxy private IP address).

2. DNS proxy saves the DNS name query request in memory and sends a new DNS name query request (source: DNS proxy public IP address, destination: Internet DNS server IP address).

3. The Internet DNS server resolves the name and sends a DNS name query response (source: Internet DNS server IP address, destination: DNS proxy public IP address).

4. DNS proxy matches the received DNS name query response with the saved DNS name query request and sends a new DNS name query response to the private computer (source: DNS proxy private IP address, destination: private computer IP address).

To the private computer, the DNS proxy is a DNS server. To the Internet DNS server, the DNS proxy is a DNS client.

Another possible scenario in a small private network in which no DHCP server exists is to enable the DNS proxy and disable the DHCP allocator. In this case, for each computer on the private network, a static IP address, subnet mask, and default gateway (the IP address of the NAT-enabled router) is configured by using the Network Connections folder to access the TCP/IP properties page for the network adapter on the private network. In addition, on the NAT-enabled router, the address of a DNS server on the Internet is configured as the DNS server for the router by using the TCP/IP properties page on the public interface of the NAT-enabled router. This configuration enables the NAT-enabled router to pass DNS name resolution requests to the Internet DNS server for which it is configured. For more information, see "Using Network Connections to Configure NAT Clients on the Private Network" in "NAT Tools and Settings."

In a setting where the local network already has a DNS server configured, the DNS proxy can still be useful. In all likelihood, an existing DNS server is configured to forward Internet name resolution requests to a static Internet DNS server address. This static configuration will fail whenever the address of the Internet DNS server changes. With automatic name resolution provided by the DNS proxy feature, you can configure the existing DNS server to forward Internet DNS requests to the local address of the DNS proxy, and the DNS proxy will then handle the task of dynamically finding the Internet DNS server address when the Internet connection is established.

Using DNS proxy provides an adequate solution even if multiple routed segments exist. In that event, you must disable the DHCP allocator (if it is enabled), configure a full DHCP server, and then configure the DHCP server to give the NAT-enabled router's local address on each subnet as the DNS server address for clients on that subnet. However, if multiple subnets are configured, the recommended option is to automatically install a full DNS server in default mode, which provides caching and name registration in addition to the name resolution.

**NAT Processes and Interactions**

This section covers the following topics:

- How NAT works with TCP/IP
- How address and port translation work
- How dynamic and static mappings and IP reservations work
- How NAT editors work
- How mapping and translation work together

**How NAT Works with TCP/IP**

Routing and Remote Access NAT is implemented as a routing protocol component that TCP/IP calls when a packet is sent or received. For the benefit of modules such as firewalls, the TCP/IP driver supports a pointer that sets the callout that TCP/IP

invokes for incoming and outgoing data packets. The parameters of the TCP/IP callout include the IP header and data and the context for the incoming or outgoing interface. The function to which TCP/IP calls out indicates whether the data packet should be forwarded, dropped, or processed as local host traffic. TCP/IP also allows the function to provide a replacement for the data packet, to accommodate any modifications that the NAT driver might make to the packet.

When mapping between public and private addresses when a pool of public addresses exists, NAT uses TCP/IP's Proxy ARP mechanism to respond to ARP queries for public addresses in the pool.

In the translation process, the NAT routing protocol component makes routing decisions in order to determine the interface over which to forward any given packet. To avoid consulting TCP/IP for each packet, a cache is implemented in the NAT. To keep the cache consistent with the TCP/IP forwarding database, the NAT registers for notification of route changes with TCP/IP.

**How Address and Port Translation Work**

The Routing and Remote Access NAT-enabled router, located, logically, at the edge point between the private and public networks, mediates between its private network and the resources on the Internet that its users want to access. To do so, the router uses both address and port translation, as described in this section.

The NAT driver modifies the source address and port in the header of TCP or UDP packets sent from a client on the private network to the public network, while also modifying the destination address and port in packets returned from the public network to the private network. Specifically, for an application for which the IPv4 address and port information is located in the IP and TCP or UDP headers (the type of application for which NAT was originally designed), the NAT-enabled router can translate the following:

- IPv4 address in the IP header
- Port number (either a TCP port number in the TCP header, or a UDP port number in the UDP header)

For example, traffic between a private network and the Internet — Hypertext Transfer Protocol (HTTP) traffic used to access Web servers — requires the translation of the IPv4 address in the IP header and, possibly, the TCP port in the TCP header. Some applications, however, embed address or port information inside the data portion of the packet or do not use TCP or UDP ports to identify the data stream. Translation for these applications is more complicated, and for such translation to take place, an appropriate NAT editor must exist. For more information about NAT editors, see "How NAT Editors Work" later in this section.

**Outgoing and Incoming Packet Translation**

When a computer user on the private network connects to a resource on the Internet (or other public network), the computer's TCP/IP protocol creates an IP packet with values for the source address and port as well as for the destination address and port. This information is set in the IP header and in the TCP header (or UDP header), as shown in the center column of the following table. The source computer (or an intermediate router) forwards this packet to the NAT-enabled router. The router then translates the source address and port of the outgoing packet, as shown in the right column of the same table. Information modified by this translation is shown in the table in italic text:

**Example of Translation of Address and Port of Outgoing Packet**

| Address and Port | Outgoing Packet Header When Client Initiates Request | Outgoing Packet Header after NAT Translates Source Address and Port |
|---|---|---|
| Source IPv4 Address | *Private IPv4 address* | *ISP-allocated public IPv4 address* [1] |
| Source Port | *Source application TCP or UDP port* | *Remapped source application TCP or UDP port* |
| Destination IPv4 Address | Internet resource IPv4 address | Internet resource IPv4 address |
| Destination Port | Internet resource TCP or UDP port | Internet resource TCP or UDP port |

[1] This example is a case in which the public address on the Internet interface of the NAT-enabled router is allocated by an organization's ISP

The NAT-enabled router then sends the remapped IP packet over the Internet. When the Internet resource sends back a response to the NAT, the incoming packet contains the information shown in the center column of the next table, "Example of Translation of Address and Port of Incoming Packet." After the NAT maps and translates the destination address and port, it contains the information as shown in the right column of that table. The NAT-enabled router forwards the translated packet to

the intranet client that made the initial request. Information modified by this translation is shown in the following table in italic text.

**Example of Translation of Address and Port of Incoming Packet**

| Address and Port | Incoming Packet Header When Internet Resource Sends Response | Incoming Packet Header After NAT Translates Destination Address and Port |
|---|---|---|
| Source IPv4 Address | Internet resource IPv4 address | Internet resource IPv4 address |
| Source Port | Internet resource TCP or UDP port | Internet resource TCP or UDP port |
| Destination IPv4 Address | *ISP-allocated public IPv4 address* [1] | *Private IPv4 address* |
| Destination Port | *Remapped source application TCP or UDP port* | *Source application TCP or UDP port* |

[1] This example is a case in which the public address on the Internet interface of the NAT-enabled router is one allocated by an organization's ISP

For outgoing packets, the source IPv4 address and TCP or UDP port numbers are mapped to a public source IPv4 address and a possibly changed TCP or UDP port number. For incoming packets, the destination IPv4 address and TCP or UDP port numbers are mapped to the private IPv4 address and original TCP or UDP port number.

**Network Address Port Translation**

All computers on the private network behind the NAT-enabled IP router, including the router itself, have a unique private IPv4 address and a private port number. The router also has at least one globally unique (public) IPv4 address. Optionally, an administrator can configure the router with a pool of public addresses so that multiple clients can request public network resources at the same time. The router can handle traffic for multiple clients on its private network even when it does not have a sufficient number of addresses in its public address pool to accommodate all of the clients requesting access to the public network. It can accommodate additional clients by using Network Address Port Translation (NAPT) to modify port information in the TCP or UDP packets being transmitted. RFC 3022 describes NAPT.

NAPT extends address translation by using many-to-one mapping — multiple private addresses are mapped to a single public address on the Internet interface of the NAT-enabled router. This is helpful because the number of clients with private addresses is ordinarily far larger than the available number of public addresses on the NAT-enabled router, even if the router is configured with a relatively large number of addresses in a public address pool. When the public addresses in the pool have all been translated, NAT starts to perform port translation instead of address translation.

For TCP or UDP communications, the address and port translation functionality made available by NAPT permits a client on a private network to access multiple computers on the Internet, and it enables multiple private clients to access the same Internet computer at the same time. Because both TCP and UDP ports have 16 bits, NAPT allows up to 65,535 ($2^{16}$-1) communications to take place at the same time. One is subtracted from the total number because port 0 for both TCP and UPD is reserved.

**Address and Port Translation Example**

How NAPT works is best understood through an example. Consider the simple case of a private network with three computers — Client A, Client B, and Client C — that use the private network IPv4 range of 192.168.0.0 with a subnet mask of 255.255.255.0. The NAT-enabled router is configured with a public pool containing the following IPv4 addresses:

157.54.35.38

157.54.35.39

The user on Client A initiates a request to look at a Web page on the Internet, so Client A sends a TCP packet to the NAT-enabled router. The NAT driver translates the packet and adds an entry for it to the NAT Mapping Table. The following figure depicts the packet translation and the entry made into the mapping table for Client A:

**Packet Translation and NAT Mapping Table Entry for Client A**

| NAT Mapping Table |
|---|
| **192.168.0.10: 3576 ← TCP → 157.54.35.38: 5000 (Dynamic Address Translation)** |

Next, the user on Client B initiates another TCP session with a host on the public network. The following figure depicts the packet translation for Client B and the new entry for Client B, which is added to the mapping table that already contains the entry for Client B.

**Packet Translation and NAT Mapping Table Entry for Client B**

| NAT Mapping Table |
|---|
| 192.168.0.10: 3576 ← TCP → 157.54.35.38: 5000 (Dynamic Address Translation) |
| **192.168.0.11: 2258 ← TCP → 157.54.35.39: 5000 (Dynamic Address Translation)** |

Finally, the user on Client C initiates traffic from the private to the public network and thus sends a packet to the NAT-enabled router. However, the public address pool configured on the NAT-enabled router contains only two addresses, which have already been used for Clients A and B. In this case, the NAT driver translates Client C's private address:port pair to a unique public address:port pair by changing the public port number. That is, when the pool of public addresses, which is fewer in number than the number of clients on the private network, is exhausted, the NAT driver switches from address translation to port translation. The following figure depicts the packet translation for Client C and the new entry for Client C in the mapping table.

**Packet Translation and NAT Mapping Table Entry for Client C**

| NAT Mapping Table |
|---|
| 192.168.0.10: 3576 ← TCP → 157.54.35.38: 5000 (Dynamic Address Translation) |
| 192.168.0.11: 2258 ← TCP → 157.54.35.39: 5000 (Dynamic Address Translation) |
| **192.168.0.12: 1944 ← TCP → 157.54.35.39: 5001 (Dynamic Port & Address Translation)** |

When the resource on the public network to which each client sent a request sends a response back to the client on the private network, the same process occurs in reverse: The NAT driver intercepts the response packet, looks up the packet's destination address in the NAT Mapping Table, finds the corresponding address of a private network client, modifies the destination address and destination port in the response packets — this time translating the packet's public destination address and port number back to the client's private address and port number — recomputes the checksum (which it must do any time it replaces an address in a packet header), and then sends the response across the private network to the client.

**How Dynamic and Static Mappings and IP Reservations Work**

In addition to the dynamic mapping just introduced in "How Address and Port Translation Work," Routing and Remote Access NAT technology provides for two additional types of entries in the NAT Mapping Table: static mapping and IP reservations. Each of the three mapping types is designed for a different purpose.

**Dynamic Mapping**

Whenever a NAT-enabled router receives an outgoing TCP or UDP packet from a local client that is initiating communications with a computer on the public network, the NAT driver creates an entry in the NAT Mapping Table, called a 5-tuple entry, that contains the following five pieces of information:

{protocol (TCP or UDP), private address, private port, public address, public port}

An alternative notation representing this 5-tuple entry is the following:

{protocol (TCP or UPD), source address, source port, destination address, destination port}

The private address and port pair are automatically (dynamically) mapped to the public address and port pair. This is the type of mapping illustrated earlier in "How Address and Port Translation Work." This entry in the NAT Mapping Table enables the NAT-enabled router to direct a response packet from a computer on the public network back to the client on the private

network that sent initial the request.

Because the number of mappings that can be established is limited by the number of available 16-bit TCP and UDP ports, the NAT driver must eventually delete the dynamic mappings that it creates in order to free up port numbers for use in new mappings. A dynamic mapping entry remains in the mapping table for the length of time that the administrator specifies on the **Translation** tab for the properties of the **NAT/Basic Firewall** component in the Routing and Remote Access snap-in. Routing and Remote Access NAT, by default, uses the RFC 1631 recommended timeouts of 24 hours for idle TCP mappings and 1 minute for idle UDP mappings.

**Static Mapping**
With dynamic mapping, in order for a TCP or UDP packet to pass through the NAT from the public network to the private network, a mapping must have been established previously by a packet sent from the private to the public network. However, if a client on the public network attempts to establish a TCP or UDP session with a computer on the private network (such as a Web server on the private network or a computer on the private network that provides a game application), no dynamic mapping will be found and the incoming packet will be discarded.

If an organization wants to allow such incoming traffic to a specific computer on the private network, Routing and Remote Access NAT allows an administrator to use the **Services and Ports** tab on the properties page of the public interface in the Routing and Remote Access snap-in to configure a static mapping for this traffic. Thus, the way that the NAT-enabled router forwards Internet traffic into its private network is either in response to traffic initiated by a user on the private network, which creates a dynamic mapping, or because an administrator has configured a static mapping to enable Internet users to access specific resources on the private network. (For an alternative to static mapping, see "IP Reservations" later in this section).

Static mappings have limited usefulness for connections between a private network and the Internet because of the large number of possible connections. Too many connections can make the NAT Mapping Table grow excessively and thus slow router performance.

A static mapping consists of a 5-tuple entry identical in content to a dynamic mapping entry:

{protocol (TCP or UDP), private address, private port, public address, public port}

Unlike a dynamic mapping, a static mapping explicitly matches a given TCP or UDP port number to both the private and the public address in the static entry in the mapping table. For example, to set up a Web server on a computer on a private network, an administrator could create a static mapping that maps [*Public IPv4 Address*, TCP Port 80] to [*Private IPv4 Address*, TCP Port 80]. Port 80 is, by convention, assigned to the World Wide Web (WWW) and used by Web servers for HTTP traffic. When a packet arrives for *Public IPv4 Address* and Port 80, the NAT-enabled router directs the packet to the Web server on the private network.

Any server running on a well-known port on the private network (such as HTTP or FTP servers) can have only one instance accessible to clients running on the public network.

Multiple interfaces can have translation enabled at the same time, as in the case of a home where a user connects both to the Internet and to a corporate network. Therefore, static mappings in Routing and Remote Access NAT can be configured on a per-interface basis.

A static mapping entry remains in the mapping table until an administrator deletes it.

**UDP Source Port Allocation and Loose Source Matching**
To better support various types of peer-to-peer applications, the NAT mapping behavior for UDP differs from that of TCP in the following two ways:

**How NAT chooses the source port for outbound dynamic mappings.**
When creating a new TCP mapping for an outbound packet, the NAT driver chooses a source port without regard for already existing mappings as long as such a choice does not result in a conflict. In contrast, when choosing a source port for a UDP mapping for an outbound packet, the NAT driver determines if a mapping exists that has the same private address and port. If such a mapping exists, the NAT driver will use the same public port for the new mapping. For example:

- If a client on the private network makes a TCP connection to two different computers on the public network from the same source port, the NAT driver will choose different source ports for those mappings.

- If a client on the private network sends UDP packets to two different computers on the public network from the same source port, the NAT driver will use the same source port for both mappings.

**How NAT determines whether an inbound packet matches an existing dynamic or static mapping.**
For TCP, an inbound packet must exactly match the 5-tuple for a mapping (that is, protocol, source address, source port,

destination address, and destination port). For UDP, however, an inbound packet must match only the protocol, destination address, and destination port of a mapping — the source address and source port of the packet are effectively ignored. This "loose matching behavior" applies only if the private port is greater than 1024. Allowing this behavior for ports below 1024 would introduce a security risk because it might allow unfettered access to such sensitive TCP and UDP ports as 137 (NetBIOS Name service) and 445 (Microsoft Common Internet File System [CIFS]).

**IP Reservation**

If you want to allow a computer on the Internet to initiate a connection to a computer on the private network behind the NAT-enabled router, an alternative to using static mapping is to configure an IP reservation to handle this traffic. If you establish a public IPv4 address reservation to one of the private IPv4 addresses on the private network, all incoming traffic addressed to the specified public address is sent to the private address reserved for it. Thus, instead of putting a computer directly on the public network, the traffic is transmitted through the NAT-enabled router. For both static mapping and IP reservations, this is an advantage because, typically, the router is configured with a firewall and other filters.

For example, you might want to use an IP reservation to allow traffic to a Web server on the private network. You can allow such incoming traffic by first using the **Address Pool** tab on the properties page of the public interface in the Routing and Remote Access snap-in to configure an IP address pool (you cannot configure an IP reservation until after you configure at least one IP address pool). You can then configure the IP reservation itself by using the **Reservations** button on the **Address Pool** tab.

IP reservations are particularly useful when the number of public IP addresses on the NAT-enabled router is large — reservations provide an easy way to map public to private addresses. In addition, IP reservations are useful for IP protocols that pick port numbers randomly, which means that the administrator does not need to know the port numbers in advance. IP reservations can also be used for IP protocols that do not use ports because this process is independent of the protocol (whether TCP, UDP, or ICMP). For an example showing how IP reservations work, see "Static Mapping and IP Reservation Examples" later in this document.

For outgoing traffic from a computer on the private network for which an IP reservation exists, the NAT-enabled router does not use the public IP address reserved for that private computer. Outgoing traffic from a computer on the private network to any destination on the Internet, including traffic to a Web server for which an IP reservation exists, is handled by the NAT-enabled router by using standard address and port translation.

When a network administrator uses the Routing and Remote Access snap-in to create an IP reservation, a 2-tuple entry is entered in the NAT Mapping Table:

{private address, public address}

An IP reservation remains in the mapping table until an administrator deletes it.

**Dynamic and Static Mappings More Restrictive than IP Reservations**

The behavior of dynamic and static mapping entries and IP reservations is determined by the amount of information each stores:

- 5-tuple dynamic and static mappings are more restrictive than IP reservations because incoming or outgoing traffic must match all five pieces of information in the NAT Mapping Table entry before the packet will be forwarded; or, in the case of UDP for ports greater than 1024, an inbound packet must match three pieces of information — the protocol, destination address, and destination port.

- 2-tuple IP reservations are less restrictive than either dynamic or static mappings because incoming or outgoing traffic that has a destination IPv4 address that matches the public IPv4 address in the NAT Mapping Table entry will be forwarded.

**Static Mapping and IP Reservation Examples**

To continue the example presented earlier in "How Address and Port Translation Work," which illustrates dynamic mapping, an administrator next decides to use Client B as a Web server and therefore uses the Routing and Remote Access snap-in to add a static mapping for Client B. This mapping means that all inbound TCP traffic directed to 157.54.35.38 and port 80 on the NAT-enabled router will match that address:port pair to Client B's own address and port 80. Thus, the NAT Mapping Table shown in the earlier figure, "Packet Translation and NAT Mapping Table Entry for Client C," changes to include a second entry for Client B (the new fourth row), as shown in the following table.

**Static Mapping of Client B's Private Address and Port to a Public Address and Port**

| Client | Private Address:Port | Protocol | Public Address:Port | Type |
|---|---|---|---|---|

| | | | | |
|---|---|---|---|---|
| A | 192.168.0.10:3576 | TCP | 157.54.35.38:5000 | Dynamic address translation |
| B | 192.168.0.11:2258 | TCP | 157.54.35.39:5000 | Dynamic address translation |
| C | 192.168.0.12:1944 | TCP | 157.54.35.39:5001 | Dynamic port and address translation |
| B | 192.168.0.11:80 | TCP | 157.54.35.38:80 | Static address translation |

If the administrator then uses the Routing and Remote Access snap-in to add an IP reservation to the NAT Mapping Table, reserving public IPv4 address 157.54.35.39 for Client A, any existing dynamic mappings to 157.54.35.39 are preempted by this change. That is, the earlier dynamic mappings to the public address 157.54.35.39 no longer exist. Only the IP reservation for 157.54.35.39 remains in the NAT Mapping Table, as shown in the following table.

**IP Reservation of Client A's Private Address to a Public Address**

| Client | Private Address:Port | Protocol | Public Address:Port | Type |
|---|---|---|---|---|
| A | 192.168.0.10:3576 | TCP | 157.54.35.38:5000 | Dynamic address translation |
| B | 192.168.0.11:80 | TCP | 157.54.35.38:80 | Static address translation |
| A | 192.168.0.10:* | * | 157.54.35.39.* | IP reservation address translation |

With an IP reservation, as the asterisks in the last row of the preceding table indicate, it is irrelevant which protocol (TCP or UDP) is used or what the destination port number is on an inbound packet. All that matters is that the destination address is matched to the public IPv4 address in the reservation. Therefore, in the example in the preceding table, any traffic with a destination IPv4 address of 157.54.35.39 is forwarded to client A.

**Summarizing Packet Translation**

To summarize outbound and inbound packet translation:

- When a TCP or UDP packet outbound to the Internet from a client on the private network arrives at the private interface of the NAT-enabled router, the NAT driver looks in the NAT Mapping Table for an existing dynamic mapping. If none is found, the NAT driver creates a new mapping, updates the checksum, and sends the packet out to the Internet over a dial-up, broadband, or other connection.

- When a TCP or UDP packet inbound from the Internet arrives at the Internet interface of the NAT-enabled router, the NAT driver looks in the NAT Mapping Table for an existing dynamic or static mapping or for an IP reservation. If any of the three types of entries is found, the NAT driver translates the incoming packet and delivers it over the private interface of the NAT-enabled router to the client. Otherwise, the packet is discarded.

**How NAT Editors Work**

In Routing and Remote Access NAT, the NAT driver is designed to translate IPv4 address and TCP or UDP port information for traffic between a private and a public network. If the IPv4 address and port information is located only in the IP and TCP or UDP headers — as is the case, for example, for HTTP (World Wide Web) traffic — the NAT driver can translate the application protocol transparently. However, the NAT driver, on its own, cannot translate packets in the following two types of cases:

**An IPv4 address, TCP port, or UDP port is stored in the payload.**

Certain applications embed address or port information inside the data portion of the packet rather than in the IP and TCP or UDP headers. One such application is the File Transfer Protocol (FTP) — for the FTP **port** command, FTP stores the IPv4 address in the FTP header. In addition, FTP stores the IPv4 address in dotted decimal format, which means that the translated IPv4 address in the FTP header can be a different size, and, therefore, the TCP sequence numbers must be modified to ensure that no data is lost. Other examples of applications that the NAT driver cannot translate transparently include streaming applications, such as RealAudio and CUSeeMe, which use a TCP connection to dynamically select a UDP port over which data is then transmitted.

**TCP or UDP is not being used to identify the data stream.**

Data that is tunneled from one geographic site to another through the Internet by using the Point-to-Point Tunneling Protocol (PPTP) does not use a TCP or UDP header. Instead, PPTP data uses a Generic Routing Encapsulation (GRE) header, and the Call ID, which is stored in the GRE header, identifies the data stream. If the NAT driver does not correctly translate the Call ID within the GRE header, connectivity problems can occur.

NAT editors are application level gateways (ALGs) that have been developed to translate packets in these two cases. A NAT editor examines the packets sent by such applications and modifies the data portion of the packet as appropriate. Because such

modifications might change the size of packets, a NAT editor must also adjust sequence numbers for TCP connections after any translation has changed the number of bytes in the TCP data stream.

The Windows Server 2003 Routing and Remote Access service installs two built-in NAT editors along with the NAT routing protocol component — Internet Control Message Protocol (ICMP) to support error messages, and Point-to-Point Tunneling Protocol (PPTP) to support PPTP VPN traffic. Both editors are always on. The NAT driver consults the editors whenever the payload of the packet being translated matches one of the installed editors. The editor modifies the payload and returns the result to the NAT driver.

### Note

- In addition to the NAT editors, Routing and Remote Access NAT includes two NAT proxies, which redirect packets to a module that builds a new packet modified so that it can cross a NAT. The NAT proxies are the File Transfer Protocol (FTP) proxy, which supports FTP traffic across a NAT, and the H.323 proxy, which supports NetMeeting calls across a NAT. Unlike NAT editors, which are always on, NAT proxies are disabled by default. Both proxies can be turned on or off by using the appropriate Netsh command in the **netsh routing ip nat context**: you can enable the NAT proxies by using **add ftp** or **add h323**; you can disable the NAT proxies by using **delete ftp** or **delete h323**.

#### How Mapping and Translation Work Together

The two flowcharts in this section, "Processing for Outbound and Inbound NAT Traffic" and "Packet Translation Process," outline the overall process that the Routing and Remote Access NAT-enabled router uses to manage outbound and inbound packets.

First, the router determines whether the packet is outbound or inbound. Depending on the outcome of that initial determination, the following occurs:

#### Outbound traffic

For traffic from the private network that is outbound to the Internet (or other public network), the NAT driver assesses whether or not an address/port mapping (whether a static or dynamic mapping, or an IP reservation) exists for the packet. If such a mapping exists, the NAT driver uses the existing mapping; if none exists, the NAT driver creates a new dynamic mapping. Whether a single IPv4 address or a pool of addresses is available determines how that mapping is made (see "How Address and Port Translation Work" earlier in this section). Next, the NAT driver checks for editors and invokes one if necessary (assuming that one exists). If no editor is needed, the NAT driver performs standard network address translation of the TCP or UDP header and the IP header (for an outbound packet, translating the source TCP or UDP port and the source IP address), and then refreshes the NAT Mapping Table. Finally, the NAT-enabled router uses its Internet interface to forward the outgoing packet to the resource computer on the Internet.

#### Inbound traffic

For a response or other specifically allowed incoming traffic from the Internet (or other public network) that is inbound to the private network, the NAT driver also assesses whether or not an address/port mapping (whether static or dynamic mapping, or an IP reservation) exists for the packet. If a mapping exists, the NAT driver uses the existing mapping; if no mapping exists, the incoming packet is discarded. Next, the NAT driver checks for editors and invokes one if necessary (assuming that one exists). If no editor is needed, the NAT driver performs standard network address translation of the TCP or UDP header and the IP header (for an inbound packet, translating the destination TCP or UDP port and the destination IP address), and then refreshes the NAT Mapping Table. Finally, the NAT-enabled router uses its private interface to forward the incoming packet to the appropriate computer on the private network.

Of the following two flowcharts, the second is a continuation of the first. In the first flowchart, "Processing for Outbound and Inbound NAT Traffic," the two process boxes (one on the left and another on the right) labeled "Performs packet translation" both point to the second flowchart, "Packet Translation Process."

### Processing for Outbound and Inbound NAT Traffic

**Packet Translation Process**

**Related Information**

For more information about NAT, see the following RFCs in the IETF RFC Database:

- RFC 1631, "The IP Network Address Translator (NAT)."
- RFC 3022, "Traditional IP Network Address Translator (Traditional NAT)."
- RFC 1918, "Address Allocation for Private Internets."
- RFC 2663, "IP Network Address Translator (NAT) Terminology and Considerations."

# NAT Tools and Settings

Updated: July 31, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- NAT Tools
- NAT Registry Entries
- Related Information

You can use the network address translation (NAT) tools and registry settings described here to enable, configure, and manage Routing and Remote Access NAT on a computer running Windows Server 2003.

**NAT Tools**
The following tools are associated with the NAT routing protocol component provided by the Microsoft Windows Server 2003 Routing and Remote Access service:

- Routing and Remote Access snap-in
- Network Connections
- Netsh command-line tools for Routing and Remote Access NAT

**Graphical User Interface Tools**
The graphical user interface tools used to install and configure Routing and Remote Access NAT include Network Connections, used to configure TCP/IP properties for NAT clients to provide the client computers access to the Internet, and the Routing and Remote Access snap-in, used to install and configure Routing and Remote Access NAT on a server.

**Network Connections Category**
Network Connections is included with the versions of the Windows operating systems as described in the next paragraph, "Version compatibility."

**Version compatibility**
You can run Network Connections on any computer running Windows Server 2003, Windows XP, Windows 2000, or Windows NT version 4.0. However, Windows NT 4.0 does not support Routing and Remote Access NAT.

**Network Connections options for NAT clients**
You use the Network Connections tool to configure TCP/IP properties for NAT clients so that the client computers can use a NAT-enabled router to gain access to the Internet (or other public network).

The properties page for TCP/IP on client computers can be used for a variety of purposes. The following table lists which TCP/IP options are used to enable NAT clients to interact with a NAT-enabled router on a private network.

**TCP/IP Properties Options Used for a NAT Client**

| Page | Tab | Option |
|---|---|---|

| | | |
|---|---|---|
| TCP/IP Properties | General | The following options on the adapter of the NAT client are used to enable the NAT client to access the NAT-enabled router:<br>1. Under **Use the following IP address**, the values needed for following options are specific to a NAT client:<br>• **IP address.** The private IPv4 address and subnet mask of the client.<br>• **Subnet mask.** The private subnet mask of the client.<br>• **Default gateway.** The private IPv4 address of the NAT-enabled router.<br>2. Under **Use the following DNS server addresses**, the value needed for the following option is specific to a NAT client:<br>**Preferred DNS server.** The private IPv4 address of the NAT-enabled router, which is acting as a DNS proxy. |
| TCP/IP Properties | Alternate Configuration | No NAT-related configuration is needed on this tab. |
| Advanced TCP/IP Settings | IP Settings | **Default gateways.** A gateway using the private address of the NAT-enabled router (if appropriate).<br>**Caution:** This option is appropriate to use only if the client computer receives its IP address from a DHCP server (that is, this option is not appropriate if the client obtains its IP address from the NAT DHCP allocator). |

**Routing and Remote Access Snap-in**
**Category**
The Routing and Remote Access snap-in is used with the Routing and Remote Access service, which is included with Windows Server 2003 and Windows 2000 Server. Routing and Remote Access is disabled by default. You can use the Routing and Remote Access snap-in, under **Administrative Tools**, to enable and configure the Routing and Remote Access service, including the optional NAT routing protocol component.

**Version compatibility**
The Routing and Remote Access snap-in is provided by the Routing and Remote Access service on computers running Windows Server 2003 and Windows 2000 Server. For Windows NT 4.0, the Routing and Remote Access Service (RRAS) and its snap-in are available as a separate download from the Microsoft Windows NT Server Routing and Remote Access Service Download page at http://go.microsoft.com/fwlink/?LinkId=22441. However, Windows NT 4.0 RRAS does not include NAT.

The following sections briefly summarize NAT-related tasks for which you can use the Routing and Remote Access snap-in. (In addition to NAT, the Routing and Remote Access snap-in is also used to configure LAN routing, dial-up or VPN remote access connections, and site-to-site connections between geographically remote networks.)

- Enabling NAT while running the Routing and Remote Access wizard
- Enabling both VPN and NAT while running the Routing and Remote Access wizard

**Enabling NAT while running the Routing and Remote Access Wizard**
If the Routing and Remote Access service is not yet enabled on a computer running Windows Server 2003, you can enable NAT when you run the Routing and Remote Access Wizard by selecting the **Network Address Translation (NAT)** option. The wizard also lets you choose to enable the Basic Firewall feature.

Choosing **Network Address Translation (NAT)** when you run the wizard establishes the following:

- Configures the IP address of the private network interface (the LAN card that connects to the private network segment).
- Configures the public interface. If the connection is a non-permanent connection (such as a dial-up modem), the wizard creates a demand-dial interface to the ISP and creates a default static route that uses the Internet interface. (If the

connection is permanent, such as DDS, T-Carrier, Frame Relay, permanent ISDN, xDSL, or cable modem, the wizard does not create a demand-dial interface or static route for the interface.)

- Adds the NAT routing protocol component.
- Adds Internet and private network interfaces to the NAT routing protocol component.
- If you chose the option to enable **Basic Firewall** while running the wizard, the wizard configures a basic stateful firewall on the public interface connected to the Internet.

**Note**

- If the network already has a firewall and you do not select the **Basic Firewall** option while running the wizard, the Routing and Remote Access snap-in entry for the NAT routing protocol component (under **IP Routing** in the console tree) displays as **NAT/Basic Firewall**. The name "NAT/Basic Firewall" does not indicate whether Basic Firewall is configured.
- You can confirm whether Basic Firewall is configured by using the **NAT/Basic Firewall** tab on the properties page of the public (Internet-connected) interface.

**Enabling both VPN and NAT while running the Routing and Remote Access Wizard**

If the Routing and Remote Access service is not yet enabled on a computer running Windows Server 2003, you can configure the server both to provide NAT for the private network and also to accept VPN connections. You can do so when you run the Routing and Remote Access Wizard by selecting the **Virtual Private Network (VPN) access and NAT** option when the wizard begins.

Choosing **Virtual Private Network (VPN) access and NAT** specifies that computers on the Internet cannot determine the IP addresses of any computer on the private network, yet allows VPN clients to connect to computers on the private network.

**Routing and Remote Access snap-in options for NAT-enabled routers**

If the Routing and Remote Access service is already enabled on a server, or if you installed NAT by using the Routing and Remote Access Wizard and want to modify the NAT configuration, you can use the tools provided by the Routing and Remote Access snap-in to enable and configure, or modify, Routing and Remote Access NAT.

The Routing and Remote Access snap-in can be used for a variety of purposes unrelated to Routing and Remote Access NAT. The following table lists which options under the **General** and **NAT/Basic Firewall** nodes in the Routing and Remote Access snap-in are used for NAT-related tasks and describes the location in the Routing and Remote Access snap-in used for each task.

**NAT-related Options in the Routing and Remote Access Console Tree**

| Node | Task |
|---|---|
| General | Adding network address translation:<br>• Under the server name for the server to be configured as the NAT-enabled router, expand **IP Routing**, right-click **General**, select **New Routing Protocol**, and then choose **NAT/Basic Firewall**. |

| | |
|---|---|
| NAT/Basic Firewall | Adding and configuring public or private interfaces for the NAT routing protocol component:<br>• Right-click **NAT/Basic Firewall**, and then click **New Interface** to add an internal interface to connect to the private network or to add a public interface to connect to the Internet.<br><br>**Note:** You do not need to manually configure public or private interfaces for the NAT component if you used the Routing and Remote Access Setup wizard to configure NAT.<br><br>Viewing the NAT mapping table:<br>• Click **NAT/Basic Firewall**, right-click the public interface in the details pane, and then click **Show Mappings**.<br><br>Viewing DHCP allocator information:<br>• Right-click **NAT/Basic Firewall**, and then select **Show DHCP Allocator Information** to display the number of instances for each of the following:<br>  • Messages ignored<br>  • DECLINE messages received<br>  • DISCOVER messages received<br>  • INFORM messages received<br>  • RELEASE messages received<br>  • REQUEST messages received<br>  • ACK messages sent<br>  • BOOTP replies sent<br>  • NAK messages sent<br>  • OFFER messages sent<br><br>Viewing DNS proxy information:<br>• Right-click **NAT/Basic Firewall**, and then select **Show DNS Proxy Information** to display the number of instances for each of the following:<br>  • Messages ignored<br>  • Queries received<br>  • Responses received<br>  • Queries sent<br>  • Responses sent |

The following table describes how each tab on the **NAT/Basic Firewall Properties** page in the Routing and Remote Access snap-in is used for NAT-related tasks.

**NAT-related Options on the NAT/Basic Firewall Properties Page**

| Tab | Task |
| --- | --- |
| General | Specifying the level of errors and warnings to be logged in the System Log in Event Viewer:<br>• **Log errors only.** Specifies that only errors are logged in the System Log in Event Viewer.<br>• **Log errors and messages.** Specifies that both errors and warnings are logged in the System Log in Event Viewer.<br>• **Log the maximum amount of information.** Specifies that the maximum amount of information is logged in the System Log in Event Viewer.<br>• **Disable event logging.** Specifies that no events are logged in the System Log in Event Viewer. |
| Translation | Specifying the number of minutes that a dynamic mapping for a TCP session or for a UDP message remains in the NAT Mapping Table. |
| Address Assignment | Configuring the DHCP allocator feature:<br>1. Specify whether the NAT-enabled router will provide DHCP-based address assignment to DHCP clients on the private network.<br>2. Specify both the private address range and any exclusions; that is, specify any addresses within the specified range of addresses that should not be assigned to DHCP clients on the private network because they are already in use.<br>If multiple routed subnets are configured, you must use a DHCP server rather than the DHCP allocator. |
| Name Resolution | Configure the DNS proxy feature:<br>1. Specify whether the NAT-enabled router relays DNS name resolution requests from hosts on the private network to the configured DNS server for the NAT-enabled router.<br>2. Specify whether a connection is attempted by using the selected demand-dial interface when a DNS name resolution request is received by a host on the private network. |

The following table describes how each tab on the properties page of the public (Internet-connected) interface in the details pane of the Routing and Remote Access snap-in is used for NAT-related tasks.

**NAT-related Options on the Public Interface Properties Page**

| Tab | Task |
| --- | --- |

| | |
|---|---|
| NAT/Basic Firewall | Configuring NAT:<br>● Select **Enable NAT on this interface** to enable the router to send data to and receive data from the Internet over this interface.<br><br>Configuring Basic Firewall:<br>● Select **Enable a basic firewall on this interface** to protect computers on the private network from unsolicited Internet traffic.<br><br>Configuring static packet filters:<br>● Under **Static packet filters**, select **Inbound Filters** or **Outbound** Filters to establish inbound and outbound packet filters on the public interface to restrict traffic based on packet attributes such as IP address or protocol. For example, you can use this option to configure filters for PPTP or L2TP/IPSec VPN connections, as described in the Windows Server 2003 Deployment Guide section about "Configuring Packet Filters for a VPN Server" in Deploying a VPN Remote Access Server Solution. |
| Address Pool | Configuring one or more IP address ranges:<br>● Select **Add** to configure an IP address pool on the public interface. You cannot configure an IP reservation until you configure at least one IP address pool.<br><br>Configuring an IP reservation to allow incoming traffic to a computer (such as a Web server) on the private network:<br>● Under **Reserve public addresses**, click **Reservations** to configure an IP reservation by specifying a public IP address from one of the configured ranges. This ensures that the reserved address cannot be used for address translation. |
| Services and Ports | Configuring a static mapping for the services on your network to which you want to provide access for Internet users:<br>● Select one of more from the list of services provided (such as **FTP Server**, **Web Server (HTTP)**, or **Remote Desktop**).<br><br>-or-<br><br>● Click **Add** to configure a service that is not on the list to which you want to provide access for Internet users.<br><br>**Note:** Configuring a service on this tab creates a static entry in the NAT Mapping Table and creates exceptions in the Basic Firewall that allow the specified incoming traffic. |
| ICMP | Configuring Internet Control Message Protocol (ICMP) options:<br>● Select the requests for error and status information (ICMP messages) from the Internet to which this computer will respond. |

The following table describes how the tab on the properties page of the **Internal** interface in the details pane of the Routing and Remote Access snap-in is used for NAT-related tasks.

**NAT-related Options on the Internal Properties Page**

| Tab | Task |
|---|---|

| | |
|---|---|
| NAT/Basic Firewall | Configuring static packet filters:<br>• Under **Static packet filters**, select **Inbound Filters** or **OutboundFilters** to establish inbound and outbound packet filters on the private interface to restrict traffic based on packet attributes such as IP address or protocol<br><br>**Note:** If the NAT/Basic Firewall component is enabled, the option **Private interface connected to private network** is selected on this tab by default and cannot be unselected. |

**Netsh Command-Line Tools for Routing and Remote Access NAT**

Netsh provides several sets of commands (also known as *contexts*) for performing a wide range of network configuration tasks. The Netsh Routing IP NAT commandsprovide the Netsh context for Routing and Remote Access NAT.

**Netsh.exe: Netsh Routing IP NAT Commands**

**Category**

The Netsh Routing IP NAT commands, a subset of the Netsh command-line toolset, are included with the Windows Server 2003 operating system.

**Version compatibility**

The Netsh Routing IP NAT commands are compatible with Windows Server 2003. Netsh commands were first introduced in Windows 2000 Server and were expanded to include additional commands, including commands to manage NAT, in Windows Server 2003.

The Netsh commands are designed to help network administrators manage a TCP/IP network. You can use the Netsh command-line set of tools to locally or remotely display or modify the configuration of services or protocols on Windows–based computers. The Netsh command-line interface is scriptable, which lets you perform batch configurations or network administration from a centralized location. In addition to the Netsh Routing IP NAT commands that are designed specifically for Routing and Remote Access NAT, NAT also inherits commands from the Netsh Routing context and the Netsh Routing IP context.

The following table contains a brief description of the commands available in the Netsh Routing IP NAT context.

**Commands Available in the Netsh Routing IP NAT Context**

| NAT Context Command | Description |
|---|---|
| ? or help | When typed at a **netsh routing ip nat>** prompt, either **?** or **help** displays a complete list of all commands in the Netsh Routing IP NAT context, including all commands inherited from the global Netsh context as well as commands inherited from the Netsh Routing and Netsh Routing IP subcontexts.<br><br>When typed at a **netsh routing ip nat>** prompt, a command name followed by **?** (such as **show ?**) displays information about that command. |
| add addressmapping | Adds an IP address mapping to the NAT address pool for the specified interface. |
| add addressrange | Adds an address range to the NAT address pool for the specified interface. |
| add ftp | Enables the NAT proxy for FTP (supports FTP traffic across a NAT). |
| add h323 | Enables the NAT proxy for H.323 (supports NetMeeting calls across a NAT). |
| add interface | Configures NAT on the specified interface. |
| add portmapping | Adds a protocol port mapping for either the TCP or the UDP protocol type on the NAT interface. |
| delete addressmapping | Deletes an address mapping from the NAT address pool for the specified interface. |

| | |
|---|---|
| delete addressrange | Deletes an address range from the NAT address pool for the specified interface. |
| delete ftp | Disables the NAT proxy for FTP. |
| delete h323 | Disables the NAT proxy for H323. |
| delete interface | Removes NAT from the specified interface. |
| delete portmapping | Deletes a protocol port mapping for either the TCP or the UDP protocol type from the specified NAT-enabled interface. |
| set global | Sets the following global parameters for NAT:<br>• The timeout value, in minutes, for TCP mappings.<br>• The timeout value, in minutes, for UDP mappings.<br>• Which events should be logged. The **none** parameter specifies that no events related to NAT should be logged. The **error** parameter specifies that only errors related to NAT should be logged. The **warn** parameter specifies that only warnings related to NAT should be logged. The **info** parameter specifies that all events related to NAT should be logged. |
| set interface | Configures NAT parameters for the specified interface. |
| show global | Displays NAT global configuration. That is, it displays the current defaults for the following:<br>• TCP timeout (in minutes)<br>• UDP timeout (in minutes)<br>• Logging level (such as errors only) |
| show interface | Displays NAT configuration for the specified interface. |

For more information about Netsh, see "Command-Line Reference for Windows Server 2003, Standard Edition" in the Tools and Settings Collection.

**NAT Registry Entries**

The following registry entry, associated with Routing and Remote Access NAT, is the only registry entry that an administrator might want to modify by using the registry editor.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**AllowInboundNonUnicastTraffic**
**Registry path**
**HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\IpNat\Parameters**

**Version**

Windows Server 2003, Windows XP SP1, or later.

If Routing and Remote Access NAT has Basic Firewall configured, the firewall always accepts broadcast and multicast packets and passes them to the NAT component. However, on a computer running the Windows Server 2003, Windows XP SP1, or later operating system, the following registry key for NAT is set by default to drop all inbound broadcast and multicast packets. If you need to change this default behavior, add the following registry key and set it to **1**. Setting the key to **1** allows broadcast and multicast packets to cross Basic Firewall:

**HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\IpNat\Parameters\AllowInboundNonUnicastTraffic**

By default, **AllowInboundNonUnicastTraffic** is set to **0**, which blocks inbound unicast traffic.

For more information about this registry entry, see the Registry Reference for Windows Server 2003.

**Related Information**
The following resources contain additional information that is relevant to this section:

- "Registry Reference for Windows Server 2003" in the Tools and Settings Collection

# Unicast IPv4 Routing Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Unicast IPv4 Routing Technical Reference**
This technical reference describes unicast Internet Protocol version 4 (IPv4) routing and explains how it works on an internetwork using servers, including routers, that run the Microsoft Windows Server 2003 operating system. IPv4 (often referred to as IP) is a major component of the Transmission Control Protocol/Internet Protocol (TCP/IP) protocol suite, which is the standard networking protocol used in most networking environments today as well as on the Internet. A TCP/IP-based internetwork, typically, is called an IP internetwork, although the IP network protocol is only a part of TCP/IP.

IP is the routable network protocol that makes communication possible across IP internetworks. Unicast IP routing refers to the process of transmitting IP packets from a single node (a host or a router) to a single node on an IP internetwork. Although, as the name Internet Protocol indicates, IP packet transmission was originally intended for traffic over the Internet, the transmission of IP packets is now also the primary type of traffic used on most intranets.

The information provided here is relevant to the IP unicast routing that occurs on any Windows-based network, including networks that use hardware routers, software-based routers such as those that use the Windows Server 2003 Routing and Remote Access service, or a combination of hardware and software routers. Included is a description of the multiple features of the Routing and Remote Access service that support unicast IP routing.

In addition to supporting IP routing, Windows Server 2003 also supports AppleTalk routing. The Windows Server 2003 family no longer supports Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX) routing. Microsoft Windows 2000 Server supports unicast routing for IP, AppleTalk, and IPX networks.

Although IPv4 will likely be replaced in the future by the next generation of IP, IP version 6 (IPv6), at present most unicast IP routing takes place over IPv4 networks. Windows Server 2003 supports both IPv4 and IPv6. For more information about Windows Server 2003 support for IPv6, including support for static routing in an IPv6 environment, see "IPv6 Technical Reference."

# What Is Unicast IPv4 Routing?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Unicast IPv4 Routing?**

**In this section**

- IPv4 Routing Enables Most Communications Worldwide
- Windows Server 2003 Supports Multiple Unicast IPv4 Routing Scenarios
- How Unicast IPv4 Routing Differs from Related or Similar Technologies
- Related Information

Internet Protocol (IP), a part of the Transmission Control Protocol/Internet Protocol (TCP/IP) protocol suite, is the routable network protocol that enables the routing of network traffic across any type of IP internetwork, including Windows internetworks, UNIX internetworks, and mixed network environments. The Windows Server 2003 family of operating systems uses IP to route communications, including unicast traffic, between computers or other network devices on private intranets, ranging in size from very small to intercontinental enterprise internetworks. IP also enables communication across the public Internet, which is itself an IP-based internetwork.

Currently, most unicast IP routing takes place over IP version 4 (IPv4) internetworks. Windows Server 2003 also supports the next generation of IP, IP version 6 (IPv6). This technical reference describes unicast IPv4 routing on IPv4 internetworks. Frequently, IPv4 internetworks are referred to simply as IP internetworks, and this technical reference follows that convention. For more information about Windows Server 2003 support for IPv6, including support for static routing in an IPv6 environment, see "IPv6 Technical Reference."

An IP internetwork, like any computer internetwork, consists of smaller networks joined together by the use of interconnecting devices known as routers. IP routing is the process of forwarding IP packets from a network device on one part of an IP internetwork to a network device on another network segment (subnet). An IP packet or datagram is a unit of information sent over an IP network that includes data intended for the recipient as well as a header containing routing information (the source and destination addresses and error-control data). IP routers forward packets between network segments.

Unicast IP routing is the process that enables unicast IP packets to be forwarded across an IP internetwork from a sending node to a destination node through one or more intermediate routers. A node is any network device that is running the TCP/IP protocol. A host is a node that does not perform routing, such as a user workstation or a non-router server. A router is a node that performs routing. That is, a router forwards packets that are not destined for the router itself either directly to the destination or to another router on the route to the destination.

**IPv4 Routing Enables Most Communications Worldwide**

Over the past few decades, the ability for people to communicate by sending messages from one computer to another, whether the computers are located on the same network in an office building or on networks at opposite sides of the globe, has become so commonplace that it is difficult to imagine a world where such communication is not possible. IP routing provides the infrastructure that enables all other IP-based technologies, such as Domain Name System (DNS), to function. The routing of unicast IP packets over IP internetworks is a major part of the technology that makes such communication possible.

Today, the majority of internetwork traffic worldwide is over IPv4 networks, and most user-initiated traffic across IPv4 internetworks is unicast traffic. Unicast IP routing occurs on every IP internetwork, including:

- An IP intranet not connected to the Internet
- The global Internet
- Intranets that connect to the Internet or to each other through the Internet

The major operating systems for which TCP/IP is the primary network protocol are Windows and UNIX.

Any Windows network supports unicast IP routing. These include networks that use only hardware routers, networks that use software-based routers such as the Routing and Remote Access service included with Windows Server 2003, or networks that use a combination of hardware and software routers.

Although all modern networking operating systems support the TCP/IP protocol suite, Windows Server 2003 TCP/IP provides the best platform for connecting Windows-based systems to earlier Windows-based systems and to non-Windows-based systems. In Windows Server 2003, TCP/IP supports enterprise networking and connectivity on computers running the Windows Server 2003, Microsoft Windows XP, Windows 2000, Windows NT, Windows Millennium Edition, and Windows 98 operating systems and on computers running the UNIX operating system.

For more information about Windows Server 2003 TCP/IP, see "TCP/IP Technical Reference."

**Windows Server 2003 Supports Multiple Unicast IPv4 Routing Scenarios**
A computer running the Windows Server 2003 Routing and Remote Access service that has two or more network adapters (each configured with an appropriate IP address and subnet mask) is a software router that can provide a wide range of services that support IP routing. A major part of this support is support for static and dynamic IP routing:

- **Static IP routing.** An administrator manually configures routing information, and routing information does not change unless the administrator manually updates or deletes it. Using static routing exclusively is appropriate only for a small internetwork.

- **Dynamic IP routing.** An administrator configures a router to use a dynamic routing protocol. A router that uses a dynamic routing protocol automatically generates routing information, shares that information with other routers, and updates the information when routing changes occur. A large internetwork that primarily uses dynamic routing typically also uses some manually configured static routes.

A computer running Routing and Remote Access that has only one interface is, by definition, a non-router computer and can provide some routing-related networking services, such as IP packet filtering or acting as a DHCP relay agent.

For a Windows Server 2003–based IP internetwork that uses hardware routers exclusively and does not install any Routing and Remote Access routers, IP routing is still the mechanism used for routing packets on the internetwork. This is because the primary networking protocol used by Windows Server 2003 is TCP/IP, and the Windows Server 2003 TCP/IP protocol is installed by default on any computer running Windows Server 2003. TCP/IP can be uninstalled on earlier versions of the Windows server operating systems, but it cannot be uninstalled on Windows Server 2003.

The Windows Server 2003 Routing and Remote Access service supports the following unicast IP routing scenarios:

**Static route management**
Support for static route management. A static IP route is an IP route that a network administrator adds to the IP routing table manually. Static IP routing is an inherent function of the TCP/IP protocol for Windows Server 2003. You can manage static routes by using the Routing and Remote Access snap-in, by using the **route** command-line tool, or by using the set of Netsh routing IP commands. A server running the Routing and Remote Access service can act exclusively as a static IP router, or it can act primarily as a dynamic IP router that also includes manually configured static routes.

**Routing Information Protocol (RIP) for IP**
Support for versions 1 and 2 of Routing Information Protocol (RIP) for IP (RIP v1 and RIP v2). A distance-vector routing protocol, RIP for IP is the primary dynamic routing protocol used in small or medium-sized IP internetworks. A server running the Routing and Remote Access service configured with RIP v2 can function as a dynamic IP router. RIP v1 is obsolete but is included to support a mixed environment that contains both RIP v1 and RIP v2 routers.

**Open Shortest Path First (OSPF)**
Support for the industry standard OSPF dynamic routing protocol. A link state routing protocol commonly used in large or very large IP internetworks, the OSPF routing protocol is available only on 32-bit versions (not 64-bit versions) of the Windows Server 2003 family. A server running the Routing and Remote Access service configured with OSPF can function as a dynamic IP router.

**DHCP relay agent**
Support for the RFC 1542–compliant Dynamic Host Configuration Protocol (DHCP) Relay Agent service, also known as Bootstrap Protocol (BOOTP) Relay Agent. DHCP Relay Agent transfers messages between DHCP clients and DHCP servers located on separate network segments. Any IP subnet that contains DHCP clients requires either a DHCP server or a DHCP relay agent to provide address leases to those DHCP clients. Using one or more DHCP relay agents makes it unnecessary to install a separate DHCP server on each subnet in an internetwork.

**IPv4 packet filtering**

Support for separately configured input and output filters for each IPv4 interface. IPv4 packet filtering specifies which traffic is allowed into and out of each interface, based on filters defined by source and destination IP addresses, Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) port numbers, Internet Control Message Protocol (ICMP) types and codes, and IP protocol numbers. In addition to IP packet filtering, the Windows Server 2003 Routing and Remote Access service also includes support for Basic Firewall, which uses stateful firewall technology similar to that used by the Internet Connection Firewall (ICF) feature available in Windows XP, Windows XP SP1, and Windows Server 2003. Basic Firewall can be used in conjunction with Routing and Remote Access NAT or on any other Internet-connected interface.

**ICMP router discovery**
Support for ICMP Router Solicitation and Router Advertisement messages to allow the automated discovery of default routers by hosts. If both routers and hosts are configured to use ICMP router discovery, this feature simplifies how IP hosts are configured with the IP addresses of local routers and it provides a way for hosts to discover routers that are down.

**Network address translation (NAT)**
Support for network address translation, which translates private and public addresses to allow small office or home office (SOHO) networks or medium-sized networks that use private addresses to connect to the Internet. The Routing and Remote Access NAT routing protocol component also includes a DHCP allocator and a Domain Name System (DNS) proxy to simplify the configuration of SOHO hosts.

Each of these unicast IP routing scenarios, except NAT, is described "How Unicast IPv4 Routing Protocols and Services Work" in this technical reference. For more information about Routing and Remote Access NAT, see "NAT Technical Reference."

For an introductory overview of protocol-independent unicast routing principles, see "Unicast Routing Overview" in the "*Microsoft Windows 2000 Resource Kit*." Windows 2000 Server supports both IP and IPX, and "Unicast Routing Overview" includes a discussion of both.

**How Unicast IPv4 Routing Differs from Related or Similar Technologies**
The following sections briefly summarize how routable and routing protocols differ from each other, how the IP routable protocol differs from the AppleTalk and IPX routable protocols, how IPv4 differs from IPv6, and how unicasting differs from broadcasting and multicasting.

**Routable Protocols and Routing Protocols**
To understand the types of protocols associated with routing, it is helpful to distinguish between routable protocols and routing protocols:

- **Routable protocol.** A network protocol that uses layer 3 (Network layer) addresses to forward packets to their destination across an internetwork. For example, IP is the routable protocol in the TCP/IP protocol suite that is responsible for IP addressing, routing, and the fragmentation and reassembly of IP packets. For information about routable protocols other than IP that provide similar services for other types of internetworks, see "IP, AppleTalk, and IPX/SPX" described later in this section.

- **Routing protocol.** A protocol that enables routers to exchange routing information with each other automatically across an internetwork by exchanging a series of periodic or on-demand messages. The major unicast IP routing protocols that route traffic over private IP internetworks are RIP v2 and OSPF. RIP v1 is now obsolete for enterprise-size internetworks.

For more information about RIP and OSPF, see "How Unicast IPv4 Routing Protocols and Services Work."

**IP, AppleTalk, and IPX/SPX Routable Protocols**
As just described, a routable protocol is a network protocol that enables the routing of packets across an internetwork. Three major routable protocols include:

- **IP internetworks use IP**. The IP portion of the TCP/IP protocol suite constitutes the industry standard for routing IP packets between nodes on an IP internetwork and enables communication across any set of interconnected IP networks. IP, the routable protocol described in this document, is the primary routable protocol for the Windows and UNIX operating systems.

- **AppleTalk internetworks use AppleTalk.** AppleTalk is the protocol suite developed by Apple Computer for AppleTalk Macintosh networks. Routing Table Maintenance Protocol (RTMP) is the routing protocol used in the AppleTalk environment. AppleTalk internetworks are also known as AppleTalk internets, which are small, physical networks connected by routers.

- **NetWare internetworks use IPX/SPX.** Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX) is the

routable protocol developed by Novell for NetWare networks. A typical IPX internetwork might contain Novell NetWare clients and servers running IPX located in multiple networks connected by IPX-enabled routers.

Windows Server 2003 and Windows 2000 Server support the AppleTalk protocol stack and AppleTalk routing software. Windows 2000 Server supports IPX routing, but Windows Server 2003 does not.

**IPv4 and IPv6 Routing**

In addition to IPv4, Windows Server 2003 TCP/IP supports the latest version of IP, IPv6. IPv6 includes unicast and multicast address types that are more complex than IPv4 unicast and multicast address types. IPv6 also includes a new type of address called anycast addresses. IPv6 addressing is a major departure from IPv4 addressing. The most obvious difference is that IPv4 uses 4-byte source and destination IP addresses, typically expressed in the familiar dotted-decimal notation, whereas IPv6 uses 16-byte addresses, expressed in colon-hexadecimal notation. Colon-hexadecimal notation uses eight 4-digit hexadecimal numbers, with colons separating the 16-bit blocks (the 4-digit numbers).

In Windows Server 2003, the Routing and Remote Access service does not support the dynamic routing protocols RIPng (the version of RIP for IPv6) or OSPF for IPv6. However, a computer running Windows Server 2003 can act as a static IPv6 router, and it is possible to route IPv6 traffic over an IPv4 internetwork using an IPv6 transition technology. For more information about routing in an IPv6 environment, see "How IPv6 Works" in "IPv6 Technical Reference."

**Unicasting, Broadcasting, and Multicasting**

In addition to forwarding unicast IP packets, IP routers can also forward broadcast and multicast IP packets from a device on one network to multiple devices on another network. Although most user-initiated traffic on an IP internetwork is unicast traffic, to understand the role of unicasting on IP networks, you must also understand how its function differs from broadcasting and multicasting:

- **Unicasting** is one-to-one communication of IP packets from a sending node to a receiving node on an IP internetwork. Unicast packets might pass through other devices as they are transmitted across the internetwork; however, unicast packets, by definition, are always sent from a single sending node to a single destination node. Any technology that involves sending packets from one node to another over an IP-based internetwork uses unicast routing.

- **Broadcasting** is one-to-everyone communication of IP packets between one node and all other accessible nodes on the same subnet. If routers are configured to forward internetwork-level broadcast traffic (highly discouraged for all IP routers), internetwork-level broadcasting forwards packets to all other network segments except the network segment on which the packet was received. The uses of broadcast communication on a subnet include announcing the availability of network services, resolving names into addresses, and resolving IP addresses into Media Access Control (MAC) addresses. DHCP and the NetBIOS name service are IP services that use broadcasting.

- **Multicasting** is one-to-many communication of IP packets between one node and multiple nodes that elect to participate in a specific multicast group. Multicast communication is used primarily for multiple-user multimedia applications such as video conferencing, distance learning, and collaborative computing. For more information about multicast routing on an IPv4 internetwork, see "IPv4 Multicasting Technical Reference."

Unicast routing performs broadcasting and multicasting for specific purposes. For example, a RIP v1 announcement (in which the router advertises the contents of its routing table to other routers) is always broadcasted. A RIP v2 router can be configured either to broadcast or to multicast its announcements.

- How OSPF Works
- How the DHCP Relay Agent Works
- How IP Packet Filtering Works
- How ICMP Router Discovery Works
- IPv4 and Routing and Remote Access APIs
- Related Information

The Microsoft Windows Server 2003 family of operating systems provides extensive support for unicast Internet Protocol version 4 (IPv4) routing — that is, routing IPv4 packets from a source node to a destination node identified by its unicast destination IPv4 address. IP, a part of the Transmission Control Protocol/Internet Protocol (TCP/IP) protocol suite, is the routable network protocol that enables the routing of network traffic across any type of IP internetwork, including Windows internetworks, UNIX internetworks, and mixed network environments. Windows Server 2003 includes support for unicast IPv4 dynamic routing protocols as well as for additional unicast routing features provided by the Windows Server 2003 Routing and Remote Access service. IPv4 is frequently referred to as IP, and that convention is used in this document.

**Note**

- Windows Server 2003 also supports Internet Protocol version 6 (IPv6). For information about Windows Server 2003 support for IPv6, including support for static routing in an IPv6 environment, see "How IPv6 Works" in IPv6 Technical Reference.

An organization's implementation of unicast IP routing can be simple or complex, depending on factors such as the size of its internetwork, the use of Dynamic Host Configuration Protocol (DHCP) to allocate IP addresses, connectivity to the Internet, and the presence of non-Windows hosts on the internetwork. To determine how best to implement or modify the unicast IP routing infrastructure for your internetwork, the first step is to understand how unicast IP routing works.

The Windows Server 2003 Routing and Remote Access service does not include support for the Internetwork Packet Exchange (IPX) protocol, such as Routing Information Protocol (RIP) for IPX, Service Advertising Protocol (SAP) for IPX, Network basic input/output system (NetBIOS) over IPX, or IPX packet filtering.

**Unicast IP Routing Architecture in Windows Server 2003**

Unicast IP routing occurs on any TCP/IP-based internetwork by using IP routers to forward IP packets from one network segment to another. Unicast IP routing occurs on a Windows Server 2003 IP internetwork whether or not any computers run the Routing and Remote Access service. You can use hardware routers on your internetwork, software routers, or a combination of hardware and software routers. The Windows Server 2003 Routing and Remote Access service can play a role in implementing and supporting unicast IP routing features on a Windows network even when most, or all, routers are hardware routers.

To see an architectural diagram showing where IP fits within the TCP/IP protocol suite, see "TCP/IP Protocol Architecture" in "How TCP/IP Works" in TCP/IP Technical Reference. The following figure shows the architecture of the Routing and Remote Access service in Windows Server 2003. The components are differentiated in the figure as follows:

- Clear boxes represent components that are used for unicast IP routing and multicast IP routing, as well as for other Routing and Remote Access–supported features.
- Dark blue boxes represent components that are unique to unicast routing.
- Light blue boxes represent components that are unique to multicast routing.
- The orange box represents the only Routing and Remote Access component — Simple Network Management Protocol (SNMP) — that is used neither for unicast nor for multicast routing.

**Unicast IP Components of the Windows Server 2003 Routing and Remote Access Service**

The following table describes the unicast IP routing components depicted in the figure, including components that are shared by unicast routing and multicast routing as well as components that are unique to unicast routing. Not included in the table are the non-unicast components: multicast-only components (light blue boxes) or SNMP (orange box). For information about SNMP, see "SNMP Technical Reference." For information about multicast IP routing, see "IPv4 Multicasting Technical Reference."

**Unicast Routing Components in the Routing and Remote Access Service**

| Component | Description |
|---|---|
| Routing and Remote Access snap-in | Management application in the Administrative Tools folder for administering unicast IP routing and other routing and remote access features. |
| Netsh | Command-line management application that provides sets of commands (known as *contexts*) used to perform a wide range of network configuration tasks, including unicast routing tasks. The Netsh contexts specific to unicast routing include **netsh routing** and **netsh routing ip**. |
| AAA | A set of components that provide authentication, authorization, and accounting (AAA) for the Routing and Remote Access service when it is configured to act as the Windows authentication provider or the Windows accounting provider. Alternatively, the computer running the Routing and Remote Access service can be configured with the Remote Authentication Dial-In User Service (RADIUS) authentication or accounting provider in the Internet Authentication Service (IAS), in which case, the local AAA components are not used. |

| | |
|---|---|
| Dynamic Interface Manager<br><br>(Mprdim.dll) | Component that provides the following services for unicast IP routing and other Routing and Remote Access–supported features:<br><br>• Communicates configuration information to the IP Router Manager.<br><br>• Manages all routing interfaces, including local area network (LAN), dial-up interfaces, non-persistent demand-dial interfaces, and persistent demand-dial interfaces. Unlike Windows 2000 Server, Windows Server 2003 Routing and Remote Access does not support IP-in-IP tunnels (which encapsulate an IP packet within another IP packet and forward the packet across the tunnel) and thus does not support IP-in-IP interfaces (logical interfaces used to send IP packets across an IP-in-IP tunnel).<br><br>• Loads configuration information from the Windows Server 2003 registry.<br><br>• Supports a remote procedure call (RPC) interface for SNMP-based management functions used by management tools such as the Routing and Remote Access snap-in.<br><br>• Communicates with the Connection Manager for demand-dial connections. |
| Connection Manager | A set of components that provides the following services:<br><br>• Manages wide area network (WAN) devices.<br><br>• Establishes connections by using the Telephony application programming interface (TAPI).<br><br>• Negotiates Point-to-Point Protocol (PPP) control protocols, including Extensible Authentication Protocol (EAP). PPP is an industry standard suite of protocols for the use of point-to-point links to transport multiprotocol datagrams. EAP is an extension to PPP that allows for arbitrary authentication mechanisms to be employed for the validation of a PPP connection.<br><br>• Implements multilink protocol (MP) and Bandwidth Allocation Protocol (BAP). MP, also known as MLP or Multilink Point-to-Point Protocol (MPPP), is an extension to PPP that is used to aggregate multiple physical links into a single logical link. BAP is a PPP control protocol that is used on a multilink connection to add and remove links dynamically.<br><br>**Note:** Routing and Remote Access Connection Manager, described here, is not the same as the Connection Manager client dialer. |
| TAPI | An API used by communications programs to work with telephony and network services. Telephony API, or TAPI, provides services to create, monitor, and terminate connections in a hardware-independent manner. Connection Manager uses TAPI to create or receive demand-dial connections. |

| | |
|---|---|
| IP Router Manager<br><br>(Iprtrmgr.dll) | Component that starts and manages other routing components, including routing protocols, the routing table manager, and the multicast group manager. The IP Router Manager provides the following services:<br><br>• Obtains configuration information from the dynamic interface manager.<br><br>• Communicates IP packet filtering configuration to the IP filtering driver.<br><br>• Communicates IP routing configuration information to the IP forwarder in the TCP/IP protocol.<br><br>• Maintains an interface database of all IP routing interfaces.<br><br>• Loads and communicates configuration information to IP routing protocols that are supplied with Windows Server 2003, such as Routing Information Protocol (RIP) and Open Shortest Path First (OSPF).<br><br>• Initiates demand-dial connections for routing protocols by communicating with Dynamic Interface Manager. |
| IP RIP<br><br>(Iprip2.dll) | A unicast distance vector dynamic routing protocol. The RIP for IP routing protocol (also known simply as RIP) provides the following services:<br><br>• Communicates RIP learned routes by using the Route Table Manager.<br><br>• Uses Windows Sockets (Winsock) to send and receive RIP traffic. Winsock is an implementation of the industry-standard Sockets API for the Windows operating system.<br><br>• Exports management APIs to support SNMP management information bases (MIBs) and other management applications by using the IP Router Manager. A MIB is a set of objects, which represent various types of information about a device that are used by SNMP to manage the device.<br><br>The Windows Server 2003 Routing and Remote Access service supports (for IPv4 only) both RIP version 1 and version 2 (RIP v1 and RIP v2). However, RIP v1 is considered outdated. For more information about RIP v1 and RIP v2, see “How RIP” later in this document. |
| OSPF<br><br>(Ospf.dll) | A unicast link state dynamic routing protocol. The OSPF routing protocol performs the following services:<br><br>• Communicates OSPF learned routes by using the Route Table Manager.<br><br>• Uses Winsock to send and receive OSPF traffic.<br><br>• Exports management APIs to support SNMP MIBs and other management applications by using the IP Router Manager.<br><br>The OSPF routing protocol is available only on 32-bit versions of Windows Server 2003. For more information about OSPF, see “How OSPF Works” later in this document. |

| | |
|---|---|
| Route Table Manager<br><br>(Rtm.dll)<br><br>(Also called Routing Table Manager) | The central repository for routing information for all routing protocols that operate under the Routing and Remote Access service and for other components such as the IP Router Manager. The Route Table Manager provides the following services:<br>• Maintains a user-mode routing table for all routes from all possible route sources.<br>• Exposes APIs for adding, deleting, and enumerating routes that are used by the routing protocols.<br>• Timestamps learned routes.<br>• Provides routing information to routing protocols, management programs, and monitoring programs.<br>• Communicates only the best routes to the appropriate IP forwarder driver. For IP routes, the best route is the route with the lowest cost based on specified criteria, such as the number of networks crossed, the type of network crossed (for example, private or public), or a monetary or bandwidth limit. The best routes become the routes in the IP forwarding table.<br>• Supports multiple instances of the same protocol, such as the Microsoft implementation of OSPF and other implementations of OSPF. |
| IP Filtering<br><br>(Ipfltdrv.sys) | Component that performs the following services:<br>• Obtains configuration information from the IP Router Manager.<br>• Applies IP filters after the IP forwarder has found a route. |
| IP Unicast Forwarder | A component of the TCP/IP protocol (Tcpip.sys). The IP Unicast Forwarder performs the following services:<br>• Obtains configuration information from the IP Router Manager.<br>• Stores the IP forwarding table, a table of the best routes obtained from the Route Table Manager.<br>• Determines the next-hop address and interface for IP packets being forwarded.<br>• Forwards unicast IP traffic from one router interface to another router interface.<br>• Initiates a demand-dial connection. |
| NDIS Wrapper<br><br>(Ndis.sys) | Code that surrounds all Network Driver Interface Specification (NDIS) device drivers. Windows Server 2003 NDIS (and Windows 2000 Server NDIS) is implemented by a file called Ndis.sys, referred to as the NDIS Wrapper. NDIS enables transport protocols such as TCP/IP to communicate with an underlying network adapter or other hardware device so that the network adapter can send or receive data over the network. The NDIS Wrapper provides a uniform interface between protocol drivers and NDIS device drivers. |

**Note**

- Network address translation (NAT) is a feature of the Routing and Remote Access service and is part of unicast routing. However, NAT is not shown in the preceding figure or table because NAT is not a routing protocol. For information about the NAT routing protocol component and Routing and Remote Access NAT architecture, see "How NAT Works" in NAT Technical Reference.

**Routing and Remote Access Unicast IP Routing Processes**

Typical unicast IP routing processes for the components of the Routing and Remote Access service described in the preceding section include the following types of communications.

**Incoming and outgoing packet (transit traffic)**

An incoming packet is passed by the TCP/IP driver to the IP forwarder, which finds a route and then passes the packet to the IP

filtering driver to check for input and output filters. If the packet is approved for acceptance by the input filters and for forwarding by the output filters, it is passed back to the IP forwarder driver, which uses NDIS to forward the packet over the appropriate interface. If the input or output filters do not permit the packet to be received or forwarded, the packet is silently discarded. If a route is not found, an Internet Control Message Protocol (ICMP) Destination Unreachable-Host Unreachable message is sent back to the source of the packet.

**Incoming packet (local host traffic)**
An incoming packet is passed by the TCP/IP driver first to the IP forwarder, which notes that the packet is not to be routed (because the destination IP address is an address assigned to the router or it is a broadcast address). The IP forwarder then hands the packet to the IP filtering driver to check for input filters. If the packet is accepted by the input filters, it is passed up to the TCP/IP driver, which processes the packet. If the packet is not accepted by the input filters, the packet is silently discarded.

**Outgoing packet (local host traffic)**
An outgoing packet is passed by the TCP/IP driver to the IP filtering driver, which checks for output filters. If the packet is approved for sending by the output filters, the packet is passed to the IP forwarder, which sends the packet by using the best route over an appropriate interface that uses NDIS. If the packet is not approved by the output filters, the packet is silently discarded. If a route is not found, an IP routing error is passed to the source application of the packet.

**Routing protocol network communication**
The RIP for IP and OSPF routing protocols operate like any other Winsock application that sends or receives IP packets. For a brief description of the Windows Sockets 2 (Winsock2) API, see "IPv4 and Routing and Remote Access APIsW2K3TR" later in this document. For more information about the Windows Sockets API, see "Microsoft Platform SDK Windows Sockets 2."

**Routing table updates**
The RIP and OSPF routing protocols update routes in the Route Table Manager. Based on the best route and route source ranking, the table of best routes (the IP forwarding table) is updated in the IP forwarder.

**Routing and Remote Access Features by Windows Server Operating System**
In addition to support for unicast IP routing features, the Routing and Remote Access service for Windows Server 2003 also includes a variety of other routing and remote access features, most of which interact with or support unicast IP routing — for example, LAN and WAN support, both of which are integral to unicast IP routing, and the Routing and Remote Access snap-in, which you can use to configure unicast IP routing features. The following table lists the routing and remote access features available in Windows operating systems from Windows NT 3.51 to Windows Server 2003.

**Comparison of Routing and Remote Access Features in Windows Operating Systems**

| Feature | Windows NT Server 3.51 SP2 | Windows NT Server 4.0 SP3 | Windows 2000 Server | Windows Server 2003 |
|---|---|---|---|---|
| Static IP routing | ● | ● | ● | ● |
| RIP for IP version 1 (RIP v1) | ● | ● | ● | ● |
| RIP for IP version 2 (RIP v2) | | ● | ● | ● |
| RIP for IPX | ● | ● | ● | |
| SAP for IPX | ● | ● | ● | |
| NetBIOS over IPX | ● | ● | ● | |
| Routing and remote access combined into one service | | ● | ● | ● |
| Inclusion of routing and remote access with Windows | | ● | ● | ● |
| OSPF | | ● | ● | ● |
| IP packet filtering | | ● | ● | ● |
| Basic stateful firewall | | | | ● |
| IPX packet filtering | | ● | ● | |
| ICMP router discovery | | ● | ● | ● |

| | | | | |
|---|---|---|---|---|
| DHCP relay agent | ● | ● | ● | ● |
| Network address translation (NAT) | | | ● | ● |
| Remote Authentication Dial-In User Service (RADIUS) client | | ● | ● | ● |
| AppleTalk routing | | | ● | ● |
| Remote access routing (dial-up) | | ● | ● | ● |
| Remote access routing using Point-to-Point Tunneling Protocol (PPTP) virtual private networking | | ● | ● | ● |
| Remote access routing using Layer Two Tunneling Protocol over Internet Protocol Security L2TP/IPSec virtual private networking | | | ● | ● |
| IP-in-IP tunneling | | | ● | |
| SNMP MIB | | | ● | ● |
| LAN and WAN support1 | | ● | ● | ● |
| Multicast IP forwarding | | | ● | ● |
| Graphical administrative tool:<br><br>Routing and RAS Admin | | ● | | |
| Graphical administrative tool:<br><br>Routing and Remote Access snap-in (MMC) | | | ● | ● |
| Command-line tool: Routemon.exe | | ● | | |
| Command-line toolset: Netsh.exe (Netsh routing IP commands) | | | ● | ● |

1. The Routing and Remote Access service works with a wide variety of hardware platforms and can run over any of the many LAN and WAN network adapters supported by Windows. For information about supported network adapters, see "Windows Server Catalog."

IPX routing is available only on Windows NT Server 3.51 Service Pack 2 (SP2), Windows NT Server 4.0 SP3, and the 32-bit versions of Windows 2000 Server. IPX is not available on any version of Windows Server 2003. OSPF is available only on Windows NT Server 3.51 SP2, Windows NT Server 4.0 SP3, and on 32-bit versions of Windows 2000 Server and Windows Server 2003.

**Unicast IP Routing in a Windows-based Internetwork**

A typical IPv4 internetwork might contain a mix of computers running Windows Server 2003, Windows XP, Windows 2000 Server, Windows 2000 Professional, or UNIX operating systems. These computers might be located in multiple subnets connected by hardware routers from Cisco Systems and software routers running the Windows Server 2003 Routing and Remote Access service. Such an internetwork can easily communicate with computers on the global Internet because the Internet is also an IP internetwork.

A medium-size or enterprise-size Windows IP internetwork typically deploys the Active Directory directory service, DNS, and

DHCP, and the following routing-related services:

- A routing protocol, such as RIP v2 or OSPF, to enable routing information exchange between routers on an IP internetwork
- DHCP relay agents to enable DHCP clients on a subnet with no DHCP server to request IP addresses from a DHCP server located on a different subnet
- IP packet filtering, such as Web traffic filtering or L2TP/IPSec traffic filtering, to allow only specific types of traffic
- ICMP router discovery to enable IP hosts to discover the best default gateway router on a subnet

**How RIP Works**

Routing Information Protocol (RIP) for IP facilitates the dynamic exchange of routing information between RIP routers over IP internetworks. Routers can add or remove routes automatically as networks are added or removed from the internetwork. RIP, the best known and currently most widely used of the distance vector dynamic routing protocols for IP internetworks, is an open standard developed by the Internet Engineering Task Force (IETF).

RIP version 1 (RIP v1), which is now outmoded, was the first routing protocol accepted as a standard for TCP/IP. The updated RIP version 2 (RIP v2) supports simple password authentication (a form of router identification, not a security option) and, more important, provides improved support for classless networks. The Windows Server 2003 Routing and Remote Access service supports both RIP v1 and RIP v2 (for IPv4 only).

### Note

- The Windows Server 2003 Routing and Remote Access service does not support RIPng, the version of RIP for IPv6, or any other IPv6 routing protocol. For information about Windows Server 2003 support for IPv6, including support for static routing in an IPv6 environment, see "How IPv6 Works" in IPv6 Technical Reference.

RIP has its origins in the Xerox Network Systems (XNS) version of RIP. RIP for IP became a popular routing protocol due to its inclusion in the Berkeley Software Distribution (BSD) UNIX (BSD 4.2 and later) as the routed server daemon (a UNIX daemon is similar to a Windows Server 2003 service). The BSD 4.2 version of UNIX, introduced in 1983, incorporated the TCP/IP protocol suite and initiated the explosive growth of TCP/IP and what later became known as the Internet. RIP v1 is defined in RFC 1058 and RIP v2 is defined in RFC 2453. In this document, when neither RIP v1 nor RIP v2 is explicitly cited, information about RIP applies to both versions.

This section describes:

- RIP features appropriate for small- to medium-sized internetworks
- How RIP convergence works
- Basic processes common to RIP v1 and RIP v2
- How RIP v1 works
- How RIP v2 works

**RIP Features Adppropriate for Small- to Medium-Sized Internetworks**

RIP is a useful solution for a small- to medium-sized IP internetwork (10 to 50 networks). As a dynamic routing protocol, it can update topology changes as networks are added or removed and as links fail and are restored.

Although RIP is simple to administer and well supported in the industry, it has some of the limitations inherent to its original LAN-based design. These limitations, in combination, make RIP an inappropriate solution for enterprise-sized IP internetworks.

**RIP Hop Counts**

RIP uses a hop count as the metric to determine the best route among multiple possible routes stored in an IP routing table. The hop count is the number of routers that must be crossed to reach a specific subnet. A computer on the local subnet is one hop, and each router crossed after that is an additional hop.

RIP has a maximum hop count of 15. Therefore, any two hosts can be separated by no more than 15 routers. Subnets that are 16 or more hops away are unreachable and are thus said to be an "infinite" distance away. Any attempt to forward packets to hosts on that subnet result in an ICMP Destination Unreachable–Host Unreachable message from the RIP router, indicating that the packet cannot be delivered. Although the accumulated hop count between any two subnets must not exceed 15 hops, this restriction is not as limiting as it might seem because, if routers are placed in a hierarchical structure, 15 hops can cover a large number of destinations.

The RIP hop count is independent of the Time-to-Live (TTL) field in the IP header. On an IP internetwork, a subnet 16 hops away would normally be reachable for an IP packet with an adequate TTL. However, to the RIP router, that subnet is unreachable.

Using the number of routers to cross as the basis for selecting the best route can produce an unwanted result. For example, if a T1 link is the primary connection between two sites and a slower satellite link is used as a backup in case the T1 link fails, RIP assigns both links the same metric. When a router chooses between these two routes, it might select either one. If the satellite link is selected, traffic is slower. To avoid this type of problem, the cost of each interface is configurable. Typically, the hop count value for slow links is set to multiple hops to ensure that fast links, which are assigned a lower hop count value, take precedence over slow links. In this example, you can assign a higher cost to the satellite interface to ensure that the T1 link is selected as the best route whenever both routes are available. Only if the T1 link fails will the satellite link be selected.

Although the maximum diameter of a RIP internetwork is defined by RFCs 1058 and 2453 to be 15 routers, for a server running the Routing and Remote Access service, the effective diameter is only 14 routers. This is because, for a Routing and Remote Access RIP router, all non-RIP learned routes — such as static routes (including static routes for directly connected networks), OSPF routes, and SNMP routes — have a fixed hop count of 2. Therefore, when the Routing and Remote Access RIP router advertises its directly connected networks, it advertises them at a hop count of 2 even though there is only one physical router to cross.

### Note

- In a networking environment that includes Routing and Remote Access RIP routers, make sure that the accumulated costs (hop counts) between any two endpoints on the internetwork does not exceed 14.

**RIP Routing Table Entries**

When a RIP router first starts up, its routing table contains only the networks to which it is physically connected. This router, as it initiates, sends periodic announcements that contain its routing table entries to inform neighboring RIP routers about the networks that it can reach. In turn, it receives route advertisements from other RIP routers that it adds to its own routing table.

For a subnet that has multiple paths, RIP allows storage of multiple entries in a routing table. For RIP routers that do store a complete list of all network IDs and all possible routes to reach each subnet, the routing table can have hundreds or even thousands of entries in a large multipath IP internetwork. The IP routing process chooses the route with the lowest metric (lowest hop count) as the best route. Because only 25 routes can be sent in a single RIP packet, large routing tables must be sent as multiple RIP messages.

Although in theory RIP can store multiple entries for a multipath subnet in a routing table, typical RIP router implementations — including Windows Server 2003 — store only a single lowest-metric route for any subnet in the routing table. If multiple lowest hop count routes are received by RIP, the first lowest-metric route received is stored in the routing table.

**"RIP Route Advertising"**

Typically, RIP either broadcasts or multicasts announcements. However, RIP can also unicast RIP announcements to specific RIP neighbors.

**RIP broadcasting of announcements for mixed environment**

Typically, a RIP router uses an IP subnet and MAC-level broadcast to advertise the entire contents of its routing table on all attached networks. The announcement interval is every 30 seconds by default. RIP v1 announcements are always broadcasted. RIP v2 announcements can be broadcasted or multicasted.

You must use broadcasting if your network is a mixed environment that includes both RIP v1 and RIP v2 routers. Both RIP v1 routers and RIP v2 routers can process a RIP v2 broadcast announcement.

**RIP multicasting of announcements for the RIP v2 environment**

RIP v2 routers are configured, by default, to broadcast RIP announcements, but they have the capability to multicast RIP announcements to the IP multicast address of 224.0.0.9 instead. The router does not register this multicast address by using Internet Group Management Protocol (IGMP) because the address is in the local network control block range, as defined by the Internet Assigned Numbers Authority (IANA).

Use RIP v2 multicast announcements only if all neighboring RIP routers on the network connected to this interface are

configured for RIP v2. A RIP v1 router cannot process a RIP v2 multicast announcement.

RIP v2 announcements must be multicast if you are performing auto-static updates across demand-dial links. An auto-static update is a one-time, one-way transfer of routing information. A router that has a demand-dial interface configured for auto-static updates sends a message across an active connection requesting all of the routes of the router on the other side of the connection. This request is *not* automatic; the request is sent only when an administrator issues a command or a scheduled task initiates auto-static updates. When the remote router responds, the routes of the remote router are automatically entered in the routing table of the requesting router. The routes are saved in the routing table even if the router is restarted or the interface goes down.

For RIP v2 to support auto-static updates, you must configure a demand-dial interface on each router to use RIP v2 multicast announcements and to accept RIP v2 announcements. Otherwise, the RIP request for routes does not receive a response from the remote router. (OSPF does not support auto-static updates.)

For more information about RIP v2 support for multicast RIP announcements, see "RIP v2 Updates RIP for Modern Internetworks" later in this document.

**RIP unicasting of announcements to specific RIP neighbors**
Although RIP typically broadcasts or multicasts announcements, it can also unicast RIP announcements to specific RIP routers known as RIP neighbors.

Unicasting RIP announcements to RIP neighbors was originally developed specifically to support nonbroadcast multiple access (NBMA) network technologies. NBMA networks, such as Frame Relay, X.25, or Asynchronous Transfer Mode (ATM), can connect more than two routers but cannot broadcast a single frame to all routers attached to that network. However, the configuration of RIP neighbors is also useful for the wider purpose of ensuring that RIP announcements are directed to specific neighboring RIP routers. Configuring a RIP router to unicast RIP announcement to specified neighboring RIP routers helps prevent RIP traffic from being received by any other node.

Configuring RIP routers to unicast to neighboring RIP routers can interfere with the ability of silent RIP hosts to receive RIP traffic. Silent RIP is a feature that lets an IP host listen to routing traffic exchanged by RIP routers and update its routing table accordingly. If you use silent RIP hosts, you can solve this interference problem by adding silent RIP hosts as neighbors. Use a static IP address for a silent RIP host. Otherwise, if you let DHCP assign an IP address to a silent RIP host, that address might change, and this host will no longer receive the unicast RIP messages sent by the RIP router.

How you configure RIP for an NBMA network depends on how Frame Relay virtual circuits appear as network interfaces on a RIP server running Routing and Remote Access. Frame Relay virtual circuits appear in the Routing and Remote Access snap-in either as a single adapter or as multiple adapters. A virtual circuit is a logical path or connection between nodes in a network. After the nodes of a virtual circuit establish a connection, the nodes can communicate as if they were directly connected by physical wires.

The following descriptions assume that you have a Frame Relay network, but other NBMA technologies, such as X.25 and ATM, function in a similar manner:

- **Single-adapter model unicasts RIP announcements.** All virtual circuits on a RIP router function as a single adapter. In the single-adapter model, also known as the NBMA model, the network of the Frame Relay service provider (also called the Frame Relay cloud) is treated as an IP network, and the endpoints on the cloud are assigned IP addresses from a designated IP network ID. To ensure that RIP traffic is received by all of the appropriate endpoints on the cloud, you must configure the Frame Relay interface to unicast its RIP announcements to each appropriate endpoint. On a Routing and Remote Access RIP router, you do this by designating the interface as an NBMA network and by configuring RIP to unicast announcements to the specified neighbor routers.

  In a hub-and-spoke Frame Relay topology in a RIP-based IP internetwork, the Frame Relay interface for the hub router must have split-horizon processing disabled. Otherwise, the spoke routers never receive each other's routes. For more information, see "Split Horizon Processing" later in this section.

- **Multiple-adapter model broadcasts or multicasts RIP announcements.** Each virtual circuit functions as a separate adapter. In the multiple-adapter model, each Frame Relay virtual circuit functions as a point-to-point link with its own network ID, and the endpoints on the cloud are assigned IP addresses from a designated IP network ID. Because each virtual circuit is its own point-to-point connection, you can either broadcast (assuming both endpoints are on the same IP network ID) or multicast RIP announcements.

On a RIP router running Windows Server 2003 Routing and Remote Access, broadcasting or multicasting RIP announcements is configurable in the Routing and Remote Access snap-in by navigating to the **IP Routing\RIP** node, and then using the

**General** tab of the ***InterfaceName*Properties** page. Unicasting RIP announcements to specific RIP neighbors is configurable on the **Neighbors** tab of the same ***InterfaceName*Properties** page.

**RIP Convergence**

Convergence is among the most important factors when considering features that make RIP appropriate for small- to medium-sized internetworks but unsuitable for large enterprise internetworks. Convergence is the process by which routers update routing tables after a change in network topology occurs — the change is replicated to all routers that need to know about it. When convergence is achieved, the internetwork is in a stable state and all routing occurs along optimal paths. If, after convergence is achieved, a link or router fails, the internetwork must reconfigure itself to reflect the new topology.

By default, on a RIP internetwork, each routing table entry that is learned through RIP is given a time-out value of three minutes after the last time the entry was received in a RIP announcement from a neighboring RIP router. Therefore, when a router stops responding because of a hardware or software failure, several minutes can elapse before RIP propagates the topology change throughout the entire internetwork. The delay that occurs before the successful propagation of routes is achieved is known as slow convergence, which is a characteristic of RIP internetworks.

For more information about RIP convergence, including how slow convergence occurs and how to improve convergence time on a RIP internetwork, see "How RIP Convergence Works," described next.

**How RIP Convergence Works**

RIP, like most distance vector routing protocols, announces its routes in an unsynchronized and unacknowledged manner. Although this imprecise announcement scheme can lead to convergence problems, you can modify the announcement algorithms to reduce convergence time on a RIP network in most situations.

**How Count-to-Infinity Occurs**

The classic distance vector convergence problem, known as count-to-infinity, results from the asynchronous announcement scheme. When a RIP router updates its routing table based on RIP announcements from other routers, the RIP router stores only the best route to each network and it updates a lower-cost route with a higher-cost route only if the higher-cost route is announced by the same source as the current lower-cost route. In some situations, as illustrated in the following series of five figures, this causes the count-to-infinity problem.

Assume that the IP internetwork in the following figure has converged. For simplicity, only announcements sent by Router 1 on Network 2 and Router 2 on Network 2 are depicted; announcements sent by Router 1 on Network 1 and Router 2 on Network 3 are not included in the discussion.

**Count-to-Infinity Phase 1: Converged RIP Internetwork**

Now, assume that the link from Router 2 to Network 3 fails, and the failure is sensed by Router 2. As the next figure shows, Router 2 changes the hop count for the route to Network 3 to indicate that it is unreachable, an infinite distance away. For RIP, infinity is 16.

**Count-to-Infinity Phase 2: Link to Network 3 Fails**

However, before Router 2 can advertise the new hop count to Network 3 in a scheduled announcement, Router 2 receives an

announcement from Router 1. The Router 1 announcement contains a route to Network 3, which is two hops away. Because two hops away is a better route than 16 hops, Router 2 updates its routing table entry for Network 3, changing it from 16 hops to 3 hops, as shown in the following figure.

**Count-to-Infinity Phase 3: Router 2 Updates from Router 1**

When Router 2 announces its new routes, Router 1 notes that Network 3 is available three hops away through Router 2. Because the route to Network 3 on Router 1 was originally learned from Router 2, Router 1 updates its route to Network 3 to four hops, as shown in the following figure.

**Count-to-Infinity Phase 4: Router 1 Updates from Router 2**

Now, when Router 1 announces its new routes, Router 2 notes that Network 3 is available four hops away through Router 1. Because the route to Network 3 on Router 2 was originally learned from Router 1, Router 2 updates its route to Network 3 to five hops, as shown in the following figure.

**Count-to-Infinity Phase 5: Router 2 Updates Again from Router 1**

The two routers continue to announce routes to Network 3 with higher and higher hop counts until infinity (16) is reached. At that point, Network 3 is considered unreachable, and the route to Network 3 is eventually timed out of the routing table. This routing loop is known as the count-to-infinity problem.

The count-to-infinity problem is one of the reasons why the maximum hop count of RIP for IP internetworks is set to 15 (16 for unreachable). A higher maximum hop count would make the convergence time longer when count-to-infinity occurs.

Note also that during the count-to-infinity process in the preceding example, the route from Router 1 to Network 3 is through Router 2, and the route from Router 2 to Network 3 is through Router 1. A routing loop exists between Router 1 and Router 2 for Network 3 for the duration of the count-to-infinity problem.

**Reducing Convergence Time**

To speed recovery of RIP internetworks when topology changes occur and to help avoid the count-to-infinity problem and routing loops that persist for the duration of the count-to-infinity process, an administrator can modify the RIP announcement process by using the following algorithms:

- Split horizon
- Split horizon with poison reverse
- Triggered updates

On a Routing and Remote Access RIP router, these options are configurable in the Routing and Remote Access snap-in by navigating to the **IP Routing\RIP** node in the console tree, and then accessing the **Advanced** tab of the appropriate ***InterfaceName*Properties** page. By default, all three options are enabled to improve convergence on a RIP internetwork.

**Split Horizon**
Split horizon is a routing technique that reduces convergence time by preventing or reducing the occurrence of the count-to-infinity problem and the associated routing loops that can occur in distance vector routing protocols such as RIP. When split-horizon processing is enabled, information about routes is not announced over the router interface through which that information was received. Thus, a router configured to use split horizon processing omits routes learned from a specific neighboring router in updates that it returns to that neighbor. If split-horizon processing is not configured, routes learned on a network are announced on the same network. The Windows Server 2003 Routing and Remote Access service enables split-horizon processing by default.

Split horizon eliminates the count-to-infinity problem and routing loops during convergence in single-path internetworks and reduces the chances of encountering count-to-infinity problems in multipath internetworks. The following figure shows how split horizon processing keeps the RIP router from advertising routes in the direction from which they were learned.

**Split Horizon Announcement Process**

**Split Horizon with Poison Reverse**
Split horizon with poison reverse processing refers to routing updates that explicitly indicate that a network or a subnet is unreachable, rather than merely implying that a network is unreachable by not including it in updates. Whereas the simple split horizon method omits routes learned from one neighbor in updates sent to that neighbor, the split horizon with poison reverse method includes such routes in updates, but announces them with a hop count of 16, indicating that the subnet for these routes is unreachable. Split horizon with poison reverse processing can be enabled only if split horizon processing is enabled.

In a single-path internetwork, split horizon with poison reverse has no greater benefit than split horizon. However, in a multipath internetwork, split horizon with poison reverse greatly reduces count-to-infinity problems and routing loops. Count-to-infinity problems can still occur in a multipath internetwork because routes to networks can be learned from multiple sources.

In the following figure split horizon with poison reverse advertises learned routes as unreachable in the direction from which they are learned. Split horizon with poison reverse, however, has the disadvantage of requiring additional RIP message overhead because all networks are advertised.

**Split Horizon with Poison Reverse Announcement Process**

On a Windows Server 2003 Routing and Remote Access RIP router, split-horizon processing and poison-reverse processing (both enabled by default) are configurable in the Routing and Remote Access snap-in by navigating to the **IP Routing\RIP** node in the console tree, and then selecting or clearing the **Enable split-horizon processing** and **Enable poison-reverse processing** options on the **Advanced** tab of the ***InterfaceName*Properties** page. Alternatively, if you do not want both options enabled, you can select **Enable split-horizon processing** and clear **Enable poison-reverse processing**. However, you cannot select **Enable poison-reverse processing** unless you first select **Enable split-horizon processing**.

**Triggered Updates**

In addition to making periodic announcements to other local RIP routers, a RIP router can also communicate routing information through triggered updates. A triggered update is an update that is announced as soon as a network topology change occurs; only the change is announced. Triggered updates improve the convergence time of RIP internetworks but do so at the expense of additional network traffic.

The trigger for an update to the routing table is one of the following:

- The router starts advertising the network ID for a subnet attached to a newly operational interface on the router.
- The router starts advertising the network ID for a subnet attached to a newly inoperational interface on the router as 16 hops (unreachable).
- The router modifies its routing table in response to an update from a neighboring router.
- The router removes a routing table entry because it has timed out.

For example, if a network becomes unavailable due to a problem such as a link or router failure, a RIP router updates its own routing table and can use a triggered update to announce the unavailable network with a hop count of 16. An interval to wait between sending triggered updates is typically specified on the router (on a Routing and Remote Access RIP router, the default is 5 seconds). Otherwise, if all routers immediately send triggered updates, these updates could cause a cascade of traffic across the IP internetwork.

On a Windows Server 2003 Routing and Remote Access RIP router, triggered updates processing (enabled by default) is configurable in the Routing and Remote Access snap-in by navigating to the **IP Routing\RIP** node in the console tree, and then selecting the **Enable triggered updates** option on the **Advanced** tab of the ***InterfaceName*Properties** page. The maximum time (in seconds) that elapses between triggered updates is configurable by using the **General** tab on the **RIP Properties** page.

**Basic Processes Common to RIP v1 and RIP v2**

The standard operation of a RIP for IP router consists of three processes: initialization, when the router learns the routes of the internetwork from neighboring routers; ongoing periodic advertisements; and advertisement of unreachable routes when a router is brought down intentionally or fails.

**Initialization**

During startup, the RIP router announces its locally attached networks on all of its interfaces. Neighboring RIP routers process the RIP announcement and add routes to their routing tables, as appropriate.

The initializing RIP router also sends a general RIP request to all locally attached networks. The general RIP request is a special RIP message that requests all routes. Neighboring RIP routers receive the general RIP request and send a unicast reply to the requesting router. The initializing RIP router uses the replies to build its routing table.

**Ongoing Maintenance**

By default, a RIP router announces its routes on all of its interfaces every 30 seconds. The type of routing announcement

depends on whether the RIP router is configured for split horizon or split horizon with poison reverse processing. The RIP router also continuously listens for RIP announcements from neighboring routers in order to add or update the routes in its own routing table.

**Advertisement of Unreachable Routes**
RIP routers send announcements for routers that are shut down by administrators for reasons such as routine maintenance and for links or routers that fail unexpectedly.

**Administrative Router Shutdown**
If a RIP router is turned off correctly through an administrative action, it sends a triggered update to neighboring routers on all locally attached networks as it shuts down, to inform neighboring routers that networks available through it have become unavailable. The triggered update announces the networks with a hop count of 16 (unreachable). The neighboring RIP routers then use triggered updates to propagate this topology change throughout the IP internetwork.

**Response to Topology Changes**
As dynamic routers, functioning RIP routers react to changes in the internetwork topology from downed links or downed routers:

**Downed link**
If a link that corresponds to one of the router's interfaces fails, and if the failure is detected by the interface hardware and is indicated to the router, the router sends this change out to neighboring routers as a triggered update.

**Downed router**
If a router stops responding due to a power outage or other hardware or software failure, it cannot inform neighboring routers that the networks available through it have become unavailable. To prevent the lingering existence of unreachable networks in routing tables, each route that is learned by RIP has a maximum lifetime of 3 minutes by default. If the entry is not refreshed by the receipt of another announcement in 3 minutes, the entry's hop count is changed to 16 (unreachable) and is, therefore, eventually removed from the routing table.

Thus, if a RIP router fails unexpectedly, it takes up to 3 minutes for the neighboring routers to mark as unreachable the routes that are learned from the failed router. Only then do they propagate the topology change throughout the internetwork by using triggered updates.

**How RIP v1 Works**
RIP v1, defined in RFC 1058, is still deployed in many small- to medium-sized intranets. However, RIP v1 is now considered outdated because it does not fully support classless addressing — including variable length subnet masking (VLSM), which enables configuring subnets of variable size, and classless interdomain routing (CIDR), which enables route summarization.

RIP v2 and OSPF do support CIDR and VLSM, so there is no reason to deploy RIP v1 as the primary routing protocol even for a small network. However, if routers that do not support RIP v2 exist on an IP internetwork, it is possible to deploy a mixed environment that includes both RIP v1 and RIP v2 routers. For more information about mixed environments, see "Mixed RIP v1 and RIP v2 Environments" later in this section.

**RIP v1 Message Format**
RIP messages are sent as User Datagram Protocol (UDP) messages from the router interface IP address and UDP port 520 to the subnet broadcast IP address and UDP port 520. The RIP v1 message consists of a 4-byte RIP header and up to 25 RIP routes. The maximum size of the RIP message is 504 bytes. With the 8-byte UDP header, the maximum size of the RIP message is a 512-byte IP payload. The following figure illustrates the format of a RIP v1 message.

### Message Format for RIP v1

The following table describes the fields depicted in the figure. The four fields named **Must Be Zero** were reserved for future use; as will be described later, RIP v2 uses three of these fields.

### RIP v1 Message Fields

| Field | Description |
|---|---|

| | |
|---|---|
| Command | A 1-byte field that contains a value of either 1 or 2, indicating request or response, respectively.<br>• **Request.** A value of **1** indicates a RIP request to neighboring routers asking for all (a general RIP request) or part of their routing tables.<br>• **Response.** A value of **2** indicates a RIP response from a neighboring router, consisting of all or part of the neighbor's routing table. A RIP response can be sent in response to a RIP request from a requesting router, or as a periodic or triggered update message generated by the sending router. |
| Version | A 1-byte field that is set to **1** to indicate RIP v1. |
| Family Identifier | A 2-byte field that identifies the routable protocol family. In an IP internetwork, this field is set to **2** to indicate the IP routable protocol family. |
| IP Address | A 4-byte field that is set to the IP network ID, which can be any of the following:<br>• A class-based network ID<br>• A subnetted network ID (advertised only within the subnetted network)<br>• An IP address (for a host route)<br>• 0.0.0.0 (for the default route)<br>For a general RIP request, the **IP Address** field is set to **0.0.0.0**. |
| Metric | A 4-byte field that indicates the number of hops to the IP subnet. This field must be a value from 1 to 16. The metric is set to **16** in a general RIP request or to indicate that the subnet is unreachable in a RIP response. |

**Why RIP v1 Is Outdated**

The following sections explain the primary historical and technical reasons that make RIP v1 out-of-date in a modern IP internetwork.

**MAC-level broadcasting of RIP announcements designed for LANs**

RIP v1 was designed in 1988 to satisfy the dynamic routing needs of LAN-based IP internetworks. Shared-access LAN technologies, such as Ethernet or Token Ring, support MAC-level broadcasting, in which a single packet can be received and processed by nodes on a subnet. All RIP v1 route announcements are addressed to the IP subnet (all host bits are set to 1) and MAC-level broadcast addresses. Non-RIP nodes also receive RIP v1 announcements.

In modern IP internetworks, the use of MAC-level broadcasts is unsatisfactory because all nodes must process all broadcasts. For large or very large RIP internetworks, the amount of broadcast traffic on each subnet can become substantial enough to affect node performance.

**Subnet mask not announced with the route**

RIP v1 originated in an era when the Internet was still using network IDs based on the standard Internet address classes. Today, however, the use of CIDR (for route summarization) and VLSM (for configuring subnets of varying size) is widespread, making the standard address classes obsolete.

RIP v1 was designed for class-based IP internetworks where the network ID can be determined from the values of the first 3 bits of the IP address in the RIP route. Because the subnet mask is not included with the route with RIP v1, the RIP router must determine the network ID based on a limited set of information. For each route in a RIP v1 message, the RIP v1 router performs the following process:

- If the network ID fits one of the standard address classes (Class A, Class B, or Class C), the default class-based subnet mask is assumed.
- If the network ID does not fit any address class, one of the following occurs:
    - If the network ID fits the subnet mask of the interface on which it is received, the subnet mask of the interface on which it was received is assumed.

- If the network ID does not fit the subnet mask of the interface on which it is received, the network ID is assumed to be a host route with the subnet mask 255.255.255.255.

As a result of the preceding assumptions, RIP v1 can misinterpret summarized routes as a single class-based network ID rather than as a range of class-based network IDs. In addition, with noncontiguous subnets, RIP v1 can misinterpret subnet routes that are advertised outside the network ID being subnetted as host routes.

RIP v1 can support only physically contiguous, fixed-size subnets. RIP v1 routers can support subnetted environments to a limited extent because they do not advertise the subnets of a subnetted class-based network ID outside the subnetted region of the IP internetwork. Subnets of a network ID in a RIP v1 environment must be contiguous, because only the class-based network ID is advertised outside the subnetted environment. Noncontiguous subnets, also known as discontiguous subnets, occur when another network with a different network ID separates subnets of a classful network. If the subnets of a network ID are noncontiguous, the class-based network ID is announced by separate RIP v1 routers in different parts of the internetwork. As a result, IP traffic can be forwarded to the wrong subnet.

**No protection from rogue RIP routers**
RIP v1 does not provide any protection from a rogue RIP router that starts up on a subnet and announces false or inaccurate routes. RIP v1 announcements are processed regardless of their source. A malicious user can use this lack of protection to overwhelm RIP routers with hundreds or thousands of false or inaccurate routes. However, on a RIP router running Windows Server 2003 Routing and Remote Access, you can configure RIP to accept only RIP announcements from specified IP addresses.

**How RIP v2 Works**
RIP v2, which is defined in RFC 2453, reduces or eliminates some of the problems associated with RIP v1. The decision to refine RIP was controversial in the context of newer, smarter routing protocols, such as OSPF. However, RIP was extended in the new RIP v2 implementation because RIP has the following advantages over OSPF:

- **Easy to implement.** In its simplest form (when defaults are accepted), implementing RIP for IP is as easy as configuring IP addresses and subnet masks for each router interface and then turning on the router.

- **Widely in use.** RIP is installed in a large number of small-sized and medium-sized IP internetworks.

**RIP v2 Updates RIP for Modern Internetworks**
RIP v2 adds several key features to RIP v1 that help today's IP internetworks minimize broadcast traffic, conserve IP addresses by using VLSM and CIDR, and help secure the routing environment from incorrectly or maliciously configured routers.

**Support for multicast RIP announcements**
As explained earlier, RIP v2 supports sending RIP announcements to the IP multicast address of 224.0.0.9. In addition, in contrast to RIP v1, non-RIP nodes are not disturbed by RIP v2 router announcement traffic when multicasting is used.

A disadvantage of the new multicast announcement feature, however, is that silent RIP nodes, if they exist, must also listen for the multicast traffic that is sent to 224.0.0.9. If your computers use silent RIP, verify that the silent RIP nodes can listen for multicasted RIP v2 announcements before you deploy multicasted RIP v2. The Windows Server 2003 (or Windows 2000 Server) Routing and Remote Access service can be configured to send out RIP v1, RIP v2, or both types of packets.

For more information about multicast RIP announcements, see "RIP Route Advertising" earlier in this section.

**Support for subnet masks**
RIP v2 announcements send the subnet mask (also known as a network mask) along with the network ID. Because RIP v2 has this capability, it supports VLSM and CIDR, which means that RIP v2 can operate in variable-length subnetted internetwork environments and can use route summarization. It also means that RIP v2 can manage noncontiguous subnets without experiencing the routing errors that occur with RIP v1.

**Support for simple password authentication**
RIP v2 supports the use of simple password authentication to verify the origin of incoming RIP announcements. Simple password authentication for RIP v2 is defined in RFC 1723. Enabling simple password authentication helps prevent an unauthorized or incorrectly configured RIP router from corrupting RIP routes on a subnet.

Newer authentication mechanisms, such as Message Digest 5 (MD5), are also available in some RIP v2 environments. However, Windows Server 2003 Routing and Remote Access supports only simple password authentication for RIP v2.

If you use RIP v2 simple password authentication, you must configure all RIP v2 interfaces on the same network with the same case-sensitive password. A RIP v2 router discards RIP announcements received from any RIP v2 interface whose password does not match the password configured on the interface of this RIP v2 router. You can use the same password for all of the

networks on your IP internetwork, or you can vary the password for each network.

**Note**

- Simple password authentication is a form of router identification. It does not provide security for RIP messages. Because the password is sent in plaintext, any user with a protocol analyzer (also known as a network sniffer), such as the Network Monitor tool, can capture the RIP v2 announcements and view the authentication password.

**Support for RIP v1 and RIP v2 compatibility**

RIP v1 was designed to be compatible with future versions of RIP. If a RIP v1 router receives a message and if the RIP version indicated in the RIP header is not 1, the RIP v1 router does not discard the RIP announcement but instead processes only the RIP v1 defined fields.

In addition, RIP v2 routers send a RIP v1 response to a RIP v1 request, unless they are configured to send only RIP v2 announcements.

**RIP v2 Message Format**

RIP v1 routers can process RIP v2 announcements in a mixed environment that contains both types of routers, because RIP v2 does not modify the structure of the RIP message format. Instead, RIP v2 makes use of fields that were defined in RIP v1 as **Must be Zero**.

The **Command**, **Family Identifier**, **IP Address**, and **Metric** fields in RIP v2 are used as they are for RIP v1. For RIP v2, the **Version** field is set to **2** to indicate that the message is a RIP v2 message. The following figure illustrates the RIP v2 message format.

**Message Format for RIP v2**

RIP v2 uses three of the four fields that were named **Must Be Zero** in RIP v1. The following table describes the new fields for RIP v2.

**Additional Message Fields Defined in RIP v2**

| Field | Description |
|---|---|
| Route Tag | A 2-byte field used to distinguish routes announced by RIP routers from non-RIP routes. The **Route Tag** field is defined by RFC 1723.<br><br>Routers that can support multiple routing protocols typically allow the **Route Tag** to be configured to indicate routes imported from differing sources. For example, an administrator typically sets the **Route Tag** for routes imported from Exterior Gateway Protocol (EGP) or OSPF to an arbitrary value to differentiate them from RIP routes.<br><br>The Windows Server 2003 Routing and Remote Access snap-in supports the configuration of the **Route Tag** on RIP v2 interfaces on the **General** tab of the ***InterfaceName* Properties** page. Routing and Remote Access does not allow you to specify a **Route Tag** by route, only by interface. For example, a route tag can be used on a router that has OSPF enabled on all of its interfaces except one, on which RIP is used. The route tag for routes on the RIP interface can be configured to tag all of the OSPF routes learned on all the other interfaces. |
| Subnet Mask | A 4-byte field that contains the subnet mask (also known as a network mask) of the network ID specified in the **IP Address** field. |

| | |
|---|---|
| Next Hop | A 4-byte field that contains the forwarding IP address (also known as the gateway address) for the network ID specified in the **IP Address** field. If the next hop is set to **0.0.0.0**, the next-hop IP address for the route is assumed to be the IP address of the source of the route announcement.<br><br>The **Next Hop** field is designed to prevent the occurrence of non-optimal routing situations. The usefulness of the **Next Hop** field is illustrated by the following example:<br><br>• If the **Next Hop** field is not used, when a router announces a host route for a host that resides on the same subnet as the router interface that is advertising the route, the next-hop IP address for the host route is the IP address of the router's interface, not the IP address of the host. Other routers on that subnet that receive the announcement forward packets destined for the host's IP address to the announcing router's IP address rather than to the host. This routing issue, which can occur with RIP v1, is avoided by RIP v2 because it uses the **Next Hop** field.<br><br>• If the **Next Hop** field is used, the router announces the host route with the host's IP address in the **Next Hop** field. Other routers on that subnet that receive the announcement correctly forward packets destined for the host to the host's IP address, rather than incorrectly forwarding the packets to the announcing router.<br><br>Because the **Next Hop** field becomes the **Gateway** address field in the routing table, the IP address in the **Next Hop** field must be directly reachable through a router interface. |

**RIP v2 Simple Password Authentication Message Format**

The simple password authentication process for RIP v2 announcements uses the first route entry in the RIP message to store authentication information. The first route entry must be used for this authentication mechanism, which leaves a maximum of 24 routes available in a RIP v2 authenticated announcement (because the RIP message format allows up to 25 routes per RIP message). To indicate authentication, the **Family Identifier** field is set to **0xFFFF**. The **Authentication Type** field (which is usually used as the **Route Tag** field) indicates the type of authentication being used. A value of **1** in the **Authentication Type** field indicates simple password authentication.

The 16-byte **Authentication Value** field, which follows the **Authentication Type** field, stores the left-justified, null-padded, case-sensitive, plaintext password used for simple password authentication. The following figure illustrates the RIP v2 authentication message format for plaintext passwords.

**RIP v2 Message Format Using Authentication**

RIP v1 routers disregard the first route in a RIP v2 authenticated announcement because RIP v1 does not recognize the **Family Identifier** (that is, **0xFFFF**) for the route.

**Mixed RIP v1 and RIP v2 Environments**

To take advantage of all RIP v2 features, use only RIP v2 in a RIP internetwork. For internetworks that contain one or more routers that do not support RIP v2, it is possible to establish a mixed environment that contains both RIP v1 and RIP v2 routers. However, you must exercise caution if you establish a mixed environment to avoid experiencing routing problems. Follow these guidelines to avoid routing problems in a mixed environment:

- Because RIP v1 routers cannot interpret the **Subnet Mask** field in the route, RIP v2 routers must not announce routes that can be misinterpreted by a RIP v1 router. Therefore, do not use VLSMs or noncontiguous subnets in a mixed environment.

- Because RIP v1 routers will misinterpret a summarized route as a single network ID rather than as a range of network IDs, do not use summarized routes in a mixed environment.

- For a RIP v2 router interface to make announcements in a way that allows RIP v1 routers to process the announced routes, the RIP v2 routers must summarize subnet routes when announcing outside a subnetted environment. A specific subnet route announced to a RIP v1 router can be misinterpreted as a host route. Therefore, in a mixed environment, use

only contiguous, fixed-size subnets or clear the **Disable subnet summarization** setting on the **Advanced** tab of each interface.

- If RIP v2 routers are on the same subnet as RIP v1 routers, you must configure the interface for each RIP v2 router to broadcast its announcements on that subnet. RIP v1 routers cannot process multicasted RIP v2 announcements.

**How OSPF Works**

Open Shortest Path First (OSPF) for IP enables OSPF routers to dynamically exchange routing information with each other over complex IP internetworks. Routers can add or remove routes automatically as networks are added or removed from the internetwork, dynamically building and synchronizing a database of the OSPF network topology. As its name implies, OSPF is designed to calculate the shortest path to any destination within an OSPF autonomous system (AS). OSPF, the best known and most widely used link state routing protocol, is an open standard developed by the Internet Engineering Task Force (IETF) as an alternative to RIP. OSPF is defined in RFC 2328. The Windows Server 2003 Routing and Remote Access service supports OSPF for IPv4 only.

### Notes

- The OSPF routing protocol is available only on 32-bit versions of Windows Server 2003
- The Windows Server 2003 Routing and Remote Access service does not support OSPF (or any other dynamic routing protocol) for IPv6. For information about Windows Server 2003 support for IPv6, including support for static routing in an IPv6 environment, see "IPv6 Routing" in "How IPv6 Works" in IPv6 Technical Reference.

This section describes:

- OSPF features appropriate for large internetworks
- How OSPF convergence works
- How OSPF forms adjacencies to synchronize the LSDB
- How OSPF multiple-area autonomous systems work

**OSPF Features Appropriate for Large Internetworks**

OSPF, an Interior Gateway Protocol (IGP) used for routing IP traffic within a single autonomous system, is commonly used on a multipath, dynamic IP internetwork that consists of more than 50 (but fewer than 100) networks.

Typically, OSPF is deployed in large private IP internetworks, including internetworks that span multiple geographical regions, nations, or continents. OSPF functions efficiently in a WAN environment by using summarized routes to reduce the size of routing tables.

You can also easily take advantage of the advanced features of OSPF in a much smaller network by accepting the default OSPF settings and the default settings for OSPF interfaces.

Both the Internetwork Operating System (IOS) used by many hardware routers and the Windows Server 2003 Routing and Remote service support OSPF.

**OSPF Database, Areas, and Routers**

In an OSPF routed internetwork, an autonomous system is made up of one or more areas. An OSPF area is made up of a logical collection of networks, routers, and links, and each area includes special OSPF routers that enable communication between the constituent areas. Each OSPF area uses a database to store its routing information. OSPF updates this database dynamically as network topology changes.

**OSPF database**

An OSPF area has a database that is shared by the routers in that area, a method to keep the database updated, and a method to calculate the routing table from the database.

**All OSPF routers in an area share the same database**

An OSPF router stores information about the state of each link between itself and other routers in an OSPF-specific database called a link state database (LSDB). The LSDB is a topological map of all routers in the same OSPF area. The LSDB maps either all routers within the autonomous system (if only one area exists) or it maps all routers within the local OSPF area (if multiple

areas exist). If multiple areas exist, each OSPF router stores a separate LSDB for each connected area.

**OSPF routers exchange advertisements to create and update the database**
OSPF routers compile the shared LSDB by flooding link state advertisements (LSAs) within the autonomous system (if only one OSPF area exists) or within the local area (if multiple OSPF areas exist). Flooding means sending traffic received on one interface out all of the other interfaces on that device. An LSA is a multicast packet that an OSPF router uses to advertise information about network neighbors and path costs. Each OSPF router in an area must receive a valid LSA from each other router.

**OSPF routers calculate the routing table from the database**
After an OSPF router compiles its LSDB from the LSAs that it receives from other routers, each router, using itself as the root, calculates a tree of shortest paths to each other router and subnet, and then creates IP routing table entries from this tree, storing a single entry for each subnet.

For detailed information about how OSPF manages its database, advertisements, and routing table, see "How OSPF Convergence Works" later in this section.

**OSPF areas**
Each OSPF area is identified by an area identification number called an area ID. The 32-bit OSPF area ID is expressed in dotted decimal notation. The area ID is an administrative identifier that is unrelated to an IP address or an IP network ID. However, if all networks within one OSPF area correspond to a single subnetted network ID, for administrative convenience you can set the area ID to match the network ID. For example, if an area contains all of the subnets of the IP network 10.1.0.0/16, you can set the area ID to 10.1.0.0.

The following table describes the possible types of OSPF area. The only required area type is a backbone area.

### Types of OSPF Areas

| Area Type | Description |
|---|---|
| Standard | An OSPF area that propagates intra-area, inter-area, and external routes:<br>• Intra-area routes are communicated within the local OSPF area.<br>• Inter-area routes are communicated between OSPF areas (connected by a backbone area) that are located in the same autonomous system. OSPF uses summarized routes for inter-area routes.<br>• External routes are communicated from an external route source into the OSPF autonomous system by an Autonomous System Border Router (ASBR). An external resource can be either from another OSPF autonomous system or from a non-OSPF source, such as another routing protocol.<br>The LSDB in an area stores OSPF router LSAs for intra-area routes, summary LSAs for inter-area routes, and external route LSAs for external routes. |
| Backbone | A standard OSPF area that is either the sole area in the OSPF autonomous system or the central area to which all other OSPF areas of an OSPF autonomous system connect. The OSPF backbone area requires the reserved area ID of 0.0.0.0; an alternative notation, the area ID of 0, is sometimes used to denote the backbone area.<br>When more than one area exists in an OSPF autonomous system, the OSPF backbone area (typically, a single high-bandwidth network) distributes routing information among all attached areas. Traffic between areas is first routed to the backbone, then routed to the destination area, and then finally routed to the destination host within the destination area. |
| Transit | A non-backbone standard OSPF area that connects another OSPF area (that does not have a physical link to the backbone) to the backbone by using a logical point-to-point connection called a virtual link. |

| | |
|---|---|
| Stub | An OSPF area that, like a standard OSPF area, accepts and advertises inter-area and intra-area routes but, unlike a standard area, does not accept or distribute external routes from external OSPF autonomous systems or from non-OSPF sources.<br><br>Internal OSPF routers in a stub area use the default route (destination 0.0.0.0, network mask 0.0.0.0) to reach all destinations outside the autonomous system. A stub area, typically, has only one router (an Area Border Router, or ABR) that connects the stub area to the rest of the autonomous system. |
| Totally Stub | A type of stub area that propagates only intra-area routes and the default route within the area; it does not accept or advertise either inter-area routes or external routes.<br><br>Internal OSPF routers in a totally stub area use the default route to send traffic destined outside the area to the local ABR, which forwards the traffic towards its destination in another OSPF area or outside the autonomous system. |

On a Windows Server 2003 Routing and Remote Access OSPF router, OSPF areas are viewable in the Routing and Remote Access snap-in by right-clicking **OSPF** under **IP Routing** in the console tree, and then clicking **Show Areas**.

For more information about OSPF areas, see "How OSPF Multiple-Area Autonomous Systems Work" later in this section.

**OSPF Routers**

When an OSPF autonomous system contains two or more areas and connects to other destinations outside the OSPF autonomous system, the routers it contains can operate in one of four roles. The following table describes these OSPF routers.

**Types of OSPF Routers**

| Router Type | Description |
|---|---|
| Internal router | An OSPF router that has two or more interfaces that all connect within the OSPF area in which the router resides. All internal routers within an area share the same LSDB. |
| Area border router (ABR) | An OSPF router that has two or more interfaces that connect directly to networks in two or more OSPF areas. One interface must connect to the backbone area; thus, an ABR is always a backbone router but the converse is not always true — a backbone router is not necessarily an ABR. An ABR stores multiple LSDBs, one for each attached area, including one for the backbone area.<br><br>An ABR routes traffic between the backbone area and all other areas connected to the backbone by sending routes for its attached area to the backbone, which, in turn, distributes this information to other OSPF areas not attached to this router within the autonomous system. |
| Backbone router | An OSPF router that has at least one interface connected to the backbone area and that routes traffic within the backbone area. All internal routers of the backbone area and all ABRs are backbone routers. |
| Autonomous system boundary router (ASBR) | An OSPF router that imports routing information from external sources and advertises external destinations throughout its own autonomous system. An ASBR in an OSPF autonomous system can connect to and exchange routes with:<br>• An ASBR in another OSPF autonomous system, by connecting the two autonomous systems.<br>• Non-OSPF sources, by connecting its own autonomous system to the external source. For example, an ASBR can connect to an external network running a different interior gateway protocol, such as RIP for IP.<br><br>Only a standard OSPF area can contain an ASBR. Each router in an OSPF autonomous system can reach the ASBRs within its autonomous system. |

**OSPF Unitless Metrics**

In contrast to the RIP hop count cost metric, OSPF uses a unitless metric to indicate the preference for one link over another. Factors in the metric include the following:

- **Delay.** The time that a packet requires to reach the destination network. Delay indicates the speed (LAN links have a low delay; WAN links have a high delay) or congestion level of the path.

- **Throughput (link speed).** The amount of data that can be sent along the path per second. Throughput does not necessarily indicate the bit rate of the link because, for example, a very busy Ethernet link might have a lower throughput

than an unused 64-kilobits per second (Kbps) WAN link.

- **Reliability.** The path constancy. Some types of links are more likely to fail than others. For example, leased line WAN links are more reliable than dial-up lines.

The cost value is advertised as the link cost for this interface in the LSA of the router. The lower the cost assigned to an interface, the more often the OSFP router uses the interface to forward packets. Therefore, typically, you assign lower costs to the interfaces of preferred paths for IP traffic. The accumulated cost for network segments in an OSPF internetwork can be as great as 65,535, which enables OSPF to accommodate enterprise-size networks.

**OSPF Route Advertising**
OSPF route advertising includes the characteristics described in the following sections.

**Advertises subnet mask**
OSPF advertises the subnet mask of a route with its network ID. As a result, OSPF supports VLSM and CIDR and, therefore, supports subnetting, noncontiguous subnets, and route summarization.

**Advertises external routes**
In OSPF, an external route is a route that is learned from a non-OSPF source, such as a static route manually configured by a network administrator or a RIP route learned from a network that uses the RIP routing protocol. Routes outside an OSPF autonomous system are advertised within the autonomous system, which enables OSPF routers to calculate the least-cost route to external networks. OSPF can use the default route (destination 0.0.0.0, network mask 0.0.0.0) to summarize routes imported from external sources.

For more information about external routes, see “Propagating External Source Routes to the OSPF Autonomous System” later in this section.

**Advertises summarized routes**
In an OSPF autonomous system with multiple areas, OSPF can be configured to send summary route advertisements in the format {*Destination, Network Mask*} to advertise networks located inside one area to other OSPF areas. The destination and network mask specify a range of addresses to be summarized. Summarizing — consolidating multiple routes into a single advertisement — is configured on an ABR at the boundary between an OSPF area and the backbone area. After receiving the summarized route from one area, the ABR forwards the summarized route through the backbone area and then through another ABR into another area.

Because OSPF can include multiple areas and can use summarized routes (which reduces the size of OSPF routing tables), OSPF can scale to large and very large internetworks. In contrast, RIP internetworks cannot be subdivided and RIP v1 performs no route summarization beyond summarizing for all subnets of a class-based network ID.

For more information about using summarized routes for inter-area routing, see “Using Route Summarization Between OSPF Areas” later in this section.

**Advertises based on network type**
The address type, multicast or unicast, used for an OSPF announcement is determined by the type of network — broadcast, point-to-point, or nonbroadcast multiple access (NBMA) — to which the OSPF interface is connected.

**OSPF multicasts announcements on broadcast networks (default)**
A broadcast network is a multiple access network, that is, more than two routers are connected to the network, which can broadcast a single frame to all routers attached to that network. Ethernet, Token Ring, and Fiber Distributed Data Interface (FDDI) are broadcast networks.

On broadcast networks, OSPF routers use the following two reserved multicast IP addresses to send OSPF messages:

- **224.0.0.5 - AllSPFRouters.** Used to send OSPF messages to all OSPF routers on the same subnet. OSPF routers use the **AllSPFRouters** multicast address to send OSPF Hello messages to each other in order to discover each other. In addition, the OSPF designated router (DR) and backup designated router (BDR) use this address to send Link State Update and Link State Acknowledgment messages. (For more information about OSPF designated routers, see “How OSPF Forms Adjacencies to Synchronize the LSDB” later in this section.)

- **224.0.0.6 - AllDRouters.** Used to send OSPF messages to all OSPF designated routers and BDRs on the same subnet. All OSPF routers, except designated routers themselves, use this multicast address to send Link State Update and Link State Acknowledgment messages to designated routers and BDRs.

The multicast protocol, Internet Group Management Protocol (IGMP), is not needed because these addresses are in the link-local range. The link-local range refers to addresses in the range of 224.0.0.0 to 224.0.0.255 (224.0.0.0/24). This multicast range is reserved for local subnet multicast traffic. IP routers do not forward packets sent to addresses in this range.

**OSPF multicasts announcements on point-to-point networks**

A point-to-point network is a network that connects only two routers. T1/E1, T3/E3, ISDN, and other types of dial-up WAN links as well as leased-line WAN links are point-to-point networks.

On point-to-point networks, OSPF routers use the **AllSPFRouters** multicast IP address (**224.0.0.5**) to send all OSPF messages.

**OSPF unicasts announcements to specific OSPF neighbors on NBMA networks**

A nonbroadcast multiple access (NBMA) network is a network that can connect more than two routers but cannot broadcast a single frame to all routers attached to that network. X.25, Frame Relay, and Asynchronous Transfer Mode (ATM) are NBMA networks. In addition to being unable to broadcast, NBMA networks also cannot multicast.

How you configure OSPF for an NBMA network depends on how Frame Relay virtual circuits appear as network interfaces on an OSPF server running Routing and Remote Access. Frame Relay virtual circuits appear in the Routing and Remote Access snap-in either as a single adapter or as multiple adapters. The following descriptions assume that you have a Frame Relay network, but other NBMA technologies, such as X.25 and ATM, function in a similar manner.

- **Single-adapter model unicasts OSPF announcements.** All virtual circuits on an OSPF router function as a single adapter. In the single-adapter model, also known as the *NBMA model*, the network of the Frame Relay service provider (also called the Frame Relay cloud) is treated as an IP network, and the endpoints on the cloud are assigned IP addresses from a designated IP network ID. To ensure that OSPF traffic is received by all of the appropriate endpoints on the cloud, you must configure the Frame Relay interface to unicast its OSPF announcements to each appropriate endpoint. On a Routing and Remote Access OSPF router, you do this by designating the interface as an NBMA network and by configuring OSPF to unicast announcements to the specified neighbor routers. (Up to this point, the single-adapter model functions the same with both RIP and OSPF.)

  In a hub-and-spoke Frame Relay topology in an OSPF-based IP internetwork, the Frame Relay interface for the hub router must have a router priority set to **1** or greater and the Frame Relay interfaces for the spoke routers must have a router priority set to **0**. Otherwise, the hub router, which is the only router that can communicate with all of the spoke routers, cannot become the designated router and adjacencies cannot form across the Frame Relay network. For more information about the router priority setting, see “Using Designated Routers” later in this section.

- **Multiple-adapter model multicasts OSPF announcements.** Each virtual circuit functions as a separate adapter. In the multiple-adapter model, each Frame Relay virtual circuit functions as a point-to-point link with its own network ID, and the endpoints on the cloud are assigned IP addresses from a designated IP network ID. Because each virtual circuit is its own point-to-point connection, you can configure the interface as the point-to-point network type rather than as the NBMA network type.

On an OSPF router running Windows Server 2003 Routing and Remote Access, the network type (broadcast, point-to-point, or NBMA) is configurable in the Routing and Remote Access snap-in by navigating to the **IP Routing\OSPF** node, and then using the **General** tab of the ***InterfaceName*Properties** page. In addition, for the NBMA network type, neighbor routers on the NBMA network can be specified on the **NBMA Neighbors** tab of the same ***InterfaceName*Properties** page.

### Note

- The use of OSPF to provide remote access over nonpermanent, non-persistent, dial-up WAN links, such as analog phone lines or dial-up ISDN, is not recommended.

**OSPF Simple Password Authentication**

OSPF supports the use of simple password authentication to verify the origin of incoming OSPF announcements. Simple password authentication, which is enabled by default on Windows Server 2003 Routing and Remote Access OSPF interfaces, helps prevent an unauthorized or incorrectly configured OSPF router from corrupting OSPF messages on a subnet. By default, Windows Server 2003 Routing and Remote Access OSPF routers send the default plaintext password "12345678" in their OSPF Hello messages.

If you specify that plaintext passwords are required for an OSPF area:

- All interfaces on the same network segment must use an identical password.

- Interfaces in the same area that are on different networks can have different passwords.

**Note**

- Simple password authentication is a form of router identification. It is not a security option. Because the password is sent in plaintext, any user with a protocol analyzer (also known as a network sniffer), such as the Network Monitor tool, can capture the OSPF messages and view the authentication password.

**OSPF Convergence**

Of the features listed in this section that make it possible for OSPF to support large internetworks, fast convergence time is one of the most important. OSPF can detect and propagate topology changes faster than RIP. Unlike RIP, the count-to-infinity problem does not occur on an OSPF network and OSPF-calculated routes are always loop-free.

For more information about OSPF convergence, see "How OSPF Convergence Works," described next.

**How OSPF Convergence Works**

OSPF-enabled routers go through the following stages to achieve convergence of an IP internetwork:

1. Compiling the LSDB.
2. Calculating the Shortest Path First tree.
3. Creating routing table entries.

The following three sections describe this process in detail. The result of this process, sometimes referred to as fast convergence, is that OSFP can quickly recalculate routing information if routers fail and can avoid the occurrence of routing loops.

**Compiling the LSDB**

OSPF compiles the LSDB by means of an ongoing exchange of LSAs between neighboring routers, leading to a state in which each router is synchronized with its neighbors. After the autonomous system converges (if only one OSPF area exists) or after the local area converges (if multiple OSPF areas exist), each router has the appropriate entries in its LSDB.

To create the LSDB, each OSPF router must receive a valid LSA from each router in the autonomous system (if only one OSPF area exists) or from each router in the local area (if multiple OSPF areas exist). The process through which OSPF routers send and receive the LSAs is called flooding (sending traffic received on one interface out all other interfaces). Each router initially sends an LSA that contains its own configuration. As it receives LSAs from other routers, it propagates those LSAs to its neighbor routers. In this way, an LSA from a specific router is flooded across the autonomous system so that each other router learns that router's LSA. Although the flooding of LSAs might appear to cause a large amount of network traffic, OSPF is very efficient in the propagation of LSA information.

The following figure shows a simple, single-area OSPF autonomous system, the flooding of LSAs between neighboring routers, and the resulting LSDB compiled on one router. After the process completes, all routers contain an identical LSDB.

**Flooding LSAs to Create the LSDB in a Single-Area Autonomous System**

On a Windows Server 2003 Routing and Remote Access OSPF router, the OSPF LSDB is viewable in the Routing and Remote

Access snap-in by right-clicking the **OSPF** routing protocol in the console tree, and then clicking **Show Link State Database**.

To keep track of LSAs in the LSDB, each router is assigned a router ID, which identifies the router in the autonomous system. The router ID is a 32-bit dotted decimal number that is unique to the autonomous system. The router ID is not the IP address of one of the router's interfaces, and it is not used as a destination IP address for sending information to the router. Typically, the largest or smallest IP address assigned to the router is the router ID. Because IP addresses are unique, this convention ensures that OSPF router IDs are also unique.

**Calculating the Shortest Path First Tree**
After the LSDB is compiled, each OSPF router uses the Dijkstra algorithm to perform a least-cost path calculation on the information in the database. The Dijkstra algorithm, from a branch of mathematics called graph theory, is an efficient method of calculating a set of least-cost paths relative to a source node. The router, using itself as the root, performs this calculation to create a tree of shortest paths to each other router and subnet in the OSPF autonomous system (if only one OSPF area exists) or to each other router in the local area (if multiple OSPF areas exist). This tree, which contains a single least-cost path to each router and subnet, is known as the Shortest Path First (SPF) tree. A least-cost path is the path with the lowest accumulated cost. Because the least-cost path calculation is performed by each router with itself as the root of the tree, the SPF tree is different for each router.

OSPF uses the Dijkstra algorithm to calculate the SPF tree. The result of the Dijkstra algorithm is the set *SPF{}*, which is a cost-sorted list of least-cost paths that contain the path (the series of nodes and links) and its accumulated cost from the source node S.

**Creating Routing Table Entries**
OSPF creates entries in the IP routing table of each router from the SPF tree. If only one OSPF area exists, the routing table stores a single route for each subnet in the autonomous system. For multi-area OSPF internetworks, typically you configure route summarization at each ABR so that only summary routes that represent the destinations of each area are added as routes to the routing table. As explained earlier, the metric for the routing table entry is the OSPF-calculated cost, not a hop count (as is the case for RIP).

To calculate the IP routing table entries from the SPF tree, OSPF analyzes the set SPF{} that results from calculating the SPF tree. The analysis produces a series of OSPF routes that are added to the routing table. Each route contains:

- An IP destination (the network ID) and its associated network mask.
- The next-hop IP address of the appropriate neighboring router.
- The next-hop interface over which the neighboring router is reachable.
- The OSPF-calculated cost to the subnet.

**Example of OSPF Convergence**
The example described in this section illustrates how an OSPF internetwork compiles the LSDB, performs the least-cost analysis, and creates routing table entries. This example is deliberately simplified to help provide an understanding of the basic principles of OSPF convergence.

**Example: Compiling the LSDB in a single-area autonomous system**
At each router interface, the network administrator assigns a unitless cost metric (reflecting bandwidth, delay, or reliability), indicating a preference for using that interface, as shown in the following figure.

### Cost Assigned for Each OSPF Router Interface in an OSPF Area

After the LSA flooding process completes convergence, each router in the single-area autonomous system has received an LSA from all other routers, and each router in the system now contains an identical LSDB. The following table illustrates the common LSDB now shared by all routers in the area.

**After Convergence Occurs, All Routers Contain the Same LSDB Information**

| Router | Attached Networks and Costs |
|---|---|
| R1 | Net 1-Cost 2, Net 3-Cost 5, Net 4-Cost 2 |
| R2 | Net 1-Cost 1, Net 2-Cost 4, Net 6-Cost 2 |
| R3 | Net 2-Cost 4, Net 3-Cost 2, Net 5-Cost 3, Net 7-Cost 2 |
| R4 | Net 4-Cost 3, Net 5-Cost 2 |
| R5 | Net 6-Cost 2, Net 7-Cost 3 |

**Example: Calculating the SPF Tree**

In the next step, OSPF applies the Dijkstra algorithm to the example single-area OSPF autonomous system. The following figure illustrates the resulting SPF tree calculation, as performed by router R4. With R4 acting as the root, the SPF tree calculation determines the series of connected routers and networks that represent the least-cost path to each router and to each subnet.

**SPF Tree Calculation Performed by Router R4**

**Example: Creating Routing Table Entries**

Next, OSPF creates the routing table from the results of the SPF tree calculation, as illustrated in the following figure.

**OSPF Derives Routing Table Entries from the SPF Tree Calculation**

The exchange of LSAs by OSPF routers on a large IP internetwork might require a brief, but large, burst of bandwidth. After the exchange of advertisements and before convergence, a large amount of memory is required to process the LSDB. In addition, running the Dijkstra algorithm requires high CPU use. Therefore, networks with links that frequently appear and disappear can cause performance issues on routers because of the bandwidth needed to generate LSAs, to store the database, and to run the Dijkstra algorithm.

Instead of using one OSPF area for the entire autonomous system, you can minimize OSPF overhead and performance issues by dividing the OSPF autonomous system into multiple areas. For more information about OSPF areas, see "How OSPF Multiple-Area Autonomous Systems Work" later in this section.

**How OSPF Forms Adjacencies to Synchronize the LSDB**

Link state routing algorithms rely on the synchronization of LSDB information among routers in an autonomous system.

However, if every router exchanges routing information with every other router, the exchange of redundant information can occur, which increases network traffic and enlarges the size of the LSDB. To avoid this unnecessary overhead, each router is required to synchronize only with specific neighboring routers known as adjacent routers. When the LSDBs of two neighboring OSPF routers are synchronized, the routers are said to be adjacent. OSPF enables the exchange of routing information only between those neighboring OSPF routers that share an adjacency relationship. Not every pair of neighboring routers becomes adjacent.

OSPF requires that adjacencies be established in order to compile the correct entries in the LSDB, and only then can OSPF calculate the SPF tree and create entries in the routing table. Failure to establish adjacencies is one of the main problems that can prevent convergence in an OSPF internetwork.

**Establishing an OSPF Adjacency**

When an OSPF router initializes, it multicasts periodic OSPF Hello messages onto all directly connected subnets in order to discover neighboring OSPF routers and to communicate its own existence to them. The OSPF Hello message contains configuration information, such as the router's router ID and the list of neighboring routers from which the router has received a Hello message. Initially, however, the neighbor list in the OSPF Hello message does not contain any neighbors.

The initializing OSPF router, while multicasting its own OSPF Hello messages, also listens for Hello messages sent from neighboring routers. From incoming Hello messages, the initializing router determines the specific router or routers with which to form an adjacency. On a multiple-access network (broadcast or NBMA), adjacencies are formed with a designated router and a backup designated router (BDR) that are identified as such in the incoming Hello messages. The designated router forms adjacencies with other routers on its subnet, avoiding redundant adjacencies by establishing only the minimum required number of adjacencies. For more information about how designated routers avoid establishing redundant adjacencies, see "Using Designated Routers" later in this section.

To form an adjacency:

1. Two routers describe the contents of their LSDBs in an exchange of database description packets known as the database exchange process. It is during the database exchange process that the two neighboring routers form a master and subordinate relationship if they become adjacent router's. The content of each router's LSDB is acknowledged by its neighboring router.

2. Each router compares its LSAs with the LSAs of its neighbor and notes which LSAs it needs to request from the neighbor in order to synchronize the LSDB. The missing or more recent LSAs are then requested through Link State Request messages. Link State Update messages are sent in response to Link State Request messages and their receipt is acknowledged. When all Link State Request messages of both routers have received a response, the LSDBs of the router and its neighboring router are fully synchronized and an adjacency is formed.

3. After the adjacency has formed, each adjacent router sends a periodic Hello message to inform the adjacent router that the router is still active on the subnet. OSPF uses the lack of Hello messages from a neighbor to detect a downed router.

4. If an event, such as a downed link or router or the addition of a new subnet that changes the LSDB of one router occurs, the databases of adjacent routers are no longer synchronized. The changed router sends Link State Update messages to its adjacent neighbors, who acknowledge the messages. After this exchange, the LSDBs of the adjacent routers are again synchronized.

**OSPF neighbor states as an adjacency forms**

The neighboring OSPF routers go through a series of states (as defined in RFC 2328) during the establishment of an adjacency. The following table lists these states in the adjacency relationship in progressive order.

### States of OSPF Neighbors as an Adjacency Forms

| Neighbor State | Description |
|---|---|
| Down<br><br>(initial state) | Router A has received no OSPF Hello message from neighbor router B. However, on NBMA networks, router A can send a Hello message to router B even though router B is in a **Down** state. |

| | |
|---|---|
| Attempt<br><br>(for NBMA networks only) | Router A has received no OSPF Hello message from neighbor router B recently, despite attempts to contact router B by sending OSPF Hello messages to it. |
| Init | Router A has received an OSPF Hello message from neighbor router B, but the router ID of router A does not appear in the neighbor list of the Hello message sent by router B. This indicates that bidirectional communication has not yet been established between router A and router B. |
| 2-way | Router A has received an OSPF Hello message from neighbor router B, and the router ID of router A now appears in the neighbor list of the Hello message sent by router B. The same process occurs in reverse, establishing two-way communications between the two routers.<br><br>After the **2-way** state is achieved, router A determines whether to become adjacent with router B. On a broadcast network (the typical case) or on an NBMA network, an OSPF router remains in a **2-way** state with all other OSPF routers except the designated router and the BDR; it will establish a **Full** state (that is, a fully adjacent state) at a later stage only with the designated router and the BDR. |
| ExStart | Master and subordinate roles for the database exchange process are negotiated between router A and neighbor router B in this stage. This negotiation is the first phase of the adjacency relationship. The router with the higher router ID becomes the master and starts the exchange. |
| Exchange | Router A and neighbor router B exchange database description packets (also known as database descriptor packets). The contents of each database description packet is compared to the information stored in each router's LSDB to determine whether new or more current link state information is available in the database description packet sent by the other router. |
| Loading | Based on information in the exchanged database description packets, router A and neighbor router B send each other Link State Request messages asking for missing or more recent LSAs. Each responds by sending the requested link state information in Link State Update messages (which contain the entire LSA) to the other router. |
| Full | The LSDBs of router A and neighbor router B are fully synchronized, and the two routers are now said to be fully adjacent with each other. This adjacency relationship is now advertised in LSAs.<br><br>On a broadcast network (the typical case) or on an NBMA network, after completing this series of states to establish an adjacency relationship, a **Full** state occurs only between an OSPF router and its designated router and BDR; the **2-way** state is the normal state for most OSPF routers in a broadcast network.<br><br>On a point-to-point network, after completing this series of states to establish an adjacency relationship, the **Full** state is the normal state for the two OSPF routers on either side of the link. |

On a Windows Server 2003 Routing and Remote Access OSPF router, the neighbor state of neighboring routers is viewable in the Routing and Remote Access snap-in by right-clicking **OSPF** in the **IP Routing** container in the console tree, and then clicking **Show Neighbors**. The window that opens, **OSPF Neighbors**, displays all neighboring routers and each neighbor's current state. In a broadcast network:

- For neighbor routers where an adjacency is established (the designated router and BDR), **Full** appears in the **State** column.
- For neighbor routers where no adjacency is established, nor will be established because the router is neither a designated router nor a BDR, **2-way** appears in the **State** column.

For more information about designated routers and BDRs, see "Using Designated Routers" later in this section.

**OSPF adjacency configuration requirements**

A common OSPF problem is that a required adjacency between two neighboring routers does not occur. To successfully establish an adjacency, the following requirements must be met:

- The router IDs of the two neighboring routers *must not match*. Router IDs must be globally unique within an autonomous system. Duplicate router IDs prevent an adjacency. A router ID is different from an IP address.

- Settings on the two neighboring routers *must match* in all of the following parameters:

    - **Authentication type.** If authentication is used, the neighboring routers must use the same authentication type.

    - **Simple password authentication password.** If simple password authentication is enabled, the neighboring routers must use the same case-sensitive password.

    - **Hello interval.** The periodic interval at which Hello messages are sent must be the same on both routers. The default is 10 seconds.

    - **Dead interval.** The amount of time after which an adjacent router is considered down if the neighboring router does not receive a Hello message must be the same on both routers. In an Internet-Draft, titled "OSPF Benchmarking Terminology and Concepts," IETF recommends that the dead interval value be four times the Hello interval. The default is 40 seconds.

    - **Area ID.** The area ID, which is configured on the interface of each router, must be the same on both routers. This is a 32-bit dotted decimal number that identifies the area of the autonomous system to which the router is attached. An OSPF area ID is different from an IP address.

    - **Location in an OSPF stub area.** The two neighbor routers must agree whether or not they are in a stub area.

**Adding a Router to a Converged OSPF Internetwork**

When a new OSPF router initializes on an existing and converged OSPF internetwork, the LSA for the new OSPF router must be propagated to all existing OSPF routers on the internetwork through the process of flooding. After each existing router receives the new LSA, it performs the Dijkstra algorithm, recalculates the SPF tree, and creates new routing table entries. After all routing tables on all routers are updated, the internetwork has reconverged. For multi-area OSPF internetworks on which route summarization is used, the set of routes that summarize the networks of the new router must be configured on each ABR of the area in which the new router exists. This ensures that the networks attached to the new router are propagated across the entire OSPF autonomous system.

The following figure illustrates the convergence process for a new router, R1, and the new adjacency propagation process in an example single-area OSPF internetwork. In this example, the link between R1 and R2 is a dedicated WAN link, which is one type of point-to-point link.

**Adjacency Propagation of a New Router**

The preceding figure shows the convergence process for the new OSPF router, R1. This process works as follows:

1. After router R1 is turned on, it begins sending periodic Hello messages across the point-to-point WAN link to router R2. Router R2 also sends periodic Hello messages across the link to R1. R1 and R2 form an adjacency.

2. R1 and R2 exchange database description packets. R1's packet contains information only about itself. R2's packet contains the latest LSAs for all routers on the internetwork (except R1).

3. R1 sends a Link State Request message to R2, requesting the advertisements of all routers on the internetwork. R2 sends the requested advertisements to R1 as Link State Update messages.

4. R2 sends a Link State Request message to R1, requesting its advertisements. R1 sends its advertisements to R2 as a Link State Update message. R1 and R2 now have synchronized their respective LSDBs. When R1 and R2 receive the advertisements, they calculate their respective SPF trees and routing tables.

5. When R2 is synchronized with R1, R2 sends a Link State Update message to all other OSPF routers to which it is adjacent (routers R3 and R4). The update message contains the advertisements learned from R1. When R3 and R4 receive the advertisements from R2, they recalculate their respective SPF trees and routing tables.

6. R3 and R4 each floods the information in a separate Link State Update message to their respective adjacent routers (routers R5 and R6). When R5 and R6 receive the flooded advertisement about R1, they recalculate their respective SPF trees and routing tables.

The example single-area OSPF internetwork has reconverged after adding R1 and its associated subnet.

**Using Designated Routers**

On a point-to-point link, such as a dedicated WAN link, the OSPF adjacency relationship must be established between the two routers on either side of the link. However, on multiple access networks — broadcast or NBMA networks that contain multiple routers — the adjacencies must be controlled. On a broadcast network with *n* routers, a total of *n* (*n*–1)/2 adjacencies are formed if no control mechanism is present. For example, a broadcast network with six OSPF routers where each router establishes an adjacency with each other router would form a total of 15 adjacency relationships. In addition, unneeded flooding traffic would occur as each router attempts to synchronize with all of its adjacent routers.

**Election of designated routers**

To solve this scaling problem, every multiple access network (both broadcast and NBMA) elects a designated router, which forms adjacencies with all other routers on the subnet. On a multiple access network, the designated router establishes only the needed number of adjacencies (eliminating redundant adjacencies), which in turn reduces both network traffic and the size of the LSDB. On a broadcast network with *n* routers, a total of (*n* -1) adjacencies must be formed; any additional adjacencies are redundant. For example, a broadcast network with six OSPF routers will form a total of five adjacency relationships. Because the designated router is adjacent to all other routers, it acts as a hub for distributing link state information and for synchronizing LSDBs.

The designated router is elected through the exchange of OSPF Hello messages. Each Hello message specifies the current designated router (if elected), and the router ID and router priority of the sending router. The router priority is an interface-specific OSPF configuration parameter that is used to elect the designated router — the router with the highest router priority is elected. The default router priority is set to **1**. Setting a router priority of **0** prevents a router from becoming a designated router. If multiple routers have the same highest router priority, the router with the highest router ID is elected designated router. The recommended practice is to assign router priorities to ensure that the least busy routers are the designated router and BDR.

On a Windows Server 2003 Routing and Remote Access OSPF router, the router priority setting is configurable in the Routing and Remote Access snap-in by navigating to the **IP Routing\OSPF** node, and then specifying the desired priority for the **Router priority** option on the **General** tab of the ***InterfaceName*Properties** page.

If a designated router is already elected for a subnet, a new router on the subnet does not become the designated router even if it has a higher router priority than the current designated router.

### Note

- At least one router on the multiple access network (broadcast or NBMA) must be configured with a router priority of **1** or greater. If all routers on a multiple access network are configured with a router priority of **0**, no router becomes the designated router and no adjacencies are established. Without adjacencies, the LSDB cannot be synchronized and no transit traffic (traffic across that subnet) can be forwarded.

**Designated routers on broadcast networks**

The following figure illustrates why a broadcast network requires a designated router. Without a designated router, six separate adjacencies (illustrated in the top half of the figure) are formed on a broadcast network that contains four routers. The redundant adjacencies consume local and network resources in order to maintain the adjacencies and to propagate changes to the LSDB.

When the same network uses a designated router, only three adjacencies (illustrated in the bottom half of the figure) are needed to synchronize the LSDB.

**Designated Router Eliminates Redundant Adjacencies on a Broadcast Network**

**Designated routers on NBMA networks**

For NBMA networks, such as a Frame Relay network in a hub-and-spoke configuration, the designated router must be the hub router because only the hub router can communicate with all of the other routers. To ensure that the hub router is the designated router, set its router priority to **1** (or greater). To ensure that no spoke router becomes a designated router, set the router priority on spoke routers to **0**.

The following figure illustrates a designated router on a Frame Relay network that uses a hub-and-spoke configuration.

**Designated Routers on a Frame Relay Network**

**Backup designated routers**

The designated router forms adjacencies with other routers on its subnet and acts as a central distribution point for topological changes on a multiple access network. If the designated router becomes unavailable, adjacencies must be reestablished with a new designated router. Until the adjacencies re-form and the internetwork reconverges, a temporary loss of connectivity for transit traffic can result.

To prevent connectivity loss due to the loss of a designated router, a backup — the BDR — is also elected for each multiple access network. Like the designated router, the BDR is adjacent to all routers on the network. When the designated router fails, the backup immediately becomes the designated router by sending LSAs that announce its new role to all adjacent routers. For a brief time only, transit traffic might be impaired while the BDR takes over the role of the designated router.

Like the designated router, the BDR is elected by the exchange of Hello messages. Each Hello message contains a field for the BDR of the subnet. If a backup is not specified, the router with the highest router priority that is not already the designated router becomes the BDR. If multiple routers have the highest router priority, the router with the highest router ID is elected the BDR.

If a BDR is already elected for a subnet, a new router on the subnet does not become the BDR even if it has a higher router priority than the current BDR. After the initial election, the designated router and the BDR retain their status, even if a higher priority router joins the subnet. Only after both the designated router and the BDR fail does the current highest priority router become the new designated router, and the current router with the second highest router priority becomes the new BDR.

**Interface states for adjacent routers**

Each OSPF interface can be in one of several states after routers form an adjacency. The following table lists these interface states.

**Interface States for Adjacent Routers**

| Interface State | Description |
|---|---|
| Down | The initial interface state. No Hello messages have been sent or received. |
| Loopback | The interface to the network is looped back (internally configured so that outgoing packets are routed back to the source computer) through hardware or software. |
| Waiting | The interface is sending and receiving Hello messages to determine the designated router and the BDR for the subnet. |
| Point-to-point | The interface is adjacent to its neighbor on a point-to-point network or through a virtual link and is not the designated router or the BDR. |
| Other | The interface is on a multiple access network (broadcast or NBMA) and is not the designated router or the BDR. |
| Designated router | The interface is the designated router for the attached subnet. |
| Backup designated router | The interface is the BDR for the attached subnet. |

On a Windows Server 2003 Routing and Remote Access OSPF router, the interface state for an OSPF interface is viewable in the Routing and Remote Access snap-in by clicking the **IP Routing\OSPF** node. In the details pane, which displays the OSPF interfaces, the **State** column indicates the interface's current state. By viewing the interface state for each OSPF interface on a specific subnet, you can determine the designated router and the BDR for the subnet.

**How OSPF Multiple-Area Autonomous Systems Work**

In an OSPF autonomous system that includes a large set of contiguous networks in a single OSPF area, each OSPF router must maintain in its database the LSAs of every other router in that area. Therefore, each router in a large single-area OSPF autonomous system has a large LSDB. The SPF calculation for a large LSDB requires a substantial amount of processing. In addition, the resulting routing table is large because it contains a route for each subnet in the autonomous system. A large OSPF autonomous system is typically configured to contain more than one OSPF area because each area then has its own smaller LSDB. Using multiple areas in an OSPF autonomous system makes processing throughout the autonomous system more efficient.

OSPF is designed to support dividing the autonomous system into multiple OSPF areas in order to decrease the size of the LSDB and to reduce the processing overhead for calculating the SPF tree and the routing table. Dividing a large IP internetwork into several OSPF areas, each made up of groups of contiguous subnets, helps keep the size of the LSDB to a minimum. The size of the LSDB is more manageable and processing is faster because LSAs for networks and routers inside one area are flooded within that area but are not flooded to routers outside the area. Each area becomes its own link state domain with its own LSDB.

For a description of the possible types of OSPF areas and the types of OSPF routers needed inside and between OSPF areas, see "OSPF Database, Areas, and Routers" earlier in this section.

**Routing Between OSPF Areas**

Routing between OSPF areas in an autonomous system takes the following course:

1. A host in one area sends a packet destined for a host in another area to an internal router within its area. The sending host has no knowledge of either its own area or the area of the destination.

2. The internal router forwards the packet along the least-cost path to the nearest ABR, which (by definition) has an

interface that connects to the backbone area. The ABR is also a backbone router.

3. The ABR forwards the packet along the least-cost path to the nearest ABR that is connected to the area containing the IP address of the destination host.

4. The ABR connected to the area containing the destination host forwards the packet along the least-cost path, including through intermediate internal routers, if any, to the destination host.

The following figure shows the route of a packet as it is forwarded across R1, an internal router in area 0.0.0.1, to ABR R2, across the backbone area (area 0.0.0.0) to router R3, and then to the destination host in area 0.0.0.2.

**Inter-Area Routing in OSPF**

OSPF routers do not make routing decisions based on area IDs. All routing decisions are based on entries in the IP routing table. For example, in the inter-area routing shown in this figure, the backbone routers do not explicitly forward the packet to area 0.0.0.2. Rather, the routers forward the packet along the least-cost path to the router that is the best match for the destination IP address in the packet.

**Using Route Summarization Between OSPF Areas**

OSPF routers within an OSPF area perform routing *within* that area by using the least-cost path to the destination subnet. Each router in that area has a route to each subnet within the area. When multiple OSPF areas exist, OSPF can be configured to manage routing *between* areas by advertising networks located inside one area to other areas by using summary route advertisements in the format {*Destination, Network Mask*}. These destination/mask pairs, known as inter-area routes, summarize a range of addresses within this OSPF area to other areas in the same autonomous system. Using route summarization for inter-area routes reduces the number of entries in the routing table of OSPF routers within each area.

Using multiple OSPF areas in combination with route summarization makes very large OSPF internetworks feasible. When designing areas for an OSPF autonomous system, assign network IDs that can be expressed as a small number of summary routes. For example, assign network IDs for the private IP address space 10.17.0.0/16 and 10.29.0.0/16 to the subnets of an OSPF area so that all of the locations within the area can be summarized with two routes. If an area can be summarized with a single route, you can set the area ID of that area to the IP network ID that summarizes the entire area. If an area has multiple ABRs, ensure that they all are configured to summarize the same routes.

Configured ABRs on the OSPF backbone advertise summarized routes for all areas to which they are connected to all other routers on the backbone. Therefore, the routing table on each router in an OSPF area contains both the individual routes available within the local area and the routes corresponding to the summary advertisements received from configured ABRs connected to other areas in the autonomous system.

In the following figure, router R1 (the ABR on the border of area 0.0.0.1 and area 0.0.0.0) uses a summary advertisement to announce all routes (the list of address ranges) inside area 0.0.0.1 to all other backbone routers (including R2 in 0.0.0.2 and R3 in 0.0.0.3). In turn, R1 receives summary advertisements from R2 about area 0.0.0.2 and from R3 about area 0.0.0.3. In addition, R1 is configured with summary advertisement information for the backbone area, area 0.0.0.0. By flooding, R1 propagates incoming summary routing information to all routers within area 0.0.0.1. Each router within area 0.0.0.1 incorporates summary routing information from areas 0.0.0.0, 0.0.0.2, and 0.0.0.3 into its routing table.

**Summary Routes Reduce Routing Table Size**

Using route summarization hides the topology — the networks and their path costs — of one area from the rest of the autonomous system. The network topology for each area is discoverable only by routers within that area. Conversely, routers within each area cannot discover detailed topological information about other areas.

Hiding the topology of an OSPF area from other areas by using route summarization protects the rest of the autonomous system from revising its routing tables when events cause a network in another area to alternately fail and reconnect. Whenever a subnet reconnects, OSPF propagates the event as a Link State Update message and floods the update through adjacencies to routers within the area. This condition, known as route flapping, causes routing table instability because numerous routes are withdrawn and re-advertised in rapid succession. However, because all subnets within the area are advertised outside the area by using summary routes, OSPF does not flood the Link State Update outside the area and route flapping is avoided.

**Using Virtual Links to Areas Not Connected to the OSPF Backbone**

OSPF areas in an IP internetwork are connected to a backbone area that links the areas in the autonomous system together. Typically, an ABR that connects an OSPF area to the backbone area has a physical connection to the backbone area. However, when it is not possible or practical to use a physical connection to the backbone, you can configure a virtual link between an OSPF area and the backbone. A virtual linkis a logical point-to-point connection between an ABR of an OSPF area that is not physically connected to the backbone area and an ABR that is physically connected to the backbone.

You can configure a virtual link between any two routers that have an interface to a single common non-backbone area, known as the transit area. The transit area must have an ABR that is connected to the backbone. You cannot configure virtual links across multiple transit areas. OSPF forms a virtual adjacency across the virtual link to enable the exchange of routing information between the two routers connected by the virtual link. Such routers are known as virtual link neighbors.

In the following figure, area 0.0.0.3 does not have a router physically connected to the backbone (area 0.0.0.0). Therefore, a virtual link between routers R2 and R3 is configured across the transit area (area 0.0.0.2). R2 and R3 are virtual link neighbors.

**OSPF Virtual Link**

A virtual link requires values for the following settings on both virtual link neighbors:

- The area ID of the transit area for the virtual link.
- The OSPF router ID of the virtual link neighbor.
- The transit delay interval, which specifies the estimated number of seconds that it takes to transmit OSPF packets to the virtual link neighbor router.

- The retransmit interval, which specifies how long the OSPF router waits before retransmitting Link State messages. This number should be significantly larger than the expected round-trip delay between the two routers at either end of the transit area. Because this can be difficult to estimate for a virtual link, it is better to make this number too large rather than too small.

- Adjacency settings, including the Hello interval, dead interval, and plaintext password. Just as in physical adjacencies, the adjacency settings of the two virtual link neighbors must match before OSPF can successfully establish an adjacency.

On a Windows Server 2003 Routing and Remote Access OSPF router, a virtual link is configurable in the Routing and Remote Access snap-in by navigating to the **IP Routing\OSPF** node, and then using the **Virtual Interfaces** tab on the **OSPF Properties** page. Existing virtual links are viewable by right-clicking **OSPF** in the **IP Routing** container, and then clicking **Show Virtual Interfaces**. The **Virtual Interfaces** window displays all configured virtual interfaces and their states.

**Propagating External Source Routes to the OSPF Autonomous System**

An *external route* is defined as any route whose source is external to the OSPF autonomous system. By default, the set of OSPF routers that define an organization's OSPF autonomous system propagate only OSPF routes that correspond to directly connected network segments within the OSPF autonomous system. OSPF can also import external routes by defining an OSPF router as an autonomous system boundary router (ASBR). External routes can come from the following sources:

- RIP v2

- Local routes

- Static routes

- Static (non-demand-dial) routes

- Auto-static routes

- Routes that SNMP sets on the router

OSPF uses one or more ASBRs to learn and propagate external routes throughout an OSPF autonomous system. The ASBR uses a series of external route LSAs to advertise the availability of external routes, flooding the external route LSAs throughout the autonomous system (except in stub areas). The external route LSAs become part of the SPF tree and are included in the routing table calculation. Traffic to external networks is routed within the autonomous system by using the least-cost path to the ASBR.

The following figure shows an autonomous system that uses an ASBR to manage external route traffic.

**An ASBR Imports Routes from an External Source (RIP) into an OSPF Autonomous System**

**ASBRs and External Route Filters**

By default, an OSPF router configured to act as an ASBR imports and advertises all external routes from all external route sources. You can choose to block routes from one or more route sources, and you can filter out specific external routes. For

example, on a Windows Server 2003 Routing and Remote Access OSPF router configured as an ASBR, you can set either or both of the following types of restrictions:

- **Exclude specific external route sources.** You can configure the ASBR to accept or discard routes originating from one or more external sources, such as the RIP v2 routing protocol, static routes, or SNMP-generated routes. Accepting routes from all listed external route sources is the default option.

- **Exclude individual routes.** You can configure the ASBR to accept or discard specific routes for all external route sources or for a particular external route source by specifying one or more {*Destination, Network Mask*} pairs.

A combination of these filters, configured at the ASBR, can prevent the ASBR from advertising inappropriate routes and help ensure that the OSPF autonomous system is protected from incorrect or malicious routing information.

**ASBRs and Default Routes**

A router configured to act an ASBR advertises, by default, all external routes, including its own default route. This default route is used by all OSPF routers in the autonomous system. A valid default route has a next-hop IP address that points to a router that can reach the external network outside the OSPF autonomous system. An invalid default route has a next-hop IP address that points to a router within the OSPF autonomous system.

If the default gateway configured on the ASBR has a next-hop IP address that points to itself (its own IP address), the default route is not valid and packets forwarded by using that default route are dropped. To avoid this problem, use either of the following solutions:

- Do not configure an IP address for the default gateway on the TCP/IP properties of the ASBR.

- If the ASBR must have a default gateway, create an OSPF external route filter to filter out its own default route (destination 0.0.0.0, network mask 0.0.0.0). The default gateway configured on the ASBR must point to an IP router that is external to the OSPF autonomous system. Then, all routers within the autonomous system can correctly use that external router as their default gateway.

**ASBRs and Remote Access Servers**

A Windows Server 2003 Routing and Remote Access OSPF router in an OSPF environment might also be configured to function as a remote access server in order to support remote or mobile users. Typically, when you create a static IP address pool for remote access connections, address ranges in the address pool can represent separate subnets (known as off-subnet address ranges).

For the router to advertise correctly the routes for off-subnet address ranges, you must:

- Configure the router as an ASBR in the Routing and Remote Access snap-in by navigating to the **IP Routing\OSPF** node, and then selecting the **Enable autonomous system boundary router** option on the **General** tab of the **OSPFProperties** page.

- Use the **External Routing** tab on the **OSPF Properties** page to select **Route Filters**, specify **Accept listed routes**, and then add the routes that correspond to the off-subnet address ranges of the static IP address pool used for remote access connections.

### Note

- The use of OSPF to provide remote access over nonpermanent, non-persistent, dial-up WAN links, such as analog phone lines or dial-up ISDN, is not recommended.

**Using OSPF Stub Areas**

OSPF provides two types of area designed to improve performance in an OSPF autonomous system: standard stub areas and an extension to stub areas known as totally stub areas. The Windows Server 2003 Routing and Remote Access service supports both. OSPF stub areas are defined in RFC 2328.

**Stub areas summarize external routes**

Using an OSPF stub area decreases the amount of routing information that floods into it and therefore reduces routing overhead on the stub area's internal routers. OSPF does not flood routes external to the OSPF autonomous system into or through a stub area. To deliver packets from a stub area to any destination IP address outside of the OSPF autonomous

system, OSPF uses only a single route, the default route (destination 0.0.0.0, network mask 0.0.0.0). In OSPF, any destination not reachable through an intra-area or inter-area route is reachable through the default route; thus, OSPF uses the default route to route packets from a stub area to any destination not reachable within the autonomous system.

A stub area:

- **Reduces memory load.** Because a stub area does not advertise individual external networks, less memory is required on internal stub area routers than is required on internal routers in a standard non-stub OSPF area.
- **Reduces routing table size.** Using the default route for routing to external networks reduces the size of the routing table.

All routers in a stub area must be configured as stub routers. Configuring a router as a stub router automatically sets the E-bit flag in the OSPF Hello message on its interface to **0**. The **0** setting identifies this router as a stub router when it attempts to establish an adjacency with another router. Otherwise, by default, for an area that is not a stub area, OSPF sets the E-bit to **1**, which allows the router to accept and flood external routes into the OSPF area.

Stub areas have the following constraints:

- You cannot configure the backbone area as a stub area.
- You cannot configure virtual links that use a stub area as a transit area.
- You cannot place an ASBR inside a stub area.

**Example Stub Area**

Area 0.0.0.3 in the following figure is configured as a stub area. All traffic to external route locations must travel through its single ABR, R3. Router R3 advertises a default route for distribution inside area 0.0.0.3 instead of flooding external routes into the area.

**OSPF Stub Areas**

A stub area can contain a single ABR (a single entry and exit point) as in the example figure, or it can contain multiple ABRs. If the stub area contains multiple ABRs, each ABR must be configured to advertise a default route instead of external routes. When configured, any of the ABRs can be used to reach external route destinations even if the path to the external destination through the closest ABR is not the optimal path.

**Totally stub areas summarize external and inter-area routes**

A totally stub area uses the default route for route summarization of routes that are external to the totally stub area's OSPF autonomous system as well as for inter-area routes within its OSPF autonomous system. The following table compares stub areas and totally stub areas.

**Contrasting an OSPF Stub Area with a Totally Stub Area**

| Stub Area | Totally Stub Area |
|---|---|
| Does not advertise external routes. | Does not advertise external routes or OSPF inter-area routes. |

| Routing table contains: | Routing table contains: |
| --- | --- |
| • Intra-area routes<br>• Inter-area routes<br>• A default route (to reach destinations external to its autonomous system) | • Intra-area routes<br>• A default route (to reach destinations in other OSPF areas within its autonomous system and to reach destinations external to its autonomous system) |

One appropriate reason to deploy a totally stub area is to configure a branch office that does not have high traffic requirements to other branch offices. The branch office uses the default route to reach the central office and other branch offices.

On a Windows Server 2003 Routing and Remote Access OSPF router, a stub area or a totally stub area is configurable in the Routing and Remote Access snap-in by navigating to the **IP Routing\OSPF** node, selecting the **Add** option on the **Areas** tab of the **OSPFProperties** page, and then selecting **Stub area** on the **General** tab of the **OSPF Area Configuration** dialog box. A stub area is differentiated from a totally stub area by selecting the **Import summary advertisements** option for a stub area or ensuring that **Import summary advertisements** is not selected (which is the default) for a totally stub area.

**How the DHCP Relay Agent Works**

Any IP subnet that contains DHCP clients requires either a DHCP server or a DHCP relay agent to provide address leases to those DHCP clients. A computer acting as a DHCP relay agent, also known as a Bootstrap Protocol (BOOTP) relay agent, relays DHCP messages between DHCP clients on an IP subnet with no DHCP server and a DHCP server located on a different subnet.

Using one or more DHCP relay agents makes it unnecessary to install a separate DHCP server on each subnet in an IP internetwork because the DHCP relay agent enables a DHCP server to lease addresses to clients on a different subnet than the subnet on which the DHCP server is located. With DHCP relay agents, two DHCP servers (the second one is a backup) on one subnet can service an entire internetwork if the subnets with no DHCP server have an IP router configured to act as a DHCP relay agent.

The Windows Server 2003 Routing and Remote Access service provides a DHCP relay agent when the **DCHP Relay Agent** routing protocol component is added and configured with the IP address of one or more DHCP servers. The Routing and Remote Access DHCP relay agent is compliant with RFC 1542.

A DHCP relay agent mediates between a DHCP client and DHCP server in three steps:

1. A client on a subnet that has no DHCP server but that does contain a DHCP relay agent broadcasts a request for a DHCP lease.

2. The DHCP relay agent accepts the request and forwards it as a unicast message to the IP address of a DHCP server on another subnet.

3. The DHCP server sends a response (a lease offer) to the unicast IP address of the DHCP relay agent, which then forwards the response as either a broadcast or unicast transmission to the DHCP client.

**Note**

- Configuring the DHCP relay agent on a computer running any of the following will impair the proper functioning of DHCP:

- The DHCP Server service

- The Routing and Remote Access NAT routing protocol component with automatic addressing enabled

- Internet Connection Sharing (ICS)

A DHCP relay agent helps direct DHCP messages between a DHCP server and a DHCP client located on different subnets and takes an active role in recording information required for DHCP configuration.

**Initial DHCP Configuration**
Initial DHCP configuration is initiated by a DHCP client that has never leased an IP address, has released its IP address, or has received a DHCPNack message (indicating a negative response to a DHCP request) when attempting to lease a previous IP address. As described next, the initial DHCP configuration process uses four DHCP messages: DHCPDiscover, DHCPOffer, DHCPRequest, and DHCPAck.

**DHCPDiscover — DHCP client broadcasts initial request to discover a DHCP server**
When a Windows DHCP client computer starts, it broadcasts a message to obtain or renew a lease from a DHCP server. The DHCP client sends a DHCPDiscover message, which contains the MAC address of the DHCP client, to the limited broadcast IP address (255.255.255.255) and the MAC-level broadcast address. If no DHCP server exists on the client's subnet, the DHCP relay agent (if one is configured) receives the DHCPDiscover message and forwards it to a DHCP server on another subnet.

As defined in RFC 1542, the DHCP relay agent can forward the packet to an IP broadcast, multicast, or unicast address. In practice, DHCP relay agents forward a DHCPDiscover message to unicast IP addresses that correspond to configured DHCP servers. Before forwarding the original DHCPDiscover message, the DHCP relay agent makes the following changes:

1. Increments the Hop Count field in the DHCP header. The DHCP Hop Count field (which is different from the Time to Live [TTL] field in the IP header) is used to indicate how many DHCP relay agents have handled this DHCP message. When the configured maximum Hop Count is exceeded, the DHCPDiscover message is silently discarded. The default maximum hop count for the Windows Server 2003 DHCP relay agent is 4.

2. If needed, updates the Relay IP Address field (also known as the Gateway IP Address field) in the DHCP header. When the DHCP client sends the DHCPDiscover message, the Relay IP Address field is set to 0.0.0.0. If the relay IP address is 0.0.0.0, the DHCP relay agent records the IP address of the interface on which the DHCPDiscover message was received. If the relay IP address is not 0.0.0.0, the DHCP relay agent does not modify it. The Relay IP Address field records the first router interface encountered by the DHCPDiscover message.

3. Changes the source IP address of the DHCPDiscover message to the IP address of the interface on which the broadcasted DHCPDiscover message was received.

4. Changes the destination IP address of the DHCPDiscover message to the unicast address of the DHCP server configured on the DHCP relay agent.

The DHCP relay agent sends the DHCPDiscover message to the DHCP server (located on another subnet) as a unicast IP packet rather than as an IP and MAC-level broadcast. If the DHCP relay agent is configured with multiple DHCP servers, it sends each DHCP server a copy of the DHCPDiscover message.

**DHCPOffer — DHCP server offers IP address to the DHCP client**
When the DHCP server responds to the DHCP client request for an IP address, the DHCP server uses the Relay IP Address field in the following ways:

1. The relay IP address and the subnet masks of the server's configured scopes are compared by using a logical **AND** operation. When the comparison finds a scope whose network ID matches the network ID of the relay IP address, the DHCP server allocates an IP address from that scope.

2. When the DHCP server sends the lease offer back to the client, the server sends the DHCPOffer message to the source address of the DHCPDiscover message.

After the DHCP relay agent receives the relay IP address, it uses the address to determine which interface over which to send the DHCPOffer message. The DHCP relay agent then looks at the value of the Broadcast flag in the DHCPOffer message. The Broadcast flag is set by the original DHCP client to indicate, when set to **1**, that the client cannot receive unicast IP traffic until the DHCP lease process for the unicast IP address is concluded. Based on the value of the Broadcast flag, the DHCP Relay Agent either readdresses and sends the DCHPOffer message to the limited broadcast IP address and MAC-level broadcast address (if the Broadcast flag is set to **1**) or readdresses and sends the DHCPOffer message to the client using the offered IP address as the destination IP address and the client's MAC address as the destination MAC address (if the Broadcast flag is set to **0**). Windows Server 2003 and Windows XP DHCP clients set the Broadcast flag to **0**.

**DHCPRequest — Client requests to lease the IP address offered by the DHCP server**
As it does with the DHCPDiscover message, the DHCP client sends the DHCPRequest message, containing the MAC address of the client, to the limited IP broadcast address 255.255.255.255 and to the MAC-level broadcast address. The DHCP relay agent receives this packet and readdresses and sends it as a unicast IP packet to the configured DHCP server or servers.

**DHCPAck — DHCP server acknowledges the DHCP client request and approves its lease**
The DHCP server initially unicasts the DHCPAck message to the relay IP address, as it did with the DHCPOffer message. When the DHCP relay agent receives the DHCPAck message, it uses the Broadcast flag to forward it as a broadcast or unicast transmission to the DHCP client. The DHCPAck message is the signal from the DHCP server to the DHCP client that the server approves the lease that the client will now use, and the server updates its DHCP database.

When the client receives the acknowledgement, it configures its TCP/IP properties using any DHCP option information (such as default gateway and DNS server addresses) contained in the DHCPAck message and completes the initialization of TCP/IP.

**Restarting a DHCP Client and Obtaining an IP Address**
By default, when a Windows Server 2003, Windows XP, or Windows 2000 DHCP client shuts down, it does not send a DHCPRelease message to the DHCP server. Instead, when the DHCP client restarts, it attempts to obtain the IP address it last used by exchanging DHCPRequest and DHCPAck messages.

### Note

- For Windows Server 2003, Windows XP, and Windows 2000 DHCP clients, you can override this default by configuring the DHCP server to send the **Release DHCP lease on shutdown** Microsoft-vendor-specific DHCP option.

**DHCPRequest**
When a Windows Server 2003, Windows XP, or Windows 2000 DHCP client restarts, it attempts to lease its previously allocated IP address by using a broadcasted DHCPRequest message. The DHCPRequest, which is sent to the limited IP broadcast address 255.255.255.255 and to the MAC-level broadcast address, contains the MAC address and the previously allocated IP address of the client. The DHCP relay agent receives this packet and treats the message in a way similar to the way that it treats a DHCPDiscover message (described earlier). Before forwarding the packet, the DHCP relay agent does the following:

1. Increments the Hop Count field in the DHCP header.

2. In the Relay IP Address field, records the IP address of the interface on which the DHCPRequest message was received.

3. Changes the source IP address to the IP address of the interface on which the broadcasted DHCPDiscover message was received.

4. Changes the destination IP address to the unicast address of the DHCP server that is recorded in the DHCPRequest, and then readdresses and sends the packet as a unicast IP packet to the DHCP server.

**DHCPAck and DHCPNack**
When the DHCP server receives the DHCPRequest, the server compares the network ID of the client's allocated IP address to the network ID of the relay IP address. Based on the result of that comparison, the server does one of the following:

- If the two network IDs are the same and if the IP address is available and thus can be reallocated to the DHCP client, the DHCP server sends a DHCPAck to the IP address of the DHCP relay agent. When the DHCP relay agent receives the DHCPAck, it readdresses and sends the message to the DHCP client.

- If the two network IDs are the same and if the IP address is not available and thus cannot be reallocated to the DHCP client, the DHCP server sends a DHCPNack to the DHCP relay agent. When the DHCP relay agent receives the DHCPNack, it readdresses and sends the message to the DHCP client. The DHCP client then restarts the IP address allocation process with a DHCPDiscover.

- If the two network IDs are not the same, the DHCP client has moved to a different subnet, and the DHCP server sends a DHCPNack to the DHCP relay agent. When the DHCP relay agent receives the DHCPNack, it readdresses and sends the message to the DHCP client. The DHCP client then restarts the IP address allocation process by sending a DHCPDiscover message.

**How IP Packet Filtering Works**
Windows Server 2003 supports several types of IP packet filtering.

**Routing and Remote Access IP Packet Filters**
Windows Server 2003 supports the following types of IP packet filtering to protect interfaces of a Routing and Remote Access

router:

- Basic Firewall, provided by the NAT/Basic Firewall component of the Routing and Remote Access service. Basic Firewall is intended for use on Internet-connected interfaces (public interfaces). For more information about Basic Firewall packet filtering, see "Basic Firewall" later in this section.

- IP packet filtering, enabled on the **General** tab of the **Properties** page of any IP interface. Although input and output filters configured in this way are typically referred to as "IP packet filters," all of the other types of packet filters listed in this section introduction are also IP packet filters. For more information about IP packet filtering provided by Routing and Remote Access, see "IP Packet Filtering" later in this section.

**Other Windows IP Packet Filters**

In addition to the IP packet filter capabilities provided by the Routing and Remote Access service, Windows Server 2003 supports the following types of IP packet filtering:

- Internet Connection Firewall (ICF) — a Network Connections component available in Windows XP, Windows XP SP1, and Windows Server 2003 — is a simple stateful firewall similar to Basic Firewall.

- TCP/IP packet filtering, configured by using the **Options** tab of the **Advanced TCP/IP Settings** page of TCP/IP properties, is used only for inbound local host traffic.

- Internet Protocol security (IPSec) packet filtering, provided as part of IPSec, is included with Windows Server 2003. IPSec can perform host-based packet filtering to provide limited firewall capabilities that help defend end systems against network-based attacks. An end system is a network device that cannot forward packets between portions of a network. For more information about IPSec packet filtering, see "IPSec Technical Reference."

**Basic Firewall**

Basic Firewall, provided by the NAT/Basic Firewall component of the Routing and Remote Access service, is a simple stateful firewall that can be enabled to protect a public interface on a computer running the Windows Server 2003 Routing and Remote Access service. A stateful firewall uses dynamic packet filtering to examine incoming and outgoing packets. Basic Firewall, which combines stateful packet filtering of network traffic with a set of static packet filters, examines network traffic in order to prevent unsolicited traffic originating on the Internet from being processed by an Internet-connected interface. Basic Firewall uses technology similar to that used by ICF.

The network address translation capability provided by the Windows Server 2003 Routing and Remote Access service can be configured with or without the Basic Firewall feature enabled. Conversely, you can enable Basic Firewall on any Internet-connected interface even when you have not deployed NAT. For a Basic Firewall with NAT, all packets that are received on the Internet interface of a NAT router that do not correspond to traffic requested by the NAT router (either for itself or for private intranet clients) are discarded. For a Basic Firewall without NAT, all packets that are received on the Internet interface of a Routing and Remote Access server that does not perform network address translation that do not correspond to traffic requested by this server are discarded.

Basic Firewall in conjunction with Routing and Remote Access NAT is primarily for use by small office or home office (SOHO) customers. For more information about using NAT with Basic Firewall, including information about how Basic Firewall filters TCP and UDP unicast packets, broadcast and multicast packets, specially defined packets, and ICMP traffic, see "How NAT Works" in NAT Technical Reference.

You can also use the NAT/Basic Firewall component of Routing and Remote Access in conjunction with the IP packet filtering capability provided by IPSec. Alternatively, you can use IPSec with ICF, which also provides stateful packet filtering.

**IP Packet Filtering**

To increase security on an IP network, an IP router configured with packet filters can allow or prevent the flow of specific types of IP traffic. IP packet filtering, by providing a way for the network administrator to define precisely which IP traffic is received and sent by the router, is an important component of connecting corporate intranets to public networks like the Internet.

When packet filtering is configured, a packet arriving at a router might be forwarded to its destination, rejected with an error message returned to notify the sender, or dropped with no error message sent.

**Filtering Inbound and Outbound Traffic**

IP packet filtering consists of creating a series of definitions, called filters, which define for the router what types of traffic are allowed or blocked on each interface. Filters can be set for incoming and outgoing traffic. Input filters define what inbound traffic the router is allowed to process locally (as the destination) or to forward (as a router) on a specific interface. Output

filters define what outbound traffic the router is allowed to send from that interface.

To filter incoming and outgoing traffic to allow a specific subset of traffic, you can implement packet filtering on a router or on a non-router computer. A computer running Routing and Remote Access that has only one interface is a non-router computer.

**Planning Carefully When Configuring Packet Filters**
Because you can configure both input and output filters for each interface, it is possible to create contradictory filters. For example, the input filter on one interface allows certain inbound traffic, but the output filter on another interface does not allow the same traffic to be sent. The result is that the traffic is not passed across the router or exchanged with a non-router computer on which these contradictory packet filters are configured.

When planning how to implement packet filters, ensure that the filters are not too restrictive. Excessively restrictive filters can impair the functionality of other protocols that might be operating on the computer. For example, if a computer that is running Windows Server 2003 is also running Internet Information Services (IIS) as a Web server and if packet filters are defined so that only Web-based traffic is allowed, you cannot use the **ping** tool to perform basic IP troubleshooting. Likewise, the Web server cannot communicate with a domain controller. If the Web server is a silent RIP host, the filters prevent the silent RIP process from receiving the RIP announcements.

Therefore, when troubleshooting connectivity or IP-based network problems on a computer running Windows Server 2003, begin by determining whether that computer is using IP packet filtering. If it is, verify whether packet filtering on that computer prevents outgoing or incoming packets for the protocol experiencing the problem.

**Windows Server 2003 IP Packet Filtering**
You can configure a computer running the Windows Server 2003 Routing and Remote Access service either to pass all traffic except that which is blocked by filters, or to discard all traffic except that which is allowed by filters. For example, you might want to configure a filter to allow all traffic except Telnet traffic (TCP port 23), or you might want to set up filters on a dedicated Web server to process only Web-based TCP traffic (TCP port 80).

**Routing and Remote Access Input and Output Filters**
The following table shows that input and output filters work in a similar manner, differing only in that they apply either to inbound or to outbound traffic.

### Similar Functionality of Input and Output Filters

| Function | Input Filters | Output Filters |
|---|---|---|
| Filtering by exception | Configured on an exception basis. You can configure the filter action to either allow all traffic except that which is specified, or to block all traffic except that which is specified. | Configured on an exception basis. You can configure the filter action to either transmit all traffic except that which is specified, or to drop all traffic except that which is specified. |
| Using multiple filters | When multiple filters are configured, the separate filters applied to the inbound packet are compared by using a logical OR operation. If the packet matches at least one of the configured filters, it is allowed or blocked depending on the filter action setting. | When multiple filters are configured, the separate filters applied to the outbound packet are compared by using a logical OR operation. If the packet matches at least one of the configured filters, it is transmitted or dropped depending on the filter action setting. |
| Troubleshooting | You can quickly and temporarily disable input packet filtering while preserving the list of configured packet filters. Do this by adding a filter that allows all traffic and set the input filter action to block all traffic except that which is specified. After troubleshooting, remove the all-traffic filter and reset the input filter action to its original value. | You can quickly and temporarily disable output packet filtering while preserving the list of configured packet filters. Do this by adding a filter that allows all traffic and set the output filter action to block all traffic except that which is specified. After troubleshooting, remove the all-traffic filter and reset the output filter action to its original value. |

**Filterable Fields in IP, TCP, UDP, and ICMP Headers**
Windows Server 2003 Routing and Remote Access can filter incoming and outgoing IP packets based on specified fields of the IP, TCP, UDP, and ICMP headers.

The Routing and Remote Access service does not support either of the following:

- Creating a filter on any protocols other than IP, TCP, UDP, and ICMP.
- Creating a filter based on *all* of the fields of the IP, TCP, UDP, or ICMP header. The Routing and Remote Access service does support creating a filter on specific fields of each of these headers.

For more information about the IP, TCP, UDP, and ICMP protocols, including the complete set of fields for each protocol's header, see *Microsoft Windows Server 2003 TCP/IP Protocols and Services Technical Reference* by Joseph Davies and Thomas Lee, 2003, Microsoft Press.

**IP Header**

The IP header has 13 fields, including source and destination IP addresses and a field that identifies the upper layer protocol (such as TCP, UDP, or ICMP) contained within the IP packet payload. Because the IP header contains the packet's source and destination addresses, the TCP, UDP, and ICMP headers do not need to contain these addresses.

To add or edit an IP packet filter, in the Routing and Remote Access snap-in select **Inbound Filters** or **Outbound Filters** on the **General** tab of the ***InterfaceName*Properties** page in the **IP Routing\General** container. You can define filters for the following IP header fields:

- **Source IP Address.** The IP address of the source network, which you can configure with a subnet mask to allow or block a single source or an entire range of IP addresses (corresponding to an IP subnet or a summarized route) to be specified with a single filter entry.

- **Destination IP Address.** The IP address of the destination network, which you can configure with a subnet mask to allow or block a single destination or an entire range of IP addresses (corresponding to an IP subnet or a summarized route) to be specified with a single filter entry.

- **Protocol.** An identifier used to indicate the upper layer protocol contained within the IP packet payload. For example, 6 indicates the TCP protocol, 17 indicates the UDP protocol, and 1 indicates the ICMP protocol.

**TCP Header**

TCP is one of two transport layer protocols within the TCP/IP protocol suite used for transporting data (the other is UDP). TCP, which supports only one-to-one communication between two hosts, guarantees delivery of data, and guarantees that packets are delivered in the same order in which they were sent. The TCP header has 11 fields, including fields for source and destination port.

If you select TCP as the protocol when adding or editing an IP packet filter, you can define filters for the following two TCP header fields:

- Source Port

- Destination Port

### Note

- Routing and Remote Access does not support the configuration of a range of TCP ports in one step. To configure a range of TCP ports, you must configure a separate filter for each port in the range.

**UDP Header**

UDP is one of two transport layer protocols within the TCP/IP protocol suite used for transporting data (the other is TCP). UDP is simpler than TCP, supports one-to-one and one-to-many communications, and, unlike TCP, sends packets without first negotiating a connection between the sending and receiving hosts, and provides only a few error recovery services. UDP thus supports a "best-effort" delivery in contrast to TCP's guaranteed delivery. The UDP header has 4 fields, including fields for source and destination port.

If you select UDP as the protocol when adding or editing an IP packet filter, you can define filters for the following two UDP fields:

- Source Port

- Destination Port

### Note

- Routing and Remote Access does not support the configuration of a range of UDP ports in one step. To configure a range of UDP ports, you must configure a separate filter for each port in the range.

**ICMP Header**

ICMP enables the generation of delivery error messages, diagnostic messages, and informational messages related to IP (such as the ICMP redirect message used to dynamically update the IP routing table).

If you select ICMP as the protocol when adding or editing an IP packet filter, you can define filters for the following two ICMP header fields:

- **Type.** Indicates the type of ICMP packet, such as an Echo or Echo Reply message.

- **Code.** Indicates one of the possible multiple functions within a specified type. If a type has only one function, the **Code** field is set to **0**.

The combination of ICMP Type and ICMP Code determines which ICMP message is sent. The following table lists commonly used ICMP types and codes.

**Common ICMP Types and Codes and Associated Messages**

| ICMP Type | ICMP Code | Use |
|---|---|---|
| 0 | 0 | Echo reply |
| 8 | 0 | Echo |
| 3 | 0 | Destination unreachable - Network unreachable |
| 3 | 1 | Destination unreachable - Host unreachable |
| 3 | 2 | Destination unreachable - Protocol unreachable |
| 3 | 3 | Destination unreachable - Port unreachable |
| 3 | 4 | Destination unreachable - Fragmentation needed and the **Don't Fragment** flag is set |
| 4 | 0 | Source quench |
| 5 | 1 | Redirect - Redirected datagrams for the host |
| 9 | 0 | Router Advertisement |
| 10 | 0 | Router Solicitation |
| 11 | 0 | Time exceeded - TTL expired in transit |
| 11 | 1 | Time exceeded - Fragmentation reassembly expiration |
| 12 | 0 | Parameter problem |

**Note**

- For a complete list of ICMP message types, see "ICMP TYPE NUMBERS" at the Internet Assigned Numbers Authority Web site.

**Routing and Remote Access Filters for IP Header Fields**

The following table shows the IP header fields for which it is possible to create a filter and the corresponding fields of the dialog boxes in the Routing and Remote Access snap-in in which the filter is created. These settings are configurable in the Windows Server 2003 Routing and Remote Access snap-in by selecting **Inbound Filters** or **Outbound Filters** on the **General** tab of the ***InterfaceName*Properties** page for an interface in the **IP Routing\General** container, and then selecting **New** or **Edit** to access the **Add IP Filter** dialog box or the **Edit IP Filter** dialog box, respectively. Typically, filters are configured in pairs, either {*Destination Network/Protocol*}, or {*Source Network/Protocol*}.

**IP Header Fields and Corresponding Routing and Remote Access Name**

| IP Header Field | Name in Routing and Remote Access Add IP Filter or Edit IP Filter Dialog Box |
|---|---|
| Source IP Address | Source Network |
| Destination IP Address | Destination Network |
| Protocol | Protocol |

**Filtering Scenarios**

This section illustrates filter configurations for commonly implemented filtering scenarios.

**Note**

- If you combine any sets of filters, ensure that the filters do not cancel each other out. Note that AND is used within a filter; OR is used between filters.

**Local Host Filtering**

Local host filtering configured on the Internet interface of an IP host permits the interface to receive only traffic that a non-router host can receive. This includes traffic to the unicast address of the host, broadcast addresses, and multicast addresses. This type of filtering allows the receipt of packets but disables the forwarding of packets on the interface on which local host filtering is enabled. Use local host filtering when an intranet is connected to the Internet and you do not want direct routing of packets between the intranet and the Internet.

Local host filtering on an interface effectively disables unicast routing on that interface because the only unicast traffic allowed through the interface is that which is destined specifically for that host. Transit unicast traffic is dropped. Local host filtering permits the interface to receive only the unicast traffic destined for this host, the broadcast traffic intended for all host's on the host's subnet, or multicast traffic.

As shown in the example in the following table, for the local host filtering scenario, five specific input filters are used on the Internet interface. In the example, the local host computer has the IP address 172.16.5.98 with the subnet mask of 255.255.255.0 (a subnet of the private IP network ID 172.16.0.0/12). The Internet interface is viewable in the Routing and Remote Access snap-in in the details pane of the **IP Routing\General** container. By adding the filters shown in the table on the **General** tab of the **Properties** page of the Internet interface, and then selecting the **Drop all packets except those that meet the criteria below** filter action, you can configure the computer to block all packets except those explicitly allowed by the configured filters. For the local host filters, the default protocol **Any** is used and no source network address is needed.

**Example: Five Input Filters for Local Host Filtering**

| Filter | Filter Characteristics |
|---|---|
| Host IP address input filter (allows packets unicast to this computer) | Destination network:<br>• IP address of this host: 172.16.5.98<br>• Subnet mask: 255.255.255.255<br><br>**Note:** An IP address for a particular computer in conjunction with a subnet mask of 255.255.255.255 represents a host route (a route to a specific IP address). |

| | |
|---|---|
| Subnet broadcast address input filter (allows packets broadcast to hosts on the local subnet) | Destination network:<br>• IP address of this host's subnet broadcast: 172.16.5.255<br>• Subnet mask: 255.255.255.255<br><br>**Note:** On a classless network (as is the case in this example), the IP subnet broadcast address is formed by setting all host bits to 1 (255 in decimal notation represents eight ones in binary notation).<br><br>Only a classless network has a subnet broadcast address; it does not have a network broadcast address. (In contrast, a classful network does not have a subnet broadcast address; it has only a network broadcast address.) |
| All-subnets-directed broadcast address input filter (allows packets broadcast to hosts on all subnets of a subnetted class-based network ID) | Destination network:<br>• IP address of this host's all-subnets-directed broadcast: 172.16.255.255<br>• Subnet mask: 255.255.255.255<br><br>**Note:** On a classless network (as is the case in this example), the all-subnets-directed broadcast address is formed by assuming that the network ID is the original classful network ID, and then setting all host bits to **1** (255 in decimal notation). If 172.16.5.98 were a class-based address, it would be a Class B address. Therefore, in the IP address, the last two octets are set to 255 for the all-subnets-directed broadcast address filter. |
| Limited broadcast address input filter (allows packets sent to the limited broadcast address) | Destination network:<br>• IP address of the limited broadcast: 255.255.255.255<br>• Subnet mask: 255.255.255.255<br><br>**Note:** The IP limited broadcast address is formed by setting all 32 bits in the IP address to 1 (255.255.255.255). All hosts, classful or classless, process packets addressed to the limited broadcast address, typically during an automated configuration process, such as the DHCP automated configuration process. |
| All possible multicast traffic input filter (allows all IP multicast packets) | Destination network:<br>• IP address for multicast traffic: 224.0.0.0<br>• Subnet mask: 240.0.0.0<br><br>**Note:** The address 224.0.0.0 with the subnet mask 240.0.0.0 is the entry in the routing table that informs IP to forward the multicast packet to the destination (in this example, to 172.16.5.98). |

**Web Traffic Filtering**

Web traffic filtering is configured on Web servers that run the Routing and Remote Access service in addition to Microsoft Internet Information Services (IIS). Web traffic filtering ensures that only Web-based traffic to and from IIS is processed to protect against malicious attacks on other services running on the Web server.

For a Web server connected to the Internet, enabling Web traffic filtering requires adding one input filter and one output filter on the Internet interface. The Internet interface is viewable in the Routing and Remote Access snap-in in the details pane of the **IP Routing\General** container. For example, if the default port of your Web server is port 80, you can add filters on the **General** tab of the **Properties** page of the Internet interface that block all packets (by using the **Drop all packets except those that meet the criteria below** filter action) except those allowed to and from the Web server by the filters described in the following table.

**Example: Input and Output Filters for Web Traffic Filtering**

| Filter | Filter Characteristics |
|---|---|
| Input filter (allows packets sent specifically to this Web server) | Destination network:<br>• IP address: *IP address of this Web server*<br>• Subnet mask: 255.255.255.255<br><br>Protocol: TCP<br>• Source port: *None*<br>• Destination port: 80 |
| Output filter (allows packets sent from this Web server) | Source network:<br>• IP address: *IP address of this Web server*<br>• Subnet mask: 255.255.255.255<br><br>Protocol: TCP<br>• Source port: 80<br>• Destination port: *None* |

If these filters are the only filters configured, the only traffic allowed through the interface is TCP traffic to and from IIS through TCP port 80 on the Windows Server 2003–based computer.

**FTP Traffic Filtering**

File Transfer Protocol (FTP) traffic filtering is done on hosts that run IIS with the FTP service enabled and run the Routing and Remote Access service. FTP traffic filtering ensures that only FTP-based traffic to and from FTP is processed to protect against malicious attacks on other services running on the FTP server.

For an FTP server connected to the Internet, enabling FTP traffic filtering requires adding two input filters and two output filters on the Internet interface. The Internet interface is viewable in the Routing and Remote Access snap-in in the details pane of the **IP Routing\General** container. For example, you can add filters on the **General** tab of the **Properties** page of the Internet interface that block all packets (by using the **Drop all packets except those that meet the criteria below** filter action) except those allowed to and from the FTP server by the filters described in the following table.

**Note**

- The example assumes that you are using the default ports of the FTP server, 20 and 21. If you use ports other than 20 and 21, substitute the appropriate ports for ports 20 and 21 in these filters.

**Example: Input and Output Filters for FTP Traffic Filtering**

| Filter | Filter Characteristics |
|---|---|

| | |
|---|---|
| Input filter (allows packets sent specifically to the FTP control port on this FTP server) | Destination network:<br>• IP address: *IP address of this FTP server*<br>• Subnet mask: 255.255.255.255<br><br>Protocol: TCP<br>• Source port: *None*<br>• Destination port: 21 (the FTP control port) |
| Input filter (allows packets sent specifically to the FTP data port on this FTP server) | Destination network:<br>• IP address: *IP address of this FTP server*<br>• Subnet mask: 255.255.255.255<br><br>Protocol: TCP<br>• Source port: *None*<br>• Destination port: 20 (the FTP data port) |
| Output filter (allows packets sent from the FTP control port on this FTP server) | Source network:<br>• IP address:. *IP address of this FTP server*<br>• Subnet mask: 255.255.255.255<br><br>Protocol: TCP<br>• Source port: 21 (the FTP control port)<br>• Destination port: *None* |
| Output filter (allows packets sent from the FTP data port on this FTP server) | Source network:<br>• IP address: *IP address of this FTP server*<br>• Subnet mask: 255.255.255.255<br><br>Protocol: TCP<br>• Source port: 20 (the FTP data port)<br>• Destination port: *None* |

If these filters are the only filters configured, the only traffic allowed through the interface is TCP traffic to and from FTP on the Windows Server 2003–based computer.

**PPTP Traffic Filtering**

Point-to-Point Tunneling Protocol (PPTP) traffic filtering on hosts that are acting as PPTP VPN servers ensures that only PPTP-based traffic to and from the PPTP VPN service on the host is processed. PPTP traffic filtering helps secure the PPTP VPN server

from malicious attacks on other services running on the PPTP VPN server. For a PPTP VPN server connected to the Internet, PPTP traffic filtering is configured on the Internet interface.

For information about IP packet filtering for PPTP traffic, see "How VPN Works" in VPN Technical Reference.

**L2TP/IPSec Traffic Filtering**
Layer Two Tunneling Protocol over IPSec (L2TP/IPSec) traffic filtering on hosts that are acting as L2TP/IPSec VPN servers ensures that only L2TP-based traffic to and from the L2TP/IPSec VPN service on the host is processed. L2TP traffic filtering helps secure the L2TP/IPSec VPN server from malicious attacks on other services running on the L2TP/IPSec VPN server. For an L2TP/IPSec VPN server connected to the Internet, L2TP traffic filtering is configured on the Internet interface.

For information about IP packet filtering for L2TP/IPSec traffic, see "How VPN Works" in VPN Technical Reference.

**Denying Spoofed Packets from Private IP Addresses**
One way to create denial-of-service attacks is to flood servers with packets, such as TCP connection request packets, from addresses to which there can be no reply. In these cases, the malicious users spoof, or substitute, the source IP address of the packets with something other than the IP address of the interface on which the packets originated. An easy address to spoof is a private address because a response sent to a private address on the Internet results in an ICMP Destination Unreachable-Host Unreachable message.

To drop Internet traffic from spoofed private IP addresses, you can use the Windows Server 2003 Routing and Remote Access snap-in to add three input filters on the Internet interface. The Internet interface is viewable in the Routing and Remote Access snap-in in the details pane of the **IP Routing\General** container. You can add filters on the **General** tab of the **Properties** page of the Internet interface that accept all packets (by using the **Receive all packets except those that meet the criteria below** filter action) except the following:

- A source IP address of 10.0.0.0 with a subnet mask 255.0.0.0.
- A source IP address of 172.16.0.0 with a subnet mask 255.240.0.0.
- A source IP address of 192.168.0.0 with a subnet mask 255.255.0.0.

**Filtering Fragmented IP Datagrams**
The Windows Server 2003 Routing and Remote Access service also supports the filtering of fragmented IP datagrams, which are datagrams that contain a fragment of an IP payload. Source hosts or routers fragment IP payloads so that the resulting IP datagram is small enough to be sent on the subnet of the next hop. The filtering of fragmented IP datagrams by the Routing and Remote Access service applies only to incoming traffic.

All interfaces are viewable in the Routing and Remote Access snap-in in the details pane of the **IP Routing\General** container. You can enable filtering of fragmented IP datagrams on the **General** tab on the properties of each interface by selecting **Enable fragmentation checking**. This setting specifies that the router discard all fragmented IP packets that do not correspond with traffic allowed by the filters (if any) configured for this interface. To prevent the router from forwarding all fragmented IP packets for transit traffic on any interface, enable fragmentation checking on all interfaces of the router. This setting does not prevent the forwarding of fragmented packets sent from the router.

You can use filtering of fragmented IP datagrams to prevent the "ping of death," which is a denial-of-service attack where malicious users send multiple 64-KB ICMP Echo messages. The 64-KB messages are fragmented and must be reassembled at the destination host. For each separate 64-KB message, the TCP/IP protocol must allocate memory, tables, timers, and other resources. If a server, including a Windows Server 2003–based computer, receives a substantial number of fragmented messages, it can become overloaded, with the result that the servicing of valid information requests is impaired. Enabling the filtering of fragmented IP datagrams causes incoming fragmented IP datagrams to be discarded immediately.

**How ICMP Router Discovery Works**
Windows Server 2003 TCP/IP and the Windows Server 2003 Routing and Remote Access service include support for the router advertisement and discovery capability that is documented in RFC 1256. ICMP itself is described in RFC 792. Enabling router discovery, an alternative to using manually or DHCP-configured default gateways, provides an improved method of configuring and detecting the default gateway. For IP nodes, the default gateway is the IP router (on the same subnet) that forwards traffic for the node to destinations not located on the local subnet.

### Note

- In IPv6, the Neighbor Discovery protocol replaces the IPv4 features ICMP Router Discovery, ARP, and ICMP Redirect. For information about IPv6, see "How IPv6 Works" in IPv6 Technical Reference.

ICMP Router Solicitation messages and Router Advertisement messages simplify how IP hosts are configured with the IP addresses of local routers and provide a way for hosts to determine whether routers are available. If enabled on both router and host, ICMP router discovery automates the discovery and configuration of the default gateway on the client. Client computers can dynamically discover the best default gateway to use on a subnet and can automatically switch to another default gateway if the first default gateway fails or if the network administrator changes router preferences.

ICMP router discovery governs the interaction between a host and a router in the following way:

- A router periodically sends a Router Advertisement message to all hosts on the subnet to notify them that the router is available. A router also sends a Router Advertisement message in response to a Router Solicitation message sent by a host.

- A host listens for Router Advertisement messages from routers. A host also sends a Router Solicitation message to discover active routers on its subnet and to discover whether known routers are currently unavailable.

On a computer running Windows Server 2003, ICMP Router Advertisement messages are disabled by default. TCP/IP for Windows Server 2003, Windows 2000, and Windows 98 supports ICMP Router Solicitation messages to discover the default gateway as well as the receipt of ICMP Router Advertisements; this capability is also disabled by default.

**Router Advertisements Sent by Routers**
Router Advertisements are explicit notifications sent by IP routers to IP hosts on the subnet that the router is available. A router sends out a pseudo-periodic Router Advertisement by using an ICMP message (Type 9, Code 0). The Router Advertisement message can be sent to the all-systems IP multicast address of 224.0.0.1, to the local IP broadcast address, or to the limited broadcast address (255.255.255.255). By default, a router sends a Router Advertisement to the all-systems IP multicast address.

**Router Solicitations Sent by Hosts**
When an IP host that supports ICMP router discovery needs to be configured with a default gateway (either upon initialization or because its default gateway is unavailable), the host sends out a Router Solicitation message by using an ICMP message (Type 10, Code 0). The Router Solicitation message can be sent to the all-routers IP multicast address of 224.0.0.2, to the local IP broadcast address, or to the limited broadcast address (255.255.255.255). By default, hosts send Router Solicitation messages to the all-routers IP multicast address when an interface initializes. Routers on the host's subnet that support ICMP router discovery immediately respond with a Router Advertisement message, and the host chooses the router for which an administrator has configured the highest preference level as its default gateway. A host sends a maximum of three solicitations at intervals of approximately 600 milliseconds.

### Note

- ICMP router discovery is not a routing protocol. Routers advertise only their existence; they do not advertise the best way to reach a specific destination subnet. If a host uses a non-optimal route, an ICMP Redirect message redirects the host to the preferred route.

**ICMP Router Discovery Settings**
Settings for ICMP router discovery for a router are configurable in the Windows Server 2003 Routing and Remote Access snap-in on the **General** tab of the properties for an interface in the **IP Routing\General** container. If you select the **Enable router discovery advertisements** option on the **General** tab, you can configure the time interval after which a router is considered down, the level of preference for this router to act as a default gateway for hosts, and the maximum and minimum rate at which the router periodically sends ICMP router advertisements.

On a client computer running Windows XP Professional, you can use the **netsh routing ip routerdiscoveryadd interface** command to configure router discovery for the specified interface from a command prompt. On a client computer running Windows 2000 Professional, you can enable router discovery by using the Registry Editor to configure the **PerformRouterDiscovery** and **SolicitationAddressBcast** registry entries.

**IPv4 and Routing and Remote Access APIs**
Microsoft platform software development kits (SDKs) provide application programming interfaces (APIs) useful for third-party developers who create software that interacts with Windows operating systems. The following are important APIs for developers working in a unicast IPv4 routing environment that includes Windows Server 2003.

**Internet Protocol Helper (IP Helper) API**
This API assists network administration of the local computer by enabling applications to retrieve information about network configuration settings of the local computer and to modify that configuration. In addition, IP Helper notification mechanisms ensure that an application is informed when specific aspects of the local computer network configuration change. The IP Helper

API is applicable in any computing environment where programmatically manipulating TCP/IP configuration is useful. Typical usage includes retrieving information about network configuration, managing network adapters, managing interfaces, managing IP addresses, using the address resolution protocol (ARP), retrieving information about IP and ICMP, managing routing, receiving notification of network events, and retrieving information about TCP and UDP. In Windows Server 2003, IP Helper has been extended to allow the retrieval of information for IPv6 and its components. For more information about the IP Helper API, see "Microsoft Platform SDK IP Helper."

**Routing and Remote Access Service API**
This API makes the Routing and Remote Access service extensible. Third-party routing protocol developers can write additional routing protocols that interact with the routing table manager of the Routing and Remote Access service. Third-party software vendors can also create applications to administer the routing and remote access capabilities of Windows Server 2003 (as well as Windows 2000 Server). For example, to augment the built-in support for RIP and OSPF, a third-party vendor can develop support for Border Gateway Protocol (BGP) for IP that works with the Routing and Remote Access service. For more information, see "Microsoft Platform SDK Routing and Remote Access Service."

**Windows Sockets 2 (Winsock2) API**
This API enables programmers to create advanced Internet, intranet, and other network-capable applications to transmit application data across the wire, independent of the network protocol being used. In Windows Server 2003, new Windows Sockets programming elements extend the capability of Winsock to simplify programming and to provide IPv6 compatibility. For more information about the Windows Sockets API, see "Microsoft Platform SDK Windows Sockets 2."

For comprehensive information about APIs supported by Microsoft Windows, including Windows Server 2003; Windows XP; Windows Advanced Server Limited Edition; Windows Millennium Edition; Windows 2000; Windows NT versions 4.0 and 3.51; Windows 98 and Windows 95; as well as Microsoft Internet Explorer, see "Microsoft Platform SDK Windows API."

To install the SDK for Windows Server 2003, see "Microsoft Platform SDK," and then click "Windows SDK" in the left column.

# How Unicast IPv4 Routing Works

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Unicast IPv4 Routing Internetwork Structure
- How Host Routing and Router Routing Work
- How IPv4 Addressing and IPv4 Routing Interact
- How the IPv4 Routing Table Works
- How Static and Dynamic Routing Work
- Related Information

Internet Protocol version 4 (IPv4) is a routable network protocol that enables the routing of network traffic across any type of IPv4 internetwork, including Windows or UNIX internetworks or mixed network environments. A part of the Transmission Control Protocol/Internet Protocol (TCP/IP) protocol suite, IPv4 is used by Windows Server 2003 to route unicast, multicast, and broadcast traffic between computers or other network devices on private intranets and across the public Internet. IPv4 is frequently referred to as IP, and that convention is used in this document.

| **Note** |
| --- |
| Windows Server 2003 also supports Internet Protocol version 6 (IPv6). For information about IPv6, including static routing in an IPv6 environment, see "How IPv6 Works" in the IPv6 Technical Reference. |

Unicast IP routing is the process of transferring data in the form of unicast IP packets across an IP internetwork from a single source node (a computer or other network device) to a single destination node. An IP router is a node that forwards IP packets between interfaces (which can be physical network adapters or logical interfaces such as tunnels) based on information that it stores in a database called a routing table. On IP internetworks, routers configured with dynamic routing protocols can exchange information with each other automatically in order to keep routing table information up-to-date. Dynamic routing contrasts with static routing, in which an administrator must manually configure routing information.

Familiarity with the protocol-independent unicast IPv4 routing principles described here provides a foundation for the in-depth discussion of dynamic routing protocols and other routing-related services provided by the Windows Server 2003 Routing and Remote Access service. For more information about Routing and Remote Access components used for unicast IPv4 routing, see How Unicast IPv4 Routing Protocols and Services Work.

**Unicast IPv4 Routing Internetwork Structure**

In unicast routing, data is transferred across an internetwork from a source node to a destination node. Routers, which connect different networks on the internetwork, accept a packet sent from one network to another and forward the packet toward its destination. This traffic requires the following types of protocols:

- **Routable protocol.** A routable protocol, such as IP or Internetwork Packet Exchange (IPX), is a network protocol that a router uses to forward packets toward their destination across the internetwork. IP, which uses network layer addresses to forward packets, is the routable protocol for an IP internetwork.

- **Dynamic routing protocol.** A dynamic routing protocol is used by routers to exchange routing information with each other dynamically. The exchange process allows routers to determine the most efficient route over which to forward a packet. The most common dynamic routing protocols used by IP are Routing Information Protocol for IP (RIP for IP) and Open Shortest Path First (OSPF).

In addition to routable and routing protocols, unicast IP routing requires the routing components and structures described in this section:

- Unicast IPv4 routing internetwork components
- IPv4 routing infrastructure

**Unicast IPv4 Routing Internetwork Components**

The following figure depicts a simple IP internetwork in which unicast IP routing takes place.

The following table describes each of the routing components, as defined by the International Organization for Standardization (ISO), depicted in the figure.

**Components of a Simple IP Internetwork**

| Internetwork Component | Description |
|---|---|
| End system | A network device that cannot forward IP packets. End systems are also known as *hosts*. A computer that is not acting as a router is an example of an end system. (Collectively, hosts and routers are known as *nodes*.) |
| Intermediate system | A network device that can forward IP packets that are not addressed to it. Bridges, switches, and routers are examples of intermediate systems. |
| Router | An intermediate system used to connect network segments (subnets) based on a common network layer protocol, such as IP. In the preceding figure, the intermediate system depicted is a router. Routers include:<br>• **Hardware routers.** A device that performs routing as a dedicated function and that is specifically designed and optimized for routing. For example, hardware routers made by Cisco Systems, Inc., are widely deployed in IP internetworks.<br>• **Software routers.** A computer that performs routing as one of multiple processes running on the computer. For example, a computer running Windows Server 2003 with the Routing and Remote Access service enabled is a software router.<br>A router can be configured to perform only static routing, only dynamic routing, or, more typically, primarily dynamic routing supplemented by some manually configured static routes. |
| Network | A portion of the networking infrastructure (encompassing repeaters, hubs, bridges, or Layer 2 switches) that is bounded by an intermediate system and whose computers and other network devices share a common network address called a network ID. Also referred to as a *network segment* or a *subnet*. |
| Internetwork | Two or more networks (subnets) connected by routers. In the preceding figure, all of the depicted components combined constitute an internetwork. |

When a node on an IP network sends a unicast IP packet to a node on another network, it typically first forwards the packet to a router. The router examines the packet and uses the destination internetwork address (defined in the following table) in the packet header to determine which of the router's interfaces to use to forward the packet towards its destination. The following table lists the generic internetworking term and the corresponding IP term used for each part of an internetwork address.

**Parts of IPv4 Unicast Internetwork Addresses**

| Generic Internetwork Address Term | IP Internetwork Address Term | Description |
|---|---|---|

| | | |
|---|---|---|
| Internetwork address<br><br>(Network address + host address) | IP address<br><br>(Network ID + host ID) | In IPv4, a 32-bit logical address for a node on an IPv4 network. By combining the network address portion and the host address portion, a unicast IPv4 address uniquely identifies a node on an internetwork.<br><br>Hosts and routers use IPv4 addresses to route packets over an IPv4 network. Unicast IPv4 addresses enable a packet to be sent from a single source node to a single destination node. |
| Network address | Network ID | In IPv4, the portion of an IP address that identifies a single network segment (also known as a subnet) bounded by routers on an IP internetwork. All systems on the same subnet share the same network ID. |
| Host address | Host ID or node ID | In IPv4, the portion of an IP address that uniquely identifies an individual node on an IP subnet. |

The network layer header of any IPv4 packet sent from a source node to a destination node on an IPv4 internetwork includes the following:

- A source IPv4 address, which contains a source network ID and a source host ID.
- A destination IPv4 address, which contains a destination network ID and a destination host ID.
- A Time-To-Live (TTL) value, which is used to prevent the packet from endlessly circulating on the internetwork. The TTL starts at a maximum value and decreases by one for each link crossed; if zero is reached, the packet is discarded and a message is returned to the sending node from which the packet originated.

| **Note** |
|---|
| The TTL link count (the number of Network Interface Layer links crossed to reach a given destination) is not the same as the hop count (the number of routers crossed to reach a specific destination). The link count, which equals the number of network segments, is the hop count plus one. For example, if two nodes are separated by five routers, the hop count is 5 but the TTL link count is 6. |

The following resources provide additional information about the structure of unicast IP routing components on an IPv4 internetwork:

- For an architectural diagram showing where IP fits within the TCP/IP protocol suite, see "TCP/IP Protocol Architecture" in "How TCP/IP Works" in TCP/IP Technical Reference.
- For information about the architecture of unicast IPv4 routing specific to the Windows Server 2003 Routing and Remote Access service, see "Unicast IP Routing Architecture in Windows Server 2003" in How Unicast IPv4 Routing Protocols and Services Work.
- For information about the architecture of the NAT unicast routing protocol component of the Windows Server 2003 Routing and Remote Access service, see "How NAT Works" in NAT Technical Reference.

**IPv4 Routing Infrastructure**

The routing infrastructure refers to the entire structure of a routed internetwork over which routing takes place. A routed internetwork is designed to route packets between its individual networks either over one path or over one of multiple paths; its structure is either flat or built into a network, subnet, and sub-subnet hierarchy; and it either groups networks under one administrative authority (autonomous system) that shares a common routing protocol, or it is divided into multiple areas within one autonomous system.

This section briefly summarizes the following background information for understanding unicast IPv4 routing on the IPv4 internetwork:

- Single-path vs. multipath routing infrastructures
- Flat vs. hierarchical routing infrastructures
- Autonomous systems

A detailed discussion of these structural issues is not included in this technical reference. However, familiarity with these topics is important in understanding how unicast IP routing is implemented in a Windows internetwork and in considering which dynamic routing protocols and other routing-related services to deploy on your IP internetwork.

**Single-Path vs. Multipath Routing Infrastructures**

A single-path routing infrastructure is one in which a unicast IP packet can take only a single route between any source node and any destination node. Although single-path routing simplifies routing tables and packet flow paths, single-path internetworks are not fault tolerant. On an internetwork in which all routing information is manually configured, a router cannot detect a failure, and if a failure occurs, networks beyond the failure are unreachable until the failure is resolved. By contrast, a router running a dynamic routing protocol can detect a failure, but, because only a single path exists, networks beyond the failure are also unreachable for a dynamic router for the duration of the failure. A downed link or router must be brought back up before packets can again be delivered successfully to all locations on the internetwork. Single-path routing is thus not feasible for a large internetwork that depends on consistent network availability.

By contrast, a multipath routing infrastructure is one in which a unicast IP packet can take one of several paths between any source node and any destination node. A multipath IP internetwork that uses dynamic routers is fault tolerant because more than one path exists, which means that routers can not only detect a failure but can also route packets to networks beyond the downed link or router by using an alternative path.

Typically, multipath internetworks provide more reliable network availability than single-path internetworks but are more complex to configure. In addition, although multipath networks that use distance vector–based routing protocols provide better availability than single-path networks, they can experience routing loops if configuration errors occur or during convergence (the process by which routers update routing tables after a change in network topology and reestablish a stable state). A multipath network that uses a link state routing protocol, such as OSPF, provides more efficient convergence and thus better stability than a distance vector routing protocol, such as RIP, but requires more effort to plan and deploy.

For more information about static and dynamic routing, see How Static and Dynamic Routing Work later in this document.

**Flat vs. Hierarchical Routing Infrastructures**

An internetwork that uses a flat routing infrastructure consists of multiple network segments connected to each other without a parent-child structure. All routers are peers, and each network segment is stored as a separate route in the routing table. The network IDs have no network or subnet structure and routes cannot be summarized, which means it is not possible to group a set of network segments as a single entry in the routing table. Therefore, although flat routing can work well for small- or medium-sized IP internetworks, it is not well-suited to large internetworks because it requires that its routers store an ever-increasing number of routes in their routing tables.

By contrast, an IP internetwork that uses a hierarchical routing infrastructure consists of multiple network segments sharing the same network ID prefix grouped into a hierarchy that consists of a network, subnet, and sub-subnet structure. Each group of network segments in the hierarchy can be represented as a single network ID through route summarization and can therefore be represented in the IP routing table as a single route. The routing table entry for the highest level (the network) is also the route used for regions of the network and for individual subnets.

In a hierarchical routing infrastructure, a collection of contiguous networks connected by routers that share routing information is referred to as a routing region (also known as a *routing domain* or *routing area*). One part of the internetwork that is divided into routing regions can be connected by a common routing region, called a *backbone*, to another part of the internetwork that is also divided into routing regions. Routers within each routing region perform intradomain routing. Routers connected to the backbone perform interdomain routing. Only a relatively few routes are required on the backbone of a well-planned hierarchical internetwork.

Some IP internetworks use both flat and hierarchical routing. For example, the Internet, originally designed as a flat routing infrastructure until the Internet community helped pioneer the introduction of classless addressing and summarized routing, now incorporates both flat and hierarchical routing. One of the factors that results in the storing of large numbers of routes in the routing tables of Internet backbone routers is the continued inclusion of flat routing within the Internet. These large Internet backbone routing tables impede the speed at which Internet traffic can be forwarded and is one of several factors driving the development of IPv6. The hierarchical routing infrastructure and new address types provided by IPv6 are designed to require relatively few routing entries in the routing tables of Internet backbone routers.

For more information about route summarization on a hierarchical IPv4 internetwork, see "CIDR Blocks and Hierarchical Routing Enabled by Route Summarization" in How IP Addressing and IP Routing Interact later in this document.

**Autonomous Systems**

Very large IP internetworks are divided into separate entities called autonomous systems. An autonomous system (AS) is a portion of the internetwork — either a single network or a collection of networks — under a common administrative authority,

such as an enterprise, a business division, or other organization, that shares a common routing protocol. The autonomous system is described in RFC 1930, "Guidelines for creation, selection, and registration of an Autonomous System (AS)" in the IETF RFC Database.

An autonomous system is sometimes said to be defined by the use of the shared routing protocol that it uses. For example, a contiguous portion of an IP internetwork that uses OSPF to exchange routing information among a group of routers is under OSPF administrative authority and is, therefore, an OSPF autonomous system.

In a large organization, one autonomous system might be subdivided into multiple routing regions (routing domains or areas) that define a hierarchy within that autonomous system. Regions within an autonomous system can use summarized routes for traffic between the regions to decrease the number of routes exchanged and stored in routing tables.

**Types of autonomous system**

The three types of autonomous system are:

- **Stub AS.** An autonomous system that is connected to only one other autonomous system. Any data sent to, or received from, a destination outside the autonomous system must travel over that connection. A network that is connected to only one other autonomous system has the same identifying number (autonomous system number, described in the next subsection) as the autonomous system to which it is connected. A small campus network is an example of a stub autonomous system.

- **Transit AS.** An autonomous system that is connected to two or more other autonomous systems and that allows traffic between other autonomous systems (that is not destined for a node within that autonomous system) to cross through it. The network of an ISP is an example of a transit autonomous system.

- **Multihomed AS.** An autonomous system that is connected to two or more other autonomous systems but does not allow transit traffic between other autonomous systems to cross through it. A multihomed autonomous system differs from a stub autonomous system in that the entrance and exit points for data traveling to or from the autonomous system can vary depending on which connection offers the shortest route to the destination. An example of a multihomed autonomous system is a corporate network that uses two or more Internet connections to different ISPs.

The terms stub AS and transit AS are not to be confused with the OSPF stub area or OSPF transit area (described in "How OSPF Works" in How Unicast IPv4 Routing Protocols and Services Work) because the former refer to types of autonomous system whereas the latter refer to types areas within an OSPF autonomous system.

Many enterprise IP networks and most ISPs consist of one autonomous system. Only very large internetworks, such as the Internet, are divided into multiple autonomous systems.

**Autonomous system numbers**

In most cases, an autonomous system is assigned a globally unique 16-bit number called an autonomous system number (ASN). Autonomous systems use ASNs to identify themselves to each other so that they can exchange routing information. ASNs, which are required for autonomous systems connected to the Internet, are obtained from Internet numbers registries, such as:

- **American Registry for Internet Numbers (ARIN)**, for the Americas, Caribbean, and sub-Saharan Africa regions.

- **Asian-Pacific Network Information Center (APNIC)**, for the Asia Pacific region.

- **Réseaux IP Européens (RIPE)**, for the Europe, Middle East, and northern Africa regions.

In nearly all cases, unless an organization is multihomed to more than one ISP or its routing policy is different from that of its ISP, it does not need its own ASN because it can use the ISP's ASN.

For information about routing protocols used by autonomous systems, see "Routing Protocols Used Between and Within Autonomous Systems" in the section How Static and Dynamic Routing Work later in this document.

**How Host Routing and Router Routing Work**

A route is the path that a packet travels across an internetwork from a sending node to a destination node. Routing, which takes place on a packet-by-packet basis, is the process of determining the best route to use to forward a packet as it crosses the internetwork. On an IP internetwork, the routing of a packet across the IP internetwork is based on the packet's destination IP address.

Routing can be either host routing or router routing:

- **Host routing.** The sending host forwards a packet. Based on the destination network ID, the sending host determines whether to forward the packet to a destination host on its subnet or forward the packet to a router for further action.

- **Router routing.** A router receives a packet (from a sending host or another router) that is not addressed to the router and that must be forwarded from one network to another, which it then sends it on its way. The packet is forwarded between routers (when the destination network is not directly attached to the router) or between the router and the destination host (when the destination network is directly attached to the router).

In the following figure, the source host forwards to Router 1 a packet destined for the destination host on a different subnet. In this example, the initial step in the routing process — from the source host to Router 1 — is host routing. Router 1 then forwards the packet to Router 2, which in turn forwards the packet to the destination host. In this example, this second step in the routing process — from Router 1 to Router 2 to the destination host — is router routing.

The following subsections describe how host routing and router routing work on an IP internetwork.

**Host Routing**

When an IP host sends data to another host on an IP internetwork, the sending host might first obtain the IP address of the destination host by referencing the logical name of the destination host. Hosts on an IP internetwork typically use Domain Name System (DNS) name resolution to resolve a DNS domain name to an IP address.

In host routing, as depicted in the following figure, two types of delivery are possible: direct and indirect delivery.

- **Direct delivery in host routing.** After obtaining the destination IP address, the source host determines whether the destination is on the locally attached network segment. When the source and destination hosts are on the same network segment, the source host sends a packet directly to the destination host and does not use a router (labeled "Direct Delivery" in the above figure). In this case, the destination host is called a *local host* or *neighboring host*. The source host uses Address Resolution Protocol (ARP) to obtain the destination link-layer address (typically, the Ethernet media access control, or MAC, address) to which it sends the packet. In a direct delivery, the destination IP address and the destination link-layer address refer to the same node.

- **Indirect delivery in host routing.** When the destination host is not on the locally attached network segment, the source host cannot deliver a packet directly to the destination. In this case, the destination host is called a *remote host*. Therefore, the source delivers the packet to an intermediate router by using ARP to obtain the MAC address of the near-side interface of the router, and then sends the packet to that interface, as shown in the preceding figure. In an indirect delivery, the destination IP address and the destination MAC address refer to different nodes.

During an indirect delivery, the source host forwards the packet to a router on its network segment by determining the router corresponding to the first hop. If multiple routers exist in the path between the source host and the destination host on the internetwork, as the packet is forwarded from router to router, the packet's network layer destination address (IP address) remains the same, but its MAC address keeps changing to that of the next router along the path.

**Host Determination of the First Hop**

An IP source host determines the next-hop IP address of a neighboring router by using one of the following methods:

**IP address currently in the host routing table**

A routing table on the host provides the IP address of a router that can forward the packet towards its destination. For more information about routing tables, see How the IPv4 Routing Table Works later in this document.

### ICMP dynamic updates of the host routing table

If a sending host forwards a packet to a neighboring router but another neighboring router is closer to the destination, the router that initially receives the packet can send an ICMP Redirect message to the sending host, informing it of the better router to use as the next-hop for the destination. When the sending host receives the Redirect message, it adds a host route for the destination to the local routing table. TCP/IP for Windows Server 2003 supports the dynamic update of the IP routing table based on the receipt of ICMP Redirect messages.

### Default route

A default route, which summarizes destinations that are not located on the local subnet, is the route on which IP packets are sent when no other route to the destination network is found in the routing table. To simplify the configuration of IP nodes and to reduce the overhead that exists if each host stored routes for all network IDs on the internetwork, a source host is configured with a single default route. In IPv4, the default route is {Network ID: 0.0.0.0, Subnet Mask: 0.0.0.0}, also expressed as 0.0.0.0/0. For more information about the default route, see How the IPv4 Routing Table Works later in this document.

### Eavesdropping

IP hosts can listen to routing protocol traffic if the capability known as *eavesdropping* or *wiretapping* is enabled. Eavesdropping hosts maintain the same routing information as do routers. An example of eavesdropping is silent RIP, which is the ability of an IP host to listen to RIP routing traffic exchanged by RIP routers and to update the routing table on the host. A computer that uses silent RIP processes RIP announcements but does not announce its own routes. You can use silent RIP on a non-router host (such as a workstation or a server running Routing and Remote Access that has only one interface and is therefore not a router) to produce a routing table that contains as much detail as the routing table on a RIP router. By including detailed routes in its routing table, a silent RIP host can perform routing more efficiently.

For example, you can configure computers running Windows XP as silent RIP hosts in an environment that includes RIP routers by installing the RIP Listener networking component. Instead of a user or administrator manually adding routes to the routing table, the computer learns other routes on the network by listening to RIP messages and then adds advertised routes in those messages to its routing table. You do not need to configure a silent RIP host with a default gateway (IP address of a directly reachable IP router).

The eavesdropping provided by silent RIP can be useful in some remote access environments, such as when a remote access computer connects to a corporate network over a dial-up connection. The additional routes added by RIP Listener can improve network access and performance over the dial-up connection by reducing the number of packets that are sent to the incorrect router. Windows Server 2003, Microsoft® Windows® XP, Windows® 2000, Microsoft Windows NT® Workstation version 4.0 Service Pack 4 (SP4) and later, and Windows NT Server version 3.51 Service Pack 2 (SP2) and later support Silent RIP.

#### Host Determination of the Entire Path: Source Routing

Some routable protocols, including IP, can enable the source host to do more than simply determine the first hop. In this scenario, IP enables the source host to determine the path between the source host and the destination, and then includes the list of routers in the network layer header of the packet. The network layer header is used by each router to forward the packet along the indicated path. This process is known generically as *source routing*.

Source routing is *not* typically implemented on IP internetworks because in source routing the path must be known. Typically, instead of using source routing, IP routing decisions are made by source hosts and IP routers based on their respective local routing tables. However, in network testing and debugging situations, you might sometimes want to specify an exact route that overrides the route as determined by routing tables as the packet travels towards its destination. Specifying an exact route through the IP internetwork is known as *IP source routing*.

In IP source routing, the source host specifies the entire route through successive IP routers between the source and destination. Each IP router addresses the IP packet to the next router by using the **Destination IP Address** field in the IP header.

IP supports two types of source routing:

- **Loose source routing.** The IP address of the next router can be one or more routers away (multiple hops).
- **Strict source routing.** The next router must be a neighboring router (single hop).

**Note**

Token Ring source routing is a MAC–sublayer routing scheme; it is not related to the internetwork-based source routing discussed here.

**Router Routing**

When a router receives a packet, the router must either deliver the packet to the destination host or to another router. As in host routing, router routing has two types of delivery, direct and indirect, as depicted in the following figure.

- **Direct delivery in router routing**. If a router is directly attached to the destination network, it forwards the packet to the local destination host by addressing the packet to the link-layer address of the destination host. The router thus performs a direct delivery to the destination.

- **Indirect delivery in router routing**. If a router is not directly attached to the network destination, it forwards the packet to an intermediate router. The first router chooses the intermediate router based on the next-hop address of the closest matching route in the routing table. The router forwards the packet by addressing the packet to the link-layer address of the intermediate router. The router thus performs an indirect delivery to the next router in the path to the destination.

**How IPv4 Addressing and IPv4 Routing Interact**

Although an IPv4 routing infrastructure can use either class-based or classless routing, the development of classless routing protocols has made classful routing obsolete for medium-sized or enterprise networks. When routing protocols are referred to as classful or classless, these designations refer to routing protocols that can handle classful or classless unicast addressing as follows:

- **Classful addressing.** Classful routing protocols recognize only classful addresses — that is, the standard IPv4 unicast address classes. Classful routing protocols determine the network ID based on the IP address class alone, do not advertise a subnet mask when advertising routes, and therefore cannot recognize a summarized route (a single route that represents a range of network IDs) in routing advertisements. Routing for multiple subnets created from one network ID is possible when classful routing protocols are used, but all subnets of a class-based network ID are of equal size and must be contiguous or else routing errors can occur. RIP version 1 (RIP v1) is an example of a classful routing protocol.

- **Classless addressing.** Classless routing protocols recognize classless addresses — that is, IPv4 unicast addresses used for variable-length subnetting or route summarization as well as IP addresses defined as standard classful IPv4 unicast addresses. Classless routing protocols include the subnet mask along with the IP address when advertising routing information and can therefore recognize and announce subnets of varying sizes as well as summary routes (each of which groups several subnets as a single entry in a routing table). Classless routing protocols let you create noncontiguous subnets from the same network ID; routers can correctly recognize these noncontiguous subnets. RIP version 2 (RIP v2), OSPF, and Border Gateway Protocol version 4 (BGP v4) are examples of classless routing protocols.

Understanding IPv4 unicast addressing is essential to understanding unicast IP routing because IP routing uses unicast IP addresses to direct packets to their destination. Medium-sized and large organizations today typically implement classless routing solutions, thus taking advantage of the flexibility that classless addressing enables. The largest IP internetwork in the world, the Internet, supports classless routing, although it was designed originally as a class-based routing infrastructure.

**Note**

The summary of IPv4 unicast addressing described in the following sections is provided as a basis for understanding the role that addressing plays in routing.

For a more complete discussion of IPv4 addressing, including unicast, multicast, and broadcast addressing, as well as an in-depth discussion of addressing, subnetting, and route summarization, see "Microsoft Windows Server 2003 TCP/IP Protocols and Services Technical Reference" by Joseph Davies and Thomas Lee, 2003, Microsoft Press.

This section describes:

- How classful addressing limits classful routing
- How classless addressing enables classless routing

**How Classful Addressing Limits Classful Routing**

Although the development of classless IP addressing has made classful IP addressing obsolete for enterprise networks, configuring classless IP addresses requires knowledge of the classful IP addressing structure out of which classless addressing later developed.

The only flexibility that classful addressing offers is the configuration of fixed-size subnets. Because classful routing protocols, such as RIP v1, recognize only the original standard IP address classes and do not include the subnet mask in routing advertisements, neither variable-length subnetting nor route summarization are possible.

This section includes:

- Classful addressing summary
- Classful subnetting enables only fixed-size subnets

**Classful Addressing Summary**

Of the five standard address classes, Class A, B, and C addresses, collectively known as IPv4 unicast addresses, are assigned to specific devices on an IPv4 network. Class D addresses, known as multicast addresses, are used for IP multicasting, simultaneously sending a message from one source to more than one network destination (for more information about multicasting, see IPv4 Multicasting Technical Reference). Class E addresses are reserved for experimental purposes.

To be able to configure fixed-size subnetting on your network (as well as variable length subnetting or route summarization, described later), you must first understand the default formats of the unicast IPv4 addresses. All 32-bit IPv4 addresses contain four 8-bit bytes called *octets* separated for readability by spaces (in binary notation) or represented as four decimal numbers separated by dots (in dotted decimal notation). If all or some of the actual numbers are not known, all or part of the IP address in dotted decimal notation is typically represented by *w.x.y.z*. The following table shows a single IP address in both decimal and binary notation.

**IP Address in Decimal and Binary Notation**

| IP Address in Decimal Notation | IP Address in Binary Notation |
|---|---|
| 131.107.65.37 | 10000011 01101011 01000001 00100101 |

**Network ID bits and host ID bits**

Like an IP address, a network ID in an IP internetwork is typically expressed in dotted decimal or binary notation. It is important to recall, however, that a network ID is not an IP address. A network ID is the leftmost portion of an IP address and identifies the set of nodes that are located on the same subnet — the network ID is the network address shared by all network interfaces on one subnet. An IP address, made up of the network ID portion and the host ID portion combined, is the unique address assigned to one network interface on a node.

Classful unicast IPv4 addresses have the following formats:

- **Class A.** The first byte, or octet, represents the network ID, and the three remaining bytes are used for the host ID.
- **Class B.** The first 2 bytes represent the network ID, and the last 2 bytes are used for the host ID.
- **Class C.** The first 3 bytes are used for the network ID, and the final byte is used for the host ID.

**Unicast IPv4 address ranges**

The following table shows the address ranges and the number of possible networks and hosts for each type of IPv4 unicast address class. Keep in mind that a network ID is not an IP address, even though both are expressed by using dotted decimal notation.

**Classful Unicast IPv4 Address Classes**

| Class | Leading Bit Pattern | First Network ID in Range | Last Network ID in Range | Available Networks | Hosts per Network |
|---|---|---|---|---|---|
| A | 0 | 1.0.0.0 | 126.0.0.0 | 126 | 16,777,214 |
| B | 10 | 128.0.0.0 | 191.255.0.0 | 16,384 | 65,534 |
| C | 110 | 192.0.0.0 | 223.255.255.0 | 2,097,152 | 254 |

| Note |
|---|
| The network ID 127.0.0.0 is reserved for loopback addresses, which are used for testing TCP/IP operation. |

The range in the first octet is used to identify the address class. For example, an address in the format 10.*x.y.z* is immediately recognizable as a class A address because 10 falls within the range 1–126. Similarly, an address in the format 131.107.*y.z* is identifiable as a class B address, and an address in the format 206.73.118.*z* is a class C address.

**Classful subnet masks**

A subnet mask, paired with an IP address, is a 32-bit value that enables a host or router to distinguish the network ID and host ID portions of its associated IPv4 address and thus determine the network ID (shared by all nodes on that subnet) for a specific IP address. When binary notation is used, the network ID bits in the subnet mask are identifiable because they are set to 1 and the host ID bits are identifiable because they are set to 0. When decimal notation is used, the network ID bits for a classful subnet mask are set to 255 (which is eight ones when translated into binary), and the host ID bits are set to 0. The following table illustrates the structure of the subnet masks used for classful unicast IPv4 addresses.

**Subnet Masks Used to Distinguish Network and Subnet Bits**

| Class | Decimal Subnet Mask: Network ID Bits 255 and Host ID Bits 0 | Binary Subnet Mask: Network ID Bits 1 and Host ID Bits 0 |
|---|---|---|
| A | 255.0.0.0 | 11111111 00000000 00000000 00000000 |
| B | 255.255.0.0 | 11111111 11111111 00000000 00000000 |
| C | 255.255.255.0 | 11111111 11111111 11111111 00000000 |

Although the table lists the default subnets masks now used for each classful address type, subnet masks were actually not defined until RFC 950, which defines subnetting procedures for fixed-size subnets, was published in August 1985.

For a technique for using an {IP Address, Subnet Mask} pair to determine the network ID for any type of IP address, including classless addresses, see “Addressing Mechanisms Required by Classless Routing” later in this section.

**Classful Subnetting Enables Only Fixed-Size Subnets**

Without some means of subdividing networks, all available IPv4 addresses would have been depleted long ago. Classful subnetting, dividing a network into subnets of equal size rather than simply using the default classful formats, is the initial strategy that was defined in RFC 950 to handle this problem and is still often used in smaller organizations.

The RIP v1 routing protocol, which does not advertise a subnet mask with the route, can reliably route only fixed-size subnets. RIP v1 advertises only the class-based network ID and therefore cannot perform routing in an environment that includes variable-size subnets.

**Using host ID bits to configure multiple subnets**

Subnet addressing lets you use one or more bits from the host ID part of the IPv4 address to configure the division of the network into multiple subnets. When subnetting is used, the subnet mask consists of the octets assigned to the network ID (set to 1) plus one or more bits for the subnet (now also set to 1). Therefore, when subnetting is implemented, the number of bits in the network ID and the host ID, respectively, vary and cannot be inferred by looking at the IP address alone. However, when each IP address on a network divided into subnets is paired with a subnet mask, the subnet mask is used to distinguish the network and subnetting bits (set to 1) from the host ID bits (set to 0).

The following table shows three alternative ways to use 131.107.65.37.

**Three Alternative Fixed-Size Subnet Masks for One IP Address**

| Bits Used for Subnets | Decimal Subnet Mask | Binary Subnet Mask | Fixed-Size Subnets | Hosts per Subnet |
|---|---|---|---|---|
| 0 | 255.255.0.0 | 11111111 11111111 00000000 00000000 | 1 | 65,534 |
| 8 | 255.255.255.0 | 11111111 11111111 11111111 00000000 | 256 | 254 |
| 4 | 255.255.240.0 | 11111111 11111111 11110000 00000000 | 16 | 4,094 |

Using the class B address 131.107.65.37 with its default subnet mask of 255.255.0.0 (first row in the example table) provides one subnet that can have up to 65,534 hosts. Because, typically, you do not need that many hosts on a single subnet, you might decide to create multiple subnets. Of the many possible choices you can make, the second and third rows in the example illustrate two:

- If you use a subnet mask that allocates an additional 8 host ID bits for subnets (shown in the second row), you obtain 256 (that is, $2^8$) subnetted network IDs (256 subnets of equal size), each of which can support up to 254 hosts.

  **Note**

  The number of hosts per subnet is listed as 254 rather than 256 because although 8 bits (28) are reserved for the host ID, you must subtract 2 (that is 28–2) because many vendors, including Microsoft, support only subnetting that excludes host IDs that consist of all ones or all zeros.

- If you use a subnet mask that allocates 4 host ID bits for subnets (shown in the third row), you obtain 16 (that is $2^4$) subnets of equal size, each of which can support up to 4,094 hosts ($2^{12}$–2).

**Using succinct network prefix notation to indicate subnetting**

Network prefix length notation, an alternative type of notation, lets you represent an {IP Address, Subnet Mask} pair in a different, more succinct form. The format is *IP address/p*, where *p* defines the number of network ID bits in the subnet mask. The remaining bits (calculated by subtracting the number of bits, *p*, from 32) represent the number of host ID bits in the subnet mask. The network ID bits (the bits set to 1) are considered the prefix because, when viewed in binary format, they always precede the host ID bits (the bits set to 0).

Network prefix length notation is sometimes referred to as Classless Interdomain Routing (CIDR) notation. CIDR, as its name implies, also encompasses the entire area of classless routing, including the use of subnet masks to enable variable-length subnets and route summarization, both described later.

The following table again shows the same address, 131.107.65.37, configured in three alternative ways, this time contrasting each address in network prefix length notation (left column) with the more cumbersome {IP Address, Subnet Mask} pair in both decimal and binary notation. Note that the number of bits set to 1 in the binary subnet mask is the same as the number after the forward slash in the network prefix length notation version of the same address, and the number of bits set to 0 is equal to 32 minus *p*.

**Network Prefix Length Notation Compared to {IP Address, Subnet Mask} Notation**

| Network Prefix Length Notation | Address / Subnet Mask (Decimal Notation) | Address / Subnet Mask (Binary Notation) |
|---|---|---|
| 131.107.65.37/16 | 131.107.65.37/255.255.0.0 | 10000011 01101011 01000001 00100101/<br>11111111 11111111 00000000 00000000 |
| 131.107.65.37/24 | 131.107.65.37/255.255.255.0 | 10000011 01101011 01000001 00100101/<br>11111111 11111111 11111111 00000000 |
| 131.107.65.37/20 | 131.107.65.37/255.255.240.0 | 10000011 01101011 01000001 00100101/<br>11111111 11111111 11110000 00000000 |

**How Classless Addressing Enables Classless Routing**

An IP internetwork that uses classless dynamic routing protocols can take advantage of classless addressing to produce the following types of network configuration:

- Subnets, each of the same size

- Subnets of different sizes
- A set of network IDs grouped into a block represented by a summary route; or an extension of this technique creating a network structure that maps to a region, department, or building; and subnet structure with a summary route representing each level of the hierarchy.

To understand the development and purpose of classless routing, a quick summary of the historical background is helpful. In the early 1990s, the Internet community recognized two interrelated problems:

- **Inadequate address space.** The existing public IPv4 address space was inadequate for handling the exponential growth of the Internet.
- **Overloaded routing tables.** Existing routers and existing routing protocols were inadequate for handling the related explosive growth of routing tables.

The long-term solution to both of these problems is the development and deployment of IPv6 (for information about Windows Server 2003 support for IPv6, see IPv6 Technical Reference). The short-term solution, described here, is to make IPv4 address allocation more efficient and to enable the aggregation of routing information. The classless interdomain routing (CIDR) techniques described in the early 1990s in RFCs 1518 and 1519 promoted conservation of the IPv4 address space and reduced the size of routing tables.

Initially, the new address allocation scheme focused on combining a set of class C addresses into one logical network (as an alternative to using class B addresses, whose availability is limited). A related goal was to create a hierarchical rather than a flat network topology, enabling a medium-size or large organization to tailor the structure of its network to match its current needs while allowing for future growth. One CIDR technique is route summarization, in which a single summary route is used to represent each level of the hierarchy, thus reducing the size of routing tables. Another CIDR technique provides a method for subdividing networks into variable-size subnets.

A major benefit of the new address allocation scheme used in conjunction with routing protocols capable of handling classless routing (such as RIP v2 or OSPF) was to free the IPv4 address space from the limitations of the original class-based IPv4 addressing system.

This section describes:

- Addressing mechanisms required by classless routing
- Subnets of varying sizes enabled by VLSM
- CIDR blocks and hierarchical routing enabled by route summarization

**Addressing Mechanisms Required by Classless Routing**
Classless routing requires the following addressing mechanisms:

**Subnet mask explicitly advertised by routing protocol**
A classless routing protocol, by definition, is one that advertises the subnet mask with the route. Routers that support a classless routing protocol can successfully route IP packets among subnets of variable size and can advertise summary routes.

**{IP Address, Subnet Mask} pair used to derive network ID**
In a routing environment that uses classless routing, the bitwise logical AND operation performed on an IP address and its subnet mask yields the network ID.

For example, {131.107.0.0, 255.255.0.0} denotes the network ID. In the subnet mask, the 16 leftmost contiguous bits are set to 1 (recall that 255 in decimal notation is 11111111 in binary). If you perform the bitwise logical AND operation on the IP address 131.107.20.30 with the subnet mask 255.255.0.0, the result is the network ID 131.107.0.0, sometimes written simply as 131.107. The following table illustrates the logical AND operation performed on each bit in the IP address with each corresponding bit in the subnet mask — the result is 1 only if both bits are 1; otherwise, the result is 0.

**Logical AND Operation to Find the Network ID**

| Description | Decimal Notation | Binary Notation |
|---|---|---|

| | | |
|---|---|---|
| IP address | 131.107.20.30 | 10000011 01101011 00010100 00011110 |
| Subnet Mask | 255.255.0.0 | 11111111 11111111 00000000 00000000 |
| Result of AND operation = network ID | 131.107.0.0 | 10000011 01101011 00000000 00000000 |

If you perform the AND operation on any other class B IP address with the class B default subnet mask, 255.255.0.0, the result is also the network ID 131.107.0.0.

For class A, B, and C addresses using the default subnet mask, the AND operation is not needed because you already know, by definition, the subnet mask and network ID for any classful IP address. However, you can use the AND operation to determine the network ID for subnetted classful IP addresses and for classless IP addresses for which no default subnet mask or definition of the network ID exists.

**{Network ID, Subnet Mask} pair used to express a summary route**

Classless routing can use a {Network ID, Subnet Mask} pair to represent a summary route. As explained earlier, a summary route is a single entry in a routing table that represents a set of entries, that is, the summary route represents a range of network IDs. RFC 1519 introduced the use of a summary route to express a range of class C network IDs to be consolidated into a single block, but the RFC also suggested that an arbitrary network number and mask can be configured for all routing destinations.

**Longest match routing**

With classless routing, routing to all destinations is done on a longest-match basis. This means that, for a specific destination that matches multiple {Network ID, Subnet Mask} pairs in the routing table, the router forwarding the IP packet uses the match with the longest mask (the mask with the most number of bits set to 1) to forward the packet.

For more information about these mechanisms, see How the IPv4 Routing Table Works later in this document.

**Subnets of Varying Sizes Enabled by VLSM**

As described earlier, standard subnetting creates subnets of equal size in a networking environment that supports only classful routing protocols. Subnets of equal size can be inefficient if each subnet does not need to support the same number of hosts. Therefore, a more useful method of subnetting, known as *variable length subnetting*, can be configured by using variable length subnet masks (VLSMs). Classless routing protocols support variable length subnetting, which is defined in RFC 1878.

Using VLSMs, you can perform subnetting on the same address space (network ID) multiple times to produce subnets of different sizes on the same network. All subnetted network IDs are unique and can be distinguished from each other by their corresponding subnet mask.

For example, by starting with a classful class B network ID of 131.107.0.0/16, you can configure one subnet that supports 1,022 hosts, a second that supports 510 hosts, and a third that supports only two hosts (for a point-to-point WAN link between two routers). The following table shows how.

**Example Using Three VLSMs to Create Three Various-Sized Subnets from 131.107.0.0**

| Network Prefix Length Notation | Decimal Mask | Binary Mask | Host |
|---|---|---|---|
| Subnet 1:<br><br>131.107.0.0/22 | 255.255.252.0 | 11111111 11111111 11111100 00000000 | 1,022<br><br>($2^{10}$–2) |
| Subnet 2:<br><br>131.107.208.0/23 | 255.255.254.0 | 11111111 11111111 11111110 00000000 | 510<br><br>($2^{9}$–2) |
| Subnet 3:<br><br>131.107.208.84/30 | 255.255.255.252 | 11111111 11111111 11111111 11111100 | 2<br><br>($2^{2}$–2) |

In this example, creating three subnets, each supporting a variable number of hosts, is the hypothetical goal. However, this simple example does not exhaust the possibilities. Instead of simply creating three subnets with 1,022, 510, and 2 hosts, respectively, you could create a more complex result by taking advantage of the number of possible subnets as well as the number of possible hosts. Because 131.107.0.0/16 is a class B network ID, the number of possible subnets is determined by the number of bits set to 1 in the third and fourth octets:

- **22-bit prefix length (Subnet 1):** 64 ($2^{6}$) possible subnets, each supporting up to 1,022 hosts.
- **23-bit prefix length (Subnet 2):** 128 ($2^{7}$) possible subnets, each supporting up to 510 hosts.

- **30-bit prefix length (Subnet 3):** 16,384 ($2^{14}$) possible subnets, each supporting up to 2 hosts.

When using VLSM, make sure that you do not overlap blocks of addresses. A good technique is to start with equal-size subnets and then subdivide them.

If variable-length subnets are also contiguous, the routes for all of the subnets can be summarized: a router can be configured to advertise the set of subnets to another router by advertising only the original network ID. Route summarization is described in the next section.

**CIDR Blocks and Hierarchical Routing Enabled by Route Summarization**

This section describes how classless routing uses a summary route to represent a range of network IDs (also known as a *CIDR block*) and how a multi-level hierarchy uses summary routes at each level of the hierarchy to make routing more efficient.

**How a summary route represents a range of network IDs**

As explained earlier, route summarization was introduced by RFC 1519 as a way to consolidate several class C network IDs into one logical network ID, sometimes referred to as a *supernet*. Because not enough class B addresses were available to meet the escalating demand, this technique enables two or more class C network IDs to be allocated to an organization in order to provide an adequate number of IP addresses.

Whereas subnetting enables the division of networks into smaller subnets of equal or variable size, route summarization enables the grouping of contiguous subnets. The use of a subnet mask is required for route summarization just as it is for subnetting. However, these subnets masks differ as follows:

- **Subnet mask used in subnetting.** Uses one or more host ID bits to create a longer subnet mask (prefix length) and uses these bits to create subnets. Subnet masks for subnetted network IDs are always more specific (that is, have more bits set to 1) than the network ID that is being subnetted.

- **Subnet mask used in route summarization.** Uses one or more network ID bits to create a shorter subnet mask (prefix length) in order to represent a set of network IDs as a single route in the routing table. This group of network IDs is the CIDR block. Subnet masks for summarized network IDs are always less specific (that is, have fewer bits set to 1) than the network IDs that are being summarized.

The following table lists a series of eight class C network IDs that, in this example, are combined into one block. The first network ID is 208.147.168.0. The first 21 bits are the same for each of the eight network IDs grouped into the single CIDR block. The last 3 bits of the third octet, which are taken from the class C–based network ID, range from 000 through 111. In decimal notation, the range is 0 through 7, or a total of 8 contiguous subnets, combined to form one block.

**Eight Class C Network IDs to be Combined into One Block**

| Range | Network ID (Decimal) | Network ID (Binary) |
|---|---|---|
| 0 (first network ID) | 208.147.168.0 | 11010000 10010011 10101000 00000000 |
| 1 (second network ID) | 208.147.169.0 | 11010000 10010011 10101001 00000000 |
| 2 (third network ID) | 208.147.170.0 | 11010000 10010011 10101010 00000000 |
| 3 (fourth network ID) | 208.147.171.0 | 11010000 10010011 10101011 00000000 |
| 4 (fifth network ID) | 208.147.172.0 | 11010000 10010011 10101100 00000000 |
| 5 (sixth network ID) | 208.147.173.0 | 11010000 10010011 10101101 00000000 |
| 6 (seventh network ID) | 208.147.174.0 | 11010000 10010011 10101110 00000000 |
| 7 (eighth network ID) | 208.147.175.0 | 11010000 10010011 10101111 00000000 |

This CIDR block is expressed as {208.147.168.0, 255.255.248.0} or, in network prefix length notation, as 208.147.168.0/21. A single route in the IP routing table represents this block. Without a list such as that shown in the preceding table, you can determine the number of network IDs in the block by raising the number of summarized bits to the power of 2. In this class C example, the subnet mask indicates that the number of bits used for summarization is three: 24–21=3, that is, 24 bits set to 1 in a standard class C subnet mask minus 21 actual bits set to 1 leaves 3 bits for summarization. Therefore, there are $2^3$=8 network IDs in this block.

Looking at this CIDR block (which, in this simple example, does not use variable length subnetting), you can double-check that it summarizes 8 class C networks by confirming that both of the following calculations produce the same number:

- Possible host IDs supported by a classful class C network ID (256) × network IDs in the block (8) = the number of possible host IDs (2048).

- Two (2) raised to the number of bits set to 0 in the subnet mask ($2^{11}$) = the number of possible host IDs (2048).

The assignable bits can be used either simply for host IDs or to create subnets of variable size, as the needs of the organization dictate. Typically, using VLSM to divide the 2048 possible host IDs into variable size subnets is the more practical option.

In this example, as the two calculations demonstrate, the CIDR block can be viewed from two perspectives:

- As a block of 8 contiguous class C network IDs grouped into one logical network ID.

- As a classless address space that has 21 fixed bits and 11 assignable bits.

**How a multi-level hierarchy using summary routes streamlines routing**

Hierarchical routing requires a method of address allocation that can reflect a hierarchical network topology and that can reduce the size of routing tables. Hierarchical routing accomplishes both requirements by using a single route to advertise a set of routes at each level of the hierarchy.

ISPs, organizations that subscribe to ISPs, and subnets within organizations are some of the typical levels in the routing hierarchy of the public Internet. An element lower in the hierarchy reports summary routing information to the level above it. For example, the allocation of large blocks of the public IPv4 address space to network service providers (such as ISPs), which then allocate subsets of these blocks to smaller organizations (such as organizations that subscribe to an ISP) is a practice recommended in RFCs 1518 and 1519.

Thus, a router within an organization does not need to advertise routing information about every subnet in that organization. Instead, the router can be configured to maintain routing information on a per region basis, in which each routing region is summarized with a single route except for the regions to which the router is connected. Likewise, an ISP router does not need to advertise routing information about individual subnets within each of the organizations that make up the set of its subscribers. Instead, the router can maintain routing information on a per subscriber basis.

Classless routing protocols, which recognize a summarized route represented by a {Network ID, Subnet Mask} pair that represents a set of reachable IP addresses, are designed to handle routing in a hierarchical infrastructure. By expressing a range of network IDs as a single route in the routing table at each level of the hierarchy, route summarization decreases the number of routes on routers. With fewer routes to check, routers can forward packets faster. One major use of route summarization is to reduce the burden for routers on the Internet backbone.

The example shown in the following figure depicts a simple hierarchical routing structure divided into routing regions based on the private network ID 10.0.0.0/8. Route summarization is used at the border of each region. Each arrow is labeled with the summarized route that is advertised outside its region by the router or routers at the border of that region. (This example figure is used by permission from the authors of "Microsoft Windows Server 2003 TCP/IP Protocols and Services Technical Reference" by Joseph Davies and Thomas Lee, Redmond, WA, Microsoft Press, 2003.)

The structure shown in this example illustrates both the advantage of hierarchical routing and its cost:

- **Advantage.** The efficiency provided by hierarchical routing reduces the size of routing tables, reduces the amount of communication required between routers in order for them to update their routing tables, and therefore reduces network traffic. With smaller routing tables, routers forward packets faster.

- **Cost.** The initial planning required to establish such a structure takes time. In a large organization, this initial investment in time is well worth the effort because of the long-term efficiency gained.

#### How the IPv4 Routing Table Works

On an IPv4 internetwork, IP makes routing decisions by consulting a database of routes known as the *IP routing table*. Each IP node uses its own routing table to store information about routes usable for forwarding unicast IP packets to any reachable location. A node running Windows Server 2003 (or Windows XP) builds its routing table automatically, based on its current TCP/IP configuration, static routing table entries, information provided by dynamic routing protocols, and ICMP Redirect messages.

This section describes:

- IPv4 routing table
- Structure of the IPv4 routing table
- How IP consults the routing table
- How to manage the IPv4 routing table

#### IPv4 Routing Table

Each entry in the routing table corresponds to one route. When an IP node needs to forward an IP packet, IP searches the routing table on the node for a route that most closely matches the destination IP address in the packet. Typically, the process is as follows:

- **For an IP host.** A host can either send a packet directly to its destination, or it can send the packet en route to the destination through a default route {Network ID: 0.0.0.0, Subnet Mask: 0.0.0.0} that points to its default gateway. A *default gateway* is a router that connects separate IP network segments.
- **For an IP router.** A router forwards a packet either by using an explicit static route for a specific network segment, a summarized route, a host route, or a default route.

#### Routing Table Example

An administrator or user can view the current state of the IP routing table on an IP node at any time. For example, consider a node configured as follows:

- **IP address:** 157.54.27.90
- **Subnet mask:** 255.255.240.0
- **Default gateway:** 157.54.16.1

In network prefix length notation, the IP address and subnet mask pair {157.54.27.90, 255.255.240.0} for this node is expressed as 157.54.27.90/20. Typing **route print** at a command prompt on this node produces the output shown in the following table.

**Example Routing Table**

```
Network Destination        Netmask          Gateway       Interface   Metric
        0.0.0.0            0.0.0.0     157.54.16.1   157.54.27.90       20
      127.0.0.0          255.0.0.0       127.0.0.1      127.0.0.1        1
    157.54.16.0      255.255.240.0   157.54.27.90   157.54.27.90       20
   157.54.27.90    255.255.255.255       127.0.0.1      127.0.0.1       20
 157.54.255.255    255.255.255.255   157.54.27.90   157.54.27.90       20
      224.0.0.0          240.0.0.0   157.54.27.90   157.54.27.90       20
255.255.255.255    255.255.255.255   157.54.27.90   157.54.27.90        1
```

This routing table, displayed on a computer running Windows Server 2003, differs from the routing table on a computer running Windows 2000 Server in the following ways:

- **New netmask for the multicast address route.** In the routing table on a server running Windows 2000 Server, the

Network Destination field and the Netmask field for the route used for IPv4 multicast addresses (defined as those in the range from 224.0.0.0 through 239.255.255.255) are both 224.0.0.0. However, the subnet mask used for IPv4 multicast addresses is 240.0.0.0. Therefore, the new Netmask of 240.0.0.0 that is used in the Windows Server 2003 routing table is more appropriate than the 224.0.0.0 Netmask used in Windows 2000, based on the class D definition of IPv4 multicast addresses.

- **Automatic metric feature.** On a server running Windows 2000 Server, the default routing metric for each route (each row) in the routing table is set to 1. On a computer running Window Server 2003 or Windows XP, the routing metric for each route is set to a value determined by the link speed of the interface. (This automatic metric feature does not apply to the default route metric when the default gateway is manually configured with a metric.)

In the output shown in "Example Routing Table," the routing metric that is set to 20 for several rows is the metric that Windows Server 2003 or Windows XP TCP/IP uses for a 100-Mbps Ethernet interface, for an 802.11g adapter, or for an 802.11a adapter. The following table lists the criteria that Windows Server 2003 or Windows XP uses to assign metrics for routes that are bound to network interfaces of varying speeds.

**Metrics Assigned by the Automatic Metric Feature**

| Link Speed | Metric |
|---|---|
| Greater than 200 Mbps | 10 |
| Greater than 20 Mbps, and less than or equal to 200 Mbps | 20 |
| Greater than 4 Mbps, and less than or equal to 20 Mbps | 30 |
| Greater than 500 Kbps, and less than or equal to 4 Mbps | 40 |
| Less than or equal to 500 Kbps | 50 |

The automatic metric feature is enabled by default through the **Automatic metric** check box on the **IP Settings** tab on **Advanced TCP/IP Settings** of the TCP/IP protocol. For DHCP-assigned default gateways, you can override the default behavior of automatically calculating a metric for the default route based on adapter speed by using the Microsoft-specific DHCP option called **Default Router Metric Base.**

**Routing Table vs. Forwarding Table**

Many router implementations, including the Windows Server 2003 Routing and Remote Access service, use both a routing table and a forwarding table:

- **Routing table.** Stores all routes from all possible sources. The command **netsh ro ip sh rtmr** (that is, **netsh routing ip show rtmroutes**) shows the routing table.

- **Forwarding table.** Used by IP to forward packets. The commands **route print** or **netsh ro ip sh rtmd** (that is, **netsh routing ip show rtmdestinations**) show the IP forwarding table.

The Routing and Remote Access service on a Windows Server 2003 router maintains the IP routing table by using a component called *Route Table Manager* (abbreviated as **rtm** in **rtmroutes** and **rtmdestinations** in the commands shown earlier). Route Table Manager updates the IP forwarding table (which is contained within the TCP/IP protocol) based on incoming route information from multiple sources.

The contents of the routing table do not necessarily match the contents of the forwarding table. However, in this introductory discussion, the routing table and the forwarding table are treated as if they are identical.

**Routing Table Stored in RAM on Local Node**

On an IPv4 internetwork, all routing decisions made by a host or a router are based on information stored in the IP routing table on that node. Because the routing table is a local database that physically resides in the remote access memory (RAM) of the node making the routing decision, the IP routing table is rebuilt whenever the node restarts. Thus, there is no single, unified view of the internetwork that is gathered by a server and downloaded to each host and router — all nodes do not have the same view of the internetwork, and all traffic does not flow along predictable pathways.

Each router in a path between a source and a destination makes a local routing decision based on its local routing table. Therefore, the path that packets take from the source to the destination might not be the same as the path taken by response packets from the destination back to the source.

If the information in the local routing table of a node is incorrect due to configuration errors or changing network conditions, routing problems can result. Troubleshooting routing problems might involve the analysis of the routing tables of the hosts (source and destination) and analysis of all of the routers that forward packets between them.

**Structure of the IPv4 Routing Table**

Understanding the IPv4 routing table requires familiarity with:

- The types of routes stored in the routing table.
- Available methods for configuring a default gateway, any of which creates a default route in the IP routing table.
- The meaning of the columns and rows that make up the routing table database.

**Types of Routes**

The following table describes the types of routes stored in an IP routing table. For a description of each route in an actual routing table, see the table "Routes in an IP Routing Table" later in this section.

**Types of Routes Stored in an IP Routing Table**

| Route Type | Description |
|---|---|
| Local network route<br><br>(Directly attached network route) | A route to a specific local network ID. This route identifies a network segment that is directly attached to the node.<br><br>For a local network route, the Gateway column (sometimes called *Next Hop*) might be blank or might contain the IP address of the interface on that network segment. |
| Remote network route | A route to a specific remote network ID. This route identifies a network segment that is not directly attached to the node but is available across one or more routers.<br><br>For a remote network route, the Gateway (Next Hop) column is the IP address of a local router located between the node and the remote network. |
| Host route | A route to a specific IP address (network ID + host ID) on the internetwork. Instead of making a routing decision based on just the network ID, as is the case for either a local or a remote network route, the routing decision for a host route is based on the combination of network ID and host ID. For a host route, the Network Destination column is the IP address of the specified host, and the Netmask column is 255.255.255.255.<br><br>Typically, a host route is used to create a custom route to a specific host in order to control or optimize specific types of internetwork traffic. |
| Default route | A route that is used when there are no other closer matching routes for the destination in the routing table. Including a default route in the routing table means that the routing table does not need to store routes for every network ID on the internetwork. Using a default route, therefore, simplifies the configuration of hosts or routers. |

**Default Gateways and Default Routes**

Configuring a default gateway creates a default route in the IP routing table. For IP nodes, the default gateway (also called a *default router*) is a neighboring IP router that forwards unicast traffic for the node by providing a next-hop IP address (the Gateway column in the routing table) and interface (the Interface column in the routing table) for all destinations that are not located on the local subnet. The default gateway address is the IP address of a directly reachable IP router.

The default gateway on a computer running Windows Server 2003 or Windows XP is configured by using one of the following methods:

- **TCP/IP properties General tab**. If you want the node to obtain its IP address configuration by using manual configuration, the default gateway is the IP address located in the **Default gateway** field on the **General** tab on the TCP/IP properties page. Multiple default gateways are configurable by adding them on the **IP Settings** tab on the **Advanced TCP/IP Settings** page of TCP/IP properties.
- **TCP/IP properties Alternate Configuration tab.** If you want the node to obtain its IP address configuration by using the user-configured alternate configuration option, the default gateway is the IP address located in the **Default gateway**

field on the **Alternate Configuration** tab on the TCP/IP properties page. You can specify only a single default gateway. The TCP/IP alternate configuration feature lets a computer function in two or more networks — one configured with static IP addresses and another configured with DHCP — without reconfiguration of network adapter parameters. When no DHCP server is available, the connection uses the configuration specified on the **Alternate Configuration** tab.

- **DHCP.** If you want the node to obtain its IP address configuration by using DHCP, the default gateway is the value of the first IP address in the Router DHCP option. The Router DHCP option specifies an ordered list of one or more default gateways. If you are using a Windows Server 2003–based DHCP server, the Router option is located in the **Details** pane in the DHCP snap-in console tree under *ServerName**ScopeName***Scope Options**.

- **ICMP Router Discovery.** If you want the node to automatically discover the best default gateway router available on a subnet, you can configure nodes on that subnet to use ICMP router discovery. ICMP Router Solicitation messages and Router Advertisement messages exchanged between routers and hosts enable hosts to dynamically discover which local routers are available, which routers are down, and which router is currently the best default gateway to use on a subnet. By using ICMP router discovery, a host can automatically switch to another default gateway if its current default gateway becomes unavailable. For information about support for ICMP router discovery in the Windows Server 2003 Routing and Remote Access service, see "How ICMP Router Discovery Works" in How Unicast IPv4 Routing Protocols and Services Work.

| **Note** |
|---|
| If the host obtains its IP address configuration by using Automatic Private IP Addressing (APIPA), no default gateway is configured and no default route is created in the routing table. APIPA is useful only for a single subnet. |

**Fields and Records in the IP Routing Table Database**

As with any database, understanding the IP routing table requires understanding the relationship between the records (rows) and the fields (columns) that make up the IP routing table. This relationship is best understood by using an example. The following table shows the same information displayed in "Example Routing Table" earlier in this section. It labels each row with the route type for that entry.

**Example Information Stored in an IP Routing Table**

| Type | Network Destination | Netmask | Gateway | Interface | Metric |
|---|---|---|---|---|---|
| Default route | 0.0.0.0 | 0.0.0.0 | 157.54.16.1 | 157.54.27.90 | 20 |
| Loopback network route | 127.0.0.0 | 255.0.0.0 | 127.0.0.1 | 127.0.0.1 | 1 |
| Local network route<br><br>(Directly attached network route) | 157.54.16.0 | 255.255.240.0 | 157.54.27.90 | 157.54.27.90 | 20 |
| Local host route<br><br>(Local IP address route) | 157.54.27.90 | 255.255.255.255 | 127.0.0.1 | 127.0.0.1 | 20 |
| Network broadcast route<br><br>(All-subnets-directed broadcast route) | 157.54.255.255 | 255.255.255.255 | 157.54.27.90 | 157.54.27.90 | 20 |
| Multicast address route | 224.0.0.0 | 240.0.0.0 | 157.54.27.90 | 157.54.27.90 | 20 |
| Limited broadcast route | 255.255.255.255 | 255.255.255.255 | 157.54.27.90 | 157.54.27.90 | 1 |

**Routing table columns**

The following table describes each field, or column, in the IP routing table.

**Columns for Each Routing Table Entry**

| Column | Description |
|---|---|

| | |
|---|---|
| Network Destination | Contains one of the following:<br>• **IP address.** An IP address for a host route<br>• **Network ID.** A class-based, subnetted, or summarized network ID |
| Netmask<br><br>(Subnet Mask) | Contains the subnet mask that IP applies to the destination IP address. If the destination AND the subnet mask equals the network destination, the route is a match for the destination. The process is as follows:<br>1. IP performs a bit-wise logical AND operation between the packet's destination IP address and the value in the Netmask column.<br>2. The result is compared to the value in the Network Destination column.<br>3. When IP compares each bit in the destination IP address to the corresponding bit in the subnet mask, the bit-wise AND operation works as follows:<br>  • If both bits are 1, the resulting bit is 1.<br>  • If both bits are not 1, the resulting bit is 0.<br><br>**Examples:**<br>• **Default route.** The netmask for the default route is 0.0.0.0, which translates to the binary value 00000000 00000000 00000000 00000000. When IP performs the AND operation between any destination IP address and this subnet mask, the result is all zeros. Therefore, no bits need to match, and any destination matches the default route.<br>• **Host route.** The netmask for a host route (a route that matches a specific IP address) is 255.255.255.255, which translates to the binary value 11111111 11111111 11111111 11111111. When IP performs the AND operation between a host route and this subnet mask, only a destination IP address that is equal to the IP address of the host route matches this route.<br>• **Packet with IP address 157.54.16.48.** When IP performs the AND operation between 157.54.16.48 and the netmask for the directly attached network route (in this example, 255.255.240.0), the result is 157.54.16.0. The subnet mask 255.255.240.0 requires that all eight bits in the first two octets and the first four bits in the third octet must match (240=11110000). Therefore, the closest match for this packet is the directly attached network (157.54.16.0/20). |
| Gateway<br><br>(Next Hop or Forwarding Address) | Contains either the IP address of a local network adapter for direct deliveries or the IP address of an IP router (such as a default gateway router) on the local network segment for indirect deliveries. This is the IP address that the local node uses to forward the IP packet. |
| Interface | Indicates the network interface (either a physical network adapter or a logical interface) that will be used to forward an IP packet. |

| | |
|---|---|
| Metric | Indicates the relative cost of routes so that the best route among possible multiple closest matching routes to the same destination can be selected. If there are multiple routes to the same destination with different metrics, the route with the lowest metric is selected.<br><br>Metrics can express the route preference in different ways:<br><br>• **Hop Count.** Indicates the number of routers to cross to reach a destination network. A computer on the local subnet is one hop, and each router crossed after that is an additional hop.<br><br>• **Delay.** Indicates the amount of time that the packet takes to reach the destination network. Delay refers to the speed (LAN links have a lower delay; WAN links have a higher delay) or congestion level of the path.<br><br>• **Throughput.** Indicates the amount of data that can be sent along the path per second. Throughput does not necessarily indicate the bit rate of the link because a very busy Ethernet link might have a lower throughput than an unused 64 kilobits per second (Kbps) WAN link.<br><br>• **Reliability.** Indicates a measure of the path constancy. Some types of links are more likely to fail than others. For example, leased-line WAN links are more reliable than dial-up lines.<br><br>RIP uses a hop count metric. OSPF can use hop count, delay, throughput, or reliability factors for its cost metric. |

**Routing table rows**

The following table describes each record, or row, in the IP routing table. Each row represents a route. In the Description column, all references are to the output "Example Routing Table" shown earlier.

**Routes in an IP Routing Table**

| Route | Destination / Netmask (Network Prefix Length Notation) | Description |
|---|---|---|
| Default route | 0.0.0.0/0.0.0.0<br><br>(0.0.0.0/0, sometimes written as 0/0) | The route used if there are no other closer matching routes for the destination address in the IP packet. In the example, the IP packet is forwarded to 157.54.16.1 (the default gateway) by using interface 157.54.27.90 (the IP address of the node). |
| Loopback network route | 127.0.0.0/255.0.0.0<br><br>(127.0.0.0/8) | The route used for any IP address of the form 127.*x.y.z* (127.0.0.0 through 127.255.255.255). In the example, as for any IP address in this range, the IP packet is forwarded to the special loopback address 127.0.0.1 by using the loopback interface. |
| Directly attached network route (Local network route) | *varies/varies* | The route used for an IP address on the locally attached subnet. The IP packet is forwarded directly to the destination IP address (not to an intermediate router). In the example, the IP packet is forwarded to its destination by using the interface assigned to 157.54.27.90 — that is, the Gateway and Interface columns contain an IP address of the node, indicating that the packet will be sent directly to its destination out a network adapter that is assigned an IP address on this node. |
| Local host route<br><br>(Local IP address route) | *varies*/255.255.255.255<br><br>(*varies*/32) | The route used if the IP address in the packet is the same as the IP address of the local host. The subnet mask 255.255.255.255 indicates that this is a host route. In the example, as for any IP address that matches the local host, the IP packet is forwarded to the loopback address 127.0.0.1 by using the loopback interface. |

| | | |
|---|---|---|
| Network broadcast route<br><br>(All-subnets-directed broadcast route) | *varies*/255.255.255.255<br><br>(*varies*/32) | The route used for an IP address that matches the all-subnets-directed broadcast address. The subnet mask 255.255.255.255 indicates that this is a host route. The IP packet is forwarded as a MAC-level broadcast to hosts on all subnets of a subnetted IP network ID by using an interface that is assigned an IP address on the local node.<br><br>A network broadcast route exists only if the local network ID is subnetted from a class-based network ID. |
| Multicast address route | 224.0.0.0/240.0.0.0<br><br>(224.0.0.0/4) | The route used for any of the class D IP addresses reserved for multicast traffic. The IP multicast packet is forwarded as a MAC-level multicast to the multicast group by using an interface that is assigned an IP address on the local node. |
| Limited broadcast route | 255.255.255.255/255.255.255.255<br><br>(255.255.255.255/32) | The route used for an IP address that matches the limited broadcast address. The subnet mask 255.255.255.255 indicates that this is a host route. The IP packet is forwarded as a MAC-level broadcast to all hosts on the same network segment by using an interface that is assigned an IP address on the local node.<br><br>The limited broadcast route is used during the DHCP configuration process, such as when a DHCP client uses the limited broadcast address to send all traffic while it waits for the DHCP server to acknowledge its lease of an IP address. |

**How IP Consults the Routing Table**

When an IP host or router needs to forward a packet to its destination, IP consults the routing table on that node to determine where to route the packet. This section provides a summary of how IP consults each row and column, and then provides a detailed description of the route determination process.

**Synopsis of How IP Consults the Routing table**

The following table summarizes how IP makes use of the IP routing table.

**Overview of How IP Uses Routing Table Rows and Columns**

| Action | Summary Steps |
|---|---|
| IP searches each row | IP checks each route in the table to find the closest matching route. Routes that match the destination vary from the most specific type of route to the least specific type of route. The closest matching routes have the following order:<br><br>1. Host route<br><br>2. Route representing the network ID for a local or remote subnet<br><br>3. Route representing a summarized network ID<br><br>4. Default route |
| Simultaneously, IP uses each column to assess each row | IP uses each column in every row as follows:<br><br>1. Network Destination and Netmask. Used together to determine if the destination address in the IP packet matches the route.<br><br>2. Metric. Used to determine which matching entry to select if two or more closest matching routes are found.<br><br>3. Gateway and Interface. Used together to determine the next-hop address to which to send the packet and the next-hop interface over which to forward the packet. |

| | |
|---|---|
| Result | Three alternative routing decisions are possible:<br>• Pass the packet up to the loopback interface (if the destination of the packet is this computer or of the form 124.*x.y.z*).<br>• Forward the packet by using one of the locally attached network interface cards (if a closest matching route was found).<br>• Discard the packet (if no matching route was found), and then (on a host) send an error message internally or (on a router) send an error message to the source host. |

The next section describes in detail the process by which IP determines which routing decision to make.

**Details of How IP Makes the Routing Decision**

IP determines the best route to a destination by comparing the destination IP address in the packet to each route currently present in the routing table. The detailed process is as follows:

1. **Determine whether the packet's destination IP address matches one or more routes.** For each entry in the routing table, IP on the node performs a bitwise logical AND operation between the destination IP address of the packet and the subnet mask listed in the Netmask column. IP compares the resulting value to the value in the Network Destination column:

   - **Match.** If one or more matching routes are found, IP compiles a list of the matching routes. IP determines if a route produces a match as follows:

     **Host route.** All 32 bits match the destination IP address. The route is to a single destination address.

     **Route representing the network ID for a local or remote subnet.** All of the bits in the network ID match the destination IP address. This route is either a route to a destination on the local subnet, or it is a route to a destination on a non-local network through a router.

     **Route representing a summarized network ID.** All of the bits in the summarized network ID match the destination IP address. The route is to a destination on the set of subnets summarized by this summary route.

     **Default route.** All destination IP addresses match the default route. This is the route used when there is no more specific match.

   - **No match.** If no route is found (including no default route), IP indicates an error condition. A "no match" condition cannot occur if a default route exists. If the node is a host, an IP routing error is sent internally to an upper layer protocol (such as TCP, UDP, or ICMP). If the node is a router, an ICMP Destination Unreachable-Host Unreachable message is sent to the source host.

   For examples illustrating the AND operation between a destination IP address and the value in the Netmask column, see the Netmask row in the table "Columns for Each Routing Table Entry" in "Structure of the IPv4 Routing Table" earlier in this section.

2. **Determine the single route to use to send or forward the packet.** The result of the route determination process is the choice of a single route in the routing table:

   - If one and only one route has the longest match — the *longest match* is the route with the highest number of bits set to 1 in the Netmask column (the longest prefix length) — that route is selected.

   - If multiple longest match routes are found (for example, multiple routes to the same network ID), IP selects the route with the lowest metric.

   - If multiple longest match routes with the same lowest metric exist, IP selects the route associated with the interface

that is first in the binding order.

| Note |
| --- |
| If a computer has more than one interface (network adapter), the binding order is the order in which the interfaces are accessed by network services. This order reflects the order in which TCP/IP is bound to each of the interfaces. To change the relative binding order of interfaces on a computer running Windows Server 2003 or Windows XP, open Network Connections, select the **Advanced** menu, select **Advanced Settings**, click the interface whose binding order you want to change, and then click the up arrow or the down arrow, as appropriate. |

3. **Determine the next-hop address and interface.** After a route is selected, IP determines from the routing table entry what the next-hop IP address is and which interface (physical network adapter or logical port) to use to forward the packet:

   - **Direct delivery (to the destination node).** If the destination is on a subnet directly connected to the host or router, IP delivers the packet to the destination node. In this case, the address in the Gateway column is the same as the address in the Interface column (or the Gateway column is blank), and the next-hop IP address is set to the destination IP address in the IP packet. The interface used is the one specified in the Interface column of the selected route.

     Again using the example shown in "Example Routing Table" described earlier, if traffic is sent to 157.54.16.48, the most specific route is the route for the directly attached network (157.54.16.0/20). The next-hop IP address is set to the destination IP address (157.54.16.48) and the interface used is the adapter card that has been assigned the IP address 157.54.27.90 (the interface on the local node).

   - **Indirect delivery (to the next router).** If the destination is not on a subnet directly connected to the node, IP delivers the packet to a neighboring router on a directly connected subnet for further routing. In this case, the address in the Gateway column is not the same as the address in the Interface column, and the next-hop IP address is set to the address in the Gateway column. The interface used is the one specified in the Interface column of the selected route.

     For example, if traffic is sent to 157.60.0.79, the most specific route is the default route (0.0.0.0/0). The next-hop IP address is set to the gateway address (157.54.16.1) and the interface used is, in this case again, the adapter card that has been assigned the IP address 157.54.27.90 (the interface on the local node).

4. **Hand off the packet to ARP.** IP hands the packet, the next-hop IP address, and the next-hop interface to ARP. ARP resolves the next-hop IP address to its MAC address and forwards the packet, as appropriate, to the next hop, which is either the destination or the router that will forward it towards its destination.

For more information about the IP routing process, including details of the host forwarding process, the router forwarding process, and the destination host receiving process, see "IP Routing from Sending Host to Destination" in "Microsoft Windows Server 2003 TCP/IP Protocols and Services Technical Reference" by Joseph Davies and Thomas Lee, Redmond, WA, Microsoft Press, 2003.

**How to Manage the IPv4 Routing Table**

On a computer running the Windows Server 2003 Routing and Remote Access service, several methods for managing the IP routing table are available:

- The **route** command-line tool, which is designed specifically to display and manage the IP routing table.

- The Netsh routing IP context, which includes several commands for managing IP routes. In Windows Server 2003, Netsh contains more commands than it did in Windows 2000 Server.

- The Routing and Remote Access snap-in, which displays the routing table with an additional column that lists the source from which the route was obtained. View the routing table by right-clicking the **IP Routing\Static Routes** node in the console tree and then selecting **Show IP Routing Table**.

In addition to using the **route print** command to view the routing table, you can also use **route** to add, change, or delete routes. Because the IP routing table is stored in RAM and is rebuilt whenever a computer is restarted, one common practice is to use **route add** with the **-p** option to add a static route that is persistent, that is, a route that persists even after the computer is restarted. Persistent routes are stored in the registry.

The IP routing table that appears in the Routing and Remote Access snap-in includes one additional column that the **route print** command does not display. This is the **Protocol** column, which identifies how the router learned each route. For example, **Local** identifies a route on the local node; **Static** identifies a static route that the administrator configured manually; **RIP** or **OSPF** identifies dynamic routes learned from routers configured to use those routing protocols. The following screenshot displays the IP routing table on a Windows Server 2003 Routing and Remote Access router.

RRAS-1 - IP Routing Table

| Destination | Network mask | Gateway | Interface | Metric | Protocol |
|---|---|---|---|---|---|
| 192.168.10.0 | 255.255.255.0 | 192.168.0.1 | 192.168 | 1 | Static (non demand-dial) |
| 192.168.0.0 | 255.255.255.0 | 192.168.0.1 | 192.168 | 2 | OSPF |
| 10.199.17.0 | 255.255.255.0 | 10.199.17.80 | Corpnet | 2 | OSPF |
| 0.0.0.0 | 0.0.0.0 | 10.199.17.1 | Corpnet | 20 | Network management |
| 255.255.255.255 | 255.255.255.255 | 192.168.0.1 | 192.168 | 1 | Local |
| 255.255.255.255 | 255.255.255.255 | 172.16.0.1 | 172.16 | 1 | Local |

If the **Protocol** column lists **RIP** or **OSPF** entries, or any other entries in addition to Local entries, the existence of these entries confirms that the router is receiving routes.

For more information about tools used for unicast IP routing, see Unicast IPv4 Routing Tools and Settings.

**How Static and Dynamic Routing Work**

For information exchange between routers to work efficiently on an IP internetwork, routers must have knowledge of other network IDs or be configured with a default route. On medium-sized or large internetworks, the routing tables must be maintained in an up-to-date state so that network traffic travels along optimal paths. How the routing tables are maintained defines the distinction between static and dynamic routing:

- **Static routing.** An administrator manually enters routing information. Routing information does not change unless the administrator manually updates or deletes it. The term static router refers to a router in an internetwork that uses only static routing. Using static routing exclusively is appropriate only for a small internetwork.

- **Dynamic routing.** An administrator configures a router to automatically generate routing information, share it with other routers, and update it when routing changes occur. The term dynamic router refers to a router in an internetwork that uses only dynamic routing or, more typically, that uses primarily dynamic routing in conjunction with some manually configured static routes. For example, each interface on a dynamic router is typically manually configured.

**Static Routing**

Static routing is based on routing table entries that are manually configured on a static router and that do not change when internetwork topology changes. On a static router, a network administrator with knowledge of the internetwork topology builds and updates the routing table. The routing table on a static router either contains a route for every subnet on the internetwork, or the router is configured to use route summarization and thus the routing table contains only summary routes. Static routers do not exchange routing information with each other.

On an internetwork based on static routing, an IP node is manually configured so that its default gateway address matches the IP address of the local router interface. When a node sends a packet to another network, it forwards the packet to the local router, which checks its own routing table and determines which route to use to forward the packet.

Static routing can work well for small internetworks. Static routing can also be appropriate for connecting a branch office to a main office across a WAN link. However, static routing does not scale well to large or frequently changing internetworks because of the manual administration it requires.

Static routers are not fault tolerant — a static router cannot sense that a neighboring router is no longer available over an operational link or that a remote network segment is no longer reachable if a link goes down. Because a static router is unaware of these changes, it cannot make adjustments to its routing table and requires an administrator to update the router.

A computer running Windows Server 2003 that has two or more network adapters (each configured with an IP address and subnet mask defining routes for local subnets) can function as a static IP router. Typically, to avoid conflicts in case the router is connected to two or more disjoint subnets, only one of the network adapters is configured with a default gateway. For information about disjoint networks, including how to configure an Internet Security and Acceleration (ISA) or virtual private network (VPN) server to prevent disjoint network unreachability, see Default Gateway Behavior for Windows TCP/IP.

On a server running Windows Server 2003 Routing and Remote Access, you can add static routes in three ways:

- In the console tree of the Routing and Remote Access snap-in, by adding a route on the **IP Routing\Static Routes** node
- By using the **route add** command-line utility (with the **-p** switch to add a persistent static route)
- By accessing the **netsh routing ip** context in a command prompt window and then using the **add persistentroute** command

**Static routing entries**

An administrator configuring a static routing entry manually specifies the following information:

- **Destination.** A destination IP address for this route, which can be a host address, a subnet address, a summarized network address, or the destination for the default route (0.0.0.0).
- **Network mask.** The subnet mask for the static route. This number is used in conjunction with the destination IP address. For example, a mask of 255.255.255.255 means that only an exact match of the network mask with the destination can use this route. A mask of 0.0.0.0 means that any destination can use this route. For more information, see "Details of How IP Makes the Routing Decision" earlier in this document.
- **Gateway.** The next-hop IP address for this route. For a LAN interface, the gateway address is the IP address of a neighboring router. For a demand-dial interface, no gateway address is configured.
- **Metric.** The cost (such as the number of hops to the destination, or a unitless metric, such as the speed or reliability of the link) associated with this route. When multiple routes to the same destination exist, IP selects the route with the lowest metric.

For more information about how IP handles entries in the routing table, see How the IPv4 Routing Table Works earlier in this section.

**Using static routing with dynamic routing**

Using static routing exclusively is appropriate only for a small internetwork that is rarely reconfigured. However, a medium-size or large internetwork that primarily uses dynamic routing typically also uses some manually configured static routes. For example, you might use a static route with a higher metric as the redundant backup for a dynamically configured route. In addition, you might use dynamic routing for most paths but configure a few static paths where you want to ensure that network traffic follows a particular route, such as configuring routers to force traffic over a specific path to a high-bandwidth link.

**Autostatic updates across temporary WAN links**

Using dynamic routing protocols across temporary dial-up WAN links is not feasible because dynamic routing protocols typically advertise the contents of the routing table at periodic intervals. Such automatic periodic advertisements are appropriate only for permanently connected LAN or WAN links. If a dial-up WAN link is configured to use dynamic routing, it might incur long-distance charges each time one router calls another router to establish a connection and update the routing table. A more cost-effective way to update the routing table over a dial-up WAN link is to configure autostatic updates. RIP supports autostatic updates; OSPF does not.

An autostatic route is a static route that is dynamically obtained through an exchange of RIP messages. An administrator can enable autostatic updates on an interface that is used for a demand-dial connection so that — whenever the demand-dial link is in a connected state — a request for updated routes can be sent over that interface. Autostatic updates are automatic only in the sense that, when the administrator gives the command to update routes, the router sends an update request across the link to the router on the other side of the connection, and then the router automatically adds the requested routes as static routes to its routing table. Although the term autostatic update might seem to imply an automatic operation, autostatic updates are not automatically performed when the demand-dial connection is made but only if the command to perform the update is given.

As an alternative to issuing a command to initiate a manual autostatic update, if you use Routing and Remote Access RIP routers, you can use the Routing and Remote Access snap-in, Netsh commands, and Task Scheduler to schedule autostatic updates:

1. In the Routing and Remote Access snap-in, enable autostatic update mode by navigating to the **IP Routing\RIP** node in the console tree, and then selecting the **Auto-static update mode** option on the **General** tab of the *InterfaceName*

**Properties** page.

2. Create a batch file or Netsh script file that contains the following commands:

   **netsh interface set interface name**=*DemandDialInterfaceName* **connect=CONNECTED**

   **netsh routing ip rip update** *DemandDialInterfaceName*

   **netsh interface set interface name**=*DemandDialInterfaceName* **connect=DISCONNECTED**

3. Open **Scheduled Tasks** in **Control Panel**, double-click **Add Scheduled Task**, and then follow the wizard instructions to establish the schedule for the batch file or Netsh script to run.

**Static routing in IPv6**

A computer running the Windows Server 2003 family can act as a static IPv6 router that forwards IPv6 packets between interfaces based on the contents of the IPv6 routing table. You can configure static routes by using the **netsh interface ipv6 add route** command.

For information about Windows Server 2003 support for static routing in an IPv6 environment, see "How IPv6 Works" in IPv6 Technical Reference.

**Dynamic Routing**

Dynamic routing is based on routing table entries that are automatically configured and automatically updated by routers whenever the topology of the internetwork changes. Dynamic routing protocols enable this ongoing maintenance of routing tables by using a series of periodic or on-demand messages containing routing information about the internetwork environment that is exchanged among routers. Any dynamic routing protocol enables routers to perform the following basic functions:

- Detect other routers (called *neighbors*) with which it will exchange routing information.
- Store the routing data that it collects from other routers as entries in its routing table.

A router with dynamically configured and updated routing tables is known as a dynamic router. Except for initial configuration, dynamic routers require little ongoing maintenance and can therefore scale to large internetworks. For dynamic routing to work, the same routing protocol must be installed on each router on the internetwork.

Dynamic routing in a multipath IP internetwork is fault tolerant (for a brief description of multipath routing, see "Single-Path vs. Multipath Routing Infrastructures" earlier in this document). Dynamic routes learned from other routers have a finite lifetime: If a router or link fails, dynamic routers detect the change in the internetwork topology when the lifetime of the learned route expires in the routing table. This change then propagates to other routers so that all routers on the internetwork become aware of the new topology.

The ability to scale and the ability to recover from internetwork faults make dynamic routing the better choice for medium, large, and very large internetworks. Routing protocols do, however, increase network traffic on the internetwork. This additional traffic can be an important factor in planning WAN link usage.

Two or more dynamic routing protocols cannot interoperate on the same internetwork because each protocol collects different types of data and uses different techniques to converge after topological changes occur. However, you can configure two or more routing protocols on a single router to connect internetworks that use different routing protocols. For example, you can configure RIP on an interface that connects to a RIP-based internetwork and configure OSPF on another interface that connects to an OSPF-based internetwork. A router with these interfaces can be configured to exchange routing information between the two networks. The exchange of routing information between networks that use different dynamic routing protocols is sometimes referred to as *route redistribution*.

A computer running the Windows Server 2003 Routing and Remote Access service can act as a dynamic router that also supports static routing. An administrator can use the Routing and Remote Access snap-in to add RIP, OSPF, or both, and then enable the protocol on the appropriate interface by adding the interface to the RIP or OSPF protocol displayed in the console tree. On a Routing and Remote Access router, you can use the snap-in to add a static route to an internetwork configured to use dynamic routing by using the **IP Routing\Static Routes** node in the console tree.

**Convergence**

An important element of a routing protocol implementation is its ability to sense and recover from internetwork faults. How

quickly the routing protocol can enable recovery from failures on the internetwork is determined by the type of failure, how it is sensed, and how the routing information is propagated throughout the internetwork.

When all routers on an internetwork have the correct routing information in their routing tables, the internetwork is said to have converged. *Convergence* is the process by which routers update routing tables after a change in network topology occurs — the change is replicated to all routers that need to know about it. When convergence is achieved, the internetwork is in a stable state and all routing occurs along optimal paths.

When a link or router fails, the internetwork must reconfigure itself to reflect the new topology. Information in routing tables must be updated. Until the internetwork reconverges, it is in an unstable state in which routing loops and black holes (both described later) can occur. The time it takes for the internetwork to reconverge is known as the *convergence time*. The convergence time varies based on the routing protocol and the type of failure — downed link or downed router.

For more information about convergence, see "Impact of Routing Loops and Black Holes During Convergence" later in this section, and see "How RIP Works" and "How OSPF Works" in How Unicast IPv4 Routing Protocols and Services Work.

**Routing Protocols Used Between and Within Autonomous Systems**

Autonomous systems (described earlier in "IPv4 Routing Infrastructure") use two types of routing protocols to update routing information:

- The protocols used to distribute routing information between two or more autonomous systems are known as Exterior Gateway Protocols (EGPs).

- The protocols used to distribute routing information within a single autonomous system are known as Interior Gateway Protocols (IGPs).

The following figure depicts two autonomous systems using interior and exterior protocols to communicate.

EGPs are inter–autonomous system routing protocols. EGPs define the way that all routes within the autonomous system are advertised outside of the autonomous system. Routers that connect autonomous systems to the Internet backbone use an EGP to advertise routing information to each other. Advertising can include a list of routes in a flat routing infrastructure or a list of summarized routes in a hierarchical routing infrastructure.

EGPs are independent of the IGPs used within an autonomous system and can enable the exchange of routes between autonomous systems that use different IGPs.

The EGPs for IP internetworks include:

- **Exterior Gateway Protocol (EGP).** An obsolete EGP that was developed to communicate information between autonomous systems on the Internet. Although EGP is the eponym for the generic protocol type for inter-autonomous system routing protocols, it is no longer used on the Internet because it cannot support multipath environments or classless routing. EGP was defined in the now obsolete RFC 904, "Exterior Gateway Protocol."

- **Border Gateway Protocol (BGP).** The EGP that is currently used to communicate information between autonomous systems on the Internet. The Internet is a large IP internetwork divided into several autonomous systems that are connected by the Internet's core routers, which use BGP for communication among themselves. BGP uses autonomous system numbers (ASNs) to avoid routing loops and to implement policy-based routing on the Internet backbone. Unlike its obsolete predecessor EGP, BGP supports complex multipath networks and classless routing. BGP is defined in RFC 1771, "A Border Gateway Protocol 4 (BGP-4)" and RFC 1772, "Application of the Border Gateway Protocol in the Internet" in the IETF RFC Database.

The Windows Server 2003 Routing and Remote Access service does not include EGP or BGP.

IGPs are intra–autonomous system routing protocols. Routers use an IGP to forward routing information to the other routers within the autonomous system. IGPs can distribute routes within the autonomous system in either a flat or hierarchical manner.

The IGPs for IP internetworks include:

- **RIP for IP.** An RFC-based distance vector IGP.
- **OSPF.** An RFC-based link state IGP.
- **IGRP.** A distance vector IGP developed by Cisco Systems, Inc.

The Windows Server 2003 Routing and Remote Access service includes RIP and OSPF, but it does not include a version of IGRP. For detailed information about RIP and OSPF, see the next section, "Common IGP Dynamic Routing Protocols," and see the companion document How Unicast IPv4 Routing Protocols and Services Work.

A third-party software vendor can develop a version of IGRP that works with the Routing and Remote Access service. For information about Microsoft platform software development kits (SDKs) that provide application programming interfaces (APIs) useful for third-party developers who create software that interacts with Windows Server 2003, including the Routing and Remote Access service, see "IPv4 and Routing and Remote Access APIs" in How Unicast IPv4 Routing Protocols and Services Work.

**Common IGP Dynamic Routing Protocols**

The most common types of dynamic routing protocols used within a single autonomous system are:

- Distance vector routing protocols
- Link state routing protocols

A distance vector routing protocol, such as RIP v2, is more appropriate for a relatively small, simple network that is not expected to grow rapidly. For a large, complex internetwork, a link state routing protocol, such as OSPF, is more appropriate. You must use RIP v2 or OSPF to support VLSM and route summarization. Although the outdated RIP v1 is still widely used in private networks, it does not support either VLSM or route summarization and thus is not well suited for enterprise networks.

| **Note** |
| --- |
| The Windows Server 2003 Routing and Remote Access service does not support the dynamic routing protocols RIPng (the version of RIP for IPv6) or OSPF for IPv6. However, a computer running Windows Server 2003 can act as a static IPv6 router, and it is possible to route IPv6 traffic over an IPv4 internetwork using an IPv6 transition technology. For information about Windows Server 2003 support for static IP routing in an IPv6 environment, see "How IPv6 Works" in IPv6 Technical Reference. |

Understanding how distance vector and link state routing protocols work is essential to choosing the type of dynamic routing that best suits your network needs. The primary differences between distance vector and link state routing protocols include:

- What routing information is exchanged
- How the information is exchanged
- How quickly the internetwork can recover from a downed link or a downed router

**Distance Vector Dynamic Routing Protocols**

A router that uses distance vector routing protocols, the earliest type of dynamic routing protocol, advertises the routes in its routing table to other routers at regular intervals. The routing information that is periodically exchanged between routers by using distance vector routing protocols is typically unsynchronized and unacknowledged.

A distance vector routing protocol advertises the number of hops to a network destination (the distance) and the direction in which a packet can reach a network destination (the vector). The distance vector algorithm, also known as the *Bellman-Ford*

*algorithm*, enables a router to pass route updates to its neighbors at set intervals. Each neighbor then adds its own distance value and forwards the routing information on to its immediate neighbors. The result of this process is a table containing the cumulative distance to each network destination.

The following table lists several common distance vector routing protocols based on three major routable network protocols.

**Common Distance Vector Dynamic Routing Protocols**

| Routable Network Protocol | Distance Vector Dynamic Routing Protocol |
|---|---|
| IP | Routing Information Protocol (RIP) for IP versions 1 and 2 (RIP v1 and RIP v2)<br><br>Interior Gateway Routing Protocol (IGRP) |
| IPX | Routing Information Protocol (RIP) for IPX |
| AppleTalk | Routing Table Maintenance Protocol (RTMP) |

The Windows Server 2003 Routing and Remote Access service includes RIP v1 and RIP v2 for IP and RTMP for AppleTalk. Windows Server 2003 Routing and Remote Access does not include IGRP or RIP for IPX.

The advantages of distance vector dynamic routing protocols include:

- **Simpler.** Distance vector routing protocols use simple router advertisement processes that are easy to understand.
- **Easy to configure.** In its most basic form, configuring a distance vector routing protocol is as easy as enabling the protocol on the router interfaces.

The disadvantages of distance vector dynamic routing protocols include:

- **Large routing tables.** Multiple routes to a specific network ID appear as multiple entries in the routing table. In a large internetwork with multiple paths, the IP routing table can have hundreds or thousands of entries.

  This disadvantage is eliminated in some RIP router implementations, including Windows Server 2003, which store only one route — the route with the lowest metric — for any subnet in the routing table.
- **High network traffic overhead.** Route advertising is done at periodic intervals, even (unnecessarily) after the internetwork has converged.
- **Does not scale.** Because of the size of the routing table and the high network traffic overhead, distance vector routing protocols do not scale well to large or very large internetworks.
- **High convergence time.** Because of the unsynchronized and unacknowledged way that distance vector information is exchanged, convergence of the internetwork can take several minutes. During convergence, routing loops and black holes can occur and result in lost or undeliverable data.

For more information about the RIP distance vector routing protocol, see the section "How RIP Works" in How Unicast IPv4 Routing Protocols and Services Work.

**Link State Dynamic Routing Protocols**

A router that uses a link state dynamic routing protocol, such as OSPF, stores information about the state of each link between itself and other routers. Link state routing protocols address some of the limitations of distance vector routing protocols. The most important of these improvements is that link state dynamic routing protocols enable faster convergence than distance vector routing protocols.

Unlike distance vector routing protocols, which broadcast updates to all routers at regularly scheduled intervals, link state routing protocols provide updates only when a network link changes state. When such an event occurs, a notification called a *link state advertisement (LSA)* is sent throughout the network to update routing tables. LSAs, which include the router network IDs, are sent at startup and again any time that changes in the internetwork topology are detected. Link state updates are sent by using unicast or multicast traffic rather than by broadcasting. Link state routers build a database of LSAs and use the database to calculate the routing table. Routing information exchanged between link state dynamic routers is synchronized and acknowledged.

Link state routing protocols are more reliable and require less bandwidth than do distance vector routing protocols. However,

link state routing protocols are also more complex, more memory-intensive, and place a greater load on the CPU of a router.

The following table lists two major link state routing protocols used on internetworks based on two major routable network protocols.

**Common Link State Dynamic Routing Protocols**

| Routable Network Protocol | Link State Dynamic Routing Protocol |
|---|---|
| IP | Open Shortest Path First (OSPF) |
| IPX | NetWare Link Services Protocol (NLSP) |

The Windows Server 2003 Routing and Remote Access service includes OSPF; it does not include NLSP.

The advantages of link state dynamic routing protocols include:

- **Smaller routing tables.** Only a single optimal route for each network ID is stored in the routing table.
- **Low network traffic overhead.** Routers that use a link state dynamic routing protocol exchange less routing information after the internetwork has converged than do distance vector dynamic routing protocols. For example, after convergence OSPF sends only Hello packets at regular intervals. Unlike distance vector routing protocols, which broadcast updates to all routers at regularly scheduled intervals, link state routing protocols provide updates (in the form of an LSA) only when a network link changes state.
- **Ability to scale.** Because of smaller routing tables and low network traffic overhead, link state routing protocols scale well to large and very large internetworks.
- **Lower convergence time.** Link state routing protocols have a much lower convergence time than distance vector routing protocols. An internetwork that uses link state routing protocols converges without producing routing loops.

The disadvantages of link state dynamic routing protocols include:

- **Complexity.** Link state routing protocols are more complex and difficult to understand than distance vector routing protocols.
- **More time needed to configure.** A link state routing protocol implementation requires additional planning and configuration.
- **Resource intensive.** For very large internetworks, the database of LSAs and the calculation of routing table entries can be memory and processor intensive.

For more information about the OSPF link state dynamic routing protocol, see the section "How OSPF Works" in How Unicast IPv4 Routing Protocols and Services Work.

**Impact of Routing Loops and Black Holes During Convergence**

Routing problems can occur when either a host routing table or a router routing table contains information that does not reflect the correct topology of the internetwork. On an internetwork that uses dynamic routing, the routing internetwork must reconfigure itself to reflect the new topology whenever a link or router fails. The internetwork is in an unstable state during the period of time it takes for convergence to take place — during this period of time, routing loops and black holes can occur.

**Routing loops**

During the routing process, packets are forwarded by the sending host and then by one or more routers in the optimal direction as determined by information in each node's local routing table. If the routing table entries on all routers are correct, a unicast packet takes the best path from the source node to the destination node. However, if any routing table entry is incorrect, either through configuration errors or through learned routes that do not accurately reflect the topology of the internetwork, routing loops can occur.

A *routing loop* is a path through the internetwork that runs in a circle instead of reaching the intended destination. A routing loop occurs when routers forward traffic to each other in a loop that does not include the network segment of the destination.

The following figure illustrates an example of a routing loop that occurs when inaccurate information is stored in local routing tables.

In this example:

- According to the routing table on Router 1, the optimal route to Network 10 is through Router 2.
- According to the routing table on Router 2, the optimal route to Network 10 is through Router 3.
- According to the routing table on Router 3, the optimal route to Network 10 is through Router 1.

The result would be an infinite loop — except that routable protocols use a counter in the network layer header of the packet to prevent the packet from perpetually looping. Each time a router passes the packet from one network segment to another, the router either increases or decreases the counter. If the count reaches its maximum value (when increasing) or reaches 0 (when decreasing), the packet is discarded by the router. For example, when an IP node sends an IP packet, IP sets a maximum link count in the Time to Live (TTL) field in the IP header. Each IP router crossed by the packet decreases the TTL value in the packet by one. When the TTL value is 0, the IP router discards the packet and sends an ICMP Time Exceeded-TTL Exceeded in Transit message back to the sending node from which the packet originated.

One common type of routing loop can be avoided by ensuring that neighboring routers are not configured with default routes that point to each other: that is, on each router, the default route (0.0.0.0, 0.0.0.0) must not have the **Default gateway** field configured with the IP address of the other router. Because a default route passes all traffic that is not on a directly connected network to the configured router, routers that have default routes pointing to each other can produce routing loops for traffic with an unreachable destination.

By typing **ping -i 255** *IP_address* at a command prompt, you can initiate the detection of a possible routing loop. The **-i** parameter sets the TTL value in the ICMP Echo message. If the command results in the message **TTL Expired In Transit**, this indicates a possible routing loop. By typing **tracert** *IP_address* at a command prompt, you can then confirm that a routing loop exists if the output displays a set of repeating router IP addresses.

**Black holes**

The IP protocol is a connectionless, datagram-based protocol, which, by definition, does not guarantee a successful delivery. IP attempts a best effort, unacknowledged delivery to the next hop or to the final destination, which can lead to conditions on the internetwork in which data is lost.

If a downstream router fails and the failure is not detected by an upstream router, the upstream router continues to forward packets to the failed router. Because the failed downstream router does not receive the packets, the packets forwarded by the upstream router are dropped from the internetwork. The upstream router is said to be sending packets to a *black hole*, which is defined as a case in which packets on an internetwork are lost without any indication of an error.

In the following figure, Router 1 is not informed that Router 2 has failed and, therefore, continues to forward packets to Router 2. Router 2 is now a black hole because the packets are dropped and no error message is returned to Router 1.

A black hole can form when a link or router fails, and the failure is not yet detected. In a dynamic routing environment, routers detect failed links or failed routers when the lifetime of learned routes expires in their routing tables. In a static routing environment, a black hole persists until the functionality of the link or router is restored or until the static routers are reconfigured by the network administrator.

Black holes can also occur when an active router discards packets without indicating why the packets are discarded. For example, a Path Maximum Transmission Unit (PMTU) black hole router discards IP packets that need to be fragmented without returning a message to the sender indicating the error. A PMTU black hole router silently discards IP packets that require

fragmentation if the Don't Fragment (DF) flag in the IP header of the received packet is set to 1. PMTU black hole routers can be difficult to detect because packets of smaller sizes are forwarded.

**Link state protocols more robust than distance vector protocols**
One of the disadvantages of distance vector dynamic routing protocols, such as RIP, is that, on a large internetwork, several minutes might be required for convergence to occur. This delay can allow routing loops or black holes to occur during convergence.

Link state dynamic routing protocols provide more robust protection against black holes and routing loops. For example, OSPF prevents routing loops due to unsynchronized databases by not advertising links until the routers at each end of a link have synchronized their databases. OSPF also reduces the occurrence of black holes caused by one-way links by not including links in its database until the links are known to be bidirectional.

**Ranking Route Sources**
On a network that uses multiple sources of routing information, route sources are ranked in order of preference. If two or more route sources provide a route to the same destination, the route learned by the route source with a lower rank number is the preferred route. One reason that route sources must be ranked — either by accepting the default ranks or by reordering them — is because metric definitions differ for different route sources, including the RIP and OSPF routing protocols. Rather than trying to reconcile these dissimilar metrics, the router uses the route learned from the most preferred route source.

For example, if you configure a Routing and Remote Access router to use both RIP and OSPF, the Routing and Remote Access service adds both RIP-learned routes and OSPF-learned routes to the Route Table Manager (RTM) IP routing table. If you specify that the metric of an OSPF-learned route is 5 and that the metric of the corresponding RIP-learned route is 3, and if OSPF is the preferred routing protocol, RTM adds only the OSPF route to the IP forwarding table.

| ⚠**Caution** |
| --- |
| If you enable both RIP and OSPF on the same router, make sure that you configure each routing protocol on a separate interface, each connecting to a different network. |

If you use Windows Server 2003 Routing and Remote Access routers, you can modify the default preference levels for the following route sources in the Routing and Remote Access snap-in by navigating to the **IP Routing\General** node in the console tree and selecting the **Preference Levels** tab on the **General Properties** page:

- Local.
- Static, which refers to a static route assigned to a demand-dial interface that is added by using the Routing and Remote Access snap-in.
- Static (non demand-dial), which refers to a static route assigned to a LAN interface that is added by using the Routing and Remote Access snap-in.
- Auto-static.
- Network Management, such as SNMP, which refers to a static route assigned to a LAN interface that is added by using the **route add** command-line tool. You cannot use **route add** to add a route for a demand-dial interface.
- OSPF.
- RIP v2.

Alternatively, you can specify the relative preference level of any of these route sources by using the **netsh routing ip set preferenceforprotocol** command.

# Unicast IPv4 Routing Tools and Settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Unicast IPv4 Routing Tools
- Unicast IPv4 Routing Registry Entries
- Related Information

You can use the unicast IPv4 routing tools and registry settings described here to enable, configure, and manage the unicast IPv4 routing features provided by the Microsoft® Windows® Server™ 2003 Routing and Remote Access service.

**Unicast IPv4 Routing Tools**

The sets of tools listed in the following table are associated with unicast IPv4 routing as supported by the Windows Server 2003 Routing and Remote Access service.

**Available Tools for Unicast IPv4 Routing**

| Category | Tools in This Set |
|---|---|
| Command-line tools used for unicast IPv4 routing | • Netsh.exe, including:<br>  • Netsh ras commands for file tracing<br>  • Netsh routing IP commands for IP packet filtering and for configuring interfaces, persistent and non-persistent static routes, and preference levels for routing protocols (route sources)<br>  • Netsh routing IP OSPF commands<br>  • Netsh routing IP relay commands (for the DHCP relay agent)<br>  • Netsh IP RIP commands<br>  • Netsh routing IP routerdiscovery commands (for ICMP router discovery)<br>• Pathping.exe<br>• Ping.exe<br>• Route.exe<br>• Tracert.exe |

| | |
|---|---|
| Graphical user interface tools used for unicast IPv4 routing | • Network Connections (default gateway options only)<br>• Rrasmgt.msc — Routing and Remote Access snap-in, including:<br>  • Options for enabling, disabling, or refreshing the Routing and Remote Access service<br>  • General options (event logging and route source preference options)<br>  • RIP for IP options<br>  • OSPF options<br>  • DHCP Relay Agent options<br>  • IP packet filtering options<br>  • ICMP router discovery options |

Each of these tools is described in the following sections.

You can specify commands for the command-line tools for one or more remote servers by establishing a remote access connection to each server from a workstation running Microsoft Windows XP or from another server, and then opening a command prompt window in the remote access window for each server. You can also specify Network Connections and Routing and Remote Access snap-in options by establishing a remote access connection. In addition, you can use the Remote Access snap-in to manage multiple servers running the Routing and Remote Access service by accessing the node for each server.

**Netsh.exe: Netsh Commands for Managing IPv4 Routing**

**Category** The Netsh commands for IPv4 routing are a subset of the Netsh command-line tools that are included with the Windows Server 2003 operating system. In many cases, a Netsh command can be used to manage the Routing and Remote Access service as an alternative to using an option available in the Routing and Remote Access snap-in. Netsh also includes commands for IPv6.

**Version compatibility** The Netsh commands for IP routing are compatible with the Windows Server 2003 operating system. Netsh commands were first introduced in Microsoft Windows 2000 Server and were expanded to include additional commands in Windows Server 2003.

The Netsh commands help network administrators manage a TCP/IP network. You can use Netsh locally or remotely to display or modify the configuration of services or protocols on Windows-based computers. The Netsh command-line interface is scriptable, which lets you perform batch configurations or remote network administration from a single location.

Netsh provides sets of commands (also known as contexts) for performing a wide range of network configuration tasks. In addition to a few commands from the Netsh ras and Netsh interface contexts, this document describes several Netsh Routing IP contexts used in conjunction with the unicast IPv4 routing features of the Routing and Remote Access service.

For more information about Netsh, see Command-Line Reference for Windows Server 2003, Standard Edition. In particular, for information about IP routing-related commands not included in this technical reference, see the following Netsh contexts:

- **Netsh ras context,** for remote access configuration.
- **Netsh interface context,** for configuration of demand-dial interfaces.
- **Netsh routing IP NAT context,** for network address translation (NAT).
- **Netsh interface IPv6 context,** for manually configuring IPv6 settings.
- **Netsh routing IP IGMP context,** for multicast routing.

Each of the listed Netsh contexts contains unicast routing–related commands not included in this technical reference, except for the IGMP context, which contains multicast routing–related commands.

**How to access Netsh commands**

You can access a particular command in any Netsh context in one of the following two ways:

**Type the entire path for the command at the command prompt.** For example, to view IPv4 router discovery configuration data, type the following command at a command prompt:

**C:\>netsh routing ip routerdiscovery show interface name="Local Area Connection"**

The preceding command produces the following output:

```
Router Discovery Information for Local Area Connection 3

---------------------------------------------------------------------

Router Discovery is: Disabled

Minimum Advertisement Interval: 7 minutes

Maximum Advertisement Interval: 10 minutes

Advertisement Lifetime: 30 minutes

Preference Level: 0
```

**Access the context containing the command that you want to use, and then type only the specific command.** The following series of commands displays the same output as the preceding example:

**C:\>netsh**

**netsh>routing**

**netsh routing>ip**

**netsh routing ip>routerdiscovery**

**netsh routing ip routerdiscovery>show interface name="Local Area Connection"**

The preceding series of commands produce the following output:

```
Router Discovery Information for Local Area Connection 3

---------------------------------------------------------------------

Router Discovery is: Disabled

Minimum Advertisement Interval: 7 minutes

Maximum Advertisement Interval: 10 minutes

Advertisement Lifetime: 30 minutes

Preference Level: 0
```

The following sections contain a brief description of unicast IPv4 routing commands that are related to the Routing and Remote Access service and that are available for the following Netsh contexts:

- Netsh ras context (includes only commands for configuring file tracing)
- Netsh routing IP context (includes only commands for configuring IP packet filtering, interfaces, persistent and non-persistent static routes, and preference levels for route sources)
- Netsh routing IP OSPF context
- Netsh routing IP relay context
- Netsh routing IP RIP context
- Netsh routing IP routerdiscovery context

**Netsh ras context**

The Routing and Remote Access service provides extensive tracing capability to help troubleshoot complex network problems. Separate routing components can be independently enabled so that tracing information can be logged to files (known as *file tracing*). Logged data includes information about internal component variables, function calls, and interactions. You can enable and disable tracing for routing protocols while the router is running.

| **Note** |
| --- |
| You can also enable file tracing for Routing and Remote Access components, such as the RIP and OSPF routing protocols, by editing the registry (see Unicast IPv4 Routing Registry Entries later in this document). However, using Netsh commands is the recommended method. |

Tracing consumes system resources and must be used sparingly. After you obtain the trace or identify the problem, immediately disable tracing. In particular, do not leave tracing enabled on multiprocessor computers.

The Netsh ras context includes primarily remote access–related commands, which are not included here. The following table lists only the file tracing commands for the RIP v2 and OSPF routing protocols that are available in the Netsh ras context.

**Unicast IPv4 Routing Commands in the Netsh Ras Context**

| Command | Task |
| --- | --- |
| Set | You can use the following commands:<br>• **Set tracing** *component* **enable**. Enables file tracing for the specified component. For example, **set tracing iprip2 enable** or **set tracing ospf enable**.<br>• **Set tracing** *component* **disable**. Disables file tracing for the specified component. For example, **set tracing iprip2 disable** or **set tracing ospf disable**.<br>• **Set tracing * enable**. Enables file tracing on all components. |
| Show | You can use the following commands:<br>• **Show tracing.** Lists components for which it is possible to enable file tracing and shows whether file tracing for each one is currently enabled or disabled.<br>• **Show tracing** *component*. Shows whether file tracing for the specific component is enabled. For example, **show tracing iprip2** or **show tracing ospf**. |

Most of the commands available in the Netsh ras context are used for remote access networking, such as for demand-dial or virtual private network (VPN) connections. These commands are also unicast IPv4 commands, but they are not covered in this technical reference. For more information about tools for remote access networking, see Demand Dial Tools and Settings and VPN Tools and Settings.

**Netsh routing IP context**

The partial set of commands included in this document for this context are the Netsh commands used to configure IP packet filtering, which can help increase security on a private IP internetwork connected to the Internet by specifying which IP packet traffic is accepted or rejected; the commands used to configure interfaces, persistent and non-persistent static routes; and preference levels for route sources. Also included, in separate sections later in this document, are several relevant contexts accessible under the Netsh routing IP context: the OSPF, RIP, relay (for the DHCP relay agent), and IP router discovery contexts.

Excluded from this technical reference are Netsh commands used for IPv4 multicast routing, network address translation (NAT), DHCP, DNS, and remote access.

The following table describes commands available in the Netsh routing IP context that are relevant to the unicast IPv4 routing services provided by the Routing and Remote Access service.

**Unicast IPv4 Routing Commands in the Netsh Routing IP Context**

| Command | Task |
| --- | --- |
| Add | • **Add filter**. Adds an IP packet filter to the specified interface and configures one or more of the following parameters: |

- The name of the interface on which to add the filter.
- The type of filter (input filter, output filter, or a filter for a dial-up interface).
- The source IP address and subnet mask of the packet to be filtered.
- The destination IP address and subnet mask of the packet to be filtered.
- The protocol type (TCP, TCP-EST, or UDP) and the source and destination ports for the packet to be filtered.
- TCP-EST refers to TCP [established] and is used, for example, in a site-to-site VPN or dial-up connection when a calling router connects to an answering router. If you specify **TCP [established]**, traffic is accepted only if the calling router has already initiated the TCP connection.
- The ICMP type and ICMP code of the packet to be filtered.

- **Add interface**. Enables IP forwarding on an interface as it adds the interface (**add interface name="***Interface Name***" state=enable**) or disables IP forwarding on an interface as it adds the interface (**add interface name= "***Interface Name***" state=disable**).

- **Add persistentroute**. Adds a persistent static route to the specified interface, including:
  - The destination IP address and subnet mask for the route.
  - The name of the interface on which the route is to be added.
  - The next hop (gateway) IP address for the route (omit for point-to-point interfaces).
  - The connection type for this route, that is, **static** (which triggers a demand-dial connection) or **nondod** (which does not trigger a demand-dial connection).
  - The preference for this route, and its metric. The metric is used to break ties among routes with equal preference.
  - The view (unicast, multicast, or both) for this route.

- **Add preferenceforprotocol**. Sets the preference level for any of the following route sources:
  - Autostatic
  - Local
  - NetMgmt (network management, such as SNMP)
  - Nondod (a static route assigned to a LAN interface)
  - OSPF
  - RIP
  - Static (a static route assigned to a demand-dial interface)

**Note**

| | |
|---|---|
| | If two routes exist to the same destination, the route learned by the route source with a higher preference is preferred over the route learned by the route source with a lower preference regardless of the route metric. For example, if the preference level for OSPF is higher than the preference level for RIP v2, an OSPF route with a metric of 5 is entered into the routing table rather than the same route discovered by RIP with a metric of 3.<br><br>• **Add rtmroute**. Adds a non-persistent route used for network management to the specified interface name, including:<br>  ◦ The destination IPaddress and subnet mask for the route.<br>  ◦ The name of the interface on which the route is to be added.<br>  ◦ The next hop (gateway) IP address for the route (omit for point-to-point interfaces).<br>  ◦ The preference for this route, and its metric. The metric is used to break ties among routes with equal preference).<br>  ◦ The view (unicast, multicast, or both) for this route. |
| Delete | • **Delete filter**. Deletes an IP packet filter from the specified interface.<br>• **Delete interface**. Deletes the specified interface, which also removes IP forwarding on that interface.<br>• **Delete persistentroute**. Deletes a persistent static route from the specified interface.<br>• **Delete preferenceforprotocol**. Deletes the preference level for a specified routing protocol type (also known as *route source*).<br>• **Delete rtmroute**. Deletes a non-persistent route used for network management when either the interface name or the next hop count is specified. |
| Dump | Creates a script that contains the current configuration for this server. If you save the script to a file, you can use it to restore altered configuration settings or to configure a new server.<br><br>"Current configuration" refers to all configuration settings in and below the specific node in the Routing and Remote Access snap-in at which the command "dump" is given. Because this table refers to the Netsh routing IP context, in this case, the dump command includes all configuration settings in the **IP Routing node** and any configured child nodes, including the **General, Static Routes**, **DHCP Relay Agent**, **OSPF**, **NAT/Basic Firewall**, and **IGMP** nodes.<br><br>If you plan to make extensive changes to the configuration of this server, a recommended practice is to begin the configuration session by using the **dump** command before you start, in case you need to restore the configuration later. |
| Set | • **Set filter**. Changes the default action (drop or forward) for a filter type (input, output, or dial-up) or changes the fragmentation check setting (enable or disable) on the specified interface.<br>• **Set interface**. Enables or disables the specified interface.<br>• **Set loglevel**. Sets the global logging level to one of the following: none; errors only; errors and warnings; or errors, warnings, and informational messages.<br>• **Set persistentroute**. Modifies a persistent static route on the specified interface by changing one or more of the following: |

- The destination IP address and subnet mask for the specified route.
- The name of the interface on which the route is to be modified.
- The next hop for the route (omit for point-to-point interfaces).
- The connection type for this route that is **static** (which triggers a demand-dial connection) or **nondod** (which does not trigger a demand-dial connection).
- The preference for the route.
- The metric for the route. The metric is used to break ties among routes with equal preference.
- Whether the route is valid only for unicast traffic, only for multicast traffic, or for both types of traffic.

- **Set preferenceforprotocol**. Sets the preference level for any of the following protocol types (also known as *route sources*):
  - Autostatic
  - Local
  - NetMgmt (network management, such as SNMP)
  - Nondod (a static route assigned to a LAN interface)
  - OSPF
  - RIP
  - Static (a static route assigned to a demand-dial interface)
- **Set rtmroute**. Modifies a non-persistent route used for network management on the specified interface:
  - The destination IP address and subnet mask for the route.
  - The interface on which the route is to be added.
  - The next hop (gateway) IP address for the route (omit for point-to-point interfaces).
  - The preference for this route.
  - The metric for this route. The metric is used to break ties among routes with equal preference.
  - The view (unicast, multicast, or both) for this route.

| | |
|---|---|
| Show | • **Show filter**. For all interfaces or for the specified interface, indicates whether input, output, or demand-dial IP packet filters are configured and shows whether fragmentation checking is enabled. If a filter exists for a given interface, displays filter information for that interface.<br><br>• **Show interface**. For all interfaces or for the specified interface, displays information including interface type, vendor, routing protocols running on a given interface, and whether or not an interface is enabled.<br><br>• **Show loglevel**. Displays the global logging level, which is one of the following: none; errors only; errors and warnings; or errors, warnings, and informational messages.<br><br>• **Show persistentroutes**. For all interfaces or for the specified interface, displays persistent static routes, including:<br><br>  ◦ Each route and its address prefix . The address prefix is shown in classless interdomain routing (CIDR) notation, for example, 10.0.0.1/8.<br><br>  ◦ The protocol (route source) that added this route.<br><br>  ◦ The preference for this route, and its metric.<br><br>  ◦ The next hop (gateway) IP address for the route, and the interface that this route uses to forward packets.<br><br>  ◦ The view (unicast, multicast, or both) for this route.<br><br>• **Show preferenceforprotocol**. Lists the current preference level (relative priority) for each IP routing protocol type (each type of route source).<br><br>• **Show protocol**. Displays all configured IP protocols, including unicast IP protocols.<br><br>• **Show rtmdestinations** [1]. Displays the IP forwarding table. IP uses the forwarding table to forward packets.<br><br>• **Show rtmroutes** [1]. Displays the IP routing table. IP uses the routing table to store all routes from all possible sources. |

1. The Routing and Remote Access service on a router running Windows Server 2003 maintains the IP routing table by using a component called the Route Table Manager, abbreviated as "rtm" in the commands **rtmroutes** and **rtmdestinations**. The Route Table Manager updates the IP forwarding table based on incoming route information from multiple sources.

**Netsh routing IP OSPF context**

Open Shortest Path First (OSPF), the most common routing protocol used on large and very large IPv4 internetworks, enables the dynamic exchange of IPv4 routing information between OSPF routers across complex internetworks. Typically, OSPF is deployed on private IP internetworks connected to the public Internet, including internetworks that span multiple geographical regions, nations, or continents.

OSPF is structured as an autonomous system made up of one or more OSPF areas. Each area is made up of a logical collection of networks, routers, and links, and each area includes special OSPF routers that enable communication among the constituent areas. OSPF routers in each area dynamically build and synchronize a database of the OSPF network topology, called a *link state database* (LSDB). The LSDB is a topological map of all routers in the same OSPF area, and OSPF routers can update the LSDB in response to topology changes.

The following table describes the commands available in the Netsh routing IP OSPF context. The OSPF routing protocol is provided by the Windows Server 2003 Routing and Remote Access service.

**Commands in the Netsh Routing IP OSPF Context**

| Command | Task |
|---|---|

| | |
|---|---|
| Add | • **Add area**. Adds an OSPF area. Specify the area ID, which is a 32-bit number expressed in dotted decimal notation. The only required OSPF area is the OSPF backbone area, which requires the reserved area ID of 0.0.0.0. An OSPF backbone area is either the sole area in the OSPF autonomous system, or it is the central area to which all other OSPF areas in this OSPF autonomous system connect and through which packets are routed from one non-backbone area to another non-backbone area.<br><br>Although an OSPF area ID is neither an IP address nor an IP network ID, if this is not the backbone area and if the entire area can be summarized with a single network ID, you can set the area ID to match the single network ID. For example, if an area contains all of the subnets for the IP network 10.1.0.0/16, you can set the area ID to 10.1.0.0.<br><br>• **Add interface**. Enables OSPF on the specified interface.<br><br>• **Add neighbor**. Adds an OSPF neighbor router on a non-broadcast multiple access (NBMA) network. Specify the IP address of the OSPF router at the opposite end of the NBMA link from this router, and then specify the router priority of the neighbor router.<br><br>• **Add protofilter**. Adds an OSPF protocol filter (autostatic, local, RIP, SNMP, non-demand-dial, or static).<br><br>• **Add range**. Adds the network ID and subnet mask pair that define a range of addresses for the specified area ID. This {network ID, subnet mask} pair is known as a *summary route* and is used to summarize routes within this OSPF area.<br><br>• **Add routefilter**. Adds an OSPF route filter. Specify the IP address and subnet mask pair of the OSPF route to be filtered.<br><br>• **Add virtif**. Adds a virtual interface (also called a *virtual link*). Specify the OSPF transit area ID and the OSPF router ID of the virtual OSPF neighbor router. A virtual link is a logical connection that enables the exchange of routing information between a backbone area border router (ABR) and an ABR that is not physically connected to the backbone area across a transit area. You cannot configure a virtual link across the backbone area. |
| Delete | • **Delete area**. Deletes the specified OSPF area by deleting its area ID.<br><br>• **Delete interface**. Disables OSPF on the specified interface.<br><br>• **Delete neighbor**. Deletes the specified OSPF neighbor router on an NBMA network.<br><br>• **Delete protofilter**. Deletes the specified OSPF protocol filter (autostatic, local, RIP, SNMP, non-demand-dial, or static).<br><br>• **Delete range**. Deletes the IP address and subnet mask pair that define a range of addresses (a summary route) for the specified OSPF area ID.<br><br>• **Delete routefilter**. Deletes the specified OSPF route filter.<br><br>• **Delete virtif**. Deletes the specified virtual interface on this OSPF router. |
| Dump | Creates a script that contains the current configuration for OSPF. If you save the script to a file, you can use it to restore altered configuration settings or to configure a new OSPF router.<br><br>If you plan to make extensive changes to the configuration of an OSPF router, a recommended practice is to begin the configuration session by using the **dump** command before you start, in case you need to restore the configuration later. |

| | |
|---|---|
| Install | Installs the OSPF routing protocol under the IP routable protocol. |
| Set | • **Set area**. For the specified OSPF area, sets the following:<br>  ◦ Whether plaintext passwords are required. Plaintext passwords are used by routers to identify each other, not for security. Passwords are enabled by default, and all interfaces in the same area must use the same password.<br>  ◦ Whether this area is a stub area, and, if so, the cost of the summary default route that an OSPF router in this area uses to reach all destinations external to its OSPF autonomous system.<br>  ◦ Whether the OSPF area imports summary advertisements.<br>• **Set global**. For the specified OSPF router, sets the following:<br>  ◦ Whether the router acts as an autonomous system boundary router (ASBR).<br>  ◦ Whether the amount of information logged is one of the following: none; errors only; errors and warnings; or errors, warnings, and informational messages.<br>• **Set interface**. For the specified OSPF interface, sets the following:<br>  ◦ The name, IP address, and subnet mask of the interface; whether the interface is enabled or disabled; and the OSPF area ID.<br>  ◦ Whether the interface is on an NBMA, point-to-point, or broadcast network, and the interface priority.<br>  ◦ The estimated number of seconds to transmit a link state update packet over this interface; the interval in seconds between link state advertisement retransmissions for adjacencies; the interval in seconds between transmissions of hello packets; the number of seconds before a neighboring router considers this router to be down; and (for an NBMA interface only) the interval in seconds between OSPF network polls.<br>  ◦ The cost of sending a packet from this interface.<br>  ◦ The password (if simple password authentication is enabled for this OSPF area). Passwords are enabled by default, and all interfaces in the same area must use the same password.<br>  ◦ The maximum size, in bytes, of IP packets carrying OSPF information that can be sent without fragmentation.<br>• **Set protofilter**. For the OSPF protocol filter (autostatic, local, RIP, SNMP, non-demand-dial, or static), specifies whether the action for IP packets is **drop** or **accept**.<br>• **Set routefilter**. For the OSPF route filter, specifies whether IP packets are accepted or dropped.<br>• **Set virtif**. For the specified OSPF virtual interface (virtual link), sets the following:<br>  ◦ The IP address of the transit area, and the OSPF router ID of the virtual neighbor router.<br>  ◦ The estimated number of seconds to transmit a link state update packet over this interface; the interval in seconds between link state advertisement retransmissions for adjacencies; the interval in seconds between transmissions of hello packets; and the number of seconds before a neighboring router considers this router to be down. |

| | |
|---|---|
| | • The password (if simple password authentication is enabled). |
| Show | • **Show area**. Shows configuration information about this OSPF area, including:<br>  • Whether the area is created and enabled as an OSPF area, or created but not enabled.<br>  • Authentication type (such as simple password authentication), if any. Plaintext passwords for this type of authentication are used by routers to identify each other, not for security.<br>  • Whether the area is a stub area, and if so, its metric.<br>  • Whether the area imports summary advertisements.<br>• **Show areastats**. For each OSPF area, or for the specified area, shows the state (**Up** or **Down**) and the shortest path first (SPF) count. The SPF count is the number of least-cost paths that this router has calculated from itself to each other router and subnet in this OSPF autonomous system (if only one OSPF area exists) or to each other router in the local area (if multiple OSPF areas exist).<br>• **Show global**. Shows global configuration information for this OSPF router:<br>  • Whether the router is created and enabled as an OSPF router, or created but not enabled.<br>  • The OSPF router ID.<br>  • Whether the router is an area border router (ABR).<br>  • The specified level of logging for this router.<br>• **Show interface**. Shows OSPF configuration information for the specified OSPF interface, including:<br>  • Whether the interface is created and enabled as an OSPF interface, or created but not enabled.<br>  • The IP address, subnet mask, area ID, interface type, and router priority of the OSPF interface.<br>  • The current values for transit delay, hello interval, dead interval, poll interval, metric, and maximum transmission unit (MTU) size.<br>• **Show lsdb**. Displays information about the OSPF link state database (LSDB):<br>  • **Area**. The identification number of the OSPF area for each link state advertisement (LSA) in the table.<br>  • **Type**. The type of advertisement, including Router, Net-Summary, Stub, Network, ASBR-Summary, or AS External.<br>  • **Link State ID**. The identification number of each advertisement shown in the output. The advertisements vary by advertisement type.<br>  • **Adv Router**. The OSPF router ID of the advertising router.<br>  • **Age**. The age (in seconds) since the advertisement originated.<br>  • **Sequence**. A sequence number that identifies old or duplicate advertisements.<br>• **Show neighbor**. Lists OSPF neighbor routers and information about each neighbor: |

| | |
|---|---|
| | • **Neighbor**. The IP address of each neighbor router.<br>• **Neighbor ID**. Each neighbor router's OSPF router ID.<br>• **State**. Displays one of the following: Down; Attempt; Init; 2-way; ExStart; Exchange; Loading; or Full. For a definition of each of these states, see "How OSPF Works" in How Unicast IPv4 Routing Protocols and Services Work.<br>• **Priority**. The router priority of each neighboring router.<br>• **State-changes and errors**. The total number of changes of state and errors.<br>• **Queue length**. The length of the retransmit queue.<br>• **Show protofilter**. For the OSPF protocol filter (autostatic, local, RIP, SNMP, non-demand-dial, or static), shows whether the action for IP packets is **drop** or **accept**.<br>• **Show routefilter**. Displays OSPF route filter information.<br>• **Show virtif**. Displays information about the specified virtual link.<br>• **Show virtifstats**. Displays information about all OSPF virtual links:<br>• **Area ID**. The area ID of the transit area for the virtual link.<br>• **Neighbor ID**. The neighboring router's OSPF router ID.<br>• **State**. Displays one of the following: Down; Loopback; Waiting; Point-to-point; Designated-router; Backup designated-router; Other; or Unknown.<br>• **Sent packets**. The number of packets sent over this virtual link.<br>• **Received packets**. The number of packets received over this virtual link.<br>• **Dropped packets**. The number of packets that failed to be transmitted over this virtual link. |
| Uninstall | Removes the OSPF routing protocol. |

**Netsh routing IP relay context**

Any IPv4 subnet that contains DHCP clients requires either a DHCP server or a properly configured DHCP relay agent to provide address leases to those DHCP clients. A computer acting as a DHCP relay agent forwards DHCP messages between DHCP clients on an IP subnet that has no DHCP server and a DHCP server located on a different subnet. Using DHCP relay agents make it unnecessary to install a separate DHCP server on each subnet.

The following table describes the commands related to DHCP and DHCP relay agent in the Netsh routing IP relay context. The capability to enable a router to act as a DHCP relay agent is provided by the Windows Server 2003 Routing and Remote Access service.

**Commands in the Netsh Routing IP Relay Context**

| Command | Task |
|---|---|
| Add | • **Add dhcpserver**. Adds a DHCP server to the global list of DHCP servers.<br>• **Add interface**. Enables the DHCP Relay Agent service on the specified interface. |

| | |
|---|---|
| Delete | • **Delete dhcpserver**. Deletes a DHCP server from the global list of DHCP servers.<br><br>• **Delete interface**. Disables the DHCP Relay Agent service on the specified interface. |
| Dump | Creates a script that contains the current configuration for the DHCP relay agent. If you save the script to a file, you can use it to restore altered configuration information.<br><br>If you plan to make extensive changes to the configuration of a DHCP relay agent, a recommended practice is to begin the configuration session by using the **dump** command before you start, in case you need to restore the configuration later. |
| Install | Installs the DHCP Relay Agent service. |
| Set | • **Set global**. Sets the logging level for a DHCP relay agent to one of the following: none; errors only; errors and warnings; or errors, warnings, and informational messages.<br><br>• **Set interface**. On the specified interface, updates the following DHCP relay agent information:<br><br>  • Whether the DHCP Relay Agent service is enabled or disabled.<br><br>  • The maximum hop count before a DHCP packet is dropped.<br><br>  • The minimum number of seconds that the DHCP relay agent waits before forwarding a DHCP packet (from a DHCP client computer initiating an IP address renewal request) to a listed DHCP server.<br><br>  • The delay allows a DHCP server on the local subnet (if one is available) time in which to respond to the DHCP client's request. If no DHCP server responds after the configured interval, the DHCP relay agent then processes the request. |

| | |
|---|---|
| Show | • **Show global**. Displays the following information about the DHCP relay agent configured on this router:<br>  • The logging level: none; errors only; errors and warnings; or errors, warnings, and informational messages.<br>  • The maximum number of DHCP packets in the router's queue (for all interfaces).<br>  • The number of DHCP servers in the global list.<br>• **Show ifbinding**. For the specified interface, displays IP address bindings. If no interface is specified, displays IP address bindings for each interface on which the DHCP relay agent is enabled.<br>• **Show ifconfig**. For the specified interface, displays:<br>  • Whether the DHCP relay agent is bound and enabled.<br>  • The maximum hop count before a DHCP packet is dropped.<br>  • The minimum number of seconds from startup before a DHCP packet is sent to a listed DHCP server.<br>  If no interface is specified, displays this information for each interface on which the DHCP relay agent is enabled.<br>• **Show ifstats**. For the specified interface, displays:<br>  • The number of send and receive failures.<br>  • Address Resolution Protocol (ARP) update failures.<br>  • Requests and replies received or discarded.<br>  If no interface is specified, displays statistics for each interface on which the DHCP relay agent is enabled.<br>• **Show interface**. For the specified interface, displays:<br>  • The state (enabled or disabled, and bound or unbound).<br>  • The relay mode (enabled or disabled).<br>  • The maximum hop count.<br>  • The minimum number of seconds that a DHCP relay agent waits after a DHCP client initiates an IP address renewal request before the DHCP relay agent forwards the DHCP client request to a remote DHCP server. |
| Uninstall | Removes the DHCP Relay Agent service. |

**Netsh routing IP RIP context**

Routing Information Protocol (RIP), the primary dynamic routing protocol used on small or medium-sized IPv4 internetworks (10 to 50 networks), enables the dynamic exchange of IPv4 routing information between RIP routers. RIP routers can update IP internetwork topology changes as networks are added or removed and as links fail and are restored.

The following table describes the commands available in the Netsh routing IP RIP context. The RIP routing protocol is provided by the Windows Server 2003 Routing and Remote Access service, which supports both the updated version of RIP, RIP version 2 (RIP v2) and the earlier version of RIP, RIP version 1 (RIP v1).

**Commands Available in the Netsh Routing IP RIP Context**

| Command | Task |
|---|---|
| Add | • **Add acceptfilter**. Adds an acceptance filter for routes received on an interface by specifying the IP address range.<br>• **Add announcefilter**. Adds a filter for routes announced on an interface by specifying the IP address range.<br>• **Add interface**. Enables RIP on the specified interface, and configures the following:<br>  ◦ A metric value for routes based on the interface.<br>  ◦ Whether to perform on-demand updates or periodic updates.<br>  ◦ Whether to announce no routes, RIP v1 routes only, RIP v1 and v2 routes, or RIP v2 routes only.<br>  ◦ Whether to accept no routes, RIP v1 routes only, RIP v1 and v2 routes, or RIP v2 routes only.<br>  ◦ An interval for route expiration, route removal, and full update.<br>  ◦ Whether simple password authorization is required. This type of authorization uses plaintext passwords, which are used by routers to identify each other, not for security.<br>  ◦ The route tag.<br>  ◦ Whether to use unicast mode in addition to the default mode, use only unicast mode, or to disable unicast mode. The default mode is to use broadcast or multicast only (but not unicast), based on the RIP version used (that is, RIP v1 broadcast, RIP v 2 broadcast, or RIP v 2 multicast).<br>  ◦ Whether to include, exclude, or disable acceptance filters.<br>  ◦ Whether to include, exclude, or disable announcement filters.<br>  ◦ A plaintext password (1–16 characters).<br>• **Add neighbor**. Adds a RIP neighbor router on an interface. Specify the IP address for the RIP neighbor router.<br>• **Add peerfilter**. Adds a filter for another RIP router from which this router will accept announcements. Specify the IP address of the peer server. By default, RIP announcements from all sources are accepted. By configuring filters accepting announcements from one or more RIP peers, RIP announcements from unauthorized RIP routers are discarded. |
| Delete | • **Delete acceptfilter**. Deletes an acceptance filter for routes received on an interface.<br>• **Delete announcefilter**. Deletes an announcement filter set for an interface.<br>• **Delete interface**. Disables RIP from the specified interface.<br>• **Delete neighbor**. Deletes a RIP neighbor from an interface.<br>• **Delete peerfilter**. Deletes a filter that specifies another RIP router from which this router will accept announcements. |

| | |
|---|---|
| Dump | Creates a script that contains the current configuration for RIP. If you save the script to a file, you can use it to restore altered configuration information or to configure a new RIP router.<br><br>If you plan to make extensive changes to the configuration of a RIP router, a recommended practice is to begin the configuration session by using the **dump** command before you start, in case you need to restore the configuration later. |
| Install | Installs the RIP routing protocol under the IP routable protocol. |
| Set | • **Set flags**. Sets RIP-related flags for the specified interface by specifying one or more of the following values:<br><br>  ◦ **Clear**. Clear all currently set RIP-related flags.<br><br>  ◦ **Splithorizon**. Enable RIP for split horizon.<br><br>  ◦ **Poisonreverse**. Enable RIP for poison reverse.<br><br>  ◦ **Triggeredupdates**. Enable RIP triggered updates.<br><br>  ◦ **Cleanupupdates**. Enable cleanup updates for RIP.<br><br>  ◦ **Accepthostroutes**. Enable acceptance of host routes.<br><br>  ◦ **Acceptdefaultroutes**. Enable acceptance of default routes.<br><br>  ◦ **Senddefaultroutes**. Enable sending of default routes.<br><br>  ◦ **Nosubnetsummary**. Disable subnet summarization.<br><br>• **Set global**. Sets the following global RIP parameters:<br><br>  ◦ Whether to set the level of logging for RIP events to one of the following: none; errors only; errors and warnings; or errors, warnings, and informational messages.<br><br>  ◦ Minimum interval in minutes between triggered updates.<br><br>  ◦ Whether to include peers, exclude peers, or disable peer mode.<br><br>• **Set interface**. Modifies one or more of the following on the specified interface:<br><br>  ◦ A metric value for routes based on this interface.<br><br>  ◦ Whether to perform on-demand updates or periodic updates.<br><br>  ◦ Whether to announce no routes, RIP v1 routes only, RIP v1 and v2 routes, or RIP v2 routes only.<br><br>  ◦ Whether to accept no routes, RIP v1 routes only, RIP v1 and v2 routes, or RIP v2 routes only.<br><br>  ◦ An interval for route expiration, route removal, and full update.<br><br>  ◦ Whether simple password authorization is required. This type of authorization uses plaintext passwords, which are used by routers to identify each other, not for security.<br><br>  ◦ The route tag.<br><br>  ◦ Whether to also use unicast mode in addition to default mode, only use unicast mode, or to disable unicast mode. The default mode is to use broadcast or multicast only (but not unicast), based on the |

| | |
|---|---|
| | RIP version used (that is, RIP v1 broadcast, RIP v 2 broadcast, or RIP v 2 multicast).<br>● Whether to include, exclude, or disable acceptance filters.<br>● Whether to include, exclude, or disable announcement filters.<br>● A plaintext password (16 characters maximum). |

| | |
|---|---|
| Show | • **Show flags**. Displays RIP flags set on the specified interface.<br><br>• **Show global**. Displays global parameters for this RIP router:<br><br>  • The specified level of logging: none; errors only; errors and warnings; or errors, warnings, and informational messages.<br><br>  • The maximum size for the receive queue and for the send queue.<br><br>  • The minimum interval in minutes between triggered updates.<br><br>  • The status (include, exclude, or disable) for peer filter mode.<br><br>  • The number of peer filters.<br><br>• **Show globalstats rr=** *n*. Displays the number of route changes and the number of responses sent every *n* seconds. In this command, rr stands for refresh rate, that is, the interval, in seconds, that you specify after which the statistics for route changes and responses sent are refreshed.<br><br>• **Show ifbinding**. Displays IP address bindings for the specified RIP interface.<br><br>• **Show ifstats**. Displays RIP statistics for the specified RIP interface, including:<br><br>  • Send and receive failures.<br><br>  • Requests sent and received.<br><br>  • Responses sent and received.<br><br>  • Bad response packets and bad response entries received.<br><br>  • Triggered updates sent.<br><br>• **Show interface**. Displays RIP configuration for the specified interface, including:<br><br>  • Metric.<br><br>  • Update, accept, and announce modes.<br><br>  • Interval for route expiration, route removal, and full update.<br><br>  • Authentication type and password.<br><br>  • Route tag.<br><br>  • Unicast peer mode, accept filter mode, and announce filter mode.<br><br>  • Unicast peer count, accept filter count, and announce filter count.<br><br>• **Show neighbor**. Shows RIP neighbor statistics. |
| Uninstall | Removes the RIP routing protocol |

**Netsh routing IP routerdiscovery context**

In unicast IPv4 routing, ICMP router discovery is an alternative to using manually configured or DHCP-configured default

gateways.

| Note |
| --- |
| In IPv6 unicast routing, IPv6 Neighbor Discovery (ND) replaces and improves the functionality of Address Resolution Protocol (ARP), ICMP Router Discovery, and ICMP Redirect, which together are the IPv4 counterparts for IPv6 ND. ND, which is a set of messages and processes that determine relationships between neighboring nodes, is described in RFC 2461, "Neighbor Discovery for IP Version 6 (IPv6)," in the IETF RFC Database. |

ICMP router discovery automates the discovery and configuration of the default gateway so that IP hosts can dynamically discover the best default gateway to use on a subnet and can automatically switch to another default gateway if the first default gateway fails or if the network administrator changes router preferences.

The following table describes the commands for ICMP router discovery in the Netsh routing IP routerdiscovery context. ICMP router discovery is provided by the Windows Server 2003 Routing and Remote Access service.

**Commands in the Netsh Routing IP Routerdiscovery Context**

| Command | Task |
| --- | --- |
| Add | **Add interface**. On the specified interface, specifies the following:<br>• Whether ICMP router discovery is enabled or disabled.<br>• A minimum and a maximum interval in minutes between router discovery packets.<br>• The time in minutes after which a host considers the interface to be failed (which is after it has received its last Router Advertisement message from this router).<br>• The preference level for using this interface as the default gateway. A higher number indicates a higher level of preference. |
| Delete | **Delete interface**. Disables ICMP router discovery configuration for the specified interface. |
| Dump | Creates a script that contains the current configuration of the ICMP router discovery component. If you save the script to a file, you can use it to restore altered configuration information.<br>If you plan to make extensive changes to the configuration of the ICMP router discovery component, a recommended practice is to begin the configuration session by using the **dump** command before you start, in case you need to restore the configuration later |
| Set | **Set interface**. On the specified interface, updates the following:<br>• Whether ICMP router discovery is enabled or disabled.<br>• A minimum and a maximum interval in minutes between router discovery packets.<br>• The time in minutes after which a host considers the interface to be failed (which is after it has received its last Router Advertisement message from this router).<br>• The preference level for using this interface as the default gateway. A higher number indicates a higher level of preference. |
| Show | **Show interface**. For the specified interface, displays:<br>• Whether ICMP router discovery is enabled or disabled.<br>• The minimum and maximum advertisement intervals.<br>• The preference level for using this interface as the default gateway. |

| | |
|---|---|
| Uninstall | Removes ICMP router discovery from all interfaces on this server. If, later, you want to reenable ICMP router discovery by using the **add interface** command, you must add ICMP router discovery one interface at a time. |

**Management and Diagnostic Command-Line Tools for Unicast IPv4 Routing**

In addition to the Netsh command-line tool, Windows Server 2003 also supports the Pathping, Ping, Route, and Tracert command-line tools for unicast IPv4 and IPv6 network traffic. This section describes each tool as used for unicast IPv4 routing–related tasks in an IPv4 internetworking environment. For information about these tools in an IPv6 internetworking environment, see IPv6 Tools and Settings.

**Pathping.exe**

**Category** The Pathping.exe diagnostic tool for IPv4 internetworks is included with the Windows Server 2003 operating system. The Windows Server 2003 version of Pathping.exe also supports IPv6.

**Version compatibility** The Pathping.exe tool runs on Windows Server 2003, Windows XP, and Windows 2000.

Pathping combines information provided by Tracert (identifying which routers exist along the path) and Ping (repeatedly sending messages to each router) with additional information that neither of those tools provides.

The Pathping tool uses ICMP Echo messages to test router latency, link latency, and packet losses on an IPv4 internetwork. Pathping tests each hop by pinging multiple times over a period of time, and then displaying delay and packet loss information per hop. Specifically, Pathping records the following:

- The average round-trip time.
- The packet loss when sending ICMP Echo messages to each router.
- The packet loss when sending ICMP Echo messages across the links between each router.

The output of the Pathping command can help you determine if there is a high-loss link or router in the path by showing the degree of packet loss at each router or link.

For more information about Pathping.exe, see Command-Line Reference for Windows Server 2003, Standard Edition.

**Ping.exe**

**Category** The Ping.exe diagnostic tool for IPv4 internetworks is included with the Windows Server 2003 operating system. The Windows Server 2003 version of Ping.exe also supports IPv6.

**Version compatibility** The Ping.exe tool runs on Windows Server 2003, Windows XP, Windows 2000, and Windows NT® 4.0.

The Ping tool tests reachability on an IPv4 internetwork by sending an ICMP Echo message from a source host to a destination IP address and recording the results. Ping indicates whether the destination responds by displaying an ICMP Echo Response message and how much time elapses (in milliseconds) before a reply is received. If Ping receives no response, it displays an error message instead.

In addition to testing connectivity to a destination computer, successfully pinging from the local computer by IP address, not by name, verifies that TCP/IP is functioning properly on the local computer. Likewise, successfully pinging the local router verifies that the router is functioning.

For more information about Ping.exe, see Command-Line Reference for Windows Server 2003, Standard Edition.

**Route.exe**

**Category** The Route.exe management tool for IPv4 internetworks is included with the Windows Server 2003 operating system. The Windows Server 2003 version of Route.exe also supports IPv6.

**Version compatibility** The Route.exe tool runs on Windows Server 2003, Windows XP, Windows 2000, and Windows NT 4.0.

The Route tool displays and modifies entries in the IPv4 routing table on the local computer. You can use Route to add a temporary or persistent route, to change an existing route, or to remove a route from the IP routing table. The Route tool has four subcommands, listed in the following table.

**Subcommands for Route.exe**

| Subcommand | Task |
|---|---|

| | |
|---|---|
| Route print | Prints the IPv4 routing table and (if IPv6 exists) the IPv6 routing table.<br><br>You can also use **route print** to display only part of the routing table. For example, if you use route print to display the entire routing table and then decide that you want to look only at the set of routes that begin with, say, 157, you can use **route print 157*** to print only those routes that match 157*. |
| Route add | Adds a static route.<br><br>In Windows Server 2003, this subcommand does not support IPv6. |
| Route delete | Deletes a static route.<br><br>In Windows Server 2003, this subcommand does not support IPv6. |
| Route change | Modifies an existing static route. This command is used only to modify gateway or metric values.<br><br>In Windows Server 2003, this subcommand does not support IPv6 |

The IP routing table is stored in RAM, which means that a non-persistent static route disappears whenever a computer restarts. Typically, therefore, you use **route add** with the **-p** option to add a persistent static route that continues to exist even after a computer restarts.

Persistent routes are stored in the registry in the **PersistentRoutes** entry under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters. Because you can add, modify, or delete a persistent static route by using the Route tool, you do not need to configure this registry entry directly.

For more information about Route.exe, see Command-Line Reference for Windows Server 2003, Standard Edition.

**Tracert.exe**

**Category** The Tracert.exe diagnostic tool for IPv4 internetworks is included with the Windows Server 2003 operating system. The Windows Server 2003 version of Tracert.exe also supports IPv6.

**Version compatibility** The Tracert.exe tool runs on Windows Server 2003, Windows XP, Windows 2000, and Windows NT 4.0.

The Tracert route tracking tool tests reachability, network latency, routing loops, and other issues on an IPv4 internetwork by determining the path (the series of routers) that unicast IPv4 traffic takes between a source host and destination IP address. Tracert sends ICMP Echo messages with incrementally higher values of the Time to Live (TTL) field in the IP header and then returns (lists) the series of near-side router interfaces on each router between the source and destination hosts. If the intended destination host does not receive the packets sent, Tracert displays the last router that successfully forwarded the packets.

For more information about Tracert.exe, see Command-Line Reference for Windows Server 2003, Standard Edition.

**Network Connections**

For unicast IPv4 routing, Network Connections is used to configure default gateway options and other options for TCP/IP.

**Category** Network Connections is included with the Windows Server 2003 operating system.

**Version compatibility** Network Connections runs on Windows Server 2003 and Windows XP. Network Connections is known as Network and Dial-up Connection in Windows 2000. Network Connections is known as the Network component of Control Panel in Windows NT 4.0.

The Network Connections management tool enables the configuration of TCP/IP properties for a variety of purposes. The following table describes only the options used for manually configuring the default gateway and the related automatic metric option.

**TCP/IP Properties Options in Network Connections**

| Page | Tab | Task |
|---|---|---|

| | | |
|---|---|---|
| TCP/IP Properties | General | Manually configuring a network adapter to point to a default gateway:<br>• Under **Use the following IP address**, specify:<br>  • **IP address** and **Subnet mask**. Together, the IP address and subnet mask identify this computer and the subnet on which it is located.<br>  • **Default gateway**. The IP address for the default gateway identifies a local IP router (on the same subnet as this computer) that forwards traffic for this computer to destinations on a different subnet. |
| Advanced TCP/IP Settings | IP Settings | Adding, editing, or removing additional default gateways for this network connection:<br>• Under **Default gateways**, click **Add:**<br>  Opens the **TCP/IP Gateway Address** dialog box, which you can use to configure an IP address and an automatic or manually configured metric. If the default gateway specified on the **General** tab fails, the local computer can switch to an alternative default gateway listed here if dead gateway detection is enabled.<br>  See the registry entry **EnableDeadGWDetect** later in this document.<br>Enabling the option to automatically calculate the interface cost based on the speed of the interface:<br>• Select **Automatic metric**. An interface metric is enabled that is calculated automatically by TCP/IP based on the speed of the interface. If multiple closest matching routes to a destination exist in the IP routing table, IP uses the route with the lowest cost so that the fastest interface is used to forward traffic to the default gateway.<br>Disabling the option to automatically calculate the interface cost based on the speed of the interface:<br>• Clear **Automatic metric**, and then specify an **Interface metric**. If you disable **Automatic metric**, the **Interface metric** field becomes available to manually configure a cost for this interface. |

For related information about tools for configuring IP routers and hosts to enable hosts to dynamically discover the best default gateway to use on a subnet, see "Netsh routing IP routerdiscovery context" earlier in this document and see "ICMP router discovery options" later in this document.

**Rrasmgmt.msc: Routing and Remote Access Snap-in**

For unicast IPv4 routing, the Routing and Remote Access snap-in is used to configure options for a variety of functions provided by the Routing and Remote Access service. These functions include event logging, route source preference levels, the RIP for IP and OSPF routing protocols, the DHCP relay agent, IP packet filtering, and ICMP router discovery.

**Category** The Routing and Remote Access snap-in of Microsoft Management Console (MMC) is included with Windows Server 2003 operating system. Routing and Remote Access is disabled by default.

**Version compatibility** The Routing and Remote Access snap-in is provided by the Routing and Remote Access service on computers running Windows Server 2003 and Windows 2000 Server. For Windows NT 4.0, the Routing and Remote Access Service (RRAS) and its snap-in are available as a separate download from the Microsoft Windows NT Server Routing and Remote Access Service Download page.

You can use the Routing and Remote Access snap-in to enable, configure, or modify, unicast IPv4 routing options for RIP, OSPF, DHCP relay agent, IP packet filtering, and ICMP router discovery. The Routing and Remote Access snap-in can also be used to configure options for a variety of other routing or remote access services unrelated to these unicast IPv4 routing topics, such as configuring remote access connections, multicast IPv4 routing options, or network address translation (NAT).

**Options for enabling, disabling, or refreshing the Routing and Remote Access service**

The Routing and Remote Access snap-in is available by default in Administrative Tools in Control Panel. However, the Routing and Remote Access service managed by means of this snap-in is disabled by default.

| Note |
| --- |
| You do not use the Add or Remove Programs icon in Control Panel to install or uninstall the Routing and Remote Access service. |

The following table describes the options to enable, disable, or refresh the Windows Server 2003 Routing and Remote Access service. These settings are available in the console tree of the Routing and Remote Access snap-in by right-clicking the *ServerName* node.

**Options to Enable, Disable, or Refresh the Routing and Remote Access Service**

| Node | Task |
| --- | --- |
| *ServerName* | Enabling the Routing and Remote Access service:<br>• **Configure and Enable Routing and Remote Access**. Starts Routing and Remote Access Server Setup Wizard. To enable LAN routing, select **Custom configuration** on the wizard's **Configuration** page, and then select **LAN routing** on the **Custom configuration** page.<br>**Note**<br>Alternatively, you can use the wizard to configure and enable connections for remote access dial-up or VPN, NAT, or a site-to-site VPN connection between two private networks from the **Configuration** page. If you select the **Custom configuration** option from the **Configuration** page, you can enable any of these connections in addition to LAN routing, or you can enable LAN routing only.<br>Disabling the Routing and Remote Access service:<br>• **Disable Routing and Remote Access**. Disables the Routing and Remote Access service, which removes all Routing and Remote Access registry settings, but it does not uninstall the service or snap-in.<br>Refreshing the Routing and Remote Access service:<br>• **Disable Routing and Remote Access**, and then **Configure and Enable Routing and Remote Access**. Refreshes the Routing and Remote Access service by first disabling it, which removes all current configuration, and then reenabling it, which starts the wizard so that you can re-enable the service and configure new settings. You do not need to restart the server. |

**General options**

Options available in the **IP Routing\General** container in the Routing and Remote Access snap-in take effect at the level of the server rather than at the level of an individual component of the Routing and Remote Access service. General options include those for setting global logging levels and for ranking route sources. You can also set logging levels at the level of the individual component.

This section includes unicast IPv4 routing options available in the console tree on the **IP Routing\General** node of the Routing and Remote Access snap-in and in the details pane on the *InterfaceName* **Properties** page. Multicast routing options are not included in this section. For more information, see IPv4 Multicasting Tools and Settings.

**General options in the console tree**

The following table describes the options for adding a new unicast IPv4 routing protocol to the Routing and Remote Access snap-in console tree and for adding an interface to the details pane. These options are available by right-clicking the **IP Routing\General** node.

**Options on the IP Routing\General Node in the Console Tree**

| Node | Task |
| --- | --- |

| | |
|---|---|
| General | Adding a new routing protocol to the console tree:<br>• **New Routing Protocol**. Provides a list from which to select one or more of the following protocols to add to the Routing and Remote Access console tree under the **IP Routing** node:<br>  • DHCP Relay Agent<br>  • IGMP Router and Proxy<br>  • RIP<br>  • OSPF<br>  • NAT/Basic Firewall<br>  This document describes the management of the DHCP relay agent, RIP, and OSPF components in the Routing and Remote Access snap-in. For information about IGMP, see IPv4 Multicasting Tools and Settings. For information about NAT/Basic Firewall, see NAT Tools and Settings.<br><br>Adding a new interface to the details pane:<br>• **New Interface.** Provides a list of available interfaces on this server that you can add to the details pane of the **IP Routing\General** node. |

The following table describes Routing and Remote Access options for configuring global IP logging and for ranking route source preference levels. These settings are available in the console tree of the Routing and Remote Access snap-in on the properties page of the **IP Routing\General** node. The properties page on the **General** node also includes a tab for **Multicast Scopes**, which is not covered in this technical reference.

**Options on the IP Routing\General Properties Page**

| Tab | Task |
|---|---|
| Logging | Configuring events to be logged in the System Log in Event Viewer for this server:<br>• **Log errors only**<br>• **Log errors and warnings**<br>• **Log the maximum amount of information** (that is, errors, warnings, and informational messages)<br>• **Disable event logging**<br><br>**Note**<br>Use information about routing events stored in the System Log to troubleshoot routing processes. Logging puts a considerable load on system resources and should be enabled only when needed. After the event is logged or the problem is identified, immediately reset logging to its default value, **Log errors only**. |

| | |
|---|---|
| Preference Levels | Configuring the rank of route sources in order of preference by moving one or more of the listed route sources up or down (route sources are listed here in default order):<br>• **Local**<br>• **Static** (a static route assigned to a demand-dial interface)<br>• **Static (non demand-dial)** (a static route assigned to a LAN interface)<br>• **Auto-static**<br>• **Network management** (such as SNMP)<br>• **Open Shortest Path First (OSPF)**<br>• **RIP Version 2 for Internet Protocol**<br><br>**Note**<br>If two routes exist to the same destination, the route learned by the route source with a higher preference is preferred regardless of the route metric. For example, if the preference level for OSPF is higher than the preference level for RIP v2, an OSPF route with a metric of 5 is entered into the routing table rather than the same route discovered by RIP with a metric of 3. |

**General options on the InterfaceName Properties page**

For a description of unicast IPv4 routing configuration options available on the **General** tab of the *InterfaceName* **Properties** page in the **IP Routing\General** container, see the separate sections for "IP Packet Filtering Options" and "ICMP router discovery options" later in this document.

This *InterfaceName* **Properties** page also provides the **Configuration** tab to specify whether the IP address for this interface is statically configured or obtained dynamically from a DHCP server, and it provides the **Multicast Boundaries** and **Multicast Heartbeat** tabs to configure options related to IPv4 multicast routing. None of these options is described here because they are outside the scope of this technical reference.

**RIP Options**

Routing Information Protocol (RIP), the primary dynamic routing protocol used on small or medium-sized IPv4 internetworks (10 to 50 networks), enables the dynamic exchange of IPv4 routing information between RIP routers. By adding RIP to the Routing and Remote Access snap-in console tree, adding RIP interfaces to the details pane, and then configuring RIP options, you can enable RIP routers to update topology changes as networks are added or removed and as links fail and are restored.

The Windows Server 2003 Routing and Remote Access service supports both the updated version of RIP, RIP version 2 (RIP v2) and the earlier version of RIP, RIP version 1 (RIP v1). The version of RIP installed when you add the RIP protocol to the Routing and Remote Access snap-in console tree is RIP v2, which includes options that make RIP v1 optionally available.

This section includes unicast IPv4 routing options available in the console tree of the Routing and Remote Access snap-in on the **IP Routing\RIP** node and in the details pane on the *InterfaceName* **Properties** page.

**RIP options in the console tree**

The following table describes options for adding one or more interfaces to the details pane and for displaying information about neighboring RIP routers. These options are available by right-clicking the **IP Routing\RIP** node.

**Options on the IP Routing\RIP Node in the Console Tree**

| Node | Task |
|---|---|

| | |
|---|---|
| RIP | Adding a new interface to the details pane:<br>• **New Interface**. Provides a list of available interfaces on this server that you can add to the details pane of the **IP Routing\RIP** node.<br><br>Displaying neighboring RIP routers:<br>• **Show Neighbors**. Displays a table of RIP routers configured as neighbor routers to this RIP router. For each RIP neighbor, the table lists its IP address, RIP version, and any bad packets or bad routes. |

The following table describes Routing and Remote Access options for the RIP routing protocol. These settings are available in console tree of the Routing and Remote Access snap-in on properties page of the **IP Routing\RIP** node.

**Options on the RIP Properties Page**

| Tab | Task |
|---|---|
| General | Configuring the delay before this RIP router sends triggered updates:<br>• **Maximum delay (seconds)**. Specifies the maximum amount of time that this router waits before it sends triggered updates (updates that are announced as soon as a network topology change occurs, rather than at periodic intervals). The default value is 5 seconds.<br><br>Configuring events to be logged in the System Log in Event Viewer for this RIP router:<br>• **Log errors only**<br>• **Log errors and warnings**<br>• **Log the maximum amount of information** (that is, errors, warnings, and informational messages)<br>• **Disable event logging**<br><br>**Note**<br>Use information about routing events stored in the System Log to troubleshoot routing processes. Logging puts a considerable load on system resources and should be enabled only when needed. After the event is logged or the problem is identified, immediately reset logging to its default value, **Log errors only**. |
| Security | Configuring the RIP routers from which this RIP router accepts announcements:<br>• **Accept announcements from all routers (default)**. Specifies that this RIP router accepts announcements from all RIP routers.<br>• **Accept announcements from listed routers only**. Specifies that this RIP router accepts only announcements from the listed RIP routers.<br>• **Ignore announcements from all listed routers**. Specifies that this RIP router ignores announcements from the listed RIP routers but accepts announcements from all other RIP routers.<br>• **Router IP address**. Specifies the list (if any) of routers whose announcements you want to accept or ignore. |

**RIP for IP options on the InterfaceName Properties page**

The following table describes Routing and Remote Access options for a RIP interface. These settings are available in the Routing and Remote Access snap-in on the specified tab of the *InterfaceName* **Properties** page for an interface in the **IP Routing\RIP** container.

**RIP Options on the InterfaceName Properties Page**

| Tab | Task |
|---|---|

| | |
|---|---|
| General | Configuring **Operation mode** options for this interface:<br><br>• **Auto-static update mode (default for demand-dial interfaces)**. Sends RIP announcements only when other routers request an update. Routes learned are marked as static routes in the IP routing table and remain in the routing table until they are manually deleted.<br><br>• **Periodic update mode (default for LAN interfaces)**. Sends RIP announcements periodically every *n* seconds as specified in **Periodic announcement interval** on the **Advanced** tab. Routes learned are marked as RIP routes in the IP routing table and are removed if the router restarts.<br><br>Configuring **Outgoing packet protocol** options for sending outgoing RIP route announcements over this interface:<br><br>• **RIP version 1 broadcast**. Broadcasts RIP v1 announcements. Specify this protocol only if all neighboring RIP routers are also RIP v1 routers.<br><br>• **RIP version 2 broadcast**. Broadcasts RIP v2 announcements. Specify this protocol for a mixed environment that uses both RIP v1 and RIP v2.<br><br>• **RIP version 2 multicast**. Multicasts RIP v2 announcements. Specify this protocol only if all neighboring RIP routers are also RIP v2 routers.<br><br>• **Silent RIP**. Disables outgoing RIP announcements on this interface. Specify this option to configure this non-router computer to listen for incoming RIP announcements and update its routing table but not to announce its own routes.<br><br>Configuring **Incoming packet protocol** options for receiving incoming RIP announcements over this interface:<br><br>• **Ignore incoming packets**. Configures this router only to announce routes (but not to receive incoming route announcements).<br><br>• **RIP version 1 and 2**. Configures this router to accept both RIP v1 and RIP v2 announcements.<br><br>• **RIP version 1 only**. Configures this router to accept only RIP v1 announcements.<br><br>• **RIP version 2 only**. Configures this router to accept only RIP v2 announcements.<br><br>Configuring metric and route tag options for this interface:<br><br>• **Added cost for routes**. Configures the cost associated with sending packets over this interface. For example, set a higher cost on a heavily trafficked route to reduce its use. Increasing the cost for all RIP routes reduces your maximum RIP network diameter.<br><br>• **Tag for announced routes**. Specifies a tag number for the routes advertised on this interface in order to distinguish these routes from non-RIP routes. Used on a router that can support multiple routing protocols.<br><br>Configuring the simple password authentication option for this interface:<br><br>• **Activate authentication**. Enables a form of authentication that uses a plaintext password for RIP v2 announcements over this interface. All incoming and outgoing RIP v2 packets from neighboring RIP v2 routers connected to this interface must contain the same plaintext password. This type of authentication uses plaintext passwords, which are used by routers to identify each other, not for security.<br><br>• **Password**. Specifies a plaintext password (1–16 characters). |

| | |
|---|---|
| Security | Configuring RIP security options for incoming routes on this interface:<br>• **Accept all routes**. Configures this RIP router to look at each route entry in an incoming RIP announcement to determine whether to update its routing table.<br>• **Accept all routes in the ranges listed**. Configures this RIP router to look at each route entry in an incoming RIP announcement but processes the route only if it falls within one of the ranges listed.<br>• **Ignore all routes in the ranges listed**. Configures this RIP router to look at each route entry in an incoming RIP announcement and discards the route if it falls into one of the ranges listed.<br><br>Configuring RIP security options for outgoing routes on this interface:<br>• **Accept all routes**. Configures this RIP router to include all appropriate route entries in outgoing RIP announcements.<br>• **Accept all routes in the ranges listed**. Configures this RIP router to include a route in the outgoing RIP announcement only if the route falls into one of the ranges listed.<br>• **Ignore all routes in the ranges listed**. Configures this RIP router to exclude a route from the outgoing RIP announcement if the route falls into one of the ranges listed. |
| Neighbors | Configuring how this RIP router interacts with neighboring RIP routers through this interface:<br>• **Use broadcast or multicast only**. Specifies that all RIP announcements are broadcasted or multicasted as specified in **Outgoing packet protocol** on the **General** tab.<br>• **Use neighbors in addition to broadcast or multicast**. Specifies that RIP announcements are unicasted to specific neighboring routers in addition to broadcasted or multicasted as specified in **Outgoing packet protocol** on the **General** tab.<br>• **Use neighbors instead of broadcast or multicast**. Specifies that RIP announcements are unicasted only to specific neighboring routers. For nonbroadcast networks, such as Frame Relay, select this option to enable RIP traffic between specific routers.<br>• **IP address**. Specifies the IP address of one or more neighboring RIP routers. Valid only if one of the preceding options to send RIP announcements only to specific neighboring routers is selected. |
| Advanced | Configuring RIP announcement and route interval options for this interface:<br>• **Periodic announcement interval (seconds)**. Specifies the interval — from 15 seconds through 86,400 seconds (24 hours) — between periodic RIP announcements. The default value is 30 seconds. Valid only if **Periodic update mode** is selected as the **Operation mode** on the **General** tab.<br>• **Time before routes expire (seconds)**. Specifies the lifetime — from 15 seconds through 259,200 seconds (72 hours) — of a route that is learned through RIP. The default value is 180 seconds. If a route is not updated with another RIP announcement within the specified time, the route expires. Valid only if **Periodic update mode** is selected as the **Operation mode** on the **General** tab.<br>• **Time before route is removed (seconds)**. Specifies the amount of time — from 15 seconds through 259,200 seconds (72 hours) — after which a RIP-learned route that has expired is removed from the routing table. The default value is 120 seconds. Valid only if **Periodic update mode** is selected as the **Operation mode** on the **General** tab.<br><br>Configuring split-horizon processing and triggered updates options for this interface:<br>• **Enable split-horizon processing**. Enabled by default. Specifies that routes learned from a neighboring RIP |

| | |
|---|---|
| | router are not announced in RIP announcements that this router sends to that neighbor (unless poison-reverse processing is also enabled, in which case such routes are announced with a metric of 16 to indicate explicitly that those routes are unavailable). Helps reduce convergence time and avoid routing loops.<br><br>• **Enable poison-reverse processing**. Enabled by default. Specifies that routes learned from a neighboring RIP router are announced with a metric of 16 (unreachable) in RIP announcements that this router sends to that neighbor. Available only if split horizon is enabled (if you disable split-horizon, poison-reverse processing is also disabled).<br><br>• **Enable triggered updates**. Specifies that a change in network topology, such as a new route or a change in metric, triggers an immediate update announcement that includes only the change. Configure **Maximum delay (seconds)** between triggered updates on the **General** tab on the **RIP Properties** page.<br><br>• **Send clean-up updates when stopping**. Enabled by default. Specifies that, if this RIP router stops, the router advertises as unreachable all of the routes that it makes available on all of its interfaces as it shuts down.<br><br>Configuring host and default route options for this interface:<br><br>• **Process host routes in received announcements**. Specifies that host routes in received RIP announcements are accepted. By default, host routes are ignored.<br><br>• **Include host routes in sent announcements**. Specifies that host routes are included in RIP announcements. By default, host routes are not included.<br><br>• **Process default routes in received announcements**. Specifies that default routes in received RIP announcements are accepted. By default, default routes are ignored.<br><br>• **Include default routes in sent announcements**. Specifies that default routes are included in RIP announcements. By default, default routes are not included.<br><br>Configuring subnet summarization option for this interface:<br><br>• **Disable subnet summarization**. Selected by default. Specifies that subnet routes are not summarized in the form of the class-based network ID when announced on a network that is not a subnet of the class-based network ID. Available only if **Outgoing packet protocol** on the **General** tab is set to either **RIP version 2 broadcast** or **RIP version 2 multicast**. In a mixed environment that contains both RIP v1 and RIP v2 routers, use only contiguous, fixed-size subnets, or clear this option. |

**OSPF options**

Open Shortest Path First (OSPF), the most common routing protocol used on large and very large IPv4 internetworks, enables the dynamic exchange of IPv4 routing information between OSPF routers across complex internetworks. Adding OSPF to the Routing and Remote Access snap-in console tree, adding OSPF interfaces to the details pane, and then configuring OSPF options enables OSPF routers to update topology changes as networks are added or removed and as links fail and are restored.

This section includes unicast IPv4 routing options available in the console tree of the Routing and Remote Access snap-in on the **IP Routing\OSPF** node and in the details pane on the *InterfaceName* **Properties** page.

**OSPF options in the console tree**

The following table describes options for adding one or more interfaces to the details pane and for displaying information about the OSPF autonomous system. These options are available by right-clicking the **IP Routing\OSPF** node.

**Options on the IP Routing\OSPF Node in the Console Tree**

| Node | Task |
|---|---|
| OSPF | Adding a new interface to the details pane:<br><br>• **New Interface**. Provides a list of available interfaces on this server that you can add to the details pane of the **IP Routing\OSPF** node. |

Displaying information about the OSPF autonomous system:

- **Show Areas**. Displays a table of OSPF areas, including:
    - **Area ID**. The identification number of each OSPF area.
    - **State**. Up or down.
    - **SPF computations**. The number of Shortest Path First (SPF) computations. An OSPF router creates a tree (the SPF tree) of shortest paths to each other router and subnet in the OSPF autonomous system.
- **Show Link-state Database**. Displays a table of information about the OSPF LSDB, including:
    - **Area ID**. The identification number of the OSPF area for each link state advertisement (LSA) in the table.
    - **Type**. The type of advertisement, such as Router, Summary (Network), Stub, Network, Summary (ASBR), or AS External.
    - **Link state ID**. The identification number of each advertisement in the table. The LSAs vary by advertisement type.
    - **Advertising router**. The OSPF router ID of the advertising router
    - **Age**. The age (in seconds) since the advertisement originated.
    - **Sequence**. A number that identifies old or duplicate advertisements.
- **Show Neighbors**. Lists information about neighboring OSPF routers, including:
    - **Neighbor**. The IP address of each neighboring router.
    - **Neighbor ID**. Each neighboring router's OSPF router ID.
    - **Type**. The network type of each neighboring router, such as NBMA.
    - **State**. The state of each neighbor router:Down, Attempt, Init, 2-way, ExStart, Exchange, Loading, or Full. For a definition of each of these states, see "How OSPF Works" in How Unicast IPv4 Routing Protocols and Services Work.
    - **Priority**. The router priority of each neighboring router.
    - **State-changes and errors**. The total number of changes of state and errors.
    - **Retransmit-queue length**. The length of the retransmit queue.
- **Show Virtual Interfaces**. Displays a table of virtual interfaces (virtual links). A virtual link is a logical connection that enables the exchange of routing information between a backbone area border router (ABR) and an ABR that is not physically connected to the backbone area across a transit area. You cannot configure a virtual link across the backbone area. For each virtual link, the table includes:
    - **Area ID**. The area ID of the transit area for the virtual link.
    - **Neighbor ID**. The neighboring router's OSPF router ID.

| | |
|---|---|
| | • **State**. The state of each virtual interface:Down, Loopback, Waiting, Point-to-point, Designated-router, Backup designated-router, Other, or Unknown.<br>• **Sent packets**. The number of packets sent over this virtual link.<br>• **Received packets**. The number of packets received over this virtual link.<br>• **Dropped packets**. The number of packets that failed to be transmitted over this virtual link. |

The following table describes Routing and Remote Access options for OSPF properties. These settings are available in the console tree of the Routing and Remote Access snap-in on the properties page of the IP Routing\OSPF node.

**Options on the OSPF Properties Page**

| Tab | Task |
|---|---|
| General | Configuring the OSPF router ID:<br>• **Router identification**. Specifies the 32-bit number (in dotted decimal notation) that uniquely identifies this OSPF router on the network. The OSPF router ID is not an IP address. Ensure that the number is unique, for example, by selecting the highest or the lowest IP address assigned to one of the interfaces on this computer.<br><br>Configuring this OSPF router as an autonomous system boundary router (ASBR):<br>• **Enable autonomous system boundary router**. Specifies that the OSPF router is an ASBR and therefore advertises routing information into the OSPF autonomous system that is from route sources external to the OSPF autonomous system. If you select this option, you can also use the **External Routing** tab to specify the route sources — such as static routes or the Routing Information Protocol (RIP) — from which this router will accept routes.<br><br>Configuring events to be logged in System Log in Event Viewer for this OSPF router:<br>• **Log errors only**<br>• **Log errors and warnings**<br>• **Log the maximum amount of information** (that is, errors, warnings, and informational messages)<br>• **Disable event logging**<br><br>**Note**<br>Use information about routing events stored in the System Log to troubleshoot routing processes. Logging puts a considerable load on system resources and should be enabled only when needed. After the event is logged or the problem is identified, immediately reset logging to its default value, **Log errors only**. |

| | |
|---|---|
| Areas | Configuring OSPF areas (each OSPF interface on this OSPF router must belong to at least one OSPF area):<br><br>• **Add**. Opens the **OSPF Area Configuration** dialog box, which you can use to configure the following options:<br><br>On the **General** tab:<br><br>• **Area ID**. Specifies an ID (a 32-bit number expressed in dotted decimal notation) that identifies the OSPF area. The only required OSPF area is the OSPF backbone area, which requires the reserved area ID of 0.0.0.0. An OSPF backbone area is either the sole area in the OSPF autonomous system, or it is the central area to which all other OSPF areas in this OSPF autonomous system connect and through which packets are routed from one non-backbone area to another non-backbone area.<br><br>Although an OSPF area ID is neither an IP address nor an IP network ID, if this is not the backbone area and if this area can be summarized with a single network ID, you can set the area ID to match the single network ID. For example, if an area contains all of the subnets for the IP network 10.1.0.0/16, you can set the area ID to 10.1.0.0.<br><br>• **Enable plaintext password**. Enabled by default. Specifies that a plaintext password is required for the OSPF area so that OSPF routers can identify each other (this is not a security option). If this password option is enabled, all interfaces in this area that are on the same subnet must use the same password. By default, the password is 12345678.<br><br>• **Stub area**. Specifies that this area is a stub area and therefore does not accept external routes from outside this OSPF autonomous system. Routing from a stub area to destinations outside this OSPF area, which includes destinations in other areas within its own autonomous system as well as to destinations outside its autonomous system, uses a summary default route. You cannot configure the backbone as a stub area, nor can you configure a virtual link through a stub area.<br><br>• **Stub metric**. Specifies the cost of the summary default route that this OSPF router uses to reach all destinations external to this OSPF autonomous system.<br><br>• **Import summary advertisements**. Specifies that inter-area routes for the OSPF autonomous system are imported into this stub area. By default, this check box is cleared and all non-intra-area destinations within the OSPF autonomous system are routed based on a single default route.<br><br>On the **Ranges** tab:<br><br>• **Destination** and **Network mask**. Specifies the network ID and subnet mask pair (that is, a summary route) that defines a range of addresses that belongs to this OSPF area. OSPF uses OSPF ranges to summarize the routes within this OSPF area.<br><br>• **Edit**. Opens the **OSPF Area Configuration** dialog box, which you can use to modify settings for the selected OSPF area. These settings are the same as those listed just above for **Add** on the **General** tab and on the **Ranges** tab.<br><br>• **Remove**. Removes the selected OSPF area. |

| | |
|---|---|
| Virtual Interfaces | Configuring a virtual interface for this OSPF router:<br><br>**Note**<br>A virtual interface, also called a virtual link, is a logical connection that enables the exchange of routing information between a backbone area border router (ABR) and an ABR that is not physically connected to the backbone area. You cannot configure a virtual link across the backbone area or a stub area.<br><br>• **Add**. Opens the **OSPF Virtual Interface Configuration** dialog box, which you can use to create a virtual link by configuring the following options:<br><br>On the **General** tab:<br><br>**Note**<br>The following settings must be the same on both routers at each end of the virtual link.<br><br>• **Transit area ID**. The OSPF area ID for the transit area for this virtual link. Select the one that you want to use from the provided list of non-backbone area IDs configured on this OSPF router.<br><br>• **Virtual neighbor router ID**. The OSPF router ID of the router at the other end of the virtual link.<br><br>• **Transit delay (seconds)**. The estimated number of seconds that it takes to transmit OSPF packets to the virtual link neighbor router over this interface. The default is 1 second.<br><br>• **Retransmit interval (seconds)**. The interval that the OSPF router waits before retransmitting link state messages. This value should be substantially larger than the expected round-trip delay between the two routers at either end of the transit area. The default is 10 seconds.<br><br>• **Hello interval (seconds)**. The interval between hello packets that are sent out over this interface. The default is 10 seconds.<br><br>• **Dead interval (seconds)**. The interval that a router's neighbors wait after they cease to hear the router's hello packets before they declare that the router is down. The default is 60 seconds.<br><br>• **Plaintext password**. The plaintext password to be shared by both routers at each end of the virtual link. This password is not the same as the plaintext password shared by all routers in an OSPF area so that OSPF routers in that area can identify each other.<br><br>• **Edit**. Opens the **OSPF Virtual Interface Configuration** dialog box, which you can use to modify the selected virtual interface. These settings are the same as those listed for the **Add** option.<br><br>• **Remove**. Removes the selected virtual interface. |

| | |
|---|---|
| External Routing | Configuring external route source options:<br>• **Accept routes from all route sources except those selected**. Specifies that routes from all selected route sources are ignored.<br>• **Ignore routes from all route sources except those selected**. Specifies that only routes from selected route sources are accepted.<br>• **Route sources**. Specifies non-OSPF route sources from which this OPSF router accepts or ignores routes:<br>  • Auto-static routes<br>  • Local routes<br>  • RIP version 2 for Internet Protocol<br>  • SNMP routes<br>  • Static (non-demand dial) Routes (refers to a static route assigned to a LAN interface)<br>  • Static routes (refers to a static route assigned to a demand-dial interface)<br>• **Route filters**. Opens the **OSPF External Route Filters** dialog box, which you can use to specify filters that accept or ignore listed external routes, and to specify the list of routes (by destination and subnet mask) to be accepted or ignored. |

**OSPF options on the InterfaceName Properties page**

The following table describes Routing and Remote Access options for an OSPF interface. These settings are available in the Windows Server 2003 Routing and Remote Access snap-in on the specified tab of the *InterfaceName* **Properties** page for an interface in the **IP Routing\OSPF** container.

**OSPF Options on the InterfaceName Properties Page**

| Tab | Task |
|---|---|

| | |
|---|---|
| General | Configuring OSPF on this interface:<br><br>• **Enable OSPF for this address**. Displays the IP address assigned to this interface, and specifies whether OSPF is enabled on this interface. If two or more IP addresses are assigned to the interface (by using the **Advanced TCP/IP Settings** page in **TCP/IP Properties**), select the IP address that you want to configure from the list provided. If more than one IP address is configured for this interface, you must configure OSPF settings on the **General**, **NBMA Neighbors**, and **Advanced** tabs for each IP address. Specify the following:<br><br>  • **Area ID**. The OSPF area ID for the interface. Select the one that you want to use from the provided list of available areas.<br><br>  • **Router priority**. The OSPF router priority for the interface. When two or more OSPF routers attached to a subnet that does not have an existing designated router attempt to become the designated router of the subnet, the router with the highest router priority setting takes precedence. If a tie exists, the router with the higher router ID takes precedence. An interface with a priority of 0 cannot become the designated router. The priority setting is ignored for point-to-point links.<br><br>  • **Cost**. The cost, advertised in the router's link state advertisement (LSA), of sending a packet out over this interface. Because an interface with a lower cost is used more frequently, typically, you configure a faster interface with a lower cost.<br><br>  • **Password**. The plaintext password for this OSPF area, which is enabled by default. All interfaces in the same OSPF area that are on the same subnet must use the same password.<br><br>Configuring the network type on this interface by selecting one of the following:<br><br>• **Broadcast**. Specifies that the interface is a broadcast OSPF interface on a multiple access broadcast network in which multiple routers can be connected to the network. Ethernet, Token Ring, and FDDI are examples of broadcast networks.<br><br>• **Point-to-point**. Specifies that this interface is a point-to-point OSPF interface that connects a single pair of routers. T1/E1, T3/E3, ISDN, and dial-up links are examples of point-to-point networks.<br><br>• **Non-broadcast multiple access (NBMA)**. Specifies that this interface is an NBMA OSPF interface. If you specify this type of interface, you can then configure neighboring routers by using the **NBMA Neighbors** tab. X.25, Frame Relay, and Asynchronous Transfer Mode (ATM) are examples of NBMA networks. |
| NBMA Neighbors | Configuring NBMA neighbors (available if **Non-broadcast multiple access (NBMA)** is selected as the network type on this interface's **General** tab) for this interface:<br><br>• **IP address**. Displays the IP address assigned to the interface. If two or more IP addresses are assigned to the interface, select the IP address that you want to configure from the list provided. If multiple IP addresses are configured for the interface, you must configure settings for each IP address.<br><br>• **Neighboring IP address**. Specifies the IP address (not the OSPF router ID) of a neighbor router on the NBMA network that you want to add.<br><br>• **Router priority**. Specifies the OSPF router priority of the neighbor router. A neighbor is eligible to become the designated router if its router priority is 1 or greater. |

| | |
|---|---|
| Advanced | Configuring advanced OSPF options for this interface:<br><br>• **IP address**. Displays the IP address assigned to the interface. If two or more IP addresses are assigned to the interface, select the IP address that you want to configure from the list provided. If multiple IP addresses are configured for the interface, you must configure settings for each IP address.<br><br>• **Transmit delay (seconds)**. The estimated number of seconds it takes for this OSPF router to transmit an OSPF link state update packet over this interface. This value should take into account the transmission and propagation delays of the interface and network media. The default setting is 1 second.<br><br>• **Retransmit interval (seconds)**. The number of seconds between link state advertisement (LSA) retransmissions on this interface. This value should exceed the expected round-trip delay between any two routers on the attached subnet; if this value is too low, needless retransmissions result. The value needs to be higher on low-speed serial lines. A sample value for a local area network (LAN) subnet is 5 seconds.<br><br>• **Hello interval (seconds)**. The interval in seconds between transmissions of OSPF Hello packets on this interface. This setting must be the same for all routers on the same subnet. The shorter the hello interval, the faster topological changes are detected. However, a shorter interval also results in more OSPF traffic. A sample value for an X.25 network is 30 seconds. A sample value for a LAN is 10 seconds.<br><br>• **Dead interval (seconds)**. The number of seconds before a neighbor router determines that this router is unavailable. The router is determined to be unavailable if a neighboring router does not receive a Hello packet sent by this router within the specified interval. For example, if the hello interval setting is 15 seconds and the dead interval is 60 seconds, after four unreceived Hello packets, neighbor routers declare that this router is unavailable. Typically, the value for this setting is four times the value in the hello interval. This value must be the same for all OSPF router interfaces attached to the same subnet.<br><br>• **Poll interval (seconds)**. For NBMA interfaces only, the number of seconds between OSPF network polls. If a neighboring router is unavailable, it might still be necessary to send Hello packets to the unavailable neighbor in order to determine if the connection has been restored. This is called the *poll interval*. Typically, the poll interval is at least twice as long as the dead interval. A sample value for a poll interval on an X.25 network is 2 minutes.<br><br>• **Maximum transmission unit (MTU) size (bytes)**. The maximum size of an IP datagram carrying OSPF information that can be sent without fragmentation. The default value of 1,500 bytes is the default IP MTU for an Ethernet network. |

**DHCP Relay Agent options**

Any IPv4 subnet that contains DHCP clients requires either a DHCP server or a DHCP relay agent to provide address leases to those DHCP clients. A computer acting as a DHCP relay agent, also known as a Bootstrap Protocol (BOOTP) relay agent, relays DHCP messages between DHCP clients on an IP subnet that has no DHCP server and a DHCP server located on a different subnet. By adding the DHCP relay agent to the Routing and Remote Access snap-in console tree, adding one or more DHCP relay agent interfaces to the details pane, and then configuring DHCP relay agent options, you can enable a router to act as a DCHP relay agent. Installation of a DHCP relay agent makes it unnecessary to install a separate DHCP server on each subnet in an IP internetwork.

This section includes unicast IPv4 routing options available in the console tree in the Routing and Remote Access snap-in on the **IP Routing\DHCP Relay Agent** node and in the details pane on the *InterfaceName* **Properties** page.

**DHCP relay agent options in the console tree**

The following table describes the option for adding one or more interfaces to the details pane. This option is available by right-clicking the **IP Routing\DHCP Relay Agent** node.

**Options on the IP Routing\DHCP Relay Agent Node in the Console Tree**

| Node | Task |
|---|---|

| | |
|---|---|
| DHCP Relay Agent | Adding a new interface to the details pane:<br>• **New Interface**. Provides a list of available interfaces on this server that you can add to the details pane of the **IP Routing\DHCP Relay Agent** node. |

The following table describes Routing and Remote Access options for DHCP relay agent properties. These settings are available in the console tree of the Routing and Remote Access snap-in on the properties page of the **IP Routing\DHCP Relay Agent** node.

**Options on the DHCP Relay Agent Properties Page**

| Tab | Task |
|---|---|
| General | Configuring one or more DHCP servers for local clients to contact through the DHCP relay agent:<br>• **Server address**. Adds the IP address of one or more DHCP servers to create a list of available DHCP servers on the network. This router acts as a DHCP relay agent by relaying DHCP messages between DHCP clients on the local subnet and the DHCP server or servers specified in this list. |

**DHCP relay agent options on the InterfaceName Properties page**

The following table describes Routing and Remote Access options for a DHCP relay agent interface. These settings are available in the Windows Server 2003 Routing and Remote Access snap-in on the **General** tab of the *InterfaceName* **Properties** page for an interface in the **IP Routing\DHCP Relay Agent** container.

**DHCP Relay Agent Options on the InterfaceName Properties Page**

| Tab | Task |
|---|---|
| General | Configuring a DHCP relay agent interface over which to route packets exchanged between DHCP clients on the local subnet and a DHCP server on another subnet:<br>• **Relay DHCP packets**. Enables DHCP messages to be relayed between DHCP clients on the subnet to which this interface is attached and a DHCP server on a different subnet. Enabled by default when you add an interface to the **IP Routing\DHCP Relay Agent** node in the console tree.<br>• **Hop-count threshold**. Specifies the maximum number of DHCP relay agents that can handle DHCP relayed traffic. The default value is 4 hops; the maximum value is 16 hops.<br>• **Boot threshold (seconds)**. Specifies the number of seconds the DHCP relay agent waits before forwarding DHCP messages. The default value is 4 seconds. This option is useful when you want a local DHCP server to respond first to a DHCP client's request for an IP address, but, if no local DHCP server responds, you want the DHCP relay agent to forward the message to a remote DHCP server. |

**IP packet filtering options**

Configuring IP packet filters on an IP router helps increase security on a private IP internetwork that connects to a public network such as the Internet. When IP packet filtering is configured, a packet arriving at a router might be forwarded to its destination, rejected with an error message returned to notify the sender, or dropped with no error message sent.

The following table describes options for IP packet filtering available in the Windows Server 2003 Routing and Remote Access snap-in by selecting **Inbound Filters** or **Outbound Filters** on the **General** tab of the *InterfaceName* **Properties** page for an interface in the **IP Routing\General** container, and then selecting **New** or **Edit**. Note that, although the options for adding an inbound or an outbound filter shown in the table appear together in the same dialog box, typically filters are configured in pairs, either {**Destination Network/Protocol**}, or {**Source Network/Protocol**}. After you add a filter, you select one of the following filter actions:

- Receive all packets except those that meet the criteria below.
- Drop all packets except those that meet the criteria below.

If you configure multiple parameters on a particular filter, when the filter is applied to an incoming packet, the parameters of the filter are compared by using a logical **AND** operator. The fields in the packet must match all of the criteria of the filter to have the filter action applied.

**IP Packet Filtering Options on the InterfaceName Properties Page**

| Tab | Task |
|---|---|
| General | Adding inbound filters or outbound filters (in the **Add IP Filter** or **Edit IP Filter** dialog box):<br><br>• **Source Network** field:<br><br>  • **IP address**. The source network ID or IP address.<br><br>  • **Subnet mask**. The subnet mask that corresponds to the source network ID, or 255.255.255.255 for a source IP address. The subnet mask bits must encompass all of the bits used in the **IP address** field. The IP address cannot be more specific than the subnet mask, that is, the IP address (in binary notation) cannot have a bit set to 1 when the corresponding bit in the subnet mask is set to 0.<br><br>• **Destination Network** field:<br><br>  • **IP address**. The destination network ID or IP address.<br><br>  • **Subnet mask**. The subnet mask that corresponds to the destination network ID, or 255.255.255.255 for a destination IP address. The subnet mask bits must encompass all of the bits being used in the **IP address** field. The IP address cannot be more specific than the subnet mask, that is, the IP address (in binary notation) cannot have a bit set to 1 when the corresponding bit in the subnet mask is set to 0.<br><br>• **Protocol** field:<br><br>  • **TCP**. Displays text boxes in which to specify a source TCP port and a destination TCP port. One or both can be specified. If nothing is specified in these text boxes, they default to **0**, which signifies any port.<br><br>  • **TCP [established]**. Displays text boxes in which to specify a source TCP port and a destination TCP port. Use this option when you want to define TCP traffic (source TCP port and destination TCP port) for TCP connections already established by the router.<br><br>  **TCP [established]** is used, for example, in a site-to-site VPN or dial-up connection when a calling router connects to an answering router. If you specify **TCP [established]**, TCP traffic is accepted only if the calling router initiates the TCP connection.<br><br>  • **UDP**. Displays text boxes in which to specify a source UDP port and a destination UDP port. One or both can be specified. If nothing is specified in these text boxes, they default to **0**, which signifies any port.<br><br>  • **ICMP**. Displays text boxes in which to specify an ICMP code and an ICMP type. One or both can be specified. If nothing is specified in these text boxes, they default to **255**, which signifies any code and any type.<br><br>  • **Any**. Configures a filter for any protocol (**Any** is the default).<br><br>  • **Other**. Lets you specify the IP protocol identifier number for the protocol you want (rather than select a protocol by name). For example, TCP is IP protocol 6, UDP is IP protocol 17, and ICMP is IP protocol 1.<br><br>**Note**<br>For a complete list of IP protocol numbers, which are used to configure firewalls, routers, and proxy servers, see the Internet Assigned Numbers Authority (IANA) list of <A HREF="http://go.microsoft.com/fwlink/?LinkID=3858" TARGET="_blank">IP protocol numbers</A> at http://go.microsoft.com/fwlink/?LinkID=3858. (The IPv4 “Protocol” field is called the “Next Header” field in IPv6.)<br><br>Configuring fragmentation checking:<br><br>• **Enable fragmentation checking**. If selected, specifies that this router discards all fragmented IP packets that it |

| | |
|---|---|
| | receives on this interface. This option applies only to incoming traffic. |

For examples of filter configurations for commonly implemented IP filtering scenarios on a Routing and Remote Access router, see "Filtering Scenarios" in How Unicast IPv4 Routing Protocols and Services Work.

**ICMP router discovery options**

Configuring ICMP router discovery, an alternative to using manually configured or DHCP-configured default gateways, provides an improved method of configuring and detecting the default gateway. For IP hosts, the default gateway is the IP router on the local subnet that forwards traffic to destinations that are not located on the local subnet.

The ICMP router discovery feature automates the discovery and configuration of the default gateway so that IP hosts can dynamically discover the best default gateway to use on a subnet and can automatically switch to another default gateway if the first default gateway fails or if the network administrator changes router preferences.

The following table describes Routing and Remote Access options for configuring ICMP router discovery on an IP router. These settings are available in the Windows Server 2003 Routing and Remote Access snap-in on the **General** tab of the *InterfaceName* **Properties** page for an interface in the **IP Routing\General** container.

**ICMP Router Discovery Options on the InterfaceName Properties Page**

| Tab | Task |
|---|---|
| General | Configuring options for ICMP router discovery on this interface:<br>• **Enable router discovery advertisements**. Specifies whether ICMP router discovery advertisements are enabled on the interface. If selected, you must also specify settings for the following (or accept the defaults):<br>  • **Advertisement lifetime (in minutes)**. The interval after which a host determines that a router is unavailable (since its last Router Advertisement message). The default is 30 minutes.<br>  • **Level of preference**. The preference level of this router to be the default gateway. The router with the highest preference level becomes the default gateway. The default is 0, which means that any other router configured with 1 or a higher number is preferred over this router by router discovery clients.<br>  • **Advertisement interval minimum time (in minutes)**. The minimum amount of time between Router Advertisement messages sent by this router. The default is 7 minutes.<br>  • **Advertisement interval maximum time (in minutes)**. The maximum amount of time between Router Advertisement messages sent by this router. The default is 10 minutes. Router Advertisements are sent at a random interval between the minimum and maximum times. |

In addition to enabling ICMP router discovery on the IP router, you must also configure router discovery on IP client computers on that router's subnet:

- For information about the tool used to configure ICMP router discovery on a client running Windows XP Professional, see "Netsh routing IP routerdiscovery context" in the section "Command-Line Tools for Unicast IPv4 Routing" earlier in this document.

- For information about the tool used to configure ICMP router discovery on a client running Windows 2000 Professional, see "PerformRouterDiscovery" and "SolicitationAddressBcast" in the section Unicast IPv4 Routing Registry Entries later in this document.

**Unicast IPv4 Routing Registry Entries**

When the Routing and Remote Access service is enabled, it creates and maintains its settings in the Windows Server 2003 registry. For performance reasons, most Routing and Remote Access service configuration information is stored in binary format in large configuration blocks, not as separate registry entries that you can easily view or modify by using the Registry Editor (Regedit.exe) tool. This section includes only unicast IPv4 routing-related Routing and Remote Access registry entries that are configurable.

For more information about these and other registry entries, see the Windows Server 2003 Resource Kit Registry Reference.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It

is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to change configuration settings rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing**

The Routing and Remote Access service provides an extensive tracing capability to help troubleshoot complex network problems. Separate routing components can be independently enabled to log tracing information to files — this capability is called file tracing. File tracing includes information about internal component variables, function calls, and interactions. You can enable and disable tracing for routing protocols while the router is running. This section includes only file tracing registry keys for the RIP v2 and OSPF routing protocols.

The following registry keys are located under the registry key HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing.

**IPRIP2**

**Registry path** HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing

**Version** Windows Server 2003 and Windows 2000 Server

Configuring entries under the IPRIP2 key enables file tracing, which logs tracing information about the RIP v2 routing protocol to files so that you can troubleshoot problems on a RIP internetwork.

| **Caution** |
|---|
| The recommended method for enabling file tracing for RIP is to use the Netsh tool rather than by changing the registry settings shown here. For more information, see “Netsh ras context” earlier in this document. |

Tracing consumes system resources and must be used sparingly. After you obtain the trace or identify the problem, immediately disable tracing. In particular, do not leave tracing enabled on multiprocessor computers.

The following table lists the registry entries for configuring file tracing for RIP v2.

**Entries for Enabling Tracing Under the IPRIP2 Registry Key**

| Entry | Task |
|---|---|
| EnableFileTracing | Configuring file tracing:<br>• 1 enables file tracing for the RIP v2 routing protocol.<br>• 0 disables file tracing for the RIP v2 routing protocol. File tracing is disabled by default. |
| FileDirectory | Configuring location of the file tracing log file:<br>• By default, the location of the tracing file is set to %windir%\Tracing\IPRIP2.LOG file.<br>• To set a new default location, you can right-click this entry and then specify an alternative for %windir%\Tracing. You cannot change the log file name. |
| FileTracingMask | Configuring how much tracing information is saved in the log file:<br>• By default, the level for file tracing is set to 0xFFFF0000, which is the maximum level.<br>• To set a new default level for file tracing, you can right-click this entry and then specify an alternative level in the range from 0 to 0xFFFF0000. |

| | |
|---|---|
| MaxFileSize | Configuring maximum log file size:<br>• By default, the maximum size of the log file is set to 0x100000, which is 1 MB.<br>• To set a new maximum size for the log file, you can right-click this entry and then specify an alternative maximum size. |

**OSPF**

**Registry path** HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing

**Version** Windows Server 2003 and Windows 2000 Server

Configuring entries under the OSPF key enables file tracing, which logs tracing information about the OSPF routing protocol to files so that you can troubleshoot problems on an OSPF internetwork.

| **Caution** |
|---|
| The recommended method for enabling file tracing for OSPF is to use the Netsh tool rather than by changing the registry settings shown here. For more information, see "Netsh ras context" earlier in this document. |

Tracing consumes system resources and must be used sparingly. After you obtain the trace or identify the problem, immediately disable tracing. In particular, do not leave tracing enabled on multiprocessor computers.

The following table lists the registry entries for configuring file tracing for OSPF.

**Entries for Enabling Tracing Under the OSPF Registry Key**

| Entry | Task |
|---|---|
| EnableFileTracing | Configuring file tracing:<br>• 1 enables file tracing for the OSPF routing protocol.<br>• 0 disables file tracing for the OSPF routing protocol. |
| FileDirectory | Configuring location of the file tracing log file:<br>• By default, the location of the tracing file is set to %windir%\Tracing\OSPF.LOG file.<br>• To set a new default location, you can right-click this entry and then specify an alternative for %windir%\Tracing. You cannot change the log file name. |
| FileTracingMask | Configuring how much tracing information is saved in the log file:<br>• By default, the level for file tracing is set to 0xFFFF0000, which is the maximum level.<br>• To set a new default level for file tracing, you can right-click this entry and then specify an alternative level in the range from 0 to 0xFFFF0000. |
| MaxFileSize | Configuring maximum log file size:<br>• By default, the maximum size of the log file is set to 0x100000, which is 1 MB.<br>• To set a new maximum size for the log file, you can right-click this entry and then specify an alternative maximum size. |

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Tcpip\Parameters**

The Routing and Remote Access service uses several TCP/IP registry keys. The entries included in this section are those that are specific to unicast IPv4 routing. For additional entries for TCP/IP, see TCP/IP Tools and Settings.

The following registry entries are located under the registry key HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters.

**DisableIPSourceRouting**

**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version** Windows Server 2003, Windows XP, Windows 2000, Windows NT 4.0, or Windows 98

This entry determines whether IP source routing is enabled. IP source routing lets the sender use a tool, such as Tracert.exe or Ping.exe, to specify the exact route that an IP packet takes through successive IP routers across the IP internetwork.

Source routing is not typically implemented on IP internetworks. Instead, IP routing is typically handled through routing decisions made by source hosts and IP routers based on entries in their respective local routing tables. Although you might want to use IP source routing in network testing and debugging situations, disable IP source routing as soon as you are finished testing or troubleshooting.

**Values for DisableIPSourceRouting**

| Value | Setting |
|---|---|
| 0 | Forwards all packets. |
| 1 (Default) | Does not forward source routed packets. |
| 2 | Drops all incoming source routed packets. |

**EnableDeadGWDetect**

**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version** Windows Server 2003, Windows XP, Windows 2000, Windows NT 4.0, or Windows 98

This entry determines whether dead gateway detection is enabled. With **EnableDeadGWDetect** enabled, TCP can detect a failure of the default gateway and inform IP to switch to a different default gateway if one is available. A default gateway is an IP router on the local subnet that can forward traffic to destinations located beyond the local subnet.

For optimal security, setting **EnableDeadGWDetect** to **0** is recommended in order to prevent an attacker from forcing this computer to switch to an unintended default gateway.

**Values for EnableDeadGWDetect**

| Value | Setting |
|---|---|
| 0 | Disables dead gateway detection. |
| 1 (default) | Enables dead gateway detection. |

**EnableFastRouteLookup**

**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version** Windows Server 2003, Windows 2000 Server

This entry, which is created only if the Routing and Remote Access Service is enabled, determines whether the fast route lookup feature is enabled. Fast route lookups make route searches faster but use a significant amount of non-paged pool memory. Fast route lookups are used only if the computer runs Windows Server 2003 or Windows 2000 Server and contains at least 64 MB of memory.

**Values for EnableFastRouteLookup**

| Value | Setting |
|---|---|
| 0 (default) | Disables fast route lookup. |
| 1 | Enables fast route lookup. |

**EnableICMPRedirects**

**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version** Windows Server 2003, Windows XP, Windows 2000

This entry determines whether a computer running Windows Server 2003 TCP/IP, or another version of Windows TCP/IP that supports Internet Control Message Protocol (ICMP) Redirect messages, updates its routing table in response to ICMP Redirect messages sent to it by a network device such as a router. An ICMP Redirect message instructs the computer to direct IP packets for the recipient along a different route. A computer running Windows Server 2003 accepts ICMP redirection messages from

any node in the route between it and the destination computer.

You must restart the computer for changes to this entry to take effect.

**Values for EnableICMPRedirects**

| Value | Setting |
|---|---|
| 0 | Disables updates of the IP routing table in response to ICMP Redirect messages. |
| 1 (default) | Enables updates of the IP routing table in response to ICMP Redirect messages. |

**EnablePMTUBHDetect**

**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version** Windows Server 2003, Windows XP, Windows 2000

This entry determines whether TCP tries to detect black hole routers during the path maximum transmission unit (PMTU) discovery process. For performance reasons, PMTU black hole router detection is disabled by default for TCP/IP in Windows Server 2003, Windows XP, and Windows 2000.

When PMTU black hole router detection is enabled, if several retransmissions of a TCP segment are not acknowledged, TCP tries sending segments with the Don't Fragment flag in the IP header of the IP packet set to **0** (which enables an IP router to fragment the TCP segment). If, as a result, a segment with the Don't Fragment flag set to **0** is acknowledged, the TCP maximum segment size (MSS) is decreased and the Don't Fragment flag is set to **1** (which prevents an IP router from fragmenting the TCP segment) in subsequent segments on the connection.

Enabling PMTU black hole detection increases the maximum number of retransmissions that are performed for a specific segment and can therefore decrease overall performance.

This registry entry is not present by default and must be added by using the Registry Editor tool, and then restarting Windows.

**Values for EnablePMTUBHDetect**

| Value | Setting |
|---|---|
| 0 (default) | Disables PMTU black hole detection. |
| 1 | Enables PMTU black hole detection. |

**EnablePMTUDiscovery**

**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version** Windows Server 2003, Windows XP, Windows 2000

This entry determines whether TCP uses a fixed, default maximum transmission unit (MTU) of 576 bytes for all connections that are not to destinations on a locally attached subnet, or alternatively, whether TCP attempts to detect the actual path maximum transmission unit (PMTU).

When PMTU Discovery is enabled, TCP attempts to discover the MTU, or largest packet size, allowed by the path to a remote host. By discovering the PMTU and limiting TCP segments to this size, TCP can eliminate fragmentation at IP routers along the path that connect networks with different MTUs. Fragmentation reduces TCP throughput and increases network congestion.

By default, this entry applies to all interfaces. However, you can use the Registry Editor to change the default value of this entry for one or more interfaces on this computer.

For optimal security, set **EnablePMTUDiscovery** to **0** in order to prevent an attacker from forcing the MTU value to a very small value and thereby overworking the TCP/IP stack.

This registry entry is not present by default and must be added by using the Registry Editor tool, and then restarting Windows.

**Values for EnablePMTUDiscovery**

| Value | Setting |
|---|---|
| 0 | Causes TCP to use an MTU of 576 bytes for all connections to nodes outside of the local subnet. |
| 1 (default) | Enables TCP to attempt to discover the actual MTU of the path to a remote node. |

**IPEnableRouter**

**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version** Windows Server 2003, Windows XP, Windows 2000

This entry determines whether IP forwarding is enabled on a computer on which the Routing and Remote Access service is not enabled. As the name **IPEnableRouter** indicates, manually enabling this entry enables the computer to act as a router. That is, when IP forwarding is enabled, the computer can route IP packets that it receives to nodes on all networks to which it is connected.

**Values for IPEnableRouter**

| Value | Setting |
|---|---|
| 0 (default) | Disables IP forwarding. The host does not route IP packets. |
| 1 | Enables IP forwarding. The host routes IP packets. |

A server running the Routing and Remote Access service does not use the **IPEnableRouter** registry entry; this entry is therefore, correctly, set to 0.

If you want to enable IP forwarding on a workstation or on a server on which you do not want to enable the Routing and Remote Access service, you must use the Registry Editor to set the **IPEnableRouter** registry entry to **1**. Typically, a workstation or multi-homed server that is not a router should not be configured to forward packets between networks, unless it is acting as a firewall.

**IPEnableRouterBackup**

**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version** Windows Server 2003, Windows XP, Windows 2000

This entry stores a backup copy of the value that was stored in the **IPEnableRouter** entry when the operating system of the computer was most recently installed or upgraded. The computer uses this entry to:

- Determine whether the value of **IPEnableRouter** has changed
- Restore the previous value if the value of **IPEnableRouter** has changed

Do not delete this entry or change its value. If you do, you might disable the IP packet routing mechanism.

There is no default value for this entry. The computer enters a value when you install or upgrade Windows.

**Values for IPEnableRouterBackup**

| Value | Setting |
|---|---|
| 0 | Disables storing a backup copy of the value stored in **IPEnableRouter**. |
| 1 | Enables storing a backup copy of the value stored in **IPEnableRouter**. |

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\Interfaces\interfaceGUID**

The Routing and Remote Access service uses several TCP/IP registry keys for interfaces. The entries included in this section are specific to unicast IPv4 routing features supported by the Routing and Remote Access service. For additional entries for TCP/IP interfaces, see TCP/IP Tools and Settings.

The following registry entries are located under the registry key HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\Interfaces*interfaceGUID*.

Before you can use the registry editor to configure a registry entry located under this key, you must first determine the globally unique identifier (GUID) for the TCP/IP interface that you want to configure.

**To determine the GUID for a specific TCP/IP interface**

1. Open Network Connections, and then note the name of the LAN connection, such as "Local Area Connection."
2. Open the Registry Editor (click **Start**, click **Run**, type **regedit.exe**, and then click **OK**).
3. In the tree view (the left pane), expand the following key: HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Network\{4D36E972-E325-11CE-BFC1-08002BE10318}
4. Under this key are one or more keys for the globally unique identifiers (GUIDs) corresponding to the installed LAN connections on this computer. Each of these GUID keys has a Connection subkey. Open each of the *GUID*\Connection keys, and then look for the Name setting whose value matches the name of your LAN connection from step 1.

5. When you have found the *GUID*\Connection key that contains the Name setting that matches the name of your LAN connection, write down, take a screenshot, or otherwise note the GUID value.

6. Use the tree view to open the following key: HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\Interfaces*interfaceGUID*.

7. Right-click the *interfaceGUID* key you want in the tree view, and then view or configure that entry.

**PerformRouterDiscovery**
**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\Interfaces*interfaceGUID*

**Version** Windows Server 2003, Windows XP, Windows 2000, Windows 98

| **Note** |
|---|
| The recommended method for configuring router discovery on a host running Windows Server 2003 or Windows XP is to set DHCP options, instead of modifying the registry. |

The **PerformRouterDiscovery** entry determines whether Windows TCP/IP attempts to perform ICMP router discovery as a host, as defined by RFC 1256, on this interface. Enabling router discovery on a client or non-router server enables that computer to listen for Router Advertisement messages from an IP router, to send Router Solicitation messages to discover active routers on its subnet, and to switch to another router if the first router fails or the network administrator changes router preferences.

Windows does not add the **PerformRouterDiscovery** entry to the registry. To enable ICMP router discovery, you must add this entry (as type REG_DWORD) and set its value to one of the options listed in the following table.

**Values for Enabling PerformRouterDiscovery**

| Value | Setting |
|---|---|
| 0 | Disables router discovery. |
| 1 | Enables router discovery. |
| 2 (default) | Enables DHCP-controlled router discovery.<br><br>The value 2 is the default, but it is used only if the DHCP options **Perform Router Discovery** and **Router Solicitation Address** are configured. The DHCP **Perform Router Discovery** option is DHCP scope option 31 and the DHCP **Router Solicitation Address** option is DHCP scope option 32. Both are configured by using the DHCP snap-in. For more information, see "DHCP Options" in DHCP Tools and Settings. |

For ICMP router discovery to take place, in addition to configuring **PerformRouterDiscovery** on a client or non-router server, the following requirements must also be met:

- A Routing and Remote Access router on the same subnet must be configured for ICMP router discovery, to enable it to send Router Advertisement messages to all hosts on the subnet. For more information, see "Netsh routing IP routerdiscovery context" or "ICMP router discovery options" earlier in this technical reference.

- The entry **SolicitationAddressBcast** must be added to the registry, and its value configured. For more information, see "SolicitationAddressBcast" later in this technical reference.

**PerformRouterDiscoveryBackup**
**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\Interfaces*interfaceGUID*

**Version** Windows Server 2003, Windows XP, Windows 2000

This entry stores a backup copy of the value stored in the **PerformRouterDiscovery** entry (if an entry for **PerformRouterDiscovery** has been configured). The computer uses this entry only when IP routing is enabled and the value of **PerformRouterDiscovery** is **0**.

| **Caution** |
|---|
| This entry is used internally by the Windows operating system. Do not delete this entry or change its value. If you do, you might disable the router discovery mechanism. |

There is no default value for this entry.

**Values for PerformRouterDiscoveryBackup**

| Value | Setting |
|---|---|
| 0 | Disables storing a backup copy of the value stored in **PerformRouterDiscovery**. |
| 1 | Enables storing a backup copy of the value stored in **PerformRouterDiscovery**. |

**SolicitationAddressBcast**

**Registry path** HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\Interfaces*interfaceGUID*

**Version** Windows Server 2003, Windows XP, Windows 2000, Windows 98

| **Note** |
|---|
| The recommended method for configuring router discovery on a host running Windows Server 2003 or Windows XP is to set DHCP options, instead of modifying the registry. |

The **SolicitationAddressBcast** entry, as defined by RFC 1256, determines whether Windows sends router discovery messages as broadcasts rather than as multicasts on this interface. Enabling router discovery on a client or non-router server computer lets that computer listen for **Router Advertisement** messages from a router and lets that computer send **Router Solicitation** messages to discover active routers on its subnet and to discover the unavailability of previously available routers that are currently down.

Windows does not add the **SolicitationAddressBcast** entry to the registry. To specify how router solicitation messages are sent, you must add this entry (as type REG_DWORD) and set its value to one of the options listed in the following table.

**Values for Enabling SolicitationAddressBcast**

| Value | Setting |
|---|---|
| 0 (Default) | Enables the sending of router solicitation messages to the all-routers multicast group (224.0.0.2). This is the recommended option. |
| 1 | Enables the sending of router solicitation messages as limited broadcast messages by using the IP address 255.255.255.255.<br><br>The value 1 is not recommended because it causes all clients to broadcast router solicitation messages, creating a large volume of unnecessary broadcast traffic that must be processed by other clients. |

For ICMP router discovery to take place, in addition to configuring the value for this entry, the following requirements must also be met:

- A Routing and Remote Access router on the same subnet must be configured for ICMP router discovery, to enable it to send Router Advertisement messages to all hosts on the subnet. For more information, see "Netsh routing IP routerdiscovery context" or "ICMP router discovery options" earlier in this technical reference.

- The entry **PerformRouterDiscovery** must be added to the registry, and its value configured. For more information, see "PerformRouterDiscovery" earlier in this technical reference.

Note that **PerformRouterDiscovery** option 2 enables DHCP-controlled router discovery, but only if the DHCP options **Perform Router Discovery** and **Router Solicitation Address** are configured.

# Network Monitoring Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Monitoring Technologies**
In Microsoft Windows Server 2003 network monitoring technologies help network administrators track and manage the functions of devices on the network.

**Network Monitoring Components**
There are two network monitoring technologies that help network administrators track and manage the functions of devices on the network:

- Simple Network Management Protocol (SNMP)

  SNMP is a network management protocol that can monitor and alert administrators regarding the condition of hardware components such as workstations and servers.

- Microsoft Computer Browser Service

  The Computer Browser Service in computers running Windows enables network administrators and users to browse and gain access to the resources of the network. The browser service provides a convenient listing of devices such as workstations and printers, and allows network users access to them with the proper authentication.

**SNMP**
SNMP management software is used to monitor any network device on which SNMP agent software is installed. The SNMP agent, an optional component of Windows Server 2003, interacts with other SNMP management software to enable the transport of information about network status between monitored devices and applications and the management systems that monitor them.

**SNMP Management Systems and Agents**
SNMP provides a method of managing network hosts such as workstation or server computers, routers, bridges, and hubs from a centrally-located computer that runs network management software. SNMP performs management services by using a distributed architecture of management systems and agents.

**SNMP management system**
The management system, also called management console, sends information and update requests to an SNMP agent. Any computer running SNMP management software is an SNMP management system. The management software application does not need to run on the same host as the SNMP agent.

The SNMP management system requests information from a managed computer, (SNMP agent), such as the amount of hard disk space available or the number of active sessions. The management system can also initiate a change to an agent's configuration. However, this is rare because most clients have read-only access.

**SNMP agent**
The SNMP agent responds to management system requests for information. Any computer running SNMP agent software is an SNMP agent. The Windows Server 2003 SNMP service, which is agent software, responds to information requests from one or multiple management systems. The SNMP service can be configured to determine which statistics are tracked and which management systems are authorized to request information.

Typically, agents do not originate messages, but only respond to them. A trap message is the only agent-initiated SNMP communication. A trap is an alarm-triggering event on an agent, such as a system reboot or illegal access, which provides enhanced security.

Management hosts and agents belong to an SNMP community, which is a collection of hosts grouped together for administrative purposes. Defining communities provides security by allowing only management systems and agents within the same community to communicate.

**Computer Browser Service**
The Computer Browser service is the mechanism that collects and distributes the list of workgroups and domains and the servers within them. The list is displayed in the window of Microsoft Windows Network and related windows in My Network

Places.

The architecture of the browser service is complete when several computers are brought together on a network to perform Browser Service roles. Individually, these roles are just parts of the Browser Service, but when combined on the network, they form a browser system that enables efficient sharing of network resource information. The computers that perform these roles make up the components of the browser system.

**Browser System Roles**
There are four Browser Service roles that computers can play in the browser system:

- Potential browser
- Backup browse server
- Master browse server
- Domain master browse server

**Network Monitoring Scenarios**
The need for network monitoring corresponds to the size of the network. Small networks with few devices attached and with a small geographical size might be easily managed without SNMP or a large reliance on the Computer Browser Service. A large network with many devices is more difficult to monitor. Unlike a small network where administrators might be able to visually inspect network devices regularly, large networks might require the use of SNMP and the Computer Browser Service to make it possible to track network devices from a single computer. Thus, these technologies become more useful and more essential as networks expand.

# SNMP Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SNMP Technical Reference**
Simple Network Management Protocol (SNMP) lets you monitor network devices configured as SNMP agents. Microsoft Windows Server 2003 provides SNMP agent software that works with third-party SNMP management software to monitor the status of managed devices and applications. Use SNMP to monitor network performance, audit network usage, detect network faults or inappropriate access, and, in some cases, configure remote devices.

**In this subject**

# What Is SNMP?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is SNMP?**

**In this section**

- Automating Network Management
- Related Information

Simple Network Management Protocol (SNMP) is a popular protocol for network management. It is used for collecting information from, and configuring, network devices, such as servers, printers, hubs, switches, and routers on an Internet Protocol (IP) network. Microsoft Windows Server 2003 provides SNMP agent software that works with third-party SNMP management software to monitor the status of managed devices and applications.

**Automating Network Management**

Large networks with hundreds or thousands of nodes are difficult to manage without a large staff to monitor every computer. SNMP, which is widely used in local area networks (LANs), lets you monitor network nodes from a management host. You can monitor network devices such as servers, workstations, printers, routers, bridges, and hubs, as well as services such as Dynamic Host Configuration Protocol (DHCP) or Windows Internet Name Service (WINS).

Use SNMP management software to monitor any network device on which you install SNMP agent software. The SNMP agent, which is an optional component of Windows Server 2003, interacts with third-party SNMP management software to enable the sharing of network status information between monitored devices and applications and the SNMP management system that monitors them. The following figure shows this process.

**Computer Running SNMP Manager Requests Status Information from Devices Running SNMP Agent**

Using SNMP, you can monitor network performance, audit network usage, detect network faults or inappropriate access, and in some cases configure remote devices. SNMP is designed to be deployed on the largest possible number of network devices, to have minimal impact on the managed nodes, to have minimal transport requirements, and to continue working when most other network applications fail.

**SNMP Background**

Developed in 1988 to provide network-device-monitoring capability for TCP/IP-based networks, SNMP was approved as an Internet standard in 1990 by the Internet Architecture Board (IAB) and has been in wide use since that time. More recently, Internetwork Packet Exchange (IPX)-based networks have added support for SNMP. Currently, most network equipment vendors provide SNMP support in their products.

Windows Server 2003 supports SNMP versions 1 and 2c, which are based on the industry standards described in the following table.

**Industry Standards for SNMP Versions 1 and 2c**

| Standard | RFCs |
|---|---|

| | |
|---|---|
| SNMP | RFC 1157, "A Simple Network Management Protocol (SNMP)," a standard that defines how communication occurs between SNMP-capable devices and defines the SNMP message types.<br><br>Windows Server 2003 also supports SNMPv2c, which is defined in RFC 1901, "Introduction to Community-Based SNMPv2," RFC 1905, "Protocol Operations for Version 2 of the Simple Network Management Protocol (SNMPv2)," and RFC 1906, "Transport Mappings for Version 2 of the Simple Network Management Protocol (SNMPv2)." SNMPv2c updates protocol operations by introducing the **GetBulk** request and authentication based on community names.<br><br>RFC 1420, "SNMP over IPX" describes SNMP support now provided by the Internetwork Packet Exchange (IPX) protocol used in Novell NetWare environments. SNMP typically uses the User Datagram Protocol (UDP). SNMP over IPX is intended for use in environments in which the UDP transport is not available. IPX provides a datagram service similar to that provided by IP/UDP. |
| MIB | RFC 1213, "Management Information Base for Network Management of TCP/IP based Internets: MIB II." A standard that defines a set of objects that represent information about IP and IPX components on your network, such as the list of network interfaces, the routing table, the Address Resolution Protocol (ARP) table, the list of open TCP connections, or Internet Control Message Protocol (ICMP) statistics.<br><br>RFC 1213 is updated (but not made obsolete) by RFC 2011, "SNMPv2 Management Information Base for the Internet Protocol using SMIv2," RFC 2012, "SNMPv2 Management Information Base for the Transmission Control Protocol using SMIv2," and RFC 2013, "SNMPv2 Management Information Base for the User Datagram Protocol using SMIv2." |
| SMI | RFC 2578, "Structure of Management Information Version 2 (SMIv2)." A standard that describes the object syntax for specifying how MIB data is referenced and stored. |

For a list of additional SNMP-related RFCs, see "Related Information" below.

**Implementing Windows Server 2003 and SNMP**

SNMP is a service that you can install on computers that are running TCP/IP or the IPX protocol. Windows Server 2003 supports SNMPv1 and SNMPv2c, which define how network management information is structured, stored, and communicated between SNMP agents and SNMP managers on IP-based or IPX-based networks. Windows Server 2003 adds support for the IPv6 Management Information Base (MIB) for SNMP.

**SNMP agent**

The Windows Server 2003 SNMP service provides an SNMP agent that enables the remote monitoring of computers running Windows Server 2003, Windows XP, or Windows 2000. The Windows XP 64-Bit Edition operating system and the 64-bit version of Windows Server 2003 do not support the Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX) protocol.

The Windows Server 2003 SNMP agent lets you manage the services listed in the following table.

**Services That Can Be Monitored or Configured Using SNMP Agent**

| Service | Monitor | Configure | Windows Operating Systems That Provide SNMP Support for This Service Version |
|---|---|---|---|
| WINS | • | • | Windows Server 2003, Windows XP, and Windows 2000. |
| DHCP | • | | Windows Server 2003, Windows XP, Windows 2000, and Windows NT-based Dynamic Host Configuration Protocol (DHCP). |
| IIS | • | | Windows Server 2003, Windows XP, Windows 2000, and Windows NT-based Microsoft Internet Information Services (IIS). |
| LAN Manager | • | • | Microsoft LAN Manager. |
| Routing and Remote Access | • | | Windows Server 2003, and Windows 2000 Routing and Remote Access service. |
| IAS | • | • | Windows Server 2003, and Windows 2000 Internet Authentication Service (IAS). |

| | | | |
|---|---|---|---|
| System Monitor counters | • | | Windows Server 2003, Windows XP, and Windows 2000 System Monitor counters.<br><br>You can use SNMP to monitor all performance counters related to System Monitor TCP/IP, including ICMP, IP, Network Interface, TCP, UDP, DHCP, File Transfer Protocol (FTP), WINS, and IIS performance counters. |

In addition to retrieving status information, SNMP can send a **Set** request to configure any object to which the SNMP manager has read/write permission.

**SNMP manager**

The Windows Server 2003 SNMP service provides only the SNMP agent. Unless you develop your own SNMP management application, you must install third-party SNMP management software, such as HP Openview, Novell NMS, IBM NetView, or Sun Net Manager to work with the SNMP agent. You can install third-party SNMP management software on one or more hosts.

Alternatively, you can develop your own SNMP management software application by using the two application programming interfaces (APIs) that Windows Server 2003 provides:

WinSNMP API (Wsnmp32.dll) provides a set of functions for encoding, decoding, sending, and receiving SNMP messages.

Management API (Mgmtapi.dll) provides a basic set of functions for developing fast and simple SNMP management systems.

**Related Information**

For more information about SNMP, see the following RFCs in the IETF RFC Database.

The following RFCs relate to SNMP version 1:

RFC 1157, “Simple Network Management Protocol (SNMP).”

RFC 1155, “Structure and Identification of Management Information for TCP/IP-based Internets.”

RFC 1213, “Management Information Base for Network Management of TCP/IP-based Internets: MIB-II.”

RFC 1573, “Evolution of the Interfaces Group of MIB-II.”

The following RFCs relate to SNMP version 2:

RFC 1901, “Introduction to Community-Based SNMPv2.”

RFC 1902, “Structure of Management Information for Version 2 of the Simple Network Management Protocol (SNMPv2).”

RFC 1903, “Textual Conventions for SNMPv2.”

RFC 1904, “Conformance Statements for Version 2 of the Simple Network Management Protocol (SNMPv2).”

RFC 1905, “Protocol Operations for Version 2 of the Simple Network Management Protocol (SNMPv2).”

RFC 1906, “Transport Mappings for Version 2 of the Simple Network Management Protocol (SNMPv2).”

RFC 1907, “Management Information Base for Version 2 of the Simple Network Management Protocol (SNMPv2).”

RFC 1908, “Coexistence between Version 1 and Version 2 of the Internet-standard Network Management Framework.”

RFC 2089, “V2ToV1 Mapping SNMPv2 onto SNMPv1 Within a Bi-Lingual SNMP Agent.”

RFC 2465, “Management Information Base for IP Version 6: Textual Conventions and General Group.”

RFC 2466, “Management Information Base for IP Version 6: ICMPv6 Group.”

# How SNMP Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How SNMP Works**
**In this section**

- SNMP Architecture
- SNMP Manager/Agent Communication
- SNMP Management Systems and Agents
- SNMP Messages
- SNMP Communities
- Related Information

Use Simple Network Management Protocol (SNMP) management software to monitor any network device configured with SNMP agent software. The SNMP agent, which is an optional component of Windows Server 2003, interacts with third-party SNMP management software to enable the flow of network status information between monitored devices and applications and the management systems that monitor them.

You can use SNMP in environments that include large networks with hundreds or thousands of nodes that would otherwise be difficult and costly to monitor. SNMP allows monitoring of network devices such as servers, workstations, printers, routers, bridges, and hubs, as well as services such as Dynamic Host Configuration Protocol (DHCP) or Windows Internet Name Service (WINS).

The following sections describe the architecture, components, and processes used by SNMP.

**SNMP Architecture**
To perform its monitoring services, SNMP uses a distributed architecture of management systems and agents and several related components. Windows Server 2003 provides an SNMP agent that is designed to be capable of interacting with any SNMP manager. The following components are the building blocks of SNMP and the Windows Server 2003 SNMP agent:

- SNMP management systems and agents
- Management Information Base (MIB)
- SNMP Messages
- SNMP Communities
- The communication process between SNMP managers and agents

The internal architecture of the Windows Server 2003 implementation of SNMP is divided into management and agent functions, which, in some cases, overlap. The following figure illustrates how the Windows Server 2003 SNMP structure fits into the layers of the underlying TCP/IP protocol architecture.

**Windows Server 2003 SNMP Components at Each TCP/IP Layer**

The following table lists the Windows Server 2003 SNMP internal components.

**Windows Server 2003 SNMP Components**

| Component Name | Associated Programs | Component Type | Description |
|---|---|---|---|
| Microsoft SNMP Service<br><br>(Also called master agent or extendible agent) | Snmp.exe | Agent | Receives SNMP requests and delivers them to the appropriate SNMP subagent DLL for processing. The service is also responsible for intercepting events (traps) from the SNMP subagents and forwarding trap messages to the appropriate management systems. |
| SNMP Subagents<br><br>(Also called extension agents) | Inetmib1.dll, Hostmib.dll, Lmmib2.dll, and others | Agent | Provides a set of entry points. When an SNMP request is received, the SNMP service delivers it to the appropriate subagent by calling one of these entry points. After the subagent processes the message, it passes the information back to the SNMP service, which then forwards the message to the SNMP manager. |
| SNMP Utility API | Snmpapi.dll | Both Agent and Manager | Provides utilities that the SNMP service uses for memory management operations, address-decoding routines, object identifier handling routines, and so forth.<br><br>Provides a set of routines that SNMP subagents use to handle and order SNMP objects.<br><br>Although use of the Snmpapi.dll is not required, the framework defined by this tool greatly facilitates the development of new SNMP subagents. |
| WinSNMP API<br><br>-and-<br><br>Management API | Wsnmp32.dll<br><br>-and-<br><br>Mgmtapi.dll | Manager | Helps develop SNMP management software applications:<br><br>• The WinSNMP API provides a set of functions for encoding, decoding, sending, and receiving SNMP messages.<br><br>• The Management API is a simple API that resides on top of the WinSNMP and SNMP Utility APIs. It provides a limited set of functions that you can use to develop basic SNMP management applications quickly. |
| SNMP Trap Service | Snmptrap.exe | Manager | Uses the WinSNMP API to forward a trap message sent by an SNMP agent to the appropriate SNMP manager application. |

| | | | |
|---|---|---|---|
| SNMP Manager Application | Snmputil.exe | Manager | Provides a basic command-line utility with which to retrieve information from any SNMP agent in your network. This example of a management application was developed using the Management API. |

**SNMP Manager/Agent Communication**
The following figure shows an example of the communication process between SNMP managers and agents.

**Manager Requesting Number of Sessions from an SNMP Agent**

The communication between the SNMP manager and SNMP agent in the example proceeds in the following fashion:

1. The SNMP manager, Host A, forms an SNMP message that contains an information request (Get) for the number of active sessions, the name of the community to which the SNMP manager belongs, and the destination of the message — the IP address (131.107.3.24) of the SNMP agent, Host B.

   The SNMP manager can use either the Microsoft SNMP Management API library (Mgmtapi.dll) or the Microsoft WinSNMP API library (Wsnmp32.dll) to perform this step.

2. The SNMP manager sends the information request to Host B by using the SNMP service libraries.

3. When Host B receives the message, it verifies that the community name (MonitorInfo) contained in the packet is on its list of acceptable community names, evaluates the request against the agent's list of access permissions for that community, and verifies the source IP address.

   If the community name or access permission is incorrect, and the SNMP service has been configured to send an authentication trap, the agent sends an "authentication failure" trap to the specified trap destination, Host C. Hosts B and C belong to the TrapAlarm community.

4. The master agent component of the SNMP agent calls the appropriate extension agent to retrieve the requested session information from the MIB.

5. Using the session information that it retrieved from the extension agent, the SNMP service forms a return SNMP message that contains the number of active sessions and the destination — the IP address (131.107.7.29) of the SNMP manager, Host A.

6. Host B sends the response to Host A.

**SNMP Management Systems and Agents**
SNMP locates the network management component on one or more computers and locates the managed component on multiple managed devices:

- **SNMP manager.** An SNMP manager, also known as an SNMP management system or a management console, is any computer that sends queries for IP-related information to a managed computer, known as an SNMP agent. In some

cases, the SNMP manager can send a request to an SNMP agent to change a configuration value.

- **SNMP agent.** An SNMP agent is any computer or other network device that monitors and responds to queries from SNMP managers. The agent can also send a trap message to the manager when specified events, such as a system reboot or illegal access, occur.

A computer on which you install SNMP management software is an SNMP manager, and a computer on which you install agent software, such as the Microsoft SNMP agent included with Windows Server 2003, is an SNMP agent. The SNMP manager displays the information it receives in a user-friendly graphical user interface. You configure SNMP options, including traps, on the SNMP agent, but the SNMP agent does not display the managed information that it sends to an SNMP manager. For more information about SNMP requests and trap messages, see "SNMP Messages" later in this section.

To enable SNMP communications between an SNMP manager and SNMP agents, you configure the SNMP manager and the SNMP agents that it manages as members of an SNMP community. The community name functions like a password to authenticate communications between the SNMP manager and agent. The SNMP community is an SNMP-defined group, not a group defined in the Active Directory directory service. For more information about SNMP communities, see "SNMP Communities" later in this section.

An SNMP manager can request the following types of information from the SNMP agents that it monitors:

- Network protocol identification and statistics
- Dynamic identification (discovery) of devices attached to the network
- Hardware and software configuration data
- Device performance and usage statistics
- Device error and event messages
- Program and application usage statistics

If you assign the SNMP manager write permission for the SNMP agent, the SNMP manager can also send a configuration request to the agent (using a **Set** message) to change a local parameter. However, **Set** requests are limited to a small set of client parameters that have read-write access defined. Most client parameters allow only read-only access.

**Understanding the Management Information Base (MIB)**

When an SNMP manager requests information from an SNMP agent, the SNMP agent retrieves the current value of the requested information from the Management Information Base (MIB). The MIB defines the managed objects that an SNMP manager monitors (or sometimes configures) on an SNMP agent.

Each system in a network (workstation, server, router, bridge, and so forth) maintains a MIB that reflects the status of the managed resources on that system, such as the version of the software running on the device, the IP address assigned to a port or interface, the amount of free hard drive space, or the number of open files. The MIB does not contain static data, but is instead an object-oriented, dynamic database that provides a logical collection of managed object definitions. The MIB defines the data type of each managed object and describes the object.

**The MIB Tree**

The SNMP-related branches of the MIB tree are located in the internet branch, which contains two main types of branches:

- *Public branches (mgmt=2)*, which are defined by the Internet Engineering Task Force (IETF) RFCs, are the same for all SNMP-managed devices.
- *Private branches (private=4)*, which are assigned by the Internet Assigned Numbers Authority (IANA), are defined by the companies and organizations to which these branches are assigned.

The following figure shows the structure of the SNMP MIB tree. There are no limits on the width and depth of the MIB tree.

**The Structure of the SNMP MIB Tree**

Immediately beneath the root of the MIB tree, International Organization for Standardization (iso), is the Organization (org) branch, followed by Department of Defense (dod), and then Internet (internet). Management (mgmt), the main public branch, defines network management parameters common to devices from all vendors. Underneath the Management branch is MIB-II (mib-2), and beneath this are branches for common management functions such as system management, printers, host resources, and interfaces.

The private branch of the MIB tree contains branches for large organizations, organized under the enterprises branch. Each organization has a root branch node under this object. Each organization creates its own subset of MIB branches and objects, which must comply with a common definition of SNMP information known as Structure of Management Information (SMI). SMI defines the allowed data types for MIB objects.

**MIB Objects**

At the programmatic level, the definition of each MIB object that an SNMP agent manages includes the following elements:

- The object name and object identifier (also known as an OID).
- A text description of the object.
- The object's data-type definition (such as counter, string, gauge, or address).
- The index for objects that are assigned complex data types. The index specifies the key field for the table — that is, the field that can be used to identify a row.

  The only complex SNMP data type that is allowed is a table, and tables cannot be nested. Examples include the list of a system's network interfaces, a routing table, or the Address Resolution Protocol (ARP) table.
- The level of access to the object (such as read or read/write) that is allowed.
- Size restrictions.
- Range information.

SNMP references each MIB variable by using its unique object identifier, which identifies the location of a given managed object within the MIB namespace. The object identifier reflects the object's position within the hierarchy of the MIB tree, containing a sequence of subidentifiers that begin at the root of the MIB tree and end at the object (leaf node). Subidentifiers are separated with a period.

To reference a MIB object, you can use either numeric or text subidentifiers. For example, the following text-based object identifier is interchangeable with its numeric counterpart, shown beneath it. The value of this object identifier, in either format, identifies the current operational state of a network adapter.

.iso.org.dod.internet.mgmt.mib-2.interfaces.ifTable.ifEntry.ifOperStatus

.1.3.6.1.2.1.2.2.1.8

Corresponding to each object identifier is a value that represents the current state of the object. SNMP, which accesses only the

leaf nodes in the MIB tree, references a MIB variable by the dotted numeric string that represents its object identifier in order to retrieve the current value of the variable.

Microsoft has the authority to assign names to objects within the 311 (microsoft) namespaces. For example, Microsoft (itself represented in MIB notation as .1.3.6.1.4.1.311) defines various MIB branches under its root node, such as:

.1.3.6.1.4.1.311.1.3 — Dynamic Host Configuration Protocol (DHCP)

.1.3.6.1.4.1.311.1.2 — Windows Internet Name Service (WINS)

.1.3.6.1.4.1.311.1.7.2 — File Transfer Protocol (FTP)

.1.3.5.1.4.1.311.1.7.3 — Hypertext Transfer Protocol (HTTP)

**Interacting with MIB Objects**
To understand how SNMP interacts with MIB objects, you must first understand that the SNMP agent consists of a master agent and one or more subagents, also known as extension agents, which are the dynamic link libraries (DLLs) that SNMP uses to process a request received from an SNMP manager.

When the SNMP service starts, it loads each SNMP extension agent that is listed in the registry. When the master agent receives a request from the SNMP manager, it passes the request to an extension agent, which accesses the appropriate MIB and returns the current value of the relevant MIB object to the SNMP master agent. The SNMP agent then returns the information to the SNMP manager. An SNMP agent can also send unsolicited MIB information to the SNMP manager in response to an event that has been defined as an SNMP trap (unexpected event). In some cases, the SNMP agent changes (or sets) the value of the MIB object.

For example, in order to assess the network load at a particular point in your network, you can use SNMP to retrieve the value of a counter that tracks the number of packets sent over a link to the SNMP agent. Or you might use SNMP to retrieve the value that represents the amount of disk space available for storage. Although SNMP is used less commonly to set the value of a MIB object, to ensure that a link is not used, you might use SNMP to set the link state value of a MIB object to a disabled state.

**Compiling a New or Updated MIB File by Using Mibcc.exe**
As explained earlier, the SNMP-related branches of the MIB tree are located in the internet branch of the tree. The internet branch contains public branches that are defined by the IETF and private branches that are defined by large organizations. When an organization creates its own subset of MIB branches and objects, or updates an existing MIB file, the new or updated MIB file must be created in compliance with SMI-prescribed data types.

If your organization adds or updates a new MIB file, use the Mibcc.exe tool to compile the MIB file so that the SNMP Management API (Mgmtapi.dll) can use the MIB objects in the new or updated MIB file. After you compile the MIB file, you can reference objects by their text object identifiers instead of their numeric object identifiers. The ASN.1 language is used to define the formats of the protocol data units (PDUs) that are exchanged by SNMP entities and to define the objects that are managed through SNMP. Mibcc.exe converts the ASN.1 MIB description into the binary Mib.bin file, which the Management API then uses to map text-based object names to numeric object identifiers.

You can find Mibcc.exe in the C:\Program Files\Resource Kit folder when you install the Windows Server 2003 Resource Kit companion CD. The Mib.bin file is located in *systemroot* on Windows Server 2003.

**SNMP Messages**
SNMP sends operation requests and responses as SNMP messages. An SNMP message consists of an SNMP protocol data unit (PDU) plus additional message header elements defined by the relevant RFC. An SNMP agent sends information in two situations:

- When it responds to a request from an SNMP manager
- When a trap event occurs

**SNMP Message Types**
The following table describes each type of message that the SNMP manager and agent programs use to communicate with each other.

### SNMP Message Types

| SNMP Message | From / To | Message Description |
|---|---|---|

| | | |
|---|---|---|
| Get | Manager / agent | Accesses and retrieves the current value of one or more MIB objects on an SNMP agent . |
| GetResponse | Agent / manager | Replies to a **Get**, **GetNext**, or **Set** operation. |
| GetNext | Manager / agent | Browses the entire tree of MIB objects, reading the values of variables in the MIB sequentially. Typically, you use **GetNext** to obtain information from selected columns from one or more rows of a table. **GetNext** is especially useful for browsing dynamic tables, such as an internal IP route table or an ARP table, reading through the table one row at a time. |
| GetBulk<br><br>(SNMPv2c only) | Manager / agent | Retrieves data in units as large as possible within the given constraints on the message size. **GetBulk**, which accesses multiple values at one time without using a **GetNext** message, minimizes the number of protocol exchanges required to retrieve a large amount of information.<br><br>To avoid fragmentation, restrict the maximum message size to a size smaller than the path maximum transmission unit (MTU), the largest frame size allowed for a single frame on your network. Typically, when it is not known how many rows are in a table, **GetBulk** is used (rather than **GetNext**) to browse all rows in the table. |
| Set | Manager / agent | Changes the current value of a MIB object. In order to update a MIB value on the SNMP agent, the SNMP manager must have write access to the object. **Set** is used infrequently, because most MIB objects are read-only by default, so that unauthorized changes cannot be made. |
| Trap | Agent / manager | Notifies the specified SNMP manager (the trap destination) when an unexpected event occurs locally on the managed host. You can use traps for limited security checking (such as notifying the trap destination if the agent receives an information request from an SNMP manager that it does not recognize) or for troubleshooting (such as notifying the trap destination if the WINS service fails). |

SNMP uses the connectionless User Datagram Protocol (UDP) service to transmit SNMP messages. SNMP uses the simple UDP transport service, which guarantees neither delivery nor correct sequencing of delivered packets, so that SNMP can continue functioning after many other network services have failed. By default, UDP port 161 is used to listen for SNMP messages and port 162 is used to listen for SNMP traps. If necessary — for example, because your organization already uses ports 161 and 162 for some other protocol or service — you can change these port settings by configuring the local Services file (this Services file is different from the Windows Services snap-in). The following figure shows messages moving between an SNMP manager and several SNMP agents.

**Messages Sent Between an SNMP Manager and its Managed Devices**

**Get Message Requires Instance Identifier**

When typing an SNMP command (such as Snmputil.exe), you can specify a MIB object by using either numeric or text subidentifiers. For example, as explained earlier, both of the following notations refer to the object identifier whose value is the current operational status of an interface:

.iso.org.dod.internet.mgmt.mib-2.interfaces.ifTable.ifEntry.ifOperStatus

.1.3.6.1.2.1.2.2.1.8

The object identifier of a MIB object identifies the type of object. The instance identifier of a MIB object, used only in SNMP **Get** operations, indicates which value to retrieve. That is, a **Get** operation must specify *ObjectIdentifier.SpecificValueToRetrieve*. Two types of instance identifiers exist:

- **Object is not in a table.** If an object can return only one value (such as the description of a system), you append the suffix **.0** to the end of the object identifier.

- **Object is in a table.** If an object can return different values (such as a router that has more than one interface), you append an index at the end of the object identifier to indicate which instance to return. For example, if a router has four interfaces and you want to use a **Get** command with Snmputil.exe to return the current status of an interface that has an interface index (ifIndex) of 3, you type **.3** at the end of the object identifier.

**SNMP Trap Types**

The SNMP standard defines six types of traps and provides a seventh trap type that an organization can use to implement enterprise-specific traps. The following table lists the seven trap types.

**SNMP Trap Types**

| Trap Type | Trap Name | Description |
|---|---|---|
| 0 | ColdStart | The SNMP agent initialized its configuration tables. |
| 1 | WarmStart | The SNMP agent re-initialized its configuration tables. |
| 2 | LinkDown | The state of a network adapter on the SNMP agent changed from up to down. |
| 3 | Linkup | The state of a network adapter on the SNMP agent changed from down to up. |
| 4 | authenticationFailure | The SNMP agent received a message from an SNMP manager, but the message contained an invalid community name. |
| 5 | egpNeighborLoss | The SNMP agent could not communicate with its Exterior Gateway Protocol (EGP) peer. |
| 6 | enterpriseSpecific | Reserved for vendor-defined error conditions and error codes. |

The Windows Server 2003 SNMP service can send enterprise-specific traps on behalf of the Event To Trap Translator.

**SNMP Communities**

SNMP version 2c introduced the use of shared community names for authentication of SNMP traffic. By default, in Windows Server 2003, no community names are configured and the SNMP service accepts SNMP requests only from the host name, localhost. To enable successful communication between an SNMP agent and an SNMP manager, you must configure at least one community name in SNMP. SNMP community names are case-sensitive.

A community name acts as a password that is shared, typically, by multiple SNMP agents and one or more SNMP managers. You configure the SNMP manager and the computers or devices that it manages as members of a single SNMP community. An SNMP agent only accepts requests from SNMP managers that are on the agent's list of acceptable community names.

When an SNMP manager sends a query or set request to the SNMP agent, the SNMP service compares the community name of the requestor with the community name of the agent and its access permissions. If the names match, the SNMP manager is successfully authenticated, and the agent replies to the query or performs the set request. If the community names do not match, the SNMP agent considers the request a failed access attempt and — if configured to do so — can send an SNMP trap message notifying the trap destination that an improper access has been attempted.

One computer or device can belong to several communities. SNMP community names are specific to SNMP and are not related to Active Directory or Workgroup names. In the past, the SNMP default community name, Public, was used widely for read-only access and the name, Private, was used for read-write access. To increase security, specify a unique community name and change it frequently, as you would a password.

By defining an SNMP community, you can group computers together for administrative convenience and provide limited security by restricting communication to only those computers that are members of the community. Two common bases for grouping computers into an SNMP community are by physical proximity or by function. The recommended practice is to create SNMP communities based on function rather than location.

In addition to specifying that the SNMP agent can communicate only with a specified set of SNMP managers, you can specify the access permission (such as **Read Only** or **Read Write**) for each community and specify that a trap be sent, alerting a trap destination to the authentication failure if either the community name or access permission is incorrect. For the community name, specify the most restrictive permission possible. For example, do not choose the **Read Write** permission if the **Read Only** permission is sufficient. Also check the permission level of the MIB access variable. It interacts with the community security level. For example, if your community access level is set to **Read Only** and the MIB access variable is set to **Read Write**, the following operations are valid: **Get**, **GetNext**, **GetResponse**, and **Trap**. However, the **Set** request is blocked by the more restrictive community access level.

You might want to specify one community name for the SNMP agent and its trap destination and another community name for the SNMP agent and any SNMP manager that sends the agent query and set requests. Using separate community names for requests and traps ensures that the agent has an available destination to which it can send an alert if an unauthorized SNMP manager tries to request information.

The security that the SNMP service provides through the use of community names used in conjunction with access permissions and authentication traps is rudimentary. Because community names are sent across the network as clear text (which is unencrypted), even secret and frequently changed community names with restricted permissions represent a potential security risk. Clear text messages are easily intercepted and decoded by network analyzers such as Microsoft Network Monitor. Community names sent in clear text can be captured and used by unauthorized personnel to access valuable information about network resources.

To help prevent the interception of SNMP messages, configure Internet Protocol Security (IPSec) policies on all SNMP managers and SNMP agents.

**Related Information**

- For more information about SNMP, see the following RFCs in the IETF RFC Database.

The following RFCs relate to SNMP version 1:

- RFC 1157, “Simple Network Management Protocol (SNMP).”
- RFC 1155, “Structure and Identification of Management Information for TCP/IP-based Internets.”
- RFC 1213, “Management Information Base for Network Management of TCP/IP-based Internets: MIB-II.”
- RFC 1573, “Evolution of the Interfaces Group of MIB-II.”

The following RFCs relate to SNMP version 2:

- RFC 1901, “Introduction to Community–Based SNMPv2.”
- RFC 1902, “Structure of Management Information for Version 2 of the Simple Network Management Protocol (SNMPv2).”
- RFC 1903, “Textual Conventions for SNMPv2.”
- RFC 1904, “Conformance Statements for Version 2 of the Simple Network Management Protocol (SNMPv2).”
- RFC 1905, “Protocol Operations for Version 2 of the Simple Network Management Protocol (SNMPv2).”
- RFC 1906, “Transport Mappings for Version 2 of the Simple Network Management Protocol (SNMPv2).”
- RFC 1907, “Management Information Base for Version 2 of the Simple Network Management Protocol (SNMPv2).”
- RFC 1908, “Coexistence between Version 1 and Version 2 of the Internet-standard Network Management Framework.”
- RFC 2089, “V2ToV1 Mapping SNMPv2 onto SNMPv1 Within a Bi-Lingual SNMP Agent.”

# Computer Browser Service Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Computer Browser Service Technical Reference**
Users often rely on the list of workgroups, domains, and computers visible from the My Network Places folder to determine which resources are accessible from their local computers. Computer Browser service, which operates on all Microsoft Windows–based computers, collects and distributes this list. Computer Browser service also provides interoperability with domains and computers that do not use the Active Directory directory service.

The Computer Browser Service Technical Reference documentation includes information about Computer Browser service mechanisms, time intervals, announcements and elections, and interoperability with various network configurations.

# What Is Computer Browser Service?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Computer Browser Service?**
Computer Browser service is the mechanism that collects and distributes the list of workgroups and domains and the servers within them. The list displays in the Microsoft Windows Network window and related windows in My Network Places.

Microsoft Active Directory services in Windows Server 2003 and Windows XP create a searchable list of computers and resources that is separate from the list of domains, workgroups, and servers in My Network Places. Computer Browser service provides backward compatibility with computers running earlier versions of Windows that must use Network Basic Input/Output System (NetBIOS) over TCP/IP (NetBT) and are not Active Directory–capable.

**In this section**

- Computer Browser Service Concepts

In Windows Server 2003, Computer Browser service is included with Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and the 64-bit editions of the Windows Server 2003 family. It is also included in other Windows operating systems as follows:

- Microsoft Windows XP
- Microsoft Windows 2000
- Microsoft Windows Millennium Edition
- Microsoft Windows 98

Computer Browser service (and NetBT, which it uses), is enabled by default when any of the above operating systems are installed.

Users often need to know which resources are accessible from their local computers. Computer Browser service enables users to easily browse for available domains, workgroups, servers, and resources in My Network Places. Computer Browser service also provides interoperability with domains and computers that do not use the Active Directory directory service.

In pure Windows Server 2003, Windows XP, and Windows 2000 environments that are configured to use Active Directory, Active Directory itself can display information about available network resources. In Windows 98 and Windows Millennium Edition, however, Computer Browser service must be used for this purpose. Computer Browser service is also still required in Windows Server 2003, Windows XP, and Windows 2000 for using applications such as My Network Places and Windows Explorer, or the **net view** command.

**Computer Browser Service Concepts**
Networked computers can play a variety of roles as different types of browse servers. The different types of browse servers and browse clients together are called the browser system.

In versions of Windows that support Computer Browser service, the operating system assigns tasks to specific computers on the network to provide browse services. Any networked computer that can collect, maintain, and distribute a browse list can be a browse server. Computers that are designated as browse servers work together to provide a centralized browse list, which contains a list of all known domains, workgroups, and the set of file servers in the domain to which the computer belongs.

Browse clients on the network access the browse list when users want to view the list of workgroups and domains or the list of servers in a workgroup or domain. For example, when a user at a computer running Windows 98 opens My Network Places, Computer Browser service computer obtains a copy of the browse list from a browse server on the same subnet in order to display the requested list of domains, workgroups, and computers. By working together, browse servers reduce the CPU cycles and network traffic needed to build and maintain the browse list.

When an individual server starts, it announces its presence by sending a broadcast datagram called a host announcement on the subnet. The announcement is received by a master browse server for the workgroup or domain. When the master browse

server receives a host announcement from a computer, it adds that computer to the browse list.

When a domain spans more than one subnet, the master browse server:

- Maintains the browse list for the portion of the domain on its subnet.
- Provides lists of backup browse servers on local subnets of a TCP/IP-based network.

If a TCP/IP-based subnet encompasses more than one domain, each domain has its own master browse server and backup browse servers. On networks using the NWLink IPX/SPX–Compatible protocol, routers forward the NetBIOS over IPX broadcast host announcement packets, a mechanism which allows the network to use only one master browse server.

Whenever a computer starts, if the value of the **MaintainServerList** entry in its registry is set to **Auto**, the master browse server must instruct the newly started computer whether to become a backup browse server.

As the master browse server for the network, a computer running Windows Server 2003 contacts the primary domain controller (PDC) every 12 minutes to provide it with the local network's browse list and to obtain the domain-wide browse list.

For a computer running Windows 98 to be a master browse server, the computer and the PDC for the domain must both be WINS clients. A Windows 98 master browse servermust also:

- Use TCP/IP.
- Use WINS for name resolution.
- Be in a workgroup that has the same name as the domain.

**Domain Master Browse Server**
The domain master browse server:

- Collects announcements for the entire domain.
- Collects browse lists from master browse servers on other subnets.
- Provides a browse list to other master browse servers.

A PDC typically functions as the domain master browse server on its subnet. When Computer Browser service runs on a PDC, the PDC is always the domain master browse server. To ensure that the PDC becomes the domain master browse server, you must give the PDC priority in browse server elections. For information about browse server elections, see "Browser Elections" in How Computer Browser Service Works.

In a domain that uses TCP/IP and that spans more than one subnet, each subnet functions as an independent browsing entity, with each subnet having its own master browse server and backup browse servers. On the other hand, NWLink and NetBEUI Frame (NBF) transports do not use the domain master browse server role; these transports have only a single master browse server for the entire network. When a domain spans multiple subnets, the master browse server of each subnet announces itself as the master browse server to the domain master browse server, using a directed datagram called a MasterBrowserAnnouncement. The domain master browse server then sends a remote **NetServerEnum** API call to each master browse server, to collect the list of servers from each subnet. The domain master browse server merges the server list from each subnet master browse server with its own server list, forming the server-list portion of the browse list for the domain. This process is repeated every 12 minutes to ensure that the domain master browse server has an updated and complete browse list of all the servers in the domain.

**Note**

- The domain master browse server must be able to resolve the server name of each master browse server on a TCP/IP network (using WINS, for example). Each master browse server must be able to resolve the name of the domain, as well as the computer name of the primary domain controller.

For additional information about Computer Browser service, see Help and Support Center in Windows Server 2003.

# How Computer Browser Service Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Computer Browser Service Works**

**In this section**

- Computer Browser Service Architecture
- Registration and Propagation
- Computer Browser Service Announcements
- Browser Elections
- Number of Browsers in a Domain
- Multiple Subnets
- Computer Browser Service Across an IP Router
- Name Resolution

Computer Browser service is a networking technology used by Windows-based computers to collect, distribute, and obtain browse lists, which are collections of information about workgroups, domains, and the computers within them. The service is essential for computers running Windows 98 or Windows Millennium Edition to browse for resources and it is required in Windows Server 2003, Windows XP, and Windows 2000 for using applications such as My Network Places, Windows Explorer, and the **net view** command.

Computer Browser service typically uses connectionless server broadcasts to communicate between nodes. Registration, announcements, and browser elections are performed by the service to provide the network with a list of available resources.

Computer Browser service operates ideally in a Windows network where several computers play various browser roles. Together, these browser roles form the browser system.

**Computer Browser Service Architecture**

The architecture of Computer Browser service is complete when several computers are brought together on a network to perform browse service roles. Individually, these roles are just parts of the browse service, but when combined on the network, they form a browser system that enables efficient sharing of network resource information.

**Browser System Roles**

There are five browse service roles that computers can play in the browser system:

- Non-browser
- Potential browser
- Backup browse server
- Master browse server
- Domain master browse server

The figure below shows an example of browser system roles played by computers on a single subnet.

**Browser System Containing Browsers and Non-Browsers on a Subnet**

The table below lists each of the browse service roles and describes its function in the architecture of the browser system.

**Browser Roles and Functions**

| Role | Function |
|---|---|
| Non-browser | A non-browser is a computer that has been configured not to maintain a browse list. |
| Potential browser | A potential browser is a computer that is configured to be capable of maintaining a browse list. Such a computer can act as a backup browse server if instructed to do so by the master browse server. Or, it can be elected as a master browse server. |
| Backup browse server | The backup browse server receives a copy of the browse list from the master browse server and distributes the list, upon request, to computers in the domain or workgroup. All Windows Server 2003 domain controllers are configured as either master browse servers or backup browse servers. |
| Master browse server | The master browse servercollects the information necessary to create and maintain the browse list. The browse list includes the names of all servers in the same domain or workgroup as the master browse server and a list of all domains on the network. |
| Domain master browse server | The domain master browse server collects browse lists from master browse servers on other subnets and also serves as the master browse server for its subnet. This role is typically performed by the primary domain controller (PDC) for a domain. |

**Registration and Propagation**

When a server starts, it immediately broadcasts a Host Announcement message to announce its presence to the master browse server. Host Announcement messages are transmitted again after four, eight, and 12 minutes, and then every 12 minutes thereafter.

Allowing for the loss of a few messages, the server acting as the master browse server adds the new server to its browse list within 12 minutes after the new server starts. The process of adding a new server entry to the master browse server's browse list is called registration.

After the initial host announcements are sent, new entries are transmitted through unicast sessions:

- To the browse list from the master browse server and to the domain master browse server.
- From the domain master browse server to master browse servers when master browse servers and domain master browse servers are located on different subnets.

Unicast sessions provide reliable data delivery of browse list updates.

Within the second 12 minutes after the server starts, the master browse server connects to the domain master browse server to obtain the domain-wide list. Concurrently, the domain master browse server connects to the master browse server and obtains a browse list containing the new server. Master browse servers on remote subnets connect to the domain master browse server at 12-minute intervals, so they are quickly informed of the new server's existence. Immediately after these

remote master browse servers are informed, all of the backup browse servers will connect to their respective master browse servers, and so will also be informed of the new server. The figure below shows the propagation sequence for a host announcement.

**Host Announcement Propagation**

Removing computers from the browse list when they are no longer connected to the network can take longer than adding new ones. To allow for messages that might be lost during transmission, the master browse server does not remove a server from its list until three announcement periods (36 minutes) have passed.

If the server is shut down gracefully, it sends a single Host Announcement message to the master browse server, indicating that it is no longer acting as a server. Upon receipt of this message, the master browse server immediately removes the server from its local list. On a healthy network, the removal of a server's name takes 36 minutes or less to propagate to all the master browse servers in the domain.

If the server is not shut down gracefully, or if network connectivity is lost, the server remains in the master browse server's list for up to 36 minutes. After that time, the domain master browse server is notified by the master browse server to remove the server name from its list. Within another 12 minutes, a master browse server on a remote subnet obtains the domain-wide list from the domain master browse server, and within an additional 12 minutes, each backup browse server on the remote subnet is notified to remove the server name from its list. Thus, removing a computer from the browse list can take as long as 72 minutes.

Unlike WINS or DNS server roles, browse server roles are not statically defined. Instead, they are dynamically defined with periodic browser elections. (As a result, it can be difficult to determine the flow of communication that is used by the servers in a specific instance to provide the browse list to a particular browse client.)

If a master browse server is gracefully shut down, it forces an election and a new master browse server is established promptly. This conversion occurs most quickly when a backup browse server, which already has a fully populated list, wins the election.

If a server acting as the master browse server for a subnet is not gracefully shut down, or if the Request Election message is lost, there might be a delay of several minutes until browsing is active again on that subnet. If a client cannot find a master browse server by sending the Get Backup List Request message, the client forces an election. If no client requests a browse list, it can take up to 12 minutes until a backup browse server discovers that there is no master browse server. Whenever a backup browse server discovers that there is no master browse server, it forces an election, and within another 12 minutes, browsing is active again.

**Browser Requests**

The purpose of Computer Browser service is to make the browse list — a list of workgroups, domains, and the computers within them — available to browse clients. To obtain the list of network resources, the browse client must first select an appropriate computer from which to request a copy of the list. The client selects a computer by sending a broadcast Get Backup List Request message. The master browse server on the subnet responds with a unicast message containing a list of up to three backup browse servers. The browse client then chooses one of the backup browse servers and sends it a message requesting the browse list. The selected browse server sends the contents of its browse list. The figure below shows the flow of the messages.

**Browser Request Flow**

If the master browse server for the workgroup or domain being queried cannot be found after three attempts, the client forces the election of a new master browse server in the domain.

**Computer Browser Service Announcements**

Every computer running Windows that has the file sharing component installed and enabled on a network interface broadcasts a periodic (every 12 minutes) Host Announcement message on the local subnet. On the master browse server for the subnet, these messages are used to maintain the list of available servers in the browse list

### Browser Announcements

Master browse servers receive announcements from, and return lists of backup browse servers to, computers running Windows 98, Windows Millennium Edition, Windows 2000, Windows XP, or Windows Server 2003.

When a computer starts, if the value of the **MaintainServerList** entry in its registry is **Auto**, the master browse server is responsible for telling the computer whether or not to become a backup browse server.

When a computer becomes the master browse server by winning an election, its browse list is empty, so it broadcasts an Announcement Request message. All computers that receive an Announcement Request message must reply with an announcement after a random delay of up to 30 seconds. This 30-second range for responses prevents the master browse server from becoming overloaded and losing replies, and it protects the network from being flooded with responses.

A master browse server cannot be directly forced to rebuild the browse list for a workgroup or domain. However, shutting down and restarting a computer that is configured as the preferred master browse server, or stopping and restarting Computer Browser service on that computer, forces the building of a new browse list. This happens because when a preferred master browse server starts, it forces an election, which it wins. The preferred master browse server has no browse list at startup, so it then forces all members of the domain or workgroup to announce themselves.

If a master browse server receives an announcement from another computer that claims to be the master browse server, the master browse server receiving the announcement demotes itself from its role as a master browse server and forces an election. This demotion process ensures that there is never more than one master browse server in each workgroup or domain.

**Non-Browser Announcements**

After a non-browser computer starts, it periodically broadcasts a Host Announcement message on the subnet to announce its availability. Announcements are sent 1 minute, 2 minutes, 4 minutes, 8 minutes, and 12 minutes after the non-browser starts, and every 12 minutes thereafter. If the master browse server has not received an announcement from the non-browser for three consecutive announcement periods (36 minutes), the master browse server removes the non-browser from the browse list.

**Potential Browser Announcements**

Most computers are potential browsers — that is, they are capable of becoming either backup browse servers or master browse servers. These computers announce themselves in the same manner as non-browsers.

**Backup Browse Server Announcements**

Backup browse servers announce themselves in the same manner as non-browsers. However, backup browse servers do participate in browser elections. Backup browse servers connect to the master browse server every 12 minutes to obtain

updates to the browse list. The backup browse server stores these lists and returns the browse list to any client that sends it a browse request. If the backup browse server cannot find the master browse server, it forces an election.

**Browser Announcement Time Configuration**

To change how often a computer running Computer Browser service announces itself, add a registry entry called **Announce** with a value that has the REG_DWORD data type. Set the value of the **Announce** entry to the number of seconds that the browser should wait between announcements. Add **Announce** to the following registry subkey:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\lanmanserver\parameters**

For example, the default value of the **Announce** entry is 720, which defines an announcement interval of 12 minutes.

The value of the **Announce** entry must be changed on all computers in the workgroup or domain before all computers can use the new value. Decreasing this value has the effect of decreasing the length of time that an unavailable computer appears on the browse list, but it also increases announcement traffic. On the other hand, increasing the value of **Announce** reduces the amount of announcement traffic, but it increases the length of time that an unavailable computer appears on the browse list.

### Note

- Do not use a registry editor to edit the registry directly unless you have no alternative. The registry editors bypass the standard safeguards provided by administrative tools. These safeguards prevent you from entering conflicting settings or settings that are likely to degrade performance or damage your system. Editing the registry directly can have serious, unexpected consequences that can prevent the system from starting and require that you reinstall Windows Server 2003. To configure or customize Windows Server 2003, use the programs in Microsoft Management Console (MMC) or Control Panel whenever possible.

**Browser Elections**

Browser elections occur to select a new master browse server under the following circumstances:

- When a computer cannot locate a master browse server.
- When a preferred master browse server comes online.
- When a Windows-based domain controller starts.
- When a back-up browse server cannot contact the master browse server to obtain updates to the browse list.

A computer initiates an election by broadcasting a Request Election message. When an election occurs, Computer Browser service on the computer forcing the election logs an event in the system log, indicating that it forced the election.

All browsers can receive Request Election messages. When a browser receives a Request Election message, it examines the election criteria of that message. If the browser has a higher ranking value of the same election criteria than the sender of the Request Election message, the browser sends its own Request Election message and enters an election in progress state. If the browser does not have higher ranking value of the same election criteria than the sender of the Request Election message, the browser attempts to determine which computer is the new master browse server. The following figure shows computers performing a browser election.

### Browser Election

RE =Request Election message

The election criteria for a browser are based on the current role of the browser in the domain and its current state, as shown in

the following table.

**Browser Election Criteria**

| Election Criteria Value | Windows Election Field |
|---|---|
| Windows 98 | 0x01000000 |
| Windows XP Professional, Windows 2000 | 0x10000000 |
| Windows Server 2003, Windows 2000 Server | 0x20000000 |
| Election version | 0x00FFFF00 |
| Version-specific criteria | 0x000000FF |
| PDC | 0x00000080 |
| WINS system | 0x00000020 |
| Preferred master | 0x00000008 |
| Running master | 0x00000004 |
| MaintainServerList = Yes | 0x00000002 |
| Running backup browse server | 0x00000001 |

The browser uses all of the appropriate election criteria to determine the election ranking of the sending computer.

The following rules determine whether a browser has won an election:

- If the election version of the browser is greater than the election version of the sender, the browser wins. If not, the browser uses the next election criterion. (The election version is a constant value that identifies the version of the browser-election protocol; it is not related to the operating-system version.)

- If the value of the election criteria for the browser is greater than that for the sender, the browser wins. If not, the browser uses the next election criterion.

- If the browser has been running longer than the sender, the browser wins. If not, the browser uses the next election criterion.

- If none of the rules above have determined the election, then the server with the lexically (alphabetically, including numbers and symbols) lowest name wins. For example, a server named “A” will win an election to become master browse server over a server named “B.”

**Running Election State**

When a browser receives a Request Election message indicating that it wins an election, the browser enters the running election state. While in this state, the browser sends out a Request Election message after a delay. The delay is based on the current role of the browser in the domain:

- Master browse servers and the primary domain controllers delay for 100 microseconds (ms).

- Backup browse servers and backup domain controllers randomly delay for 200 ms and 600 ms.

- All other browsers randomly delay between 800 ms and 3000 ms.

The browser sends up to four Request Election messages. If no other browser responds with a Request Election message that wins the election, the browser that sent the Request Election messages is promoted to master browse server. If the browser receives a Request Election message indicating that another computer wins the election, and the computer is currently the master browse server, the computer demotes itself from master browse server and becomes a backup browse server.

**Number of Browsers in a Domain**
Computer Browser service uses the following rules to set the number of browsers in a domain:

- If there is currently a primary domain controller (PDC) in the domain, it is designated as the domain master browse server.

- Every backup domain controller (BDC) in the domain is a backup browse server for the domain. The only exception to this rule occurs when the PDC has failed. In that case, the BDC becomes the domain master browse server.

**Note**

- PDC failure can be a problem because the DOMAIN[1B] entry, used to locate the Domain Master browse server, is only updated if the backup domain controller is promoted.

If the registry of a computer has the value of the **MaintainServerList** entry set to **Yes**, the computer is a backup browse server for the domain or IP subnet.

If no backup browse servers are selected for the domain based on the preceding rules, the master browse server sets the number of backup browse servers to be used for the domain, and then selects — from among those computers that have the value of the **MaintainServerList** entry set to **Auto —** that number of specific computers to act as browsers.The table below shows the number of backup browse servers that are selected, based on the number of computers in the domain.

**Number of Master or Backup Browse Servers in a Domain**

| Number of Computers* | Number of Backup Browse Servers | Number of Master Browse Servers |
|---|---|---|
| 1 | 0 | 1 |
| 2 to 31 | 1 | 1 |
| 32 to 63 | 2 | 1 |

* For each additional 32 computers added to a domain, another backup browse server is added.

In a TCP/IP network, each subnet independently enforces the preceding rules.

**Multiple Subnets**
Users might need to query multiple workgroups and domains to retrieve a list of servers within their workgroup or domain and create lists of other workgroups and domains. The figure below shows Computer Browser service operating with multiple domains and workgroups on the same subnet.

**Computer Browser Service Across Multiple Domains**

Upon becoming a master browse server, the master browse server for each subnet broadcasts a Local Master Announcement message every minute for the first five minutes. After the first five minutes, the master browse server broadcasts a Local

Master Announcement message once every 12 minutes. If a subnet has not announced itself for three consecutive announcement periods, the subnet is removed from the list. Thus, a subnet might remain in the browse list for up to 45 minutes after failing or being shut down.

A Local Master Announcement message contains the following information:

- The name of the domain or workgroup
- The name of a master browse server (which might or might not be a PDC) for that domain
- The version number of the operating system

If the browser computer is running Windows Server 2003 or Windows 2000 Server, the Local Master Announcement message also specifies whether or not the browser computer is the domain PDC.

**Computer Browser Service Across an IP Router**

When you use domains that are split across routers, the TCP/IP subnets function as independent browsing entities, each with its own master browse server and backup browse servers. Therefore, browser elections occur within each subnet. In contrast, workgroups do not span across an IP router.

Domain master browse servers collect the domain browse list, which includes the set of computers in the domain, and the set of other domains and workgroups. The master browse server on each subnet collects the set of computers in the domain and other domains and workgroups from received announcements; then the master browse server forwards this information to the domain master browse server. The domain master browse server periodically downloads the domain browse list to each master browse server, which in turn updates its backup browse servers.

The figure below shows Computer Browser service functioning across an IP router.

**Computer Browser Service Across an IP Router**

When a domain spans multiple subnets, the master browse servers for each subnet use a unicast Master Announcement message to announce themselves to the domain master browse server. This message notifies the domain master browse server that the sending computer is a master browse server in the same domain. When the domain master browse server receives a Master Browse Server Announcement message, it returns to the "announcing" master browse server a request for a list of the server's in that master browse server's subnet. When that list is received, the domain master browse server merges it with its own server list.

This process, repeated every 12 minutes, guarantees that the domain master browse server has a complete browse list of all the servers in the domain. Thus, when a client sends a browse request to a backup browse server, the backup browse server can return a list of all the servers in the domain, regardless of the subnet on which those servers are located.

**Note**

- It is possible on some routers to enable the forwarding of NetBIOS broadcasts. This causes Computer Browser service to work as if all computers were connected to the same subnet. However, this practice propagates broadcast traffic and can create problems with browser elections. Microsoft recommends that you do not enable the forwarding of NetBIOS (UDP port 137 and UDP port 138) broadcast packets across routers.

**Name Resolution**

Name resolution is critical for browsing to operate properly across IP routers. For most networks, this means that the Windows

Internet Name Service (WINS) infrastructure must be working properly:

- All computers that have the potential to become master browse servers on an IP internetwork must be able to resolve the *DomainName*<1b> entry for the domain master browse server.

- The master browse servers must also be able to resolve the *ComputerName*<00> of the domain master browse server.

The unicast Master Announcement messages sent by the master browse servers on each subnet contain the name of the master browse server computer. The domain master browse server resolves the NetBIOS name *ComputerName*<00> to obtain the IP address of the master browse server and to request the master browse server's locally collected browse list.

A browse client must be able to resolve the names of the backup browse servers sent to it by the master browse server on the subnet. When a client views the shared resources of a specific computer, it must be able to resolve the NetBIOS name *ComputerName*<20>. Therefore, all clients in the domain must be able to resolve the IP address of any server in the domain.

To resolve NetBIOS names so that browsing can work across IP routers, you can use WINS (recommended) or Lmhosts file entries.

**Windows Internet Name Service**
The Windows Internet Name Service (WINS) resolves IP addresses from NetBIOS names so that messages can be sent to the targeted computer. Implementing WINS eliminates the need to configure the Lmhosts file. Using WINS requires the following configuration:

- A WINS server is configured on a computer running the Windows Server 2003 family or Windows 2000 Server.

- Clients are WINS-enabled.

WINS clients can be computers running Windows Server 2003, Windows XP, Windows 2000, Windows Me, and Windows 98.

It is recommended that you implement WINS for name resolution and browsing support.

Windows Me and Windows 98 clients will participate in domain browsing only if they are configured to use a workgroup name that is the same as the domain name.

**Lmhosts File**
NetBIOS name resolution is typically performed through broadcasts, which will resolve names only on the local subnet. To resolve names of computers located on another subnet, the Lmhosts file (located in the directory *systemroot*\System32\drivers\etc) must be configured. The Lmhosts file must contain a NetBIOS name–to–IP address mapping for all computers that are not on the local subnet.

To implement communication between subnets and the domain master browse server, the administrator must configure the Lmhosts file with the NetBIOS names and IP addresses of all browsers. To ensure that the master browse server for each subnet can access the domain's PDC, the PDC for each domain must have an entry in the Lmhosts file for each master browse server. Also, each entry must have the tag #DOM, which designates the named computer as a domain controller.

To guarantee that the domain master browse server can request the local browse list from the master browse server of each subnet, the Lmhosts file on the domain master browse server must contain entries for all the potential master browse servers. Thus, the Lmhosts file on the master browse server of each subnet needs to contain the following information:

- IP address and NetBIOS name of the domain master browse server

- Domain name, preceded by the tags #PRE and #DOM

The following is an example of such an Lmhosts file entry:

```
131.107.7.80 MasterBrowserName #PRE #DOM:domain_name
```

# Name Resolution Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Name Resolution Technologies**
Microsoft Windows Server 2003 operating systems use name resolution to translate the numerical IP addresses that are used for TCP/IP communications to computer names, which are easier for users to remember. With name resolution, computer names are assigned to the IP addresses of the source and destination hosts, and are then used to contact these hosts, rather than using the 32-bit IP addresses.

In Windows Server 2003, there are two types of TCP/IP names to resolve:

- Host names
- NetBIOS names

**Name Resolution Components**
Windows Server 2003 provides Domain Name System (DNS) for host name resolution and Windows Internet Name Service (WINS) for NetBIOS name resolution.

**DNS Name Resolution**
DNS name resolution means successfully mapping a DNS domain or host name to an IP address. A host name is an alias that is assigned to an IP node to identify it as a TCP/IP host. The host name can be up to 255 characters long and can contain alphabetic and numeric characters, hyphens, and periods. Multiple host names can be assigned to the same host.

Windows Sockets (Winsock) programs, such as Internet Explorer and the FTP utility, can use one of two values for the destination host: the IP address or a host name. When the IP address is specified, DNS name resolution is not needed. When a host name is specified, the host name must be resolved to an IP address before IP-based communication with the desired resource can begin.

Host names can take various forms. The two most common forms are a nickname and a domain name. A nickname is an alias to an IP address that individuals can assign and use. A domain name is a structured name in a hierarchical namespace called DNS. An example of a domain name is www.microsoft.com.

Nicknames are resolved through entries in the Hosts file, which is stored in the systemroot\System32\Drivers\Etc folder. For more information, see TCP/IP Technical Reference.

Domain names are resolved by sending DNS name queries to a DNS server. The DNS server is a computer that stores domain name-to-IP address mapping records or has knowledge of other DNS servers. The DNS server resolves the queried domain name to an IP address and returns the name-to-IP address mapping records in response to a query.

Windows Server 2003 client computers must be configured with the IP address of a DNS server in order to resolve domain names. Active Directory-based computers running Microsoft Windows XP Professional or Windows Server 2003 operating systems must be configured with the IP address of a DNS server. For more information, see DNS Technical Reference.

**WINS Name Resolution**
WINS name resolution means successfully mapping a NetBIOS name to an IP address. A NetBIOS name is a 16-byte address that is used to identify a NetBIOS resource on the network. A NetBIOS name is either a unique (exclusive) or group (nonexclusive) name. When a NetBIOS process is communicating with a specific process on a specific computer, a unique name is used. When a NetBIOS process is communicating with multiple processes on multiple computers, a group name is used.

The exact mechanism by which NetBIOS names are resolved to IP addresses depends on the NetBIOS node type that is configured for the node. RFC 1001, "Protocol Standard for a NetBIOS Service on a TCP/UDP Transport: Concepts and Methods," defines the NetBIOS node types, as listed in the following table.

**NetBIOS Node Types**

| Node Type | Description |
|---|---|

| | |
|---|---|
| B-node(broadcast) | B-node uses broadcast NetBIOS name queries for name registration and resolution. B-node has two major limitations: (1) Broadcasts disturb every node on the network, and (2) Routers typically do not forward broadcasts, so only NetBIOS names on the local network can be resolved. |
| P-node (peer-peer) | P-node uses a NetBIOS name server (NBNS), such as a WINS server, to resolve NetBIOS names. P-node does not use broadcasts; instead, it queries the name server directly. |
| M-node (mixed) | M-node is a combination of B-node and P-node. By default, an M-node functions as a B-node. If an M-node is unable to resolve a name by broadcast, it queries a NBNS using P-node. |
| H-node(hybrid) | H-node is a combination of P-node and B-node. By default, an H-node functions as a P-node. If an H-node is unable to resolve a name through the NBNS, it uses a B-node to resolve the name. |

Computers running Windows Server 2003 operating systems are B-node by default and become H-node when they are configured with a WINS server. Those computers can also use a local database file called Lmhosts to resolve remote NetBIOS names. The Lmhosts file is stored in the *systemroot*\System32\Drivers\Etc folder. For more information, see TCP/IP Technical Reference.

Typically, Windows-based computers are configured with the IP address of a WINS server so remote NetBIOS names can be resolved. Active Directory-based computers, such as Windows XP Professional, Microsoft Windows 2000 and Windows Server 2003 operating systems, must be configured with the IP address of a WINS server if they are to communicate with computers running Microsoft Windows NT, Windows 95, Windows 98, or Windows Millennium Edition that are not Active Directory-based. For more information about WINS, see WINS Technical Reference.

**Name Resolution Scenarios**

DNS is the name resolution service of Windows 2000, Windows XP, and Windows Server 2003. Windows clients use DNS for name resolution and service location, including locating Active Directory domain controllers for logon. Pre-Active Directory clients (Windows NT 3.5 and 3.51, Windows NT 4.0, Windows 95, and Windows 98), however, rely on NetBIOS, which can use WINS, broadcast, or flat Lmhosts file. In particular, WINS is used by Pre-Active Directory clients for domain controller location. Windows NT 4.0-based clients can register themselves in Windows Server 2003 WINS. Clients running Windows 2000, Windows XP, and Windows Server 2003 can register in Windows NT 4.0 WINS.

The DNS implementation in Windows 2000, Windows XP, and Windows Server 2003 is WINS-aware, and, as a result, a combination of both DNS and WINS is typically used to achieve maximum efficiency in locating various network resources in a mixed environment.

**DNS Technical Reference**

**In this subject**

- What Is DNS?
- How DNS Works
- DNS Tools and Settings

Domain Name System (DNS) is the default name resolution service used in a Microsoft Windows Server 2003 network. DNS is part of the Windows Server 2003 TCP/IP protocol suite and all TCP/IP network connections are, by default, configured with the IP address of at least one DNS server in order to perform name resolution on the network. Windows Server 2003 components that require name resolution will attempt to use this DNS server before attempting to use the previous default Windows name resolution service, Windows Internet Name Service (WINS).

Windows Server 2003 includes an IETF standard-based DNS server as a service. The Windows Server 2003 DNS Server service is RFC-compliant and therefore it is fully compatible with any other RFC-compliant DNS server. A DNS Client resolver is included as a service in all client and server versions of the Windows operating system.

The Technical Reference DNS subject describes how the DNS Server and Client services form a Windows Server 2003 DNS infrastructure.

# What Is DNS?

**What Is DNS?**

**In this section**

- Technologies That Use DNS
- Related Information

Domain Name System (DNS) is one of the industry-standard suite of protocols that comprise TCP/IP. Microsoft Windows Server 2003. DNS is implemented using two software components: the DNS server and the DNS client (or resolver). Both components are run as background service applications.

Network resources are identified by numeric IP addresses, but these IP addresses are difficult for network users to remember. The DNS database contains records that map user-friendly alphanumeric names for network resources to the IP address used by those resources for communication. In this way, DNS acts as a mnemonic device, making network resources easier to remember for network users.

The Windows Server 2003 DNS Server and Client services use the DNS protocol that is included in the TCP/IP protocol suite. DNS is part of the application layer of the TCP/IP reference model.

**DNS in TCP/IP**

For more information and to view logical diagrams illustrating how DNS fits with other Windows Server 2003 technologies, see "How DNS Works" in this collection.

By default, Windows Server 2003 DNS is used for all name resolution in a Windows Server 2003 network. In the most typical scenario, when a Windows Server 2003 network user specifies the name of a network host or an internet DNS domain name, the DNS Client service running on the Windows Server 2003 computer of the user contacts a DNS server to resolve the name to an IP address.

**Technologies That Use DNS**

**DNS and Active Directory**

Windows Server 2003 Active Directory directory service uses DNS as its domain controller location mechanism. When any of the principal Active Directory operations is performed, such as authentication, updating, or searching, Windows Server 2003 computers use DNS to locate Active Directory domain controllers and these domain controllers use DNS to locate each other. For example, when a network user with an Active Directory user account logs in to an Active Directory domain, the user's computer uses DNS to locate a domain controller for the Active Directory domain to which the user wants to log in. For more information about integrating DNS and Active Directory, see "How DNS Works" in this collection.

**DNS and WINS**

The earlier method of name resolution for a Windows network was Windows Internet Name Service (WINS). DNS is different than WINS in that DNS is a hierarchical namespace and WINS is a flat namespace. Down-level clients and applications that rely on NetBIOS names continue to use WINS for name resolution. Since Windows Server 2003 DNS is WINS-aware, a combination of both DNS and WINS can be used in a mixed environment to achieve maximum efficiency in locating various network services and resources. For more information about using DNS in a mixed environment, see "How DNS Works" in this collection.

**DNS and DHCP**

For Windows Server 2003 DNS, the DHCP service provides default support to register and update information for legacy DHCP clients in DNS zones. Legacy clients typically include other Microsoft TCP/IP client computers that were released prior to Windows 2000. The Windows Server 2003 DNS-DHCP integration enables a DHCP client that is unable to dynamically update DNS resource records directly to have this information updated in DNS forward and reverse lookup zones by the DHCP server.

**How DNS Works**
**In this section**

- DNS Architecture
- DNS Protocol
- DNS Physical Structure
- DNS Processes and Interactions
- Network Ports Used By DNS
- Related Information

Domain Name System (DNS) is the default name resolution service used in a Microsoft Windows Server 2003 network. DNS is part of the Windows Server 2003 TCP/IP protocol suite and all TCP/IP network connections are, by default, configured with the IP address of at least one DNS server in order to perform name resolution on the network. Windows Server 2003 components that require name resolution will attempt to use this DNS server before attempting to use the previous default Windows name resolution service, Windows Internet Name Service (WINS).

Typically, Windows Server 2003 DNS is deployed in support of Active Directory directory service. In this environment, DNS namespaces mirror the Active Directory forests and domains used by an organization. Network hosts and services are configured with DNS names so that they can be located in the network, and they are also configured with DNS servers that resolve the names of Active Directory domain controllers.

Windows Server 2003 DNS is also commonly deployed as a non-Active Directory, or standard, Domain Name System solution, for the purposes of hosting the Internet presence of an organization, for example.

**DNS Architecture**
DNS architecture is a hierarchical distributed database and an associated set of protocols that define:

- A mechanism for querying and updating the database.
- A mechanism for replicating the information in the database among servers.
- A schema of the database.

DNS originated in the early days of the Internet when the Internet was a small network established by the United States Department of Defense for research purposes. The host names of the computers in this network were managed through the use of a single HOSTS file located on a centrally administered server. Each site that needed to resolve host names on the network downloaded this file. As the number of hosts on the Internet grew, the traffic generated by the update process increased, as well as the size of the HOSTS file. The need for a new system, which would offer features such as scalability, decentralized administration, support for various data types, became more and more obvious.

The Domain Name System introduced in 1984 became this new system. With DNS, the host names reside in a database that can be distributed among multiple servers, decreasing the load on any one server and providing the ability to administer this naming system on a per-partition basis. DNS supports hierarchical names and allows registration of various data types in addition to host name to IP address mapping used in HOSTS files. Because the DNS database is distributed, its potential size is unlimited and performance is not degraded when more servers are added.

The original DNS was based on Request for Comment (RFC) 882 (“Domain Names: Concepts and Facilities”) and RFC 883 (Domain Names–Implementation and Specification), which were superseded by RFC 1034 (“Domain Names–Concepts and

Facilities"), and RFC 1035 ("Domain Names–Implementation and Specification"). Additional RFCs that describe DNS security, implementation, and administrative issues later augmented the original design specifications.

The implementation of DNS — Berkeley Internet Name Domain (BIND) — was originally developed for the 4.3 BSD UNIX Operating System. The Microsoft implementation of DNS became a part of the operating system in Microsoft Windows NT Server 4.0. The Windows NT 4.0 DNS server, like most DNS implementations, has its roots in RFCs 1034 and 1035.

The RFCs used in Microsoft Windows 2000 and Windows Server 2003 operating systems are 1034, 1035, 1886, 1996, 1995, 2136, 2308, and 2052.

**DNS Domain Names**

The Domain Name System is implemented as a hierarchical and distributed database containing various types of data, including host names and domain names. The names in a DNS database form a hierarchical tree structure called the domain namespace. Domain names consist of individual labels separated by dots, for example: mydomain.microsoft.com.

A Fully Qualified Domain Name (FQDN) uniquely identifies the hosts position within the DNS hierarchical tree by specifying a list of names separated by dots in the path from the referenced host to the root. The next figure shows an example of a DNS tree with a host called mydomain within the microsoft.com. domain. The FQDN for the host would be mydomain.microsoft.com.

**Understanding the DNS Domain Namespace**

The DNS domain namespace, as shown in the following figure, is based on the concept of a tree of named domains. Each level of the tree can represent either a branch or a leaf of the tree. A branch is a level where more than one name is used to identify a collection of named resources. A leaf represents a single name used once at that level to indicate a specific resource.

### DNS Domain Name Hierarchy

The previous figure shows how Microsoft is assigned authority by the Internet root servers for its own part of the DNS domain namespace tree on the Internet. DNS clients and servers use queries as the fundamental method of resolving names in the tree to specific types of resource information. This information is provided by DNS servers in query responses to DNS clients, who then extract the information and pass it to a requesting program for resolving the queried name. In the process of resolving a name, keep in mind that DNS servers often function as DNS clients, querying other servers in order to fully resolve a queried name.

**How the DNS Domain Namespace Is Organized**

Any DNS domain name used in the tree is technically a domain. Most DNS discussions, however, identify names in one of five ways, based on the level and the way a name is commonly used. For example, the DNS domain name registered to Microsoft (microsoft.com.) is known as a second-level domain. This is because the name has two parts (known as labels) that indicate it is located two levels below the root or top of the tree. Most DNS domain names have two or more labels, each of which indicates a new level in the tree. Periods are used in names to separate labels.

The five categories used to describe DNS domain names by their function in the namespace are described in the following table, along with an example of each name type.

### Types of DNS Domain Names

| Name Type | Description | Example |
|---|---|---|
| Root domain | This is the top of the tree, representing an unnamed level; it is sometimes shown as two empty quotation marks (""), indicating a null value. When used in a DNS domain name, it is stated by a trailing period (.) to designate that the name is located at the root or highest level of the domain hierarchy. In this instance, the DNS domain name is considered to be complete and points to an exact location in the tree of names. Names stated this way are called fully qualified domain names (FQDNs). | A single period (.) or a period used at the end of a name, such as "example.microsoft.com." |
| Top level domain | A name used to indicate a country/region or the type of organization using a name. | ""."com", which indicates a name registered to a business for commercial use on the Internet. |
| Second level domain | Variable-length names registered to an individual or organization for use on the Internet. These names are always based upon an appropriate top-level domain, depending on the type of organization or geographic location where a name is used. | ""microsoft.com. ", which is the second-level domain name registered to Microsoft by the Internet DNS domain name registrar. |
| Subdomain | Additional names that an organization can create that are derived from the registered second-level domain name. These include names added to grow the DNS tree of names in an organization and divide it into departments or geographic locations. | ""example.microsoft.com. ", which is a fictitious subdomain assigned by Microsoft for use in documentation example names. |
| Host or resource name | Names that represent a leaf in the DNS tree of names and identify a specific resource. Typically, the leftmost label of a DNS domain name identifies a specific computer on the network. For example, if a name at this level is used in a host (A) RR, it is used to look up the IP address of computer based on its host name. | ""host-a.example.microsoft.com.", where the first label ("host-a") is the DNS host name for a specific computer on the network. |

**DNS and Internet Domains**

The Internet Domain Name System is managed by a Name Registration Authority on the Internet, responsible for maintaining top-level domains that are assigned by organization and by country/region. These domain names follow the International Standard 3166. Some of the many existing abbreviations, reserved for use by organizations, as well as two-letter and three-letter abbreviations used for countries/regions are shown in the following table:

**Some DNS Top-level Domain Names (TLDs)**

| DNS Domain Name | Type of Organization |
|---|---|
| com | Commercial organizations |
| edu | Educational institutions |
| org | Non-profit organizations |
| net | Networks (the backbone of the Internet) |
| gov | Non-military government organizations |
| mil | Military government organizations |
| arpa | Reverse DNS |
| "xx" | Two-letter country code (i.e. us, au, ca, fr) |

**Resource Records**

A DNS database consists of resource records (RRs). Each RR identifies a particular resource within the database. There are various types of RRs in DNS. This section provides information about the common structure of resource records. RRs are

discussed in greater detail in “Resource Records in DNS” later in this document.

The following table provides detailed information about structure of common RRs.

**Common DNS Resource Records**

| Description | Class | Time To Live (TTL) | Type | Data |
|---|---|---|---|---|
| Start of Authority | Internet (IN) | Default TTL is 60 minutes | SOA | Owner Name<br>Primary Name Server DNS Name, Serial Number<br>Refresh Interval<br>Retry Interval<br>Expire Time<br>Minimum TTL |
| Host | Internet (IN) | Record-specific TTL if present, or else zone (SOA) TTL | A | Owner Name (Host DNS Name)<br>Host IP Address |
| Name Server | Internet (IN) | Record-specific TTL if present, or else zone (SOA) TTL | NS | Owner Name<br>Name Server DNS Name |
| Mail Exchanger | Internet (IN) | Record-specific TTL if present, or else zone (SOA) TTL | MX | Owner Name<br>Mail Exchange Server DNS Name, Preference Number |
| Canonical Name<br>(an alias) | Internet (IN) | Record-specific TTL if present, or else zone (SOA) TTL | CNAME | Owner Name (Alias Name)<br>Host DNS Name |

**Distributing the DNS Database: Zone Files and Delegation**

A DNS database can be partitioned into multiple zones. A zone is a portion of the DNS database that contains the resource records with the owner names that belong to the contiguous portion of the DNS namespace. Zone files are maintained on DNS servers. A single DNS server can be configured to host zero, one or multiple zones.

Each zone is anchored at a specific domain name referred to as the zone’s root domain. A zone contains information about all names that end with the zone’s root domain name. A DNS server is considered authoritative for a name if it loads the zone containing that name. The first record in any zone file is a Start of Authority (SOA) RR. The SOA RR identifies a primary DNS name server for the zone as the best source of information for the data within that zone and as an entity processing the updates for the zone.

A name within a zone can also be delegated to a different zone that is hosted on a different DNS server. Delegation is a process of assigning responsibility for a portion of a DNS namespace to a DNS server owned by a separate entity. This separate entity could be another organization, department or workgroup within your company. Such delegation is represented by the NS resource record that specifies the delegated zone and the DNS name of the server authoritative for that zone. Delegating across multiple zones was part of the original design goal of DNS.

The primary reasons to delegate a DNS namespace include:

- A need to delegate management of a DNS domain to a number of organizations or departments within an organization.
- A need to distribute the load of maintaining one large DNS database among multiple DNS servers to improve the name resolution performance as well as create a DNS fault tolerant environment.
- A need to allow for a host’s organizational affiliation by including them in appropriate domains.

The name server (NS) RRs facilitate delegation by identifying DNS servers for each zone and the NS RRs appear in all zones.

Whenever a DNS server needs to cross a delegation in order to resolve a name, it will refer to the NS RRs for DNS servers in the target zone.

In the figure below, the management of the microsoft.com. domain is delegated across two zones, microsoft.com. and mydomain.microsoft.com.

**DNS Delegation**

**Note**

- If multiple NS records exist for a delegated zone identifying multiple DNS servers available for querying, the Windows Server 2003 DNS Server service will be able to select the closest DNS server based on the round trip intervals measured over time for every DNS server.

**Replicating the DNS Database**

There could be multiple zones representing the same portion of the namespace. Among these zones there are three types:

- Primary
- Secondary
- Stub

Primary is a zone to which all updates for the records that belong to that zone are made. A secondary zone is a read-only copy of the primary zone. A stub zone is a read-only copy of the primary zone that contains only the resource records that identify the DNS servers that are authoritative for a DNS domain name. Any changes made to the primary zone file are replicated to the secondary zone file. DNS servers hosting a primary, secondary or stub zone are said to be authoritative for the DNS names in the zone.

As mentioned above, a DNS server can host multiple zones. A DNS server can therefore host both a primary zone (which has the writeable copy of a zone file) and a separate secondary zone (which obtains a read-only copy of a zone file). A DNS server hosting a primary zone is said to be the primary DNS server for that zone, and a DNS server hosting a secondary zone is said to be the secondary DNS server for that zone.

**Note**

- A secondary or stub zone cannot be hosted on a DNS server that hosts a primary zone for the same domain name.

**Zone Transfer**

The process of replicating a zone file to multiple DNS servers is called zone transfer.Zone transfer is achieved by copying the zone file from one DNS server to a second DNS server. Zone transfers can be made from both primary and secondary DNS servers.

A master DNS server is the source of the zone information during a transfer. The master DNS server can be a primary or

secondary DNS server. If the master DNS server is a primary DNS server, then the zone transfer comes directly from the DNS server hosting the primary zone. If the master server is a secondary DNS server, then the zone file received from the master DNS server by means of a zone transfer is a copy of the read-only secondary zone file.

The zone transfer is initiated in one of the following ways:

- The master DNS server sends a notification (RFC 1996) to one or more secondary DNS servers of a change in the zone file.

- When the DNS Server service on the secondary DNS server starts, or the refresh interval of the zone has expired (by default it is set to 15 minutes in the SOA RR of the zone), the secondary DNS server will query the master DNS server for the changes.

**Types of Zone File Replication**
There are two types of zone file replication. The first, a full zone transfer (AXFR), replicates the entire zone file. The second, an incremental zone transfer (IXFR), replicates only records that have been modified. Zone transfer is discussed in detail later in this document.

BIND 4.9.3 and earlier DNS server software, as well as Windows NT 4.0 DNS, support full zone transfer (AXFR) only. There are two types of the AXFR: one requires single record per packet, the other allows multiple records per packet. The Windows 2000 and Windows Server 2003 DNS Server service supports both types of zone transfer, but by default uses multiple records per packet. It can be configured differently for compatibility with servers that do not allow multiple records per packet, such as BIND servers versions 4.9.4 and earlier.

**Querying the Database**
DNS queries can be sent from a DNS client (resolver) to a DNS server, or between two DNS servers.

A DNS query is merely a request for DNS resource records of a specified resource record type with a specified DNS name. For example, a DNS query can request all resource records of type A (host) with a specified DNS name.

There are two types of DNS queries that may be sent to a DNS server:

- Recursive

- Iterative

A recursivequery forces a DNS server to respond to a request with either a failure or a successful response. DNS clients (resolvers) typically make recursive queries. With a recursive query, the DNS server must contact any other DNS servers it needs to resolve the request. When it receives a successful response from the other DNS server(s), it then sends a response to the DNS client. The recursive query is the typical query type used by a resolver querying a DNS server and by a DNS server querying its forwarder, which is another DNS server configured to handle requests forwarded to it. For more information about forwarders, see “Forwarding” later in this document.

When a DNS server processes a recursive query and the query cannot be resolved from local data (local zone files or cache of previous queries), the recursive query must be escalated to a root DNS server. Each standards-based implementation of DNS includes a cache file (or root server hints) that contains entries for the root DNS servers of the Internet domains. (If the DNS server is configured with a forwarder, the forwarder is used before a root server is used.)

An iterative query is one in which the DNS server is expected to respond with the best local information it has, based on what the DNS server knows from local zone files or from caching. This response is also known as a referral if the DNS server is not authoritative for the name. If a DNS server does not have any local information that can answer the query, it simply sends a negative response. A DNS server makes this type of query as it tries to find names outside of its local domain(s) (when it is not configured with a forwarder). It may have to query a number of outside DNS servers in an attempt to resolve the name.

The following figure shows an example of both types of queries.

**DNS Query Types**

As shown in the graphic above, a number of queries were used to determine the IP address for www.whitehouse.gov. The query sequence is described below:

1. Recursive query for www.whitehouse.gov (A resource record)

2. Iterative query for www.whitehouse.gov (A resource record)

3. Referral to the .gov name server (NS resource records, for .gov); for simplicity, iterative A queries by the DNS server (on the left) to resolve the IP addresses of the Host names of the name server's returned by other DNS servers have been omitted.

4. Iterative query for www.whitehouse.gov (A resource record)

5. Referral to the whitehouse.gov name server (NS resource record, for whitehouse.gov)

6. Iterative query for www.whitehouse.gov (A resource record)

7. Answer to the interative query from whitehouse.gov server (www.whitehouse.gov's IP address)

8. Answer to the original recursive query from local DNS server to Resolver (www.whitehouse.gov's IP address)

**Time to Live for Resource Records**

The Time to Live (TTL) value in a resource record indicates a length of time used by other DNS servers to determine how long to cache information for a record before expiring and discarding it. For example, most resource records created by the DNS Server service inherit the minimum (default) TTL of one hour from the start of authority (SOA) resource record, which prevents extended caching by other DNS servers.

A DNS client resolver caches the responses it receives when it resolves DNS queries. These cached responses can then be used to answer later queries for the same information. The cached data, however, has a limited lifetime specified in the TTL parameter returned with the response data. TTL ensures that the DNS server does not keep information for so long that it becomes out of date. TTL for the cache can be set on the DNS database (for each individual resource record, by specifying the TTL field of the record and per zone through the minimum TTL field of the SOA record) as well as on the DNS client resolver side by specifying the maximum TTL the resolver allows to cache the resource records.

There are two competing factors to consider when setting the TTL. The first is the accuracy of the cached information, and the second is the utilization of the DNS servers and the amount of network traffic. If the TTL is short, then the likelihood of having old information is reduced considerably, but it increases utilization of DNS servers and network traffic, because the DNS client must query DNS servers for the expired data the next time it is requested. If the TTL is long, the cached responses could become outdated, meaning the resolver could give false answers to queries. At the same time, a long TTL decreases utilization of DNS servers and reduces network traffic because the DNS client answers queries using its cached data.

If a query is answered with an entry from cache, the TTL of the entry is also passed with the response. This way the resolvers that receive the response know how long the entry is valid. The resolvers honor the TTL from the responding server; they do not reset it based on their own TTL. Consequently, entries truly expire rather than live in perpetuity as they move from DNS server to DNS server with an updated TTL.

**Note**

- In general, never configure the TTL to zero. The different between a setting of 0 or 60 is minimal to the accuracy of the record, but when the TTL is set to 0 there is a major impact on DNS server performance because the DNS server is constantly querying for the expired data.

**Updating the DNS Database**

Since the resource records in the zone files are subjected to changes, they must be updated. The implementation of DNS in Windows 2000 and Windows Server 2003 supports both static and dynamic updates of the DNS database. The details of the dynamic update are discussed later in this document.

**DNS Architecture Diagrams**

The following diagrams illustrate how the DNS Client and Server services work and provide additional information regarding name resolution, update, and administration operations.

The first diagram illustrates the DNS Client service architecture in its name resolution and update operations. In this diagram, name resolution architecture is demonstrated using a Web browser and Microsoft Outlook and updates are represented by the DHCP client.

**DNS Client Service Architecture**

The following diagram illustrates the DNS Server service architecture with its administration tools and the Windows Management Instrumentation (WMI) interface.

**DNS Server Service Architecture**

**DNS Protocol**

The DNS protocol consists of DNS different types of DNS messages that are processed according to the information in their message fields. This section discusses the different types of DNS messages and the different fields in each message type.

In this section, the following DNS message topics are discussed:

- Message types
- DNS query message format
- DNS query message header
- DNS query question entries
- DNS resource records
- Name query message
- Name query response
- Reverse name query message
- DNS update message format
- DNS update message flags
- Dynamic update response message

**Message Types**

There are three types of DNS messages:

- Queries
- Responses
- Updates

Queries and responses are defined in the original DNS standard, and updates are defined in RFC 2136. All three types follow a common message format.

**DNS Query Message Format**
The common DNS message format has a fixed-length, 12-byte header and a variable position reserved for question, answer, authority, and additional DNS resource records. The common message format can be illustrated as follows:

**Standard DNS Query Message Format**

| **DNS Message Format** |
|---|
| DNS Header (fixed length) |
| Question Entries (variable length) |
| Answer Resource Records (variable length) |
| Authority Resource Records (variable length) |
| Additional Resource Records(variable length) |

**DNS Query Message Header**
The DNS message header contains the following fields, in the following order:

**DNS Query Message Header Fields**

| **Field Name** | **Description** |
|---|---|
| **Transaction ID** | A 16-bit field identifying a specific DNS transaction. The transaction ID is created by the message originator and is copied by the responder into its response message. Using the transaction ID, the DNS client can match responses to its requests. |
| **Flags:** | A 16-bit field containing various service flags that are communicated between the DNS client and the DNS server, including: |
| Request/response | 1-bit field set to 0 to represent a name service request or set to 1 to represent a name service response. |
| Operation code | 4-bit field represents the name service operation of the packet: 0x0 is a query. |
| Authoritative answer | 1-bit field represents that the responder is authoritative for the domain name in the query message. |
| Truncation | 1-bit field that is set to 1 if the total number of responses exceeded the User Datagram Protocol (UDP) datagram. Unless UDP datagrams larger than 512 bytes or EDNS0 are enabled, only the first 512 bytes of the UDP reply are returned. |
| Recursion desired | 1-bit field set to 1 to indicate a recursive query and 0 for iterative queries. If a DNS server receives a query message with this field set to 0 it returns a list of other DNS servers that the client can choose to contact. This list is populated from local cache data. |
| Recursion available | 1-bit field set by a DNS server to 1 to represent that the DNS server can handle recursive queries. If recursion is disabled, the DNS server sets the field appropriately. |
| Reserved | 3-bit field that is reserved and set to 0. |

| | |
|---|---|
| Return code | 4-bit field holding the return code:<br>• 0 is a successful response (query answer is in the query response).<br>• 0x3 is a name error, indicating that an authoritative DNS server responded that the domain name in the query message does not exist. For more information about return codes, see "Related Information" at the end of this document. |
| **Question Resource Record count** | A 16-bit field representing the number of entries in the question section of the DNS message. |
| **Answer Resource Record count** | A 16-bit field representing the number of entries in the answer section of the DNS message. |
| **Authority Resource Record count** | A 16-bit field representing the number of authority resource records in the DNS message. |
| **Additional Resource Record count** | A 16-bit field representing the number of additional resource records in the DNS message. |

**DNS Query Question Entries**

The DNS message's Question Entries section contains the domain name that is being queried and has the following three fields:

**DNS Query Question Entry Fields**

| **Field Name** | **Description** |
|---|---|
| **Question Name** | The domain name that is being queried. DNS domain names are expressed as a series of labels, such as microsoft.com, but in the Question Name field the domain name is encoded as a series of length-value pairs consisting of a 1-byte file that indicates the length of the value, followed by the value (the label). For example, the domain microsoft.com is expressed as *0x09microsoft0x03com0x00*, where the hexadecimal digits represent the length of each label, the ASCII characters indicate the individual labels, and the final 0 indicates the end of the name. |
| **Question Type** | Uses a 16-bit integer to represents the resource record type that should be returned, as expressed below: |
| Type value | Record(s) Returned |
| 0x01 | Host (A) record |
| 0x02 | Name server (NS) record |
| 0x05 | Alias (CNAME) record |
| 0x0C (12) | Reverse-lookup (PTR) record |
| 0x0F (15) | Mail exchange (MX) record |
| 0x21 (33) | Service (SRV) record |
| 0xFB (251) | Incremental zone transfer (IXFR) record |
| 0xFC (252) | Standard zone transfer (AXFR) record |

| | |
|---|---|
| 0xFF (255) | All records |
| **Question Class** | Represents the IN (Internet) question class and is normally set to 0x0001. |

**DNS Resource Records**

The answer, authority, and additional information sections of a DNS response message can contain resource records that answer the query message question section. Resource records are formatted as follows:

**DNS Resource Record Message Fields**

| Field Name | Description |
|---|---|
| **Resource record name** | The DNS domain name recorded as a variable-length field following the same formatting as the Question Name field. |
| **Resource record type** | The resource record type value. |
| **Resource record class** | The resource record class code, the Internet class, 0x0001. |
| **Time-to-live** | The TTL expressed in seconds as a 32-bit unsigned field. |
| **Resource data length** | 2-byte field indicating the length of the resource data. |
| **Resource data** | Variable-length data corresponding to the resource record type. |

The Resource Record Name field is encoded in the same way as the Question Name field unless the name is already present elsewhere in the DNS message, in which case a 2-byte field is used in place of a length-value encoded name and acts as a pointer to the name that is already present.

**Name Query Message**

A Name Query message format is the same as the DNS message format described above. In a typical Name Query message, the DNS message fields would be set as follows:

**DNS Name Query Message Fields**

| Field Name | Description |
|---|---|
| **Query identifier (Transaction ID)** | Set to a unique number to enable the DNS client resolver to match the response to the query. The query response transaction ID always matches the query request transaction ID. |
| **Flags** | Set to indicate a standard query with recursion enabled. |
| **Question count** | Set to 1. |
| **Question entry** | Set to the domain name queried and the resource record type to return. |

**Name Query Response**

A Name Query Response message format is the same as the DNS message format described above. In a typical Name Query message, the DNS message fields would be set as follows:

**DNS Name Query Response Fields**

| Field Name | Description |
|---|---|
| **Query identifier (Transaction ID)** | Set to a unique number to enable the DNS client resolver to match the response to the query. |
| **Flags** | Set to indicate a standard query with recursion enabled. |
| **Question count** | Set to 1. |

| | |
|---|---|
| **Question entry** | Set to the domain name queried and the resource record type to return. |

**Reverse Name Query Message**

Reverse name query messages use the common message format with the following differences:

- The DNS client resolver constructs the domain name in the in-addr.arpa domain based on the IP address that is queried.
- A Pointer (PTR) resource record is queried rather than a host (A) resource record.

**DNS Update Message Format**

The DNS update message format uses a header defining the update operation to be performed and a resource record set that contains the update. The DNS update message format has the following fields:

- **Identification**. A 16-bit identifier assigned by the DNS client requestor. This identifier is copied in the corresponding reply and can be used by the requestor to match replies to outstanding requests, or by the server to detect duplicated requests from some requestor.
- **Flags**. A 16-bit DNS update message flags field. For a description of each flag, see "DNS Update Message Flags" below.
- **Number of zone entries**. The number of resource records in the Zone entry section.
- **Number of prerequisite resource records**. The number of resource records in the Prerequisite resource records section.
- **Number of update resource records**. The number of resource records in the Update resource records section.
- **Number of additional resource records**. The number of resource records in the Additional resource records section.
- **Zone entry**. Denotes the zone of the records being updated. All records to be updated must be in the same zone, and therefore the Zone Section is allowed to contain exactly one record. It has three values: ZNAME is the zone name, the ZTYPE must be SOA, and the ZCLASS is the zone's class.
- **Prerequisite resource records**. Contains a set of resource record prerequisites which must be satisfied at the time the update message is received by the master DNS server. There are five possible sets of values that can be expressed:
    - Resource record set exists (value independent). At least one resource record with a specified name and type (in the zone and class specified by the Zone Section) must exist.
    - Resource record set exists (value dependent). A set of resource records with a specified name and type exists and has the same members with the same data as the resource record set specified in this section.
    - Resource record set does not exist. No resource records with a specified name and type (in the zone and class denoted by the Zone section) exist.
    - Name is in use. At least one resource record with a specified name (in the zone and class specified by the Zone section) exists. This prerequisite is not satisfied by empty nonterminals.
    - Name is not in use. No resource record of any type is owned by a specified name. This prerequisite is satisfied by empty nonterminals.
- **Update resource records**. Contains the resource records that are to be added or deleted from the zone. One of four operations are performed during the update:
    - Add resource records to an resource records set.
    - Delete an resource records set

- Delete all resource records sets from a name.
- Delete a resource record from an resource records set.

- **Additional resource records**. Contains resource records which are related to the update, or to new resource records being added by the update.

**DNS Update Message Flags**

The DNS update message flags field uses the following flags:

- **Request/response**. 1-bit field set to 0 to represent an update request and 1 to represent an update response.
- **Operation code**. 4-bit field set to 0x5 for DNS updates.
- **Reserved**. 7-bit reserved field set to 0.
- **Return code**. 4-bit field containing codes to represent the result of the update query. The codes are as follows:

  **DNS Update Message Flag Field Return Code Values**

| Result Code Value | Description |
|---|---|
| 0 (NOERROR) | No error; successful update. |
| 1 (FORMERR) | Format error; DNS server did not understand the update request. |
| 0x2 (SERVFAIL) | DNS server encountered an internal error, such as a forwarding timeout |
| 0x3 (NXDOMAIN) | A name that should exist does not exist. |
| 0x4 (NOTIMP) | DNS server does not support the specified Operation code. |
| 0x5 (REFUSED) | DNS server refuses to perform the update because |
| 0x6 (YXDOMAIN) | A name that should not exist does exist. |
| 0x7 (YXRRSET) | A resource record set that should not exist does exist. |
| 0x8 (NXRRSET) | A resource record set that should exist does not exist. |
| 0x9 (NOTAUTH) | DNS server is not authoritative for the zone named in the Zone section. |
| 0xA (NOTZONE) | A name used in the Prerequisite or Update sections is not within the zone specified by the Zone section. |

**Dynamic Update Response Message**

The dynamic update response message follows the same format as the DNS update message, with the exception of the DNS flags. The dynamic update response message header flags indicate whether or not the update is successful by including the successful response code or one of the error codes described in DNS update message flags above.

**DNS Physical Structure**

The logical structure of Windows Server 2003 DNS involves DNS namespace partitioning, which extends the DNS domain name hierarchy into multiple subdomains. The physical structure of DNS involves distributing the DNS database using DNS servers to host DNS zones for the subdomains of the DNS domain name hierarchy. Both the DNS Client and Server service applications manage the physical DNS data in the DNS database.

**DNS Client Service**

The Windows Server 2003 operating system, as well as Microsoft Windows XP and Windows 2000 include a DNS Client service. This service performs all necessary DNS lookups and provides a local cache for DNS queries that reduces DNS network traffic and speeds name resolution.

This service can be stopped and started using the **Services** console. Computers running Windows 2000, Windows XP and Windows Server 2003 enable the DNS Client service by default.

The Windows Server 2003 DNS Client service performs the following tasks:

- Registers its names in DNS.
- Name resolution.
- Caching responses to name resolution queries.
- Removes previously resolved names from the cache when it receives a negative response for the name.
- Negative caching.
- Keeps track of transitory (Plug and Play) network connections and the DNS server lists based on their IP configurations.
- Maintains connection-specific domain name suffixes.
- Prioritizes which DNS servers it uses according to whether they respond to a query if multiple DNS server are configured on the client.
- Prioritizes the multiple A resource records it receives from a DNS server based on their IP address.
- Initiates a network failure timeout when all DNS Client service queries time out, and does not submit any queries for 30 seconds. This feature applies to every adapter separately.

Windows XP, Windows 2000 and Windows Server 2003 DNS client configuration involves the following settings in the TCP/IP properties for each computer:

- **Domain Names**. Domain names are to form the fully qualified domain name (FQDN) for DNS clients.
- **Host names**. A DNS computer or host name for each computer. For example, in the fully qualified domain name (FQDN) wkstn1.example.microsoft.com., the DNS computer name is the leftmost label client1.
- **Primary DNS suffixes**. A primary DNS suffix for the computer, which is placed after the computer or host name to form the FQDN. Using the previous example, the primary DNS suffix would be example.microsoft.com.
- **Connection-specific names.** Each network connections of a multihomed computer can be configured with a connection-specific DNS domain name
- **NetBIOS names**. NetBIOS names are used to support legacy Microsoft networking technology.
- **DNS servers list.** A list of DNS servers for clients to use when resolving DNS names, such as a preferred DNS server, and any alternate DNS servers to use if the preferred server is not available.
- **DNS suffix search list**. The DNS suffix search list or search method to be used by the client when it performs DNS query searches for short, unqualified domain names.

**Domain Names**

The domain name is used with the client computer name to form the fully qualified domain name (FQDN), known also as the full computer name. In general, the DNS domain name is the remainder of the FQDN that is not used as the unique host name for the computer.

For example, the DNS domain name used for a client computer could be the following: If the FQDN, or **Full computer name**, is wkstn1.example.microsoft.com, the domain name is the example.microsoft.com portion of this name.

DNS domain names have two variations — a DNS name and a NetBIOS name. The full computer name (a fully qualified DNS

name) is used during querying and location of named resources on your network. For earlier version clients, the NetBIOS name is used to locate various types of NetBIOS services that are shared on your network.

An example that shows the need for both NetBIOS and DNS names is the Net Logon service. In Windows Server 2003 DNS, the Net Logon service on a domain controller registers its service (SRV) resource records on a DNS server. For Windows NT Server 4.0 and earlier versions, domain controllers register a DomainName entry in Windows Internet Name Service (WINS) to perform the same registration and to advertise their availability for providing authentication service to the network.

When a client computer is started on the network, it uses the DNS resolver to query a DNS server for SRV records for its configured domain name. This query is used to locate domain controllers and provide logon authentication for accessing network resources. A client or a domain controller on the network optionally uses the NetBIOS resolver service to query WINS servers, attempting to locate DomainName [1C] entries to complete the logon process.

Your DNS domain names should follow the same standards and recommended practices that apply to DNS computer naming described in the previous section. In general, acceptable naming conventions for domain names include the use of letters A through Z, numerals 0 through 9, and the hyphen (-). The use of the period (.) in a domain name is always used to separate the discrete parts of a domain name, commonly known as labels. Each label corresponds to an additional level defined in the DNS namespace tree.

For most computers, the primary DNS suffix configured for the computer can be the same as its Active Directory domain name, although the two values can be different.

**Host Names**
Computers using the underlying TCP/IP protocol of a Windows-based network use an IP address, a 32-bit numeric value (in the case of IPv4) or a 128-bit numeric value (in the case of IPv6), to identify the computer network connection of network hosts. However, network users prefer to use memorable, alphanumeric names. To support this need, network resources in a Windows-based network are identified by both alphanumeric names and IP addresses. DNS and WINS are two name resolution mechanisms that enable the use of alphanumeric names, and convert these names into their respective IP addresses.

**NetBIOS vs. DNS Computer Names**
In networks running Windows NT 4.0 and earlier, users typically locate and access a computer on the network using a NetBIOS (Network Basic Input Output System) name. In Windows 2000, Windows XP, and Windows Server 2003 operating systems, users locate and access a computer using DNS. In this implementation of DNS, a computer is identified by its full computer name, which is a DNS fully qualified domain name (FQDN).

**Primary DNS Suffixes**
The full computer name is a concatenation of the single-label host name, such as hostcomputer, and a multilabel primary DNS suffix name, such as corp.example.com, which is the DNS name of the Active Directory domain to which the computer is joined. Using the host and primary DNS suffix examples, the full computer name is hostcomputer.corp.example.com.

The host name is the same as the computer name specified during the installation of Windows Server 2003 and is listed in System Properties. The primary DNS suffix name is the same as the domain name specified during installation of Windows Server 2003 and is listed in System Properties. The full computer name is also listed in System Properties.

In addition, connection-specific DNS suffixes can be applied to the separate network adapter connections used by a multihomed computer. Connection-specific DNS suffixes identify the host when it is connected to separate networks that use different domain names. When using connection-specific DNS suffixes, a full computer name is also a concatenation of the host name and a connection-specific DNS suffix.

Using its host name and DNS suffixes, a single computer can have its full computer name configured using two possible methods:

- A primary full computer name, which applies as the default full computer name for the computer and all of its configured network connections.

- A connection-specific full computer name, which can be configured as an alternate DNS domain name that applies only for a single network adapter installed and configured on the computer.

Note that when using Active Directory, by default, the primary DNS suffix portion of a computer's full computer name must be the same as the name of the Active Directory domain where the computer is located. To allow different primary DNS suffixes, a domain administrator may create a restricted list of allowed suffixes by creating the **msDS-AllowedDNSSuffixes** attribute in the domain object container. This attribute is created and managed by the domain administrator using Active Directory Service Interfaces (ADSI) or the Lightweight Directory Access Protocol (LDAP).

**Connection-specific Names**

As shown in the following figure, a multihomed server computer named "host-a" can be named according to both its primary and connection-specific DNS domain names.

**Connection-specific DNS Names**

In this example, the server computer host-a attaches to two separate subnets — Subnet 1 and Subnet 2 — which are also linked at redundant points using two routers for additional paths between each subnet. Given this configuration, host-a provides access as follows through its separately named local area network (LAN) connections:

- The name "host-a.public.example.microsoft.com" provides access using LAN connection 1 over Subnet 1, a lower-speed (10 megabit) Ethernet LAN, for normal access to users who have typical file and print service needs.

- The name "host-a.backup.example.microsoft.com" provides access using LAN connection 2 over Subnet 2, a higher-speed (100 megabit) Ethernet LAN, for reserved access by server applications and administrators who have special needs, such as troubleshooting server networking problems, performing network-based backup, or replicating zone data between servers.

In addition to the connection-specific DNS names, the computer can also be accessible using either of the two LAN connections by specifying its primary DNS domain name, "host-a.example.microsoft.com".

When configured as shown, a computer can register resource records in DNS according to its three distinct names and sets of IP addresses, as shown in the following table:

**DNS Names**

| DNS Name | IP Addresses | Description |
|---|---|---|
| host-a.example.microsoft.com | 10.1.1.11, 10.2.2.22 | Primary DNS name for computer. The computer registers A and PTR resource records for all configured IP addresses under this name in the "example.microsoft.com" zone. |
| host-a.public.example.microsoft.com | 10.1.1.11 | Connection-specific DNS name for LAN connection 1, which registers A and PTR resource records for IP address 10.1.1.11 in the "public.example.microsoft.com" zone. |
| host-a.backup.example.microsoft.com | 10.2.2.22 | Connection-specific DNS name for LAN connection 2, which registers A and PTR resource records for IP address 10.2.2.22 in the "backup.example.microsoft.com" zone. |

When a computer changes between connections to different networks hosting different DNS domains, the host name does not need to be changed unless there is a host in the new DNS domain with the same host name. The primary DNS suffix for the computer can be changed from the old domain name to the new domain and the computer will register the new full computer name in DNS.

**Note**

- If you have any multihomed dynamic update clients and at least one adapter is using DHCP, configure the DHCP server to update resource records according to the request of the client. If the DHCP server is configured to register both A and PTR resource records, the DHCP server may replace all A resource records for the name it attempts to register. As a result, A resource records that correspond to the computer's other IP addresses might be deleted.

In Windows XP and Windows Server 2003 operating systems, the full computer name is viewed and set in the **Computer Name** tab of **System Properties**. Connection-specific DNS suffixes are configured in the **Advanced TCP/IP Settings** dialog box of the **Internet Protocol (TCP/IP) Properties** for a network connection.

**NetBIOS Names**

The NetBIOS name is created using the first 16 bytes of the host name, which is the maximum number of characters for NetBIOS names. The NetBIOS name is a 16-byte string that uniquely identifies a computer or service for network communication. If the DNS host name is 15 or fewer bytes, the NetBIOS name is the host name plus enough spaces to form a 15-byte name, followed by a 1-byte unique identifier. The sixteenth byte specifies the network service associated with the computer. When the computer name exceeds the maximum length for NetBIOS, the NetBIOS computer name is created by truncating the host name to form a 15-byte name, followed by a 1-byte unique identifier.

**Note**

- Because host names are encoded in UTF-8 format, they do not necessarily have only 1 byte per character. ASCII characters are 1 byte each, but the size of extended characters is more than 1 byte. For details of naming restrictions and a fuller description of UTF8, see “Naming Restrictions for Hosts and Domains” later in this chapter.

If you have an investment in using NetBIOS names to support legacy Microsoft networking technology, it is recommended that you revise NetBIOS computer names used on your network to prepare for migration to a standard DNS-only environment. This prepares your network well for long term growth and compatibility with future naming requirements. For example, if you use the same computer name for both NetBIOS and DNS resolution, consider converting any special characters in your current NetBIOS names that do not comply with DNS naming standards, such as the underscore (_). While these characters are permitted in NetBIOS names, they are more often incompatible with traditional DNS host naming requirements and most existing DNS resolver client software.

**Note**

- If WINS lookup is enabled for zones hosted by your Windows DNS servers, you need to use the same name for both NetBIOS and DNS computer naming. Otherwise, the results of clients attempting to query and resolve the names of these computers will be inconsistent.

The following table summarizes the differences between DNS and NetBIOS names using the example FQDN client1.example.com.

**DNS and NetBIOS Names**

| Name Type | Description |
|---|---|
| NetBIOS name | The NetBIOS name is used to uniquely identify the computer’s NetBIOS services. This unique NetBIOS name is resolved to the IP address of the computer through broadcast, WINS, or the LMHosts file. By default, the computer’s NetBIOS name is the same as the host name up to 15 bytes, plus any spaces necessary to make the name 15 bytes long, plus the service identifier.<br><br>For example, a NetBIOS name might be Client1. |
| Host name | The host name is the first label of a FQDN.<br><br>For example, the first label of the FQDN client1.example.com is client1. |
| Primary DNS suffix | Every Windows XP and Windows Server 2003 computer can be assigned a primary DNS suffix to be used in name resolution and name registration. You can view the primary DNS suffix for your computer from the **Computer Name** tab of **SystemProperties**.<br><br>The primary DNS suffix is also known as the primary domain name.<br><br>For example, the FQDN client1.example.com has the primary DNS suffix example.com. |

| | |
|---|---|
| Connection-specific DNS suffix | The connection-specific DNS suffix is a DNS suffix that is assigned to a network connection. The connection-specific DNS suffix is also known as an adapter-specific DNS suffix. For example, a connection-specific DNS suffix might be acquired01-ext.com. |
| Fully Qualified Domain Name (FQDN) | The FQDN is a DNS name that uniquely identifies the computer in the DNS namespace. By default, it is a concatenation of the host name, the primary DNS suffix, and a period. For example, an FQDN might be client1.example.com. |
| Full computer name | The full computer name is the FQDN for a Windows XP, Windows 2000 or Windows Server 2003 computer. It is the concatenation of the host name and primary DNS suffix (or host name and connection-specific DNS suffix). |

**DNS Servers List**

For DNS clients to operate effectively, a prioritized list of DNS name servers must be configured for each computer to use when processing queries and resolving DNS names. In most cases, the client computer contacts and uses its preferred DNS server, which is the first DNS server on its locally configured list. Listed alternate DNS servers are contacted and used when the preferred server is not available. For this reason, it is important that the preferred DNS server be appropriate for continuous client use under normal conditions.

For computers running Windows XP, the DNS server list is used by clients only to resolve DNS names. When clients send dynamic updates, such as when they change their DNS domain name or a configured IP address, they might contact these servers or other DNS servers as needed to update their DNS resource records.

By default, the DNS client on Windows XP does not attempt dynamic update over a Remote Access Service (RAS) or virtual private network (VPN) connection. By default, the Windows XP and Windows Server 2003 DNS Client service does not attempt dynamic update of top-level domain (TLD) zones. Any zone named with a single-label name is considered a TLD zone, for example, com, edu, blank, my-company. When DNS clients are configured dynamically using a DHCP server, it is possible to have a larger list of provided DNS servers. To effectively share the load when multiple DNS servers are provided in a DHCP options-specified list, you can configure a separate DHCP scope that rotates the listed order of DNS and WINS servers provided to clients.

**DNS Suffix Search List**

For DNS clients, you can configure a DNS domain suffix search list that extends or revises their DNS search capabilities. By adding additional suffixes to the list, you can search for short, unqualified computer names in more than one specified DNS domain. Then, if a DNS query fails, the DNS Client service can use this list to append other name suffix endings to your original name and repeat DNS queries to the DNS server for these alternate FQDNs.

For computers and servers, the following default DNS search behavior is predetermined and used when completing and resolving short, unqualified names.

When the suffix search list is empty or unspecified, the primary DNS suffix of the computer is appended to short unqualified names, and a DNS query is used to resolve the resultant FQDN. If this query fails, the computer can try additional queries for alternate FQDNs by appending any connection-specific DNS suffix configured for network connections.

If no connection-specific suffixes are configured or queries for these resultant connection-specific FQDNs fail, then the client can then begin to retry queries based on systematic reduction of the primary suffix (also known as devolution).

For example, if the primary suffix were “example.microsoft.com”, the devolution process would be able to retry queries for the short name by searching for it in the microsoft.“com” and “com” domains.

When the suffix search list is not empty and has at least one DNS suffix specified, attempts to qualify and resolve short DNS names are limited to searching only those FQDNs made available by the specified suffix list. If queries for all FQDNs that are formed as a result of appending and trying each suffix in the list are not resolved, the query process fails, producing a “name not found” result.

If the domain suffix list is used, clients continue to send additional alternate queries based on different DNS domain names when a query is not answered or resolved. Once a name is resolved using an entry in the suffix list, unused list entries are not tried. For this reason, it is most efficient to order the list with the most commonly used domain suffixes first.

Domain name suffix searches are used only when a DNS name entry is not fully qualified. To fully qualify a DNS name, a trailing period (**.**) is entered at the end of the name.

**Name Restrictions for Hosts and Domains**

Different DNS implementations allow different characters and lengths, and differ from NetBIOS naming restrictions. The

following table shows the restrictions for standard DNS names, DNS names in Windows Server 2003 and NetBIOS Names.

| Restriction | Standard DNS (Including Windows NT 4.0) | DNS in Windows Server 2003 | NetBIOS |
|---|---|---|---|
| Characters | Supports RFC 1123, which permits "A" to Z, "a" to "z", "0" to "9", and the hyphen (-) | Several different configurations are possible, as described at the end of this section | Permits Unicode characters, numbers, white space, symbols: ! @ $ % ^ & ) ( . - _ { } ~ |
| Fully qualified domain name length | Permits 63 bytes per label and 255 bytes for an FQDN | Permits 63 bytes per label and 255 bytes for an FQDN; the FQDN for an Active Directory domain name is limited to 64 bytes | Permits 16 bytes for a host name |

**Note**

- Although you can create long, complex DNS names, it is recommended that you create shorter, user-friendly names.

Adherence to DNS RFC 1123 can present a problem during an upgrade from Windows NT 4 to Windows 2000 or Windows Server 2003 because the host name of a Windows 2000 or Windows Server 2003 computer is set to the NetBIOS name that was set prior to the upgrade. NetBIOS names can use characters that violate the RFC 1123 DNS name restrictions, and converting NetBIOS names to strict DNS names can be time consuming.

Windows 2000 and Windows Server 2003 support migration by supporting a wider character set than RFC 1123. RFC 2181 enlarges the character set allowed in DNS names. It states that a DNS label can be any binary string, and it does not necessarily need to be interpreted as ASCII. Based on this definition, Microsoft has proposed that the DNS name specification be readjusted to accommodate a larger character set: UTF-8 character encoding, as described in RFC 2044.

UTF-8 character encoding is a superset of ASCII and a translation of the UCS-2 (also known as Unicode) character encoding. The UTF-8 character set includes characters from most of the world's written languages; this enables a far greater range of possible names. The Windows Server 2003 DNS service includes support for UTF-8 character encoding. For more information about UTF-8, see "Unicode Character Support" later in this document.

However, before using additional characters in DNS names, consider the following issues:

- Some third-party DNS client software supports only the characters listed in RFC 1123. Third-party DNS client software may not able to resolve the DNS names of computers with names that use characters outside the set supported by RFC 1123.

- A DNS server that does not support UTF-8 encoding might accept a zone transfer of a zone containing UTF-8 names, but it cannot write back those names to a zone file or reload those names from a zone file. Therefore, you must not transfer a zone that contains UTF-8 characters to a DNS server that does not support them.

- If you attempt to register a DNS name in Active Directory that contains an extended character that cannot be rendered in an LDAP distinguished name, Active Directory will respond with an invalid syntax error.

  You can configure the Windows Server 2003 DNS server to allow or reject the use of UTF-8 characters in DNS names. You can do this for each DNS server administered using the DNS console.

  **Note**

  - When you are modifying a host name or DNS suffix, or creating an Active Directory domain, if you enter a DNS name that includes UTF-8 or underscore characters not listed in RFC 1123, a warning message appears explaining that some DNS server implementations might not support these characters.

**Subnet Prioritization**

DNS subnet prioritization returns local IP addresses to the DNS Client service in preference to IP addresses on different subnets. This feature reduces network traffic by encouraging client computers to connect to network resources closer to them.

For example, suppose the three Web servers that host www.example.com are located on different subnets. On the DNS server, you can create the following resource records:

```
www.example.com.  IN A  172.16.64.11
www.example.com.  IN A  172.17.64.22
www.example.com.  IN A  172.18.64.33
```

When a user queries for www.example.com, all three resource records are returned. With subnet prioritization, the DNS Client service reorders the list of records returned so that it begins with the IP addresses from networks to which the computer is directly connected. For example, if a user with the IP address 172.17.64.93 queries for www.example.com, the DNS Client service returns the resource records in the following order:

```
www.example.com.  IN A  172.17.64.22
www.example.com.  IN A  172.16.64.11
www.example.com.  IN A  172.18.64.33
```

**Note**

- Subnet prioritization prevents the DNS Client service from using the Round Robin feature on the DNS Server service. For more information, see “Round Robin” later in this document.

Although subnet prioritization can reduce network traffic across subnets, you might prefer to use round robin as described in RFC 1794.

**DNS Server Service**

The DNS Server service is the component that provides the server implementation of DNS. The settings discussed in this section include:

- Disabling the use of recursion.
- Round robin use of resource records.
- Subnet prioritization.
- Advanced parameters.

**Disabling Recursion**

By default, recursion is enabled for the DNS Server service, and clients typically request that the server use recursion to resolve a name when sending a query. If recursion is disabled, the DNS Server service always uses referral, regardless of the client request.

In general, DNS servers can answer queries for names outside of their authoritative zones in two ways:

- Servers can send referral answers, which are an immediate response to the requesting client with a list of resource records for other DNS servers that it knows about that appear to be closer or more likely to be of help in resolving the queried name.
- Servers can use recursion to query other servers on behalf of the requesting client, attempting to fully resolve the name. Recursive lookups continue until the server receives an authoritative answer for the queried name. The server then forwards this answer in response to the original query from the requesting client.

In most cases, recursion is disabled on a DNS server when DNS clients are limited to resolving names authoritatively managed on a specific server. For example, this is the case when a DNS server has only DNS names data for an internal network or when the DNS server is incapable of resolving external DNS names (such as Internet DNS names) and clients are expected to retry another DNS server to resolve these names.

**Note**

- If you disable recursion on the DNS server, you will not be able to use forwarders on the same server. For more information about forwarders, see “Forwarding” later in this document.

**Round Robin**

Round robin DNS is a method of managing server congestion by distributing connection loads across multiple servers (containing identical content). Round robin works on a rotating basis in that one server IP address is handed out, then moves to the back of the list; the next server IP address is handed out, then it moves to the end of the list; and so on, depending on the number of servers being used. This works in a looping fashion.

This local balancing mechanism is used by DNS servers to share and distribute network resource loads. You can use round robin to rotate all resource record types contained in a query answer if multiple RRs are found.

By default, DNS uses round robin to rotate the order of RR data returned in query answers where multiple RRs of the same type exist for a queried DNS domain name. This feature provides a simple method for load balancing client use of Web servers and other frequently queried multihomed computers.

If round robin is disabled for a DNS server, the order of the response for these queries is based on a static ordering of RRs in the answer list as they are stored in the zone (either its zone file or Active Directory).

**Example: Round-robin rotation**
A forward lookup-type query (for all Host Address [A] RRs that match a DNS domain name) is made for a multihomed computer (multihomed.example.microsoft.com) that has three IP addresses. Separate A RRs are used to map the host's name to each of these IP addresses in the zone. In the stored example.microsoft.com zone, the RRs appear in this fixed order:

```
multihomed   IN  A  10.0.0.1
multihomed   IN  A  10.0.0.2
multihomed   IN  A  10.0.0.3
```

The first DNS client that queries the server to resolve this host's name receives the list in default order. When a second client sends a subsequent query to resolve this name, the list is rotated as follows:

```
multihomed   IN  A  10.0.0.2
multihomed   IN  A  10.0.0.3
multihomed   IN  A  10.0.0.1
```

**Restricting round robin rotation for selected RR types**
By default, DNS will perform round robin rotation for all RR types. You can now specify that certain RR types are not to be round-robin rotated in the registry. These modifications can be made in the registry.

**Restricting round-robin rotation for all RR types**
By default, all RR types are rotated, except those that have been specified as excluded from rotation in the registry.

**Subnet Prioritization**
By default, the DNS Server service uses local subnet prioritizing as the method for giving preference to IP addresses on the same network when a client query resolves to a host name that is mapped to more than one IP address. This feature requires that the client application attempt to connect to the host using its closest (and typically fastest) IP address available for connection.

The DNS Server service uses local subnet priority as follows:

1. The DNS Server service determines if local subnet prioritization is needed to order the query response.

   If more than one A resource record (RR) matches the queried host name, the DNS Server service can reorder the records by their subnet location. If the queried host name only matches a single A resource record, or if the IP network address of the client does not match an IP network address for any of the mapped addresses in an answer list of multiple RRs, no prioritizing is necessary.

2. For each RR in the matched answer list, the DNS Server service determines which records (if any) match the subnet location of the requesting client.

3. The DNS Server service reorders the answer list so that A RRs which match the local subnet of the requesting client are placed first in the answer list.

4. Prioritized by subnet order, the answer list is returned to the requesting client.

**Simple example: Local network prioritizing**
A multihomed computer, multihomed.example.microsoft.com, has three A RRs for its three separate host IP addresses in the

example.microsoft.com zone. A separate A RR is used for each of the host's addresses, which appear in this order in the zone:

```
multihomed   IN  A  192.168.1.27
multihomed   IN  A  10.0.0.14
multihomed   IN  A  172.16.20.4
```

If a DNS client resolver at IP address 10.4.3.2 queries the server for the IP addresses of host multihomed.example.microsoft.com, the DNS Server service notes that the originating IP network address (10.0.0.0) of the client matches the network (class A) portion of the 10.0.0.4 address in the answer list of RRs. The DNS Server service then reorders the addresses in the response as follows:

```
multihomed   IN  A  10.0.0.14
multihomed   IN  A  192.168.1.27
multihomed   IN  A  172.16.20.4
```

If the IP address of the requesting client has no local network match with any of the RRs in the answer list, then the list is not prioritized.

**Complex example: Local subnet prioritizing**
In Windows Server 2003, addresses are prioritized by matching the class C subnet by default, regardless of the subnet mask or address class of the target address.

For example, a multihomed computer, multihomed.example.microsoft.com, has four A RRs for four separate host IP addresses in the example.microsoft.com zone. Two of these IP addresses are for nonlocal networks. The other two IP addresses share a common IP network address but, because IP subnetting is used, represent different physical subnetted network connections based on their custom (nondefault) subnet mask value of 255.255.248.0. These example RRs appear in the following order in the zone:

```
multihomed   IN  A  192.168.1.27
multihomed   IN  A  172.16.22.4
multihomed   IN  A  10.0.0.14
multihomed   IN  A  172.16.31.5
```

If the IP address of the requesting client is 172.16.22.8, both of the IP addresses that match the same IP network as the client, the 172.16.0.0 network, are returned at the top of the answer list to the client. However, in this example, the 172.16.22.4 address is placed ahead of the 172.16.31.5 address because it matches the client IP address down through the 172.16.20.0 subnet address.

The reordered answer list returned by the DNS Server service would be:

```
multihomed   IN  A  172.16.22.4
multihomed   IN  A  172.16.31.5
multihomed   IN  A  192.168.1.27
multihomed   IN  A  10.0.0.14
```

### Note

- IP subnetting is imposed by using a custom or nondefault subnet mask value with all of the IP addresses on a network. Local subnet priority supersedes the use of round robin rotation for multihomed names. When round robin is enabled, however, RRs continue to be rotated using round robin as the secondary method of sorting the response list.

**Advanced DNS Server Service Parameters**
When initialized for service, DNS servers use server configuration settings taken from the parameters stated in a boot information file, the registry, and possibly zone information provided through Active Directory integration.

In most situations, the installation defaults are acceptable and should not require modification. However, when needed, you can use the DNS console to tune the following advanced parameters, accommodating special deployment needs and situations.

### DNS Server Service Advanced Parameters

| Value | Description |
|---|---|

| | |
|---|---|
| Disable recursion | Determines whether or not the DNS server uses recursion. By default, the DNS Server service is enabled to use recursion. |
| BIND secondaries | Determines whether to use fast transfer format when transferring a zone to DNS servers running legacy Berkeley Internet Name Domain (BIND) implementations.<br><br>By default, all Windows-based DNS servers use a fast zone transfer format, which uses compression and can include multiple records per TCP message during a connected transfer. This format is also compatible with more recent BIND-based DNS servers that run versions 4.9.4 and later. |
| Fail on load if bad zone data | Sets the DNS server to parse files strictly.<br><br>By default, the DNS Server service logs data errors, ignore any erred data in zone files, and continue to load a zone. This option can be reconfigured using the DNS console so that the DNS Server service logs errors and fails to load a zone file containing records data that is determined to have errors. |
| Enable round robin | Determines whether the DNS server uses round robin to rotate and reorder a list of resource records (RRs) if multiple RRs exist of the same type exisit for a query answer. |
| Enable netmask ordering | Determines whether the DNS server reorders A resource records within the same resource record set in its response to a query based on the IP address of the source of the query. |
| Secure cache against pollution | Determines whether the server attempts to clean up responses to avoid cache pollution. This setting is enabled by default.<br><br>By default, DNS servers use a secure response option that eliminates adding unrelated resource records included in a referral answer to their cache. In most cases, any names added in referral answers are typically cached and help expedite the speed of resolving subsequent DNS queries.<br><br>With this feature, however, the server can determine that referred names are potentially polluting or insecure and discard them. The server determines whether to cache the name offered in a referral on the basis of whether or not it is part of the exact related DNS domain name tree for which the original queried name was made.<br><br>For example, if a query was originally made for “example.microsoft.com” and a referral answer provided a record for a name outside of the “microsoft.com” domain name tree, such as msn.com, then that name would not be cached where this feature is enabled for use. |

**Resource Records in DNS**

DNS resource records are the data that is associated with DNS names in the DNS namespace. Each domain name of the DNS namespace tree contains a set of resource records, and each resource record in the set contains different types of information relating to the domain name. A DNS query includes the DNS domain name that is to be resolved and the type of information desired (the resource records that are requested). Queries for the IP addresses of DNS hosts return A resource records, and queries for the DNS servers authoritative for a DNS domain name return name server (NS) resource records.

Resource records are typically discussed in two categories: authority records and other records. Authority records identify the DNS servers that are authoritative for the domain names in the DNS namespace and how their zones should be managed, and all other DNS records contain information about a domain name that is unrelated to authority.

**Authority Records**

Zones are based on a concept of server authority. When a DNS server is configured to load a zone, it uses two types of resource records to determine the authoritative properties of the zone:

- First, the start of authority (SOA) resource record indicates the name of origin for the zone and contains the name of the server that is the primary source for information about the zone. It also indicates other basic properties of the zone.

- Next, the name server (NS) resource record is used to notate which DNS servers are designated as authoritative for the zone. By listing a server in the NS RR, it becomes known to others as an authoritative server for the zone. This means that any server specified in the NS RR is to be considered an authoritative source by others, and is able to answer with certainty any queries made for names included in the zone.

The SOA and NS resource records occupy a special role in zone configuration. They are required records for any zone and are

typically the first resource records listed in files.

**The SOA resource record**

The start of authority (SOA) resource record is always first in any standard zone. It indicates the DNS server that either originally created it or is now the primary server for the zone. It is also used to store other properties such as version information and timings that affect zone renewal or expiration. These properties affect how often transfers of the zone are done between servers authoritative for the zone.

The SOA resource record contains the following information:

**SOA Resource Record Fields**

| Field | Description |
|---|---|
| Primary server (owner) | The host name for the primary DNS server for the zone. |
| Responsible person | The e-mail address of the person responsible for administering the zone. A period (**.**) is used instead of an at sign (**@**) in this e-mail name. |
| Serial number | The revision number of the zone file. This number increases each time a resource record in the zone changes. It is important that this value increase each time the zone is changed, so that either partial zone changes or the fully revised zone can be replicated to other secondary servers during subsequent transfers. |
| Refresh interval | The time, in seconds, that a secondary DNS server waits before querying its source for the zone to attempt renewal of the zone. When the refresh interval expires, the secondary DNS server requests a copy of the current SOA record for the zone from its source, which answers this request. The secondary DNS server then compares the serial number of the source server's current SOA record (as indicated in the response) with the serial number in its own local SOA record. If they are different, the secondary DNS server requests a zone transfer from the primary DNS server. The default for this field is 900 seconds (15 minutes). |
| Retry interval | The time, in seconds, a secondary server waits before retrying a failed zone transfer. Normally, this time is less than the refresh interval. The default value is 600 seconds (10 minutes). |
| Expire interval | The time, in seconds, before a secondary server stops responding to queries after a lapsed refresh interval where the zone was not refreshed or updated. Expiration occurs because at this point in time, the secondary server must consider its local data unreliable. The default value is 86,400 seconds (24 hours). |
| Minimum (default) TTL | The default Time-To-Live (TTL) of the zone and the maximum interval for caching negative answers to name queries. The default value is 3,600 seconds (1 hour). |

The following is an example of a default SOA resource record:

```
@   IN  SOA     nameserver.example.microsoft.com.  postmaster.example.microsoft.com. (
                                1            ; serial number
                                3600         ; refresh   [1h]
                                600          ; retry     [10m]
                                86400        ; expire    [1d]
                                3600 )       ; min TTL   [1h]
```

In the example SOA record shown above, the primary or originating server for the zone is shown as nameserver.example.microsoft.com. The e-mail address for the person to contact regarding questions about this zone is postmaster.example.microsoft.com.

Periods are used to represent e-mail addresses when writing and storing DNS domain names in a zone. In an e-mail application, the previous example address would instead likely appear as postmaster@example.microsoft.com. The parentheses used in the SOA resource record as it appears in a zone file are used to enable wrapping of the record over multiple lines of text. If an individual TTL value is assigned and applied to a specified resource record used in the zone, it overrides the minimum (default) TTL set in the SOA record.

**The NS resource record**

Name server (NS) resource records can be used to assign authority to specified servers for a DNS domain name in two ways:

- By establishing a list of authoritative servers for the domain so that those servers can be made known to others that request information about this domain (zone).

- By indicating authoritative DNS servers for any subdomains that are delegated away from the zone.

In the case of assigning servers with host names in the same zone, corresponding address (A) resource records are normally used in the zone to resolve the names of specified servers to their IP addresses. For servers that are specified using this RR as part of a zone delegation to a subdomain, the NS resource record usually contains out-of-zone names. For the out-of-zone names to be resolved, A resource records for the specified out-of-zone server's might be needed. When these out-of-zone NS and A records are needed to provide delegation, they are known as glue records.

The following table shows the basic syntax of how a NS RR is used.

**Basic Syntax of a Name Server Resource Record**

| |
|---|
| **Description:** Used to map a DNS domain name as specified in **owner** to the name of hosts operating DNS servers specified in the *name_server_domain_name* field. |
| **Syntax:** *owner ttl* **IN NS** *name_server_domain_name*. |
| **Example:**<br>`example.microsoft.com.  IN NS nameserver1.example.microsoft.com` |

**Other Important Records**

After a zone is created, additional resource records need to be added to it. The following table lists the most common resource records (RRs) to be added.

**Common DNS Resource Records**

| Resource Record | Description |
|---|---|
| Host (A) | For mapping a DNS domain name to an IP address used by a computer. |
| Alias (CNAME) | For mapping an alias DNS domain name to another primary or canonical name. |
| Mail Exchanger (MX) | For mapping a DNS domain name to the name of a computer that exchanges or forwards mail. |
| Pointer (PTR) | For mapping a reverse DNS domain name based on the IP address of a computer that points to the forward DNS domain name of that computer. |
| Service location (SRV) | For mapping a DNS domain name to a specified list of DNS host computers that offer a specific type of service, such as Active Directory domain controllers. |

**Host (A) resource records**

Host (A) resource records are used in a zone to associate DNS domain names of computers (or hosts) to their IP addresses, and can be added manually, Windows clients and servers can also use the DHCP Client service to dynamically register and update their own A resource records in DNS when an IP configuration change occurs. DHCP-enabled client computers running earlier versions of Microsoft operating systems can have their A resource records registered and updated by proxy if they obtain their IP lease from a qualified DHCP server (only the Windows 2000 and Windows Server 2003 DHCP Server service currently supports this feature).

The host (A) resource record is not required for all computers, but is needed by computers that share resources on a network. Any computer that shares resources and needs to be identified by its DNS domain name, needs to use A resource records to provide DNS name resolution to the IP address for the computer.

Most A RRs that are required in a zone can include other workstations or servers that share resources, other DNS servers, mail servers, and Web servers. These resource records comprise the majority of resource records in a zone database.

**Alias (CNAME) resource records**

Alias (CNAME) resource records are also sometimes called canonical names. These records allow you to use more than one name to point to a single host, making it easy to do such things as host both an FTP server and a Web server on the same

computer. For example, the well-known server names (ftp, www) are registered using CNAME RRs that map to the DNS host name, such as "server-1" for the server computer that hosts these services.

CNAME RRs are recommended for use in the following scenarios:

- When a host specified in an A RR in the same zone needs to be renamed.
- When a generic name for a well-known server such as www needs to resolve to a group of individual computers (each with individual A RRs) that provide the same service. An example would be a group of redundant Web servers.

When renaming a computer with an existing A RR in the zone, you can use a CNAME RR temporarily, to allow a grace period for users and programs to switch from specifying the old computer name to using the new one. To do this, you need the following:

- For the new DNS domain name of the computer, a new A RR is added to the zone.
- For the old DNS domain name, a CNAME RR is added that points to the new A RR.
- The original A RR for the old DNS domain name (and its associated PTR RR if applicable) is removed from the zone.

When using a CNAME RR for aliasing or renaming a computer, set a temporary limit on how long the record is used in the zone before removing it from DNS. If you forget to delete the CNAME RR and later its associated A RR is deleted, the CNAME RR can waste server resources by trying to resolve queries for a name no longer used on the network.

The most common or popular use of a CNAME RR is to provide a permanent DNS aliased domain name for generic name resolution of a service-based name, such as www.example.microsoft.com to more than one computer or one IP address used in a Web server. For example, the following shows the basic syntax of how a CNAME RR is used.

```
alias_name IN CNAME primary_canonical_name
```

In this example, a computer named host-a.example.microsoft.com needs to function as both a Web server named "www.example.microsoft.com."; and an FTP server named "ftp.example.microsoft.com."; To achieve the intended use for naming this computer, you can add and use the following CNAME entries in the example.microsoft.com zone:

```
                host-a    IN  A      10.0.0.20
ftp       IN  CNAME  host-a
www       IN  CNAME  host-a
```

If you later decide to move the FTP server to another computer, separate from the Web server on "host-a", simply change the CNAME RR in the zone for ftp.example."microsoft.com" and add an additional A RR to the zone for the new computer hosting the FTP server.

Based on the earlier example, if the new computer were named "host-b.example.microsoft.com", the new and revised A and CNAME RRs would be as follows:

```
                host-a    IN  A      10.0.0.20
host-b    IN  A      10.0.0.21
ftp       IN  CNAME  host-b
www       IN  CNAME  host-a
```

**Mail exchanger (MX) resource records**

The mail exchanger (MX) RR is used by e-mail applications to locate a mail server based on a DNS domain name used in the destination address for the e-mail recipient of a message. For example, a DNS query for the name example.microsoft.com; could be used to find an MX RR, enabling an e-mail application to forward or exchange mail to a user with the e-mail address user@microsoft.com.

The MX RR shows the DNS domain name for the computer or computers that process mail for a domain. If multiple MX RRs exist, the DNS Client service attempts to contact mail servers in the order of preference from lowest value (highest priority) to highest value (lowest priority). The following shows the basic syntax for use of an MX RR.

```
mail_domain_name IN MX preference mailserver_host
```

By using the MX RRs shown below in the example.microsoft.com zone, mail addressed to user@example.microsoft.com is delivered to user@mailserver0.example.microsoft.com first if possible. If this server is unavailable, the resolver client can then use user@mailserver1.example.microsoft.com instead.

```
@          IN  MX   1    mailserver0
@          IN  MX   2    mailserver1
```

Note that the use of the at sign (**@**) in the records indicates that the mailer DNS domain name is the same as the name of origin (example.microsoft.com) for the zone.

**Pointer (PTR) resource records**
Pointer (PTR) RRs are used to support the reverse lookup process, based on zones created and rooted in the in-addr.arpa domain. These records are used to locate a computer by its IP address and resolve this information to the DNS domain name for that computer.

PTR RRs can be added to a zone in several ways:

- You can manually create a PTR RR for a static TCP/IP client computer using the DNS , either as a separate procedure or as part of the procedure for creating an A RR.
- Computers use the DHCP Client service to dynamically register and update their PTR RR in DNS when an IP configuration change occurs.
- All other DHCP-enabled client computers can have their PTR RRs registered and updated by the DHCP server if they obtain their IP lease from a qualified server. The Windows 2000 and Windows Server 2003 DHCP Server service provides this capability.

The pointer (PTR) resource record is used only in reverse lookup zones to support reverse lookup.

**Service location (SRV) resource records**
To locate Active Directory domain controllers, service location (SRV) RRs are required. Typically, you can avoid manual administration of the SRV RR when installing Active Directory.

By default, the Active Directory installation wizard attempts to locate a DNS server based on the list of preferred or alternate DNS servers, configured in any of its TCP/IP client properties, for any of its active network connections. If a DNS server that can accept dynamic update of the SRV RR (and other RRs related to registering Active Directory as a service in DNS) is contacted, the configuration process is complete.

If, during the installation, a DNS server that can accept updates for the DNS domain name used to name your Active Directory is not found, the wizard can install a DNS server locally and automatically configure it with a zone to support the Active Directory domain.

For example, if the Active Directory domain that you chose for your first domain in the forest was example.microsoft.com, a zone rooted at the DNS domain name of example.microsoft.com would be added and configured to use with the DNS server running on the new domain controller.

Whether or not you install the DNS Server service locally, a file (Netlogon.dns) is written and created during the Active Directory installation process that contains the SRV RRs and other RRs needed to support the use of Active Directory. This file is created in the systemroot\System32\Config folder.

If you are using a DNS server that fits one of the following descriptions, you should use the records in Netlogon.dns to manually configure the primary zone on that server to support Active Directory.

- The computer operating your DNS server is running on another platform, such as UNIX, and cannot accept or recognize dynamic updates.
- A DNS server at this computer that is not the DNS Server service provided with the Windows Server 2003 operating system is authoritative for the primary zone corresponding to the DNS domain name for your Active Directory domain.

- The DNS server supports the SRV RR, as defined in the Internet draft, "A DNS RR specifying the location of services (DNS SRV)", but does not support dynamic updates.

- For example, the DNS Server service provided with Windows NT Server 4.0, when updated to Service Pack 4 or later, fits this description.

In the future, the SRV RR might also be used to register and lookup other well-known TCP/IP services on your network if applications implement and support DNS name queries that specify this record type.

Other additional resource records are supported by Windows Server 2003 DNS and are used less frequently in most zones. These additional types of resource records can be added as needed using the DNS console. For more information about supported resource records, see "Related Information" later in this document.

**DNS-related Files**
The following files relate to using and configuring DNS servers and clients.

| File | Description |
|---|---|
| Boot | BIND boot configuration file. This file is not created by the DNS console. However, as an optional configuration for the DNS Server service, it can be copied from another DNS server running the Berkeley Internet Name Domain (BIND) server implementation of DNS. To use this file with the DNS Server service, you need to click From file in Server properties. On BIND servers, this file is often called the "named.boot" file. |
| Cache.dns | Used to preload resource records into the DNS server names cache. DNS servers use this file to help locate root servers on either your network or the Internet.<br><br>By default, this file contains DNS resource records that prime the local cache of the server with the addresses of authoritative root servers for the Internet. If you are setting up a DNS server to resolve Internet DNS names, the information in this file is required unless you enable the use of another DNS server as a forwarder to resolve these names.<br><br>Traffic to the Internet root servers is heavy, but because host names are not usually resolved at this level, the load can be reasonably handled. Instead, the root hints file provides referral information that can be useful during DNS name resolution to redirect a query to other servers that are authoritative for names located beneath the root.<br><br>For DNS servers operating privately on your internal network, the DNS console can learn and replace the contents of this file with internal root servers on your network, provided they are reachable through the network when you are setting up and configuring new DNS servers. It can be updated using the DNS console from the Root Hints tab located under the applicable server properties.<br><br>This file preloads the server names cache when it is started. |
| Root.dns | Root zone file. This file can appear at a DNS server if it is configured as a root server for your network. |
| *zone_name*.dns | Used when a standard zone (either primary or secondary) is added and configured for the server. Files of this type are not created or used for primary type zones that are directory-integrated, which are stored in the Active Directory database. |

These files can be found in the systemroot\System32\Dns folder on the server computer.

**Zones and Zone Transfer**
DNS distributes the DNS namespace database using DNS zones, which store name information about one or more DNS domains. There are three types of DNS zones supported in Windows Server 2003:

- Primary zone. Original copy of a zone where all resource records are added, modified, and deleted.

- Secondary zone. Read-only copy of the primary zone that is created and updated by transferring zone data from the primary zone.

- Stub zone. Read-only copy of the primary zone containing only the DNS resource records for the DNS servers listed in the zone (SOA, NS, and glue A resource records).

**Difference Between Zones and Domains**
A zone starts as a storage database for a single DNS domain name. If other domains are added below the domain used to create the zone, these domains can either be part of the same zone or belong to another zone. Once a subdomain is added, it can then either be:

- Managed and included as part of the original zone records, or
- Delegated away to another zone created to support the subdomain

For example, the following figure shows the microsoft.com domain, which contains domain names for Microsoft. When the microsoft.com domain is first created at a single server, it is configured as a single zone for all of the Microsoft DNS namespace. If, however, the microsoft.com domain needs to use subdomains, those subdomains must be included in the zone or delegated away to another zone.

**DNS Domain Names and Subdomain Names**

In this example, the example.microsoft.com domain shows a new subdomain — the example.microsoft.com domain — delegated away from the microsoft.com zone and managed in its own zone. However, the microsoft.com zone needs to contain a few resource records to provide the delegation information that references the DNS servers that are authoritative for the delegated example.microsoft.com subdomain.

If the microsoft.com zone does not use delegation for a subdomain, any data for the subdomain remains part of the microsoft.com zone. For example, the subdomain dev.microsoft.com is not delegated away but is managed by the microsoft.com zone.

**Why Zone Replication and Zone Transfers Are Needed**
Because of the important role that zones play in DNS, it is intended that they be available from more than one DNS server on the network, to provide availability and fault tolerance when resolving name queries. Otherwise, if a single server is used and that server is not responding, queries for names in the zone can fail. For additional servers to host a zone, zone transfers are required to replicate and synchronize all copies of the zone used at each server configured to host the zone.

When a new DNS server is added to the network and is configured as a new secondary server for an existing zone, it performs a full initial transfer of the zone to obtain and replicate a full copy of resource records for the zone. For most earlier DNS server implementations, this same method of full transfer for a zone is also used when the zone requires updating after changes are made to the zone. For DNS servers running Windows Server 2003, the DNS service supports incremental zone transfer, a revised DNS zone transfer process for intermediate changes.

**Domain Delegation**
A subordinate domain name, or subdomain, can be delegated from the DNS zone where its parent name is stored to a zone on another DNS server. When deciding whether to delegate your DNS namespace to make additional zones, consider the following reasons to use additional zones:

- A need to delegate management of part of your DNS namespace to another location or department within your organization.
- A need to divide one large zone into smaller zones for distributing traffic loads among multiple servers
- A need to extend the namespace by adding numerous subdomains at once, such as to accommodate the opening of a new branch or site.

If, for any of these reasons, you could benefit from delegating subordinate domain names to additional zones, it might make sense to restructure your namespace by adding additional zones. When choosing how to structure zones, you should use a plan that reflects the structure of your organization.

When delegating zones within your namespace, be aware that for each new zone you create, you will need delegation records in other zones that point to the authoritative DNS servers for the new zone. This is necessary both to transfer authority and to provide correct referral to other DNS servers and clients of the new servers being made authoritative for the new zone.

When a standard primary zone is first created, it is stored as a text file containing all resource record information about a single DNS server. This server acts as the primary master for the zone. Zone information can be replicated to other DNS servers to improve fault tolerance and server performance.

When structuring your zones, there are several good reasons to use additional DNS servers for zone replication:

- Additional DNS servers provide zone redundancy, enabling DNS names in the zone to be resolved for clients if a primary server for the zone stops responding.
- Additional DNS servers can be placed so as to reduce DNS network traffic. For example, adding a DNS server to the opposing side of a low-speed wide area network (WAN) link can be useful in managing and reducing network traffic.
- Additional DNS secondary servers can be used to reduce loads on a primary server for a zone.

**Example: Delegating a subdomain to a new zone**
As shown in the following figure, when a new zone for a subdomain (example.microsoft.com) is created, delegation from the parent zone (microsoft.com) is needed.

**Delegating a Subdomain**

In this example, an authoritative DNS server computer for the newly delegated example.microsoft.com subdomain is named based on a derivative subdomain included in the new zone (ns1.na.example.microsoft.com). To make this server known to others outside of the new delegated zone, two RRs are needed in the microsoft.com zone to complete delegation to the new zone.

These RRs include:

- An NS RR to effect the delegation. This RR is used to advertise that the server named ns1.na.example.microsoft.com is an authoritative server for the delegated subdomain.
- An A RR (also known as a glue record) is needed to resolve the name of the server specified in the NS RR to its IP address. The process of resolving the host name in this RR to the delegated DNS server in the NS RR is sometimes referred to as glue chasing.

  **Note**

  - When zone delegations are correctly configured, normal zone referral behavior can sometimes be circumvented

if you are using forwarders in your DNS server configuration. For more information, see "Forwarding" later in this document.

**Incremental Zone Transfers**

Incremental zone transfers are described in RFC 1995 as an additional DNS standard for replicating DNS zones. When incremental transfers are supported by both a DNS server acting as the source for a zone and any servers that copy the zone from it, the incremental transfer provides a more efficient method of propagating zone changes and updates.

In earlier DNS implementations, any request for an update of zone data required a full transfer of the entire zone database using an AXFR query. With incremental transfer, an alternate query type (IXFR) can be used instead. This allows the secondary server to pull only those zone changes it needs to synchronize its copy of the zone with its source, either a primary or secondary copy of the zone maintained by another DNS server.

With IXFR zone transfers, differences between the source and replicated versions of the zone are first determined. If the zones are identified to be the same version — as indicated by the serial number field in the SOA resource record of each zone — no transfer is made.

If the serial number for the zone at the source is greater than at the requesting secondary server, a transfer is made of only those changes to RRs for each incremental version of the zone. For an IXFR query to succeed and changes to be sent, the source DNS server for the zone must keep a history of incremental zone changes to use when answering these queries. The incremental transfer process requires substantially less traffic on a network and zone transfers are completed much faster.

**Example: Zone Transfer**

A zone transfer might occur during any of the following scenarios:

- When the refresh interval expires for the zone
- When a secondary server is notified of zone changes by its master server
- When the DNS Server service is started at a secondary server for the zone
- When the DNS console is used at a secondary server for the zone to manually initiate a transfer from its master server

Zone transfer requests are always initiated at the secondary server for a zone, and then sent to their configured master servers which act as their source for the zone. Master servers can be any other DNS server that loads the zone, such as either the primary server for the zone or another secondary server. When the master server receives the request for the zone, it can reply with either a partial or full transfer of the zone to the secondary server.

**Zone transfer process**

As shown in the following figure, zone transfers between servers follow an ordered process. This process varies depending on whether a zone has been previously replicated, or if initial replication of a new zone is being performed.

### Zone Transfer Process

1. During new configuration, the destination server sends an initial "all zone" transfer (AXFR) request to the master DNS server configured as its source for the zone.
2. The master (source) server responds and fully transfers the zone to the secondary (destination) server.

   The zone is delivered to the destination server requesting the transfer with its version established by use of a Serial number field in the properties for the start of authority RR. The SOA RR also contains a stated refresh interval in seconds

(by default, 900 seconds or 15 minutes) to indicate when the destination server should next request to renew the zone with the source server.

3. When the refresh interval expires, an SOA query is used by the destination server to request renewal of the zone from the source server.

4. The source server answers the query for its SOA record.

   This response contains the serial number for the zone in its current state at the source server.

   The destination server checks the serial number of the SOA record in the response and determines how to renew the zone.

   If the value of the serial number in the SOA response is equal to its current local serial number, it concludes that the zone is the same at both servers and that a zone transfer is not needed. The destination server then renews the zone by resetting its refresh interval based on the value of this field in the SOA response from its source server.

   If the value of the serial number in the SOA response is higher than its current local serial number, it concludes that the zone has been updated and that a transfer is needed.

5. If the destination server concludes that the zone has changed, it sends an IXFR query to the source server, containing its current local value for the serial number in the SOA record for the zone.

6. The source server responds with either an incremental or full transfer of the zone.

   If the source server supports incremental transfer by maintaining a history of recent incremental zone changes for modified resource records, it can answer with an incremental zone transfer (IXFR) of the zone.

   If the source server does not support incremental transfer, or does not have a history of zone changes, it can answer with a full (AXFR) transfer of the zone instead.

   **Note**

   - For servers running Windows 2000 and Windows Server 2003, incremental zone transfer through IXFR query is supported. For earlier versions of the DNS service and for many other DNS server implementations, incremental zone transfer is not available and only full-zone (AXFR) queries and transfers are used to replicate zones.

**DNS Notify**

Windows-based DNS servers support DNS Notify, an update to the original DNS protocol specification that permits a means of initiating notification to secondary servers when zone changes occur (RFC 1996). DNS notification implements a push mechanism for notifying a select set of secondary servers for a zone when the zone is updated. Servers that are notified can then initiate a zone transfer as described above, to pull zone changes from their master servers and update their local replicas of the zone.

For secondaries to be notified by the DNS server acting as their configured source for a zone, each secondary server must first have its IP address in the notify list of the source server. When using the DNS console, this list is maintained in the Notify dialog box, which is accessible from the Zone Transfer tab located in zone Properties.

In addition to notifying the listed servers, the DNS console permits you to use the contents of the notify list as a means to restrict or limit zone transfer access to only those secondary servers specified in the list. This can help prevent an undesired attempt by an unknown or unapproved DNS server to pull, or request, zone updates.

**DNS notification process**

The following is a brief summary of the typical DNS notification process for zone updates:

- The local zone at a DNS server acting as a master server, a source for the zone to other servers, is updated. When the zone is updated at the master or source server, the serial number field in the SOA RR is also updated, indicating a new local version of the zone.

- The master server sends a DNS notify message to other servers that are part of its configured notify list.
- All secondary servers that receive the notify message can then respond by initiating a zone transfer request back to the notifying master server.

The normal zone transfer process can then continue as described in the previous section.

You cannot configure a notify list for a stub zone.

Use DNS notification only to notify servers operating as secondary servers for a zone. For replication of directory-integrated zones, DNS notification is not needed. This is because any DNS servers that load a zone from Active Directory automatically poll the directory (as specified by the SOA resource record's Refresh Interval) to update and refresh the zone. In these cases, configuring a notify list can actually degrade system performance by causing unnecessary additional transfer requests for the updated zone.

**Note**

- By default, the Windows Server 2003 DNS Server service will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.

**Stub Zones**

In Windows Server 2003, a new zone type named stub zone has been introduced. A stub zone is a copy of a zone that contains only those resource records necessary to identify the authoritative DNS servers for that zone. A stub zone is used to resolve names between separate DNS namespaces. The need for this type of resolution can occur when a corporate merger requires that the DNS servers for two separate DNS namespaces resolve names for clients in both namespaces.

A stub zone consists of:

- The start of authority (SOA) resource record, name server (NS) resource records, and the glue A resource records for the delegated zone.
- The IP address of one or more master servers that can be used to update the stub zone.

The master servers for a stub zone are one or more DNS servers authoritative for the child zone, usually the DNS server hosting the primary zone for the delegated domain name.

**Stub zone resolution**

When a DNS client performs a recursive query operation on a DNS server hosting a stub zone, the DNS server uses the resource records in the stub zone to resolve the query. The DNS server sends an iterative query to the authoritative DNS servers specified in the NS resource records of the stub zone as if it were using NS resource records in its cache. If the DNS server cannot find the authoritative DNS servers in its stub zone, the DNS server hosting the stub zone attempts standard recursion using its root hints.

The DNS server will store the resource records it receives from the authoritative DNS servers listed in a stub zone in its cache, but it will not store these resource records in the stub zone itself; only the SOA, NS, and glue A resource records returned in response to the query are stored in the stub zone. The resource records stored in the cache are cached according to the Time-to-Live (TTL) value in each resource record. The SOA, NS, and glue A resource records, which are not written to cache, expire according to the expire interval specified in the stub zone's SOA record, which is created during the creation of the stub zone and updated during transfers to the stub zone from the original, primary zone.

If the query was an iterative query, the DNS server returns a referral containing the servers specified in the stub zone.

**Stub zone updates**

Stub zone updates involve the following conditions:

- When a DNS server loads a stub zone, it queries the zone's master server for the SOA resource record, NS resource records at the zone's root, and glue A resource records.
- During updates to the stub zone, the master server is queried by the DNS server hosting the stub zone for the same resource record types requested during the loading of the stub zone.

- The Refresh interval of the SOA resource record determines when the DNS server hosting the stub zone will attempt a zone transfer (update).
- If an update fails, the Retry interval of the SOA resource record determines when the update is retried.
- Once the Retry interval has expired without a successful update, the expiration time as specified in the Expires field of the SOA resource record determines when the DNS server stops using the stub zone data.

**Root Hints**

Root hints are used to prepare servers authoritative for non-root zones so that they can learn and discover authoritative servers that manage domains located at a higher level or in other subtrees of the DNS domain namespace. These hints are essential for servers authoritative at lower levels of the namespace when locating and finding servers under these conditions.

For example, suppose a DNS server (Server A) has a zone called sub.example.microsoft.com. In the process of answering a query for a higher-level domain, such as the example.microsoft.com domain, Server A needs some assistance to locate an authoritative server (such as Server B) for this domain.

In order for Server A to find Server B, or any other servers that are authoritative for the microsoft.com domain, it needs to be able to query the root servers for the DNS namespace. The root servers can then refer Server A to the authoritative servers for the com domain. The servers for the com domain can, in turn, offer referral to Server B or other servers that are authoritative for the microsoft.com domain.

The root hints used by Server A must have helpful hints to the root servers for this process to locate Server B (or another authoritative server) as intended.

To configure and use root hints correctly, first determine how the following applies to your DNS servers:

- Are you using DNS on the Internet or on a private network?
- Is the server used as a root server?

By default, the DNS Server service implements root hints using a file, Cache.dns, stored in the systemroot\System32\Dns folder on the server computer. This file normally contains the NS and A resource records for the Internet root servers. If, however, you are using the DNS Server service on a private network, you can edit or replace this file with similar records that point to your own internal root DNS servers.

Another server configuration in which root hints are treated differently is one in which a DNS server is configured to be used by other DNS servers in an internal namespace as a forwarder for any DNS queries of names managed externally (the Internet, for example). Even though the DNS server used as a forwarder can be located internally on the same network as servers using it as a forwarder, it needs hints for the Internet root servers to work properly and resolve external names.

**Note**

- If you are operating internal root servers, do not use root hints. Instead, delete the Cache.dns file entirely for any of your root servers.

**EDNS0**

Extension Mechanisms for DNS (EDNS0 as defined in RFC 2671) allow DNS requestors to advertise the size of their UDP packets and facilitate the transfer of packets larger than 512 octets, the original DNS restriction for UDP packet size (RFC 1035). When a DNS server receives a request over the UDP Transport Layer, it identifies the requestor's UDP packet size from the option (OPT) RR and scales its response to contain as many resource records as are allowed in the maximum UDP packet size specified by the requestor.

Windows Server 2003 DNS support for EDNS0 is enabled by default. It can be disabled using the registry. Locate the following registry subkey:

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

Add the entry **EnableEDNSProbes** to the subkey. Give the entry a DWORD value and set it to 0x0 to disable EDNS0.

Use extreme caution when editing the registry Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the

system..

For more information about resource records, see "Related Information" at the end of this document.

**ENDS0 UDP responses**
Before a DNS server assumes that the requestor supports EDNS0, the DNS server must receive a query containing an OPT resource record. An OPT record contains no actual DNS data and its contents relate to the UDP Transport Layer message only. The OPT record stores the sender's UDP payload size in its CLASS field and lists the number of octets in the largest UDP payload that the requestor can deliver in the requestor's network.

When the DNS server receives a query containing an OPT record advertising the maximum UDP packet size, it will truncate any UDP response's size larger than the limit specified in the OPT record.

By default, the DNS server includes OPT resource records indicating its UDP maximum in responses to queries containing OPT resource records.

If the DNS server receives a query that does not contain an OPT resource record, it assumes the requestor's server does not support EDNS0 and will respond to the requestor assuming that the sender does not accept UDP packets larger than 512 octets. In this case, the DNS server will truncate its UDP response size to a maximum of 512 octets.

**EDNS0 UDP queries**
Before the requesting DNS server sends a query, it checks its cache to identify if the responding DNS server supports EDNS0. If the responding DNS server supports EDNS0, the requesting DNS server attaches an OPT resource record to the additional section of the query it sends. (All queries have five sections: header, question, answer, authority, and additional.) If, according to the requesting DNS server's cache, the responding DNS server does not support EDNS0, the requesting DNS server will not attach an OPT resource record to the query before it is sent.

**Identifying and caching EDNS0 support**
When the DNS server receives a request or response from a host containing an OPT record, the DNS server caches the EDNS version supported by the host (such as EDNS0). If there is no OPT record in a request or response from a host, the DNS server's cache will indicate that the host does not support EDNS0. If the cache already indicates that the host does support ENDS0, then cache will not be changed.

The default value for how long a host's EDNS0 support information is cached is 86400 (one day specified in seconds). This value can be modified in the registry.

The DNS server decides that a host does not support EDNS0 when it requests an OPT resource record and receives a response containing one of the following RCODE values in the header, as shown in the following table.

### EDNS0 Failure Code Values

| Name | Value | Description |
|---|---|---|
| FORMERR | 1 | Format Error. The name server did not interpret the OPT resource record. |
| SERVFAIL | 2 | Server Failure. The name server did not process the query because of a problem with the name server. |
| NOTIMPL | 4 | Not Implemented. The name server does not support the kind of query requested. |

(The RCODE field, or response code field, is a 4-bit field set in the header section as part of responses.) In this situation (as a requester), the DNS server identifies that the server does not support EDNS0 and caches this information.

### Note

- When considering packet sizes, you should take account of the network transmission path's discovered Maximum Transmission Unit (MTU), if this information is available. When configuring the UDP packet size to be larger than 512 octets, remember that the UDP packets must travel through devices other than UDP hosts and these devices, such as routers, may not support UDP packets larger than 512 octets. The maximum UDP packet size should always be compared with the MTU, which in some cases may be smaller. It is recommended that you establish the maximum UDP packet length support for all devices, and configure your UDP hosts for this maximum.

**DNSSEC**
Windows Server 2003 DNS provides basic support of the DNS Security Extensions (DNSSEC) protocol as defined in RFC 2535. The current feature support allows DNS servers to perform as secondary DNS servers for existing DNSSEC–compliant, secure zones. DNS supports the storing and loading of the DNSSEC-specific resource records. Currently, a DNS server is not capable

of signing zones and resource records (creating cryptographic digital signatures) or validating the SIG RRs. The DNSSEC resource records are KEY, SIG, and NXT. For more information about resource records, see the "DNS Resource Records Reference" later in this document. For more information about related RFCs, see "Related Information" at the end of this document.

**Server support for DNSSEC**
When loading a zone containing DNSSEC resource records, the DNS server loads these records along with all other types of resource records contained in the zone. When receiving a zone transfer containing DNSSEC resource records (SIG, KEY, NXT), the DNS server writes these records to the zone storage (zone data file or Active Directory) along with all other resource records.

When a DNS server receives a request or response containing DNSSEC resource records, it does not verify the digital signatures but caches the response and uses it for ensuing queries. When a DNS server receives a request for a resource record in a zone also containing DNSSEC resource records, it attaches the appropriate DNSSEC records to the response.

When a signed zone contains resource records for an owner name, including a CNAME resource record for that name, the DNS server will return the DNSSEC resource records associated with the owner name and the CNAME resource record's alias name. The DNS server will not suppress the retrieval of the CNAME resource record, and it will not return a SIG resource record for the canonical name. Rather, it will return the SIG resource record for the alias name.

**Client support for DNSSEC**
The DNS client does not read and store a key for the trusted zone and, consequently, it does not perform any cryptography, authentication, or verification. When a resolver initiates a DNS query and the response contains DNSSEC resource records, programs running on the DNS client will return these records and cache them in the same manner as any other resource records. This is the extent to which Windows XP DNS clients support DNSSEC. When the DNS client receives the SIG RR relating to the RRset, it will not perform an additional query to obtain the associated KEY record or any other DNSSEC records.

Resolvers do not authenticate resource records by verifying the signature information contained in the SIG resource record. The DNS client does not contain any information to indicate which resource records have been authenticated or to what extent they have been authenticated.

When a resolver receives a response or performs a query operation, it does not recognize the checking disabled (CD) query header bit, which in DNSSEC indicates that the data is authenticated by the server according to its policies, nor does it set the authentic data query header bit, which in DNSSEC indicates that unauthenticated data is acceptable to the resolver.

### Note

- If there is a signing agent running on the DNS server running Windows Server 2003 that signs the zone resource records, this DNS server may also be used as a primary server for DNSSEC-compliant secure zones.

**Active Directory Integration**
The DNS Server service is integrated into the design and implementation of Active Directory. Active Directory provides an enterprise-level tool for organizing, managing, and locating resources in a network.

In addition to supporting a conventional way of maintaining and replicating DNS zone files, the implementation of DNS in Windows Server 2003 has the option of using Active Directory as the data storage and replication engine for DNS. DNS is the domain controller location mechanism for Active Directory.

**Benefits of Integrating DNS with Active Directory**
Using Active Directory as the data storage and replication engine provides the following benefits:

- DNS replication is performed by Active Directory, so there is no need to support a separate replication topology for DNS servers.
- Active Directory service replication provides per-property replication.
- Active Directory service replication is secure.
- A primary DNS server is eliminated as a single point of failure. Original DNS replication is single-master and relies on a primary DNS server to update all the secondary servers. Unlike original DNS replication, Active Directory service replication is multimaster; an update can be made to any domain controller in it, and the change will be propagated to other domain controllers. In this way if DNS is integrated into Active Directory service the replication engine will always synchronize the DNS zone information.

Thus Active Directory integration significantly simplifies the administration of a DNS namespace. At the same time, standard zone transfers to other DNS servers (DNS servers other than Windows 2000 Server or Windows Server 2003 DNS servers, as well as earlier versions of Microsoft DNS servers) is still supported.

**How DNS Integrates with Active Directory**

When you install Active Directory on a server, you promote the server to the role of a domain controller for a specified domain. When completing this process, you are prompted to specify a DNS domain name for the Active Directory domain for which you are joining and promoting the server.

### Note

- When specifying the DNS domain name for the first Active Directory domain in the first Active Directory forest, known as the forest root domain, Windows Server 2003 does not support single-label domain names.

If during this process, a DNS server authoritative for the domain that you specified either cannot be located on the network or does not support the DNS dynamic update protocol, you are prompted with the option to install a DNS server. This option is provided because a DNS server is required to locate this server or other domain controllers for members of an Active Directory domain.

Once you have installed Active Directory, you have two options for storing and replicating your zones when operating the DNS server at the new domain controller:

- Standard zone storage, using a text-based file.

  Zones stored this way are located in .dns files that are stored in the systemroot\System32\Dns folder on each computer operating a DNS server. Zone file names correspond to the name you choose for the zone when creating it, such as "example.microsoft.com.dns" if the zone name was "example.microsoft.com."

- Directory-integrated zone storage, using the Active Directory database.

  Zones stored this way are located in the Active Directory tree under the domain or application directory partition. Each directory-integrated zone is stored in a dnsZone container object identified by the name you choose for the zone when creating it.

Zones stored in text files are typically referred to as file-backed zonesand zones stored in Active Directory are referred to as Active Directory-integrated zones.

In Active Directory-integrated DNS, each DNS zone becomes an Active Directory container object (DnsZone). The DnsZone object contains a DnsNode leaf object for every unique name within that zone. The DnsNode object has a DnsRecord multivalued attribute with an instance of a value for every record associated with the object's name.

### Note

- Active Directory-integrated zones can only be loaded onto a domain controller when the Windows Server 2003 DNS Server service is running on the domain controller.

**Replication Model**

When DNS zone information is stored in Active Directory and an update is made to a DNS server, it writes the update data to Active Directory. Active Directory is now responsible for replicating the data to other domain controllers. The DNS servers running on other domain controllers will poll the updates from the Active Directory.

Because Active Directory service uses the multimaster replication model, DNS updates can be written to any Active Directory-integrated DNS server, and the data will automatically be replicated across all the domain controllers.

The ability to write to Active Directory from multiple domain controllers at the same time can create a conflicting situation where the changes are made to the same object on two different DNS servers. The conflict will eventually be resolved in favor of the last update made to the object based on the timestamps of the updates. The same rule is applied in the case where two or more nodes with the same name are created on two or more DNS servers. Until the conflict is resolved and the DNS server, containing invalid update, polls the valid data from the Active Directory, it is possible that requests for the same object made to two different DNS servers will be resolved differently. This is why the Active Directory database is called *loosely consistent*.

Active Directory-integration provides an advantage over file-backed zones. With file-backed zones, only the primary authoritative DNS server for a zone can modify the zone. With Active Directory-integration, all domain controllers for the Active Directory domain where the zone is stored can modify the zone and then replicate the changes to other domain controllers. This replication process is called multimaster replication because multiple domain controllers can update the zone.

Windows Server 2003 domain controllers replicate resource records contained in Active Directory–integrated zones using Active Directory replication. Zones stored in Active Directory can also be transferred to secondary servers to create secondary zones in the same way that file-backed zones are transferred.

Active Directory–integration provides numerous benefits, including fault tolerance, security, simplified management, and more efficient replication of zones.

**Active Directory-integrated Zones**
When you configure a primary zone to be Active Directory–integrated, the zone is stored in Active Directory.

The following figure shows this configuration.

**Active Directory–integrated Zone**

The DNS server component contains only a copy of the zone. When DNS starts up, it reads a copy of the zone from Active Directory (step 1). Then, when the DNS server receives a change, it writes the change to Active Directory (step 2).

Through Active Directory replication, the zone is replicated to other domain controllers in the same domain. Also, through standard zone transfer, the DNS server can send its copy of the zone to any secondary DNS servers that request it. The DNS server can perform both incremental and full zone transfers. The following figure shows how the same zone can be replicated by using both Active Directory replication and standard zone transfer.

**Active Directory Replication and Zone Transfer**

By default, when the DNS Server service starts on a domain controller, it checks whether Active Directory is available and if it contains any DNS zones. If Active Directory does have zones, the DNS Server service loads them from Active Directory. The DNS Server service automatically writes back to the boot file at regular intervals. The boot file can be updated manually by using the DNS console.

The DNS Server service also loads the root hints and server and zone parameters from different locations depending on its settings. The table below shows the locations from which the DNS Server service loads and to which it writes zones, root hints, and server and zone parameters.

**Note**

- Changing the startup type is not recommended and could result in DNS infrastructure errors.

**How the DNS Server Loads Zones, Root Hints, and Parameters**

| Task | Load Data On Startup Set To: From File | Load Data On Startup Set To: From Registry | Load Data On Startup Set To: From Active Directory and Registry |
|---|---|---|---|
| **Read root hints from:** | Root hints file | If available, the root hints file. Otherwise, if the Directory is available and contains root hints, the directory | If the directory is available and contains root hints, from the directory. Otherwise, from the root hints file |
| **Write root hints to:** | Root hints file | Root hints file | If the directory is available, the directory |
| **Read zones from:** | Boot file, to get list of zones, then from zone files | Registry | The directory (for Active Directory–integrated zones) and the registry |
| **Write zones to:** | Boot file and the registry | Registry and, if the zone is Active Directory–integrated, the directory | Registry and, if the zone is Active Directory–integrated, the directory |
| **Read server and zones parameters from:** | Boot file and the registry | Registry and (for Active Directory–integrated zones) the directory | The directory (for Active Directory–integrated zones) and the registry |
| **Write server and zones parameters to:** | Boot file and the registry | Registry (for all zones) and (for Active Directory–integrated zones) the directory | The directory (for Active Directory–integrated zones) and the registry |

If you change the setting of the DNS Server service, it first writes the root hints file, zones, and parameters to the locations specified in the default setting, and then the DNS Server service reads them from the new setting.

**Directory-integrated Zone Storage Location**

Active Directory is an object-oriented X.500-compliant database that organizes resources available on your network in a hierarchical tree-like structure. This database is managed by a set of domain controllers. The portion of the Active Directory database for which a specific domain controller is authoritative is physically located on the same computer as the domain controller is. Every resource in Active Directory is represented by an object. There are two distinct types of objects supported by Active Directory:

- Containers–objects that can contain other container and leaf objects.
- Leafs–objects representing a specific resource within the Active Directory service tree.

Each Active Directory object has attributes associated with it that define particular characteristics of the object.

The classes of objects in the Active Directory database, as well as the attributes of each object, are defined in the Active Directory schema. In other words, the schema contains definitions for each class object available in Active Directory. The following are examples of Active Directory service class objects:

- User
- Group
- Organizational Unit
- DnsZone
- DnsNode

In Windows 2000 Server, Active Directory-integrated zones were stored in the domain partition of the directory. Zones stored in the domain partition are replicated to all domain controllers in the domain. This replication scope is not necessary for some

applications, such as DNS. Windows Server 2003 Active Directory provides a new type of partition, called application directory partition, to enable different replication scopes. Application directory partitions provide storage for application-specific data that can be replicated to any arbitrary set of domain controllers in the forest, as few or as many as needed by the application that uses the data.

**Note**

- At the time a DNS application directory partition is created (manually by an administrator or programmatically by an application), the domain naming flexible single master operations (FSMO) role for the forest must be held by a domain controller running Windows Server 2003. Following application directory partition creation, you can move the domain naming role to a domain controller that is running Windows 2000, if needed.

There are two default Windows Server 2003 DNS application directory partitions created to allow for different DNS zone replication scopes: the forest-wide DNS application directory partition and the domain-wide application directory partition. Active Directory-integrated zones can be stored in the domain or application directory partitions. The following table describes the Windows Server 2003 Active Directory storage options available for DNS zones.

**Windows Server 2003 Active Directory Storage Options**

| **Active Directory Storage Option** | **Description** |
|---|---|
| Domain partition | Active Directory domain partition for each domain in the forest. DNS zones stored in this partition are replicated to all domain controllers in the domain. This is the only Active Directory storage option for DNS zones that are replicated to domain controllers running Windows 2000 Server. |
| Forest-wide DNS application directory partition | DNS application directory partition for the entire forest. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controllers in the forest.<br><br>This DNS application directory partition is created when you install the DNS Server service on the first Windows Server 2003<br><br>domain controller in the forest. |
| Domain-wide DNS application directory partition | DNS application directory partition for each domain in the forest. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controllers in the domain. For the forest root domain, this DNS application directory partition is created when you first install the DNS Server service on a Windows Server 2003 domain controller in the forest.<br><br>For each new domain in the forest (child domain), this DNS application directory partition is created when you first install the DNS Server service on a Windows Server 2003 domain controller for the new domain. |
| Custom DNS application directory partition | DNS application directory partition for any domain controller that is enlisted in its replication scope. This type of DNS application directory partition does not exist by default and must be created. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controller that enlist in the partition. |

**Note**

- You can specify the DNS application directory partition where you want to store the zone by using the DNS console or the Dnscmd support tool, or you can change the zone storage option once the zone is created using DNS console or Dnscmd.

**Active Directory DNS Objects**

By default, Windows Server 2003 Active Directory-integrated zones are stored in the domain-wide application directory partition of the directory. The zone information is stored with the container whose distinguished name is: CN=MicrosoftDNS,DC=DNS domain name. The zone information for zones stored on domain controllers in the example.com domain would be stored in CN=MicrosoftDNS,DC=DomainDnsZones,DC=example,DC=com.

The DNS application directory partitions are not displayed by all Active Directory administrative tools. To see these directory partitions, you can use dnscmd (command-line tool) or ADSI Edit (adsiedit.msc) in Support Tools.

The replication scope of a custom DNS application directory partition is defined by the number of domain controllers enlisted in the partition. By default, only members of the Enterprise Admins group can enlist a DNS server in a DNS application directory partition.

Once a DNS server is enlisted in a DNS application directory partition, you can store DNS zones in that application directory partition using the DNS console. The required FQDN value specifies the name of the new DNS application directory partition. You must use a DNS fully qualified domain name.

The MicrosoftDNS container holds other objects that represent the zones and the individual DNS resource records in those zones. The following table lists the DNS object types that are stored in the Active Directory.

**DNS Objects Stored in Active Directory**

| Object | Description |
|---|---|
| DnsZone | Container created when a zone is stored in Active Directory. |
| DnsNode | Leaf object used to map and associate a name in the zone to resource data. |
| DnsRecord | Multivalued attribute of a dnsNode object used to store the resource records associated with the named node object. |
| DnsProperty | Multivalued attribute of a dnsZone object used to store zone configuration information. |

The MicrosoftDNS container object contains one or more dnsZone container objects. Each dnsZone object represents one zone.

MicrosoftDNS contains the following dnsZone objects:

- The reverse lookup zone, 72.16.172.in-addr.arpa
- The forward lookup zone, example.com
- The root hints, RootDNSServers

You can view DNS objects from within the Active Directory Users and Computers console. The following graphic shows the dnsZone objects in Active Directory.

**DNS Objects in Active Directory**

The dnsZone container object contains a dnsNode leaf object for every unique name within that zone. This figure shows the following dnsNode objects within the dnsZone container object for example.com:

- **@**, which signifies that the node has the same name as the dnsZone object.
- **delegated**, a delegated subdomain.
- **host.notdelegated**, a host in the domain not delegated.example.com, a domain that is controlled by the zone on example.com.
- **host1**, a host in the domain example.com.
- **mailserver**, the mail server in the domain example.com.
- **nameserver**, the name server in example.com.
- **notdelegated**, the domain notdelegated.example.com, which is controlled by the zone on example.com.

The dnsNode leaf object has a multivalued attribute called **dnsRecord** with an instance of a value for every record associated with the object's name. In this example, the dnsNode leaf object mailserver.example.com has an "A" attribute containing the IP address.

Although you can view the zone objects from within the Active Directory Users and Computers component, the Active Directory Users and Computers component cannot interpret the values of the **dnsRecord** attribute. If you want to view the DNS domain hierarchy and associated records, use the DNS console. Alternatively, if you want to view the zones, you can retrieve them by using Nslookup.

**Note**

- Windows 2000 domain controllers do not support application directory partitions and therefore you cannot view zones stored in DNS application directory partitions using Windows 2000 administration tools.

**DNS Processes and Interactions**

DNS processes and interactions involve the communications between DNS clients and DNS servers during the resolution of DNS queries and dynamic update, and between DNS servers during name resolution and zone administration. Secondary processes and interactions depend on the support for technologies such as Unicode and WINS.

For information about TCP/IP DNS messages, see "DNS Protocol" in this document.

**How DNS Queries Work**

When a DNS client needs to look up a name used in a program, it queries DNS servers to resolve the name. Each query message the client sends contains three pieces of information, specifying a question for the server to answer:

1. A specified DNS domain name, stated as a fully qualified domain name.
2. A specified query type, which can either specify a resource record by type or a specialized type of query operation.
3. A specified class for the DNS domain name. For Windows DNS servers, this should always be specified as the Internet (IN) class.

For example, the name specified could be the FQDN for a computer, such as ""host-a.example.microsoft.com."", and the query type specified to look for an address (A) resource record by that name. Think of a DNS query as a client asking a server a two-part question, such as "Do you have any A resource records for a computer named 'hostname.example.microsoft.com.' "? When the client receives an answer from the server, it reads and interprets the answered A resource record, learning the IP address for the computer it asked for by name.

DNS queries resolve in a number of different ways. A client can sometimes answer a query locally using cached information obtained from a previous query. The DNS server can use its own cache of resource record information to answer a query. A DNS server can also query or contact other DNS servers on behalf of the requesting client to fully resolve the name, then send an answer back to the client. This process is known as recursion.

In addition, the client itself can attempt to contact additional DNS servers to resolve a name. When a client does so, it uses separate and additional queries based on referral answers from servers. This process is known as iteration.

In general, the DNS query process occurs in two parts:

- A name query begins at a client computer and is passed to a resolver, the DNS Client service, for resolution.
- When the query cannot be resolved locally, DNS servers can be queried as needed to resolve the name.

Both of these processes are explained in more detail in the following sections.

**Part 1: DNS Client Service Resolver**
The following figure shows an overview of the complete DNS query process.

**Overview of DNS Query Process**

As shown in the initial steps of the query process, a DNS domain name is used in a program on the local computer. The request is then passed to the DNS Client service for resolution using locally cached information. If the queried name can be resolved, the query is answered and the process is completed.

The local resolver cache can include name information obtained from two possible sources:

- If a Hosts file is configured locally, any host name-to-address mappings from that file are preloaded into the cache when the DNS Client service is started.
- Resource records obtained in answered responses from previous DNS queries are added to the cache and kept for a period of time.

If the query does not match an entry in the cache, the resolution process continues with the client querying a DNS server to resolve the name.

**Part 2: Querying a DNS Server**
As indicated in the previous figure, the client queries a preferred DNS server. The actual server used during the initial client/server query is selected from a global list.

When the DNS server receives a query, it first checks to see if it can answer the query authoritatively based on resource record information contained in a locally configured zone on the server. If the queried name matches a corresponding resource record in local zone information, the server answers authoritatively, using this information to resolve the queried name.

If no zone information exists for the queried name, the server then checks to see if it can resolve the name using locally cached information from previous queries. If a match is found here, the server answers with this information. Again, if the preferred server can answer with a positive matched response from its cache to the requesting client, the query is completed.

If the queried name does not find a matched answer at its preferred server — either from its cache or zone information — the query process can continue, using recursion to fully resolve the name. This involves assistance from other DNS servers to help resolve the name. By default, the DNS Client service asks the server to use a process of recursion to fully resolve names on behalf of the client before returning an answer.

In order for the DNS server to do recursion properly, it first needs some helpful contact information about other DNS servers in the DNS domain namespace. This information is provided in the form of root hints, a list of preliminary resource records that can be used by the DNS service to locate other DNS servers that are authoritative for the root of the DNS domain

namespace tree. Root servers are authoritative for the domain root and top-level domains in the DNS domain namespace tree.

By using root hints to find root servers, a DNS server is able to complete the use of recursion. In theory, this process enables any DNS server to locate the servers that are authoritative for any other DNS domain name used at any level in the namespace tree.

For example, consider the use of the recursion process to locate the name “host-b.example.microsoft.com.” when the client queries a single DNS server. The process occurs when a DNS server and client are first started and have no locally cached information available to help resolve a name query. It assumes that the name queried by the client is for a domain name of which the server has no local knowledge, based on its configured zones.

First, the preferred server parses the full name and determines that it needs the location of the server that is authoritative for the top-level domain, “com”. It then uses an iterative query to the “com” DNS server to obtain a referral to the “microsoft.com” server. Next, a referral answer comes from the “microsoft.com” server to the DNS server for “example.microsoft.com”.

Finally, the “example.microsoft.com.” server is contacted. Because this server contains the queried name as part of its configured zones, it responds authoritatively back to the original server that initiated recursion. When the original server receives the response indicating that an authoritative answer was obtained to the requested query, it forwards this answer back to the requesting client and the recursive query process is completed.

Although the recursive query process can be resource-intensive when performed as described above, it has some performance advantages for the DNS server. For example, during the recursion process, the DNS server performing the recursive lookup obtains information about the DNS domain namespace. This information is cached by the server and can be used again to help speed the answering of subsequent queries that use or match it. Over time, this cached information can grow to occupy a significant portion of server memory resources, although it is cleared whenever the DNS service is cycled on and off.

The following three figures illustrate the process by which the DNS client queries the servers on each adapter.

**Querying the DNS Server, Part 1**

**Querying the DNS Server, Part 2**

**Querying the DNS Server, Part 3**

The DNS Client service queries the DNS servers in the following order:

1. The DNS Client service sends the name query to the first DNS server on the preferred adapter's list of DNS servers and waits one second for a response.

2. If the DNS Client service does not receive a response from the first DNS server within one second, it sends the name query to the first DNS servers on all adapters that are still under consideration and waits two seconds for a response.

3. If the DNS Client service does not receive a response from any DNS server within two seconds, the DNS Client service sends the query to all DNS servers on all adapters that are still under consideration and waits another two seconds for a response.

4. If the DNS Client service still does not receive a response from any DNS server, it sends the name query to all DNS servers on all adapters that are still under consideration and waits four seconds for a response.

5. If it the DNS Client service does not receive a response from any DNS server, the DNS client sends the query to all DNS servers on all adapters that are still under consideration and waits eight seconds for a response.

If the DNS Client service receives a positive response, it stops querying for the name, adds the response to the cache and returns the response to the client.

If the DNS Client service has not received a response from any server within eight seconds, the DNS Client service responds with a time-out. Also, if it has not received a response from any DNS server on a specified adapter, then for the next 30 seconds, the DNS Client service responds to all queries destined for servers on that adapter with a time-out and does not query those servers. Only computers running Windows 2000 or Windows Server 2003 return this time-out.

If at any point the DNS Client service receives a negative response from a server, it removes every server on that adapter from consideration during this search. For example, if in step 2, the first server on Alternate Adapter A gave a negative response, the DNS Client service would not send the query to any other server on the list for Alternate Adapter A.

The DNS Client service keeps track of which servers answer name queries more quickly, and it moves servers up or down on

the list based on how quickly they reply to name queries.

The following figure shows how the DNS client queries each server on each adapter.

**Multihomed Name Resolution**

**Alternate Query Responses**

The previous discussion of DNS queries assumes that the process ends with a positive response returned to the client. However, queries can return other answers as well. These are the most common query answers:

- An authoritative answer
- A positive answer
- A referral answer (used by the Windows Server 2003 DNS Server service only)
- A negative answer

An authoritative answer is a positive answer returned to the client and delivered with the authority bit set in the DNS message to indicate the answer was obtained from a server with direct authority for the queried name.

A positive response can consist of the queried RR or a list of RRs (also known as an RRset) that fits the queried DNS domain name and record type specified in the query message.

A referral answer contains additional RRs not specified by name or type in the query. This type of answer is returned to the client if the recursion process is not supported. The records are meant to act as helpful reference answers that the client can use to continue the query using iteration. A referral answer contains additional data such as RRs that are other than the type queried. For example, if the queried host name was "www" and no A RRs for this name were found in this zone but a CNAME RR for "www" was found instead, the DNS server can include that information when responding to the client. If the client is able to use iteration, it can make additional queries using the referral information in an attempt to fully resolve the name for itself.

A negative response from the server can indicate that one of two possible results was encountered while the server attempted to process and recursively resolve the query fully and authoritatively:

- An authoritative server reported that the queried name does not exist in the DNS namespace.
- An authoritative server reported that the queried name exists but no records of the specified type exist for that name.

The resolver passes the results of the query, in the form of either a positive or negative response, back to the requesting program and caches the response.

If the resultant answer to a query is too long to be sent and resolved in a single UDP message packet, the DNS server can initiate a failover response over TCP port 53 to answer the client fully in a TCP connected session.

Disabling the use of recursion on a DNS server is generally done when DNS clients are being limited to resolving names to a specific DNS server, such as one located on your intranet. Recursion might also be disabled when the DNS server is incapable

of resolving external DNS names, and clients are expected to fail over to another DNS server for resolution of these names. If you disable recursion on the DNS server, you will not be able to use forwarders on the same server.

By default, DNS servers use several default timings when performing a recursive query and contacting other DNS servers. These defaults include:

- A recursion retry interval of 3 seconds. This is the length of time the DNS service waits before retrying a query made during a recursive lookup.

- A recursion time-out interval of 15 seconds. This is the length of time the DNS service waits before failing a recursive lookup that has been retried.

Under most circumstances, these parameters do not need adjustment. However, if you are using recursive lookups over a slow-speed WAN link, you might be able to improve server performance and query completion by making slight adjustments to the settings.

**How Iteration Works**
Iteration is the type of name resolution used between DNS clients and servers when the following conditions are in effect:

- The client requests the use of recursion, but recursion is disabled on the DNS server.

- The client does not request the use of recursion when querying the DNS server.

An iterative request from a client tells the DNS server that the client expects the best answer the DNS server can provide immediately, without contacting other DNS servers.

When iteration is used, a DNS server answers a client based on its own specific knowledge about the namespace with regard to the names data being queried. For example, if a DNS server on your intranet receives a query from a local client for "www.microsoft.com", it might return an answer from its names cache. If the queried name is not currently stored in the names cache of the server, the server might respond by providing a referral — that is, a list of NS and A resource records for other DNS servers that are closer to the name queried by the client.

When iteration is used, a DNS server can further assist in a name query resolution beyond giving its own best answer back to the client. For most iterative queries, a client uses its locally configured list of DNS servers to contact other name servers throughout the DNS namespace if its primary DNS server cannot resolve the query.

The Windows Server 2003 DNS Client service does not perform recursion.

**How Caching Works**
As DNS servers process client queries using recursion or iteration, they discover and acquire a significant store of information about the DNS namespace. This information is then cached by the server.

Caching provides a way to speed the performance of DNS resolution for subsequent queries of popular names, while substantially reducing DNS-related query traffic on the network.

As DNS servers make recursive queries on behalf of clients, they temporarily cache resource records (RRs). Cached RRs contain information obtained from DNS servers that are authoritative for DNS domain names learned while making iterative queries to search and fully answer a recursive query performed on behalf of a client. Later, when other clients place new queries that request RR information matching cached RRs, the DNS server can use the cached RR information to answer them.

When information is cached, a Time-To-Live (TTL) value applies to all cached RRs. As long as the TTL for a cached RR does not expire, a DNS server can continue to cache and use the RR again when answering queries by its clients that match these RRs. Caching TTL values used by RRs in most zone configurations are assigned the Minimum (default) TTL which is set in the zone's start of authority (SOA) resource record. By default, the minimum TTL is 3,600 seconds (one hour) but can be adjusted or, if needed, individual caching TTLs can be set at each RR.

### Note

- By default, the DNS Server service uses a root hints file, cache.dns, that is stored in the systemroot\System32\Dns folder on the server computer. This file contains the NS and A resource records for the root servers of the DNS namespace (the Internet root servers or intranet root servers). When the DNS Server service is started, the root server list is queried for a current list of all the root servers. The results of the query are used to update the root hints file. This operation is also performed periodically while the service is running. When changes are made to the root hints by an administrator, these

changes are written back to the root hints file.

**Reverse Lookup**

In most DNS lookups, clients typically perform a forward lookup, which is a search based on the DNS name of another computer as stored in an address (A) resource record. This type of query expects an IP address as the resource data for the answered response.

DNS also provides a reverse lookup process, enabling clients to use a known IP address during a name query and to look up a computer name based on its address. A reverse lookup takes the form of a question, such as "Can you tell me the DNS name of the computer that uses the IP address 192.168.1.20?"

DNS was not originally designed to support this type of query. One problem for supporting the reverse query process is the difference in how the DNS namespace organizes and indexes names and how IP addresses are assigned. If the only method available to answer the previous question was to search all domains in the DNS namespace, a reverse query would take too long and require too much processing to be useful.

To solve this problem, a special domain called the in-addr.arpa domain was defined in the DNS standards and reserved in the Internet DNS namespace to provide a practical and reliable way to perform reverse queries. To create the reverse namespace, subdomains within the in-addr.arpa domain are formed using the reverse ordering of the numbers in the dotted-decimal notation of IP addresses.

This reversed ordering of the domains for each octet value is needed because, unlike DNS names, when IP addresses are read from left to right, they are interpreted in the opposite manner. When an IP address is read from left to right, it is viewed from its most generalized information (an IP network address) in the first part of the address to the more specific information (an IP host address) contained in the last octets.

For this reason, the order of IP address octets must be reversed when building the in-addr.arpa domain tree. The IP addresses of the DNS in-addr.arpa tree can be delegated to companies as they are assigned a specific or limited set of IP addresses within the Internet-defined address classes.

Finally, the in-addr.arpa domain tree, as built into DNS, requires that an additional RR type — the pointer (PTR) RR — be defined. This RR is used to create a mapping in the reverse lookup zone that typically corresponds to a host (A) named RR for the DNS computer name of a host in its forward lookup zone.

The in-addr.arpa domain applies for use in all TCP/IP networks that are based on Internet Protocol version 4 (IPv4) addressing. The New Zone Wizard automatically assumes that you are using this domain when creating a new reverse lookup zone.

If you are installing DNS and configuring reverse lookup zones for an Internet Protocol version 6 (IPv6) network, you can specify an exact name in the New Zone Wizard. This will permit you to create reverse lookup zones in the DNS console that can be used to support IPv6 networks, which use a different special domain name, the ip6.arpa domain.

For information about IPv6 and DNS, including examples of how to create and use ip6.arpa domain names as described in RFC 1886 ("DNS Extensions to support IP version 6"), see "Related Information" at the end of this section.

### Note

- The configuration of PTR resource records and reverse lookup zones for identifying hosts by reverse query is strictly an optional part of the DNS standard implementation. You are not required to use reverse lookup zones, although for some networked applications, they are used to perform security checks.

**Example: Reverse Query (for IPv4 networks)**

The following figure shows an example of a reverse query initiated by a DNS client (host-b) to learn the name of another host (host-a) based on its IP address, 192.168.1.20.

### Reverse Query

The reverse query process as shown in this figure occurs in the following steps:

1. The client, “host-b”, queries the DNS server for a pointer (PTR) RR that maps to the IP address of 192.168.1.20 for “host-a”.

   Because the query is for PTR records, the resolver reverses the address and appends the in-addr.arpa domain to the end of the reverse address. This forms the fully qualified domain name (“20.1.168.192.in-addr.arpa.”) for which to be searched in a reverse lookup zone.

2. Once located, the authoritative DNS server for “20.1.168.192.in-addr.arpa” can respond with the PTR record information. This includes the DNS domain name for “host-a”, completing the reverse lookup

Keep in mind that if the queried reverse name is not answerable from the DNS server, normal DNS resolution (either recursion or iteration) can be used to locate a DNS server that is authoritative for the reverse lookup zone and that contains the queried name. In this sense, the name resolution process used in a reverse lookup is identical to that of a forward lookup.

**Note**

- The DNS console provides a means for you to configure a subnetted reverse lookup “classless” zone when the **Advanced** view is selected. This allows you to configure a zone in the in-addr.arpa domain for a limited set of assigned IP addresses where a nondefault IP subnet mask is used with those addresses.

**Forwarding**

A forwarder is a Domain Name System (DNS) server on a network used to forward DNS queries for external DNS names to DNS servers outside of that network. You can also forward queries according to specific domain names using conditional forwarders.

A DNS server on a network is designated as a forwarder by having the other DNS servers in the network forward the queries they cannot resolve locally to that DNS server. By using a forwarder, you can manage name resolution for names outside of your network, such as names on the Internet, and improve the efficiency of name resolution for the computers in your network.

**Directing Name Queries Using Forwarders**

The following figure illustrates how external name queries are directed using forwarders.

**External Name Queries Directed Using Forwarders**

Without having a specific DNS server designated as a forwarder, all DNS servers can send queries outside of a network using their root hints. As a result, a lot of internal, and possibly critical, DNS information can be exposed on the Internet. In addition to this security and privacy issue, this method of resolution can result in a large volume of external traffic that is costly and inefficient for a network with a slow Internet connection or a company with high Internet service costs.

When you designate a DNS server as a forwarder, you make that forwarder responsible for handling external traffic, thereby limiting DNS server exposure to the Internet. A forwarder will build up a large cache of external DNS information because all of the external DNS queries in the network are resolved through it. In a small amount of time, a forwarder will resolve a good portion of external DNS queries using this cached data and thereby decrease the Internet traffic over the network and the response time for DNS clients.

**Behavior of a DNS Server Configured to Use Forwarding**

A DNS server configured to use a forwarder will behave differently than a DNS server that is not configured to use a forwarder. A DNS server configured to use a forwarder behaves as follows:

1. When the DNS server receives a query, it attempts to resolve this query using the primary and secondary zones that it hosts and its cache.

2. If the query cannot be resolved using this local data, then it will forward the query to the DNS server designated as a forwarder.

3. The DNS server will wait briefly for an answer from the forwarder before attempting to contact the DNS servers specified in its root hints.

When a DNS server forwards a query to a forwarder it sends a recursive query to the forwarder. This is different than the iterative query that a DNS server will send to an other DNS server during standard name resolution (name resolution that does not involve a forwarder).

**Forwarding Sequence**
The sequence in which the forwarders configured on a DNS server are used is determined by the order in which the IP addresses are listed on the DNS server. After the DNS server forwards the query to the forwarder with the first IP address, it waits a short period for an answer from that forwarder (according to the DNS server's time out setting) before resuming the forwarding operation with the next IP address. It continues this process until it receives an affirmative answer from a forwarder.

Unlike conventional resolution, where a roundtrip time (RTT) is associated with each server, the IP addresses in the forwarders list are not ordered according to roundtrip time and must be reordered manually to change preference.

**Forwarders and Delegation**
A DNS server configured with a forwarder and hosting a parent zone will use its delegation information before forwarding queries. If no delegation record exists for the DNS name in the query, then the DNS server will use its forwarders to resolve the query.

**Forwarders and Root Servers**
A common error when configuring forwarding is to attempt to configure forwarding on the root servers of a private DNS namespace. The goal of attempting to configure forwarding on root servers for a private DNS namespace is to forward all offsite queries to Internet DNS servers. Root servers cannot be configured with standard forwarding. If a root server is queried about any domain name, then it will refer to a DNS server that can answer the question (from its local zones, cache), or it will respond with a failure (NXDOMAIN), but it cannot be configured to forward to specific servers.

### Note

- A root server can be configured with a conditional forwarder. Conditional forwarding can be used to forward queries between root servers in separate DNS namespaces, although the DNS servers for the top-level domains in the namespace are better suited for this method of resolution.

**Conditional Forwarders**
A conditional forwarder is a DNS server on a network that is used to forward DNS queries according to the DNS domain name in the query. For example, a DNS server can be configured to forward all the queries it receives for names ending with widgets.example.com to the IP address of a specific DNS server or to the IP addresses of multiple DNS servers.

**Intranet Name Resolution**
A conditional forwarder can be used to improve name resolution for domains within your intranet. Intranet name resolution can be improved by configuring DNS servers with forwarders for specific internal domain names. For example, all DNS servers in the domain widgets.example.com could be configured to forward queries for names that end with test.example.com to the authoritative DNS servers for merged.widgets.example.com, thereby removing the step of querying the root servers of example.com, or removing the step of configuring DNS servers in the widgets.example.com zone with secondary zones for test.example.com.

**Internet Name Resolution**
DNS servers can use conditional forwarders to resolve queries between the DNS domain names of companies that share information. For example, two companies, Widgets Toys and TailspinToys, want to improve how the DNS clients of Widgets Toys resolve the names of the DNS clients of Tailspin Toys. The administrators from Tailspin Toys inform the administrators of Widgets Toys about the set of DNS servers in the Tailspin Toys network where Widgets can send queries for the domain dolls.tailspintoys.com. The DNS servers within the Widgets Toys network are configured to forward all queries for names ending with dolls.tailspintoys.com to the designated DNS servers in the network for Tailspin Toys. Consequently, the DNS servers in the Widgets Toys network do not need to query their internal root servers, or the Internet root servers, to resolve queries for names ending with dolls.tailspintoys.com.

**Dynamic Update**

Dynamic update enables DNS client computers to register and dynamically update their resource records with a DNS server whenever changes occur. This reduces the need for manual administration of zone records, especially for clients that frequently move or change locations and use DHCP to obtain an IP address.

The DNS Client and Server services support the use of dynamic updates, as described in RFC 2136, "Dynamic Updates in the Domain Name System." The DNS Server service allows dynamic update to be enabled or disabled on a per-zone basis at each server configured to load either a standard primary or directory-integrated zone. By default, the Windows Server 2003 DNS Client service will dynamically update host (A) resource records in DNS when configured for TCP/IP. The Windows Server 2003 DNS Server service is configured, by default, to allow only secure dynamic update. You must change this configuration if you will be using dynamic update only.

**Protocol Description**
RFC 2136 introduces a new opcode or message format called UPDATE. The update message can add and delete resource records from a specified zone as well as test for prerequisite conditions. Update is atomic, that is, all prerequisites must be satisfied or no update operation will take place.

As in any conventional DNS implementation, the zone update must be committed on a primary DNS server for that zone. If an update is received by a secondary DNS server, it will be forwarded up the replication topology until it reaches the primary DNS server. Note that in the case of an Active Directory integrated zone, an update for a resource record in a zone may be sent to any DNS server running on an Active Directory domain controller whose data store contains the zone.

A zone transfer process will always lock a zone so that a secondary DNS server receives a consistent zone view while transferring the zone data. When the zone is locked it can no longer accept dynamic updates. If the zone is large and is locked very often for zone transfer purposes, it will starve dynamic update clients, and the system can become unstable. The Windows Server 2003 DNS Server service queues the update requests that arrived during the zone transfer and processes them after the zone transfer is completed.

**How client and server computers update their DNS names**
By default, computers that are statically configured for TCP/IP attempt to dynamically register host (A) and pointer (PTR) resource records for IP addresses configured and used by their installed network connections. All computers register records based on their fully qualified domain name (FQDN).

The following defaults also apply to how computers update their DNS names:

- By default, the DNS client on Windows XP does not attempt dynamic update over a Remote Access Service or virtual private network connection. To modify this configuration, you can modify the advanced TCP/IP settings of the particular network connection or modify the registry.

- By default, the DNS client does not attempt dynamic update of top-level domain (TLD) zones. Any zone named with a single-label name is considered a TLD zone, for example, com, edu, blank, my-company.

- By default, the primary DNS suffix portion of a computer's FQDN is the same as the name of the Active Directory domain to which the computer is joined. To allow different primary DNS suffixes, a domain administrator may create a restricted list of allowed suffixes by modifying the **msDS-AllowedDNSSuffixes** attribute in the domain object container. This attribute is managed by the domain administrator using Active Directory Service Interfaces (ADSI) or the Lightweight Directory Access Protocol (LDAP).

Dynamic updates can be sent for any of the following reasons or events:

- An IP address is added, removed, or modified in the TCP/IP properties configuration for any one of the installed network connections.

- An IP address lease changes or renews with the DHCP server any one of the installed network connections. For example, when the computer is started or if the ipconfig /renew command is used.

- The ipconfig /registerdns command is used to manually force a refresh of the client name registration in DNS.

- At startup time, when the computer is turned on.

- A member server is promoted to a domain controller.

When one of the previous events triggers a dynamic update, the DHCP Client service (not the DNS Client service) sends updates. This is designed so that if a change to the IP address information occurs because of DHCP, corresponding updates in DNS are performed to synchronize name-to-address mappings for the computer. The DHCP Client service performs this function for all network connections used on the system, including connections not configured to use DHCP.

The update process described above assumes that installation defaults are in effect for computers running Windows 2000, Windows XP, or servers running Windows Server 2003. Specific names and update behavior is tunable where advanced TCP/IP properties are configured to use non-default DNS settings.

In addition to the full computer name (or primary name) of the computer, additional connection-specific DNS names can be configured and optionally registered or updated in DNS.

**Example: How dynamic update works**
Dynamic updates are typically requested when either a DNS name or IP address changes on the computer. For example, suppose a client named "oldhost" is first configured in System properties with the following names:

| | |
|---|---|
| Computer name | oldhost |
| DNS domain name of computer | example.microsoft.com |
| Full computer name | oldhost.example.microsoft.com |

In this example, no connection-specific DNS domain names are configured for the computer. Later, the computer is renamed from "oldhost" to "newhost", resulting in the following name changes on the system:

| | |
|---|---|
| Computer name | newhost |
| DNS domain name of computer | example.microsoft.com |
| Full computer name | newhost.example.microsoft.com |

Once the name change is applied in **System properties**, you are prompted to restart the computer. When the computer restarts Windows, the DHCP Client service performs the following sequence to update DNS:

1. The DHCP Client service sends a start of authority (SOA) type query using the DNS domain name of the computer.

   The client computer uses the currently configured FQDN of the computer (such as "newhost.example.microsoft.com") as the name specified in this query.

2. The authoritative DNS server for the zone containing the client FQDN responds to the SOA-type query.

   For standard primary zones, the primary server (owner) returned in the SOA query response is fixed and static. It always matches the exact DNS name as it appears in the SOA RR stored with the zone. If, however, the zone being updated is directory-integrated, any DNS server that is running on a domain controller for the Active Directory domain in the FQDN can respond and dynamically insert its own name as the primary server (owner) of the zone in the SOA query response.

3. The DHCP Client service then attempts to contact the primary DNS server.

   The client processes the SOA query response for its name to determine the IP address of the DNS server authorized as the primary server for accepting its name. It then proceeds to perform the following sequence of steps as needed to contact and dynamically update its primary server:

   - It sends a dynamic update request to the primary server determined in the SOA query response.
   - If the update succeeds, no further action is taken.
   - If this update fails, the client next sends an NS-type query for the zone name specified in the SOA record.
   - When it receives a response to this query, it sends an SOA query to the first DNS server listed in the response.

- After the SOA query is resolved, the client sends a dynamic update to the server specified in the returned SOA record.
- If the update succeeds, no further action is taken.
- If this update fails, then the client repeats the SOA query process by sending to the next DNS server listed in the response.

4. Once the primary DNS server that can perform the update is contacted, the client sends the update request and the DNS server processes it.

   The contents of the update request include instructions to add A (and possibly PTR) resource records for "newhost.example.microsoft.com" and remove these same record types for "oldhost.example.microsoft.com", the name that was previously registered.

   The DNS server also checks to ensure that updates are permitted for the client request. For standard primary zones, dynamic updates are not secured, so any client attempt to update succeeds. For Active Directory–integrated zones, updates are secured and performed using directory-based security settings. For more information, see "Secure Dynamic Updates" later in this document.

Dynamic updates are sent or refreshed periodically. By default, computers send a refresh once every seven days. If the update results in no changes to zone data, the zone remains at its current version and no changes are written. Updates result in actual zone changes or increased zone transfer only if names or addresses actually change.

Note that names are not removed from DNS zones if they become inactive or are not updated within the refresh interval (seven days). DNS does not use a mechanism to release or tombstone names, although DNS clients do attempt to delete or update old name records when a new name or address change is applied.

When the DHCP Client service registers A and PTR resource records for a computer, it uses a default caching Time to Live (TTL) of 15 minutes for host records. This determines how long other DNS servers and clients cache a computer's records when they are included in a query response.

**DNS and DHCP Clients and Servers**
Windows 2000, Windows XP, and Windows Server 2003 DHCP clients are dynamic update-aware and can initiate the dynamic update process. A DHCP client negotiates the process of dynamic update with the DHCP server when the client leases an IP address or renews the lease, determining which computer updates the A and PTR resource records of the client. Depending on the negotiation process, the DHCP client, the DHCP server, or both, update the records by sending the dynamic update requests to the primary DNS servers that are authoritative for the names that are to be updated.

Clients and servers that are running versions of Windows earlier than Windows 2000 do not support dynamic update. The Windows 2000 and Windows Server 2003 DHCP Server service can perform dynamic updates on behalf of clients that do not support the DHCP Client service FQDN option (which is described in the following section). For example, clients that are running Microsoft Windows 95, Windows 98, and Windows NT do not support the FQDN option. However, this functionality can be enabled in the **DNS** tab of the server properties for the DHCP console. The DHCP server first obtains the name of legacy clients from the DHCP REQUEST packet. It then appends the domain name given for that scope and registers the A and PTR resource records.

In some cases, stale PTR or A resource records can appear on DNS servers when the lease of a DHCP client expires. For example, when a Windows 2000, Windows XP or Windows Server 2003 DHCP client tries to negotiate a dynamic update procedure with a Windows NT 4.0 DHCP server, the DHCP client must register both A and PTR resource records itself. Later, if the Windows 2000, Windows XP or Windows Server 2003 DHCP client is improperly removed from the network, the client cannot deregister its A and PTR resource records and they become stale.

If a stale A resource record appears in a zone that allows only secure dynamic updates, no computer is able to register any other resource record for the name in that A resource record. To prevent problems with stale PTR and A resource records, you can enable the aging and scavenging feature. For more information about the aging and scavenging feature, see "Understanding Aging and Scavenging" in this document.

To provide fault tolerance for dynamic updates, consider Active Directory integration for those zones that accept dynamic updates from Windows Server 2003 network-based clients. To speed up the discovery of authoritative DNS servers, you can configure each client with a list of preferred and alternate DNS servers that are primary for that directory-integrated zone. If a

client fails to update the zone with its preferred DNS server because the DNS server is unavailable, the client can try an alternate server. When the preferred DNS server becomes available, it loads the updated, directory-integrated zone that includes the update from the client.

**Dynamic Update Process for Network Connections Configured by DHCP**

To negotiate the dynamic update process, the DHCP client sends its fully qualified domain name (FQDN) to the DHCP server in the DHCPREQUEST packet by using the DHCP Client service FQDN option. The DHCP server then replies to the DHCP client by sending a DHCP acknowledgment (DHCPACK) message that includes the FQDN option (option code 81).

The table below lists the fields of the FQDN option of the DHCPREQUEST packet.

**Fields in the FQDN Option of the DHCPREQUEST Packet**

| Field | Explanation |
|---|---|
| Code | Specifies the code for this option (81). |
| Len | Specifies the length, in octets, of this option (minimum of 4). |
| Flags | Can be one of the following values:<br>0. Client wants to register the A resource record and requests that the server update the PTR resource record.<br>1. Client wants server to register the A and PTR resource records.<br>3. DHCP server registers the A and PTR resource records regardless of the request of the client. |
| RCODE1 and RCODE 2 | The DHCP server uses these fields to specify the response code from the A and PTR resource records registrations performed on the client's behalf and to indicate whether it attempted the update before sending DHCPACK. |
| Domain Name | Specifies the FQDN of the client. |

The conditions under which DHCP clients send the FQDN option and the actions taken by DHCP servers depend on the operating system that the client and server are running and how the client and server are configured.

The client requests a dynamic update depending on whether or not it is running Windows Server 2003 operating system, Windows 2000, or earlier. It also depends on the client configuration. Clients can take any of the following actions:

- By default, the Windows 2000, Windows XP and Windows Server 2003 DHCP Client service sends the FQDN option with the Flags field set to 0 to request that the client update the A resource record, and the DHCP Server service updates the PTR resource record. After the client sends the FQDN option, it waits for a response from the DHCP server. Unless the DHCP server sets the Flags field to 3, the client then initiates an update for the A resource record. If the DHCP server does not support or is not configured to perform registration of the DNS record, then no FQDN is included in the DHCP servers response and the client attempts registration of the A and PTR resource records.

- If the DHCP client is running a Windows operating system earlier than Windows 2000, or if the client is Windows 2000 and it is configured not to register DNS resource records, then the client does not send the FQDN option. In this case, the client does not update either record.

Depending on what the DHCP client requests, the DHCP server can take different actions. If the DHCP client sends a DHCPREQUEST message without the FQDN option, behavior depends on the type of DHCP server and how it is configured. The DHCP server can update both records if it is configured to update records on behalf of DHCP clients that do not support the FQDN option.

In the following cases, the DHCP server does not perform any action:

- The DHCP server does not support dynamic update (for example, a Windows NT 4.0 server).

- The DHCP server is running Windows 2000 or Windows Server 2003 operating system and is configured not to do dynamic updates for clients that do not support the FQDN option.

- The DHCP server is running Windows 2000 or Windows Server 2003 operating system and configured not to register

DNS resource records.

If the Windows 2000, Windows XP or Windows Server 2003 network–based DHCP client requests that the server updates the PTR resource record but not the A resource record, behavior depends on the type of DHCP server and how it is configured. The server can perform any of the following actions:

- If the DHCP server is running Windows 2000 or Windows Server 2003 operating system and is configured not to perform dynamic updates, its response does not contain the FQDN option and does not update either resource record. In this case, the DHCP client attempts to update both the A and PTR resource records, if it capable.

- If the DHCP server is running Windows 2000 or Windows Server 2003 operating system and is configured to update according to the request of the DHCP client, the server attempts to update the PTR resource record. The DHCP server DHCPACK message to the DHCP client contains the FQDN option with the Flags set to 0, confirming that the DHCP server updates the PTR record. The DHCP client then attempts to update the A resource record, if it is capable.

If the DHCP server is running Windows 2000 or Windows Server 2003 operating system and is configured to always update A and PTR both records, the DHCP server attempts to update both resource records. The DHCP server DHCPACK message to the DHCP client contains the FQDN option with the Flags set to 3, notifying the DHCP client that the DHCP server updates A and PTR records. In this case, the DHCP client does not attempt to update either resource record.

**Dynamic Update Process for Statically Configured and Remote Access Clients**
Statically configured clients and remote access clients do not rely on the DHCP server for DNS registration. Statically configured clients dynamically update their A and PTR resource records every time they start and then every 24 hours in case the records become corrupted or need to be refreshed in the DNS database.

Remote access clients can dynamically update A and PTR resource records when a dial-up connection is made. They can also attempt to withdraw, or deregister, the A and PTR resource records when the user closes down the connection explicitly. Computers running Windows 2000 or Windows Server 2003 operating system with a remote access network connection attempt the dynamic registration of the A and PTR records corresponding to the IP address of this connection. By default, the DNS Client service on Windows XP does not attempt dynamic update over a Remote Access Service (RAS) or virtual private network (VPN) connection. To modify this configuration, you can modify the advanced TCP/IP settings of the particular network connection or modify the registry.

In all operating systems, if a remote access client does not receive a successful response from the attempt to deregister a DNS resource record, or if for any other reasons fails to deregister a resource record within four seconds, the DNS client closes the connection. In such cases, the DNS database might contain a stale record.

If the remote access client fails to deregister a DNS resource record, it adds a message to the event log, which you can view by using Event Viewer. The remote access client never deletes stale records, but the remote access server attempts to deregister the PTR resource record when the client is disconnected.

Windows 2000 dial-up networking clients attempt to register A and PTR records for the dial-up connection. By default, the Windows XP and Windows Server 2003 DNS Client service dial-up networking clients do not attempt to update A and PTR records automatically. Due to the nature of their business, it is common that ISPs do not enable dynamic updating of DNS information by their customers. If you use an ISP that does not support dynamic update, configure the connection properties to prevent the computer from performing dynamic updates.

**Dynamic Update Process for Multihomed Clients**
If a dynamic update client is multihomed (has more than one network connection and associated IP address), it registers the first IP address for each network connection by default. If you do not want it to register these IP addresses, you can configure the network connection to not register IP addresses.

The dynamic update client does not register all IP addresses with the DNS servers in all namespaces that the computer is connected to. For example, a multihomed computer, client1.noam.example.com, is connected to both the Internet and the corporate intranet. Client1 is connected to the intranet by adapter A, a DHCP adapter with the IP address 172.16.8.7. Client1 is also connected to the Internet by adapter B, a remote access adapter with the IP address 10.3.3.9. Client1 resolves intranet names by using a name server on the intranet, NoamDC1, and resolves Internet names by using a name server on the Internet, ISPNameServer.

**Time to Live**
Whenever a dynamic update client registers in DNS, the associated A and PTR resource records include the Time to Live (TTL), which by default is set to 10 minutes for records registered by the Net Logon service, and 15 minutes for records registered by the DHCP Client service. If the DNS Server service dynamically registers records for its own zones, the default TTL is 20

minutes. You can change the default setting in the registry. A small value causes cached entries to expire sooner, which increases DNS traffic but decreases the risk of cached records becoming outdated. Expiring entries quickly is useful for computers that frequently renew their DHCP leases. Long retention times are useful for computers that renew their DHCP leases infrequently.

**Resolving Name Conflicts**
When the DNS Client service attempts to register an A record and it discovers that the authoritative DNS zone already contains an A record for the same name but with a different IP address, by default, the DNS Client service attempts to replace the existing A record (s) with the new A record containing the IP address of the DNS client. As a result, any computer on the network can modify the existing A record unless secure dynamic update is used. Zones that are configured for secure dynamic update allow only authorized users to modify the resource record.

You can change the default setting so that the DNS Client service aborts the registration process and logs the error in Event Viewer, instead of replacing the existing A record.

**Secure Dynamic Update**
DNS update security is available only for zones that are integrated into Active Directory. Once you directory-integrate a zone, access control list (ACL) editing features are available in the DNS console so you can add or remove users or groups from the ACL for a specified zone or resource record. ACLs are for DNS administration access control only, and do not influence DNS query resolution.

By default, dynamic update security for DNS servers and clients are handled as follows:

- DNS clients attempt to use unsecured dynamic update first. If an unsecured update is refused, clients try to use secure update.

  Also, clients use a default update policy that permits them to attempt to overwrite a previously registered resource record, unless they are specifically blocked by update security.

- Once a zone becomes Active Directory–integrated, DNS servers running Windows Server 2003 default to allowing only secure dynamic updates.

  When using standard zone storage, the default for the DNS Server service is to not allow dynamic updates on its zones. For zones that are either directory-integrated or use standard file-based storage, you can change the zone to allow all dynamic updates which permits all updates to be accepted.

  Dynamic update is a recent additional DNS standard specification, defined in RFC 2136. For more information about RFCs, see "Related Information" at the end of this document.

  The dynamic registration of DNS resource records can be restricted with the use of registry entries.

**How secure dynamic update works**
The secure dynamic update process is described below:

- To initiate a secure dynamic update, the DNS client first initiates the security context negotiation process, during which the tokens are passed between client and server using TKEY resource records. At the end of the negotiation process the security context is established.

- Next, the DNS client sends the dynamic update request (containing resource records for the purpose of adding, deleting, or modifying data) to the DNS server, signed using the previously established security context and passing the signature in the TSIG resource record, included in the dynamic update packet.

- The server attempts to update Active Directory using the clients credentials and sends the result of the update to the client. These results are signed using the security context and pass the signature in the TSIG resource record included in the response.

**Secure dynamic update process**
The secure dynamic update process is described below:

1. The DNS client queries the preferred DNS server to determine which DNS server is authoritative for the domain name it is attempting to update. The preferred DNS server responds with the name of the zone and the primary DNS server that

is authoritative for the zone.

2. The DNS client attempts a standard dynamic update, and if the zone is configured to allow only secure dynamic updates (the default configuration for Active Directory-integrated zones), the DNS server refuses the non-secure update. Had the zone been configured for standard dynamic update rather than secure dynamic update, the DNS server would have accepted the DNS client's attempt to add, delete, or modify resource records in that zone.

3. The DNS client and DNS server begin TKEY negotiation.

4. First, the DNS client and DNS server negotiate an underlying security mechanism. Windows dynamic update clients and DNS servers can only use the Kerberos protocol.

5. Next, by using the security mechanism, the DNS client and DNS server verify their respective identities and establish the security context.

6. The DNS client sends the dynamic update request to the DNS server, signed using the established security context . The signature is included in the signature field of the TSIG resource record that is included in the dynamic update request packet. The DNS server verifies the origin of the dynamic update packet by using the security context and the TSIG signature.

7. The DNS server attempts to add, delete, or modify resource records in Active Directory. Whether or not it can make the update depends on whether the DNS client has the proper permissions to make the update and whether the prerequisites have been satisfied.

8. The DNS server sends a reply to the DNS client stating whether or not it was able to make the update, signed using the established security context. The signature is included in the signature field of the TSIG resource record that is included in the dynamic update response packet. If the DNS client receives a spoofed reply, it ignores it and waits for a signed response.

   **Note**

   - DHCP clients running Windows 2000, Windows XP, or Windows Server 2003 explicitly request that the DHCP server update only pointer (PTR) resource records used in DNS for the reverse lookup and resolution of the client's IP address to its name. These clients update their address (A) resource records for themselves.

   - Clients running earlier versions of Windows cannot make an explicit request for DNS dynamic update protocol preference. For these clients, the DHCP service updates both the PTR and the A resource records.

**Security for DHCP Clients That Do Not Support the FQDN Option**

Windows DHCP clients that do not support the FQDN option (option 81) are not capable of dynamic updates. If you want the A and PTR resource records for these clients dynamically registered in DNS, you must configure the DHCP server to perform dynamic updates on their behalf.

However, having the DHCP server to perform secure dynamic updates on behalf of DHCP clients that do not support the FQDN option is undesirable because when a DHCP server performs a secure dynamic update on a name, that DHCP server becomes the owner of that name, and only that DHCP server can update any record for that name. This can cause problems in a few different circumstances.

For example, suppose that the DHCP server DHCP1 created an object for the name nt4host1.example.com and then stopped responding, and that later the backup DHCP server, DHCP2, tried to update a record for the same name, nt4host1.example.com. In this situation, DHCP2 is not able to update the name because it does not own the name. In another example, suppose DHCP1 added an object for the name nt4host1.example.com, and then the administrator upgraded nt4host1.example.com to a Windows 2000-based computer. Because the Windows 2000-based computer did not own the name, it would not be able to update DNS records for the name.

To solve this problem, the built-in security group called DnsUpdateProxy is provided. If all DHCP servers are added as members of the DnsUpdateProxy group, one servers records can be updated by another server if the first server fails. Also, because all objects created by the members of the DnsUpdateProxy group are not secured, the first user (that is not a member

of the DnsUpdateProxy group) to modify the set of records associated with a DNS name becomes its owner. When legacy clients are upgraded, they can therefore take ownership of their name records at the DNS server. If every DHCP server registering resource records for older clients is a member of the DnsUpdateProxy group, the problems discussed earlier are eliminated.

**Securing records when using the DnsUpdateProxy group**
DNS domain names that are registered by the DHCP server are not secure when the DHCP server is a member of the DnsUpdateProxy group. As a result, do not use this group in an Active Directory integrated-zone that allows only secure dynamic updates without taking additional steps to allow records created by members of the group to be secured.

To protect against unsecured records, or to allow members of the DnsUpdateProxy group to register records in zones that allow only secured dynamic updates, Windows Server 2003 DHCP and DNS allow you to create a dedicated user account and configure DHCP servers to perform DNS dynamic updates with the user account credentials (user name, password, and domain). The credentials of one dedicated user account can be used by multiple DHCP servers.

The dedicated user account is a standard user account used only is supplying DHCP servers with credentials for DNS dynamic update registrations. Each DHCP server supplies these credentials when registering names on behalf of DHCP clients using DNS dynamic update. The dedicated user account is created in the same forest where the primary DNS server for the zone to be updated resides. The dedicated user account can also be located in another forest as long as the forest it resides in has a forest trust established with the forest containing the primary DNS server for the zone to be updated.

When installed on a domain controller, the DHCP Server service inherits the security permissions of the domain controller and has the authority to update or delete any DNS record that is registered in a secure Active Directory-integrated zone (this includes records that were securely registered by other computers running Windows 2000 or Windows Server 2003, including domain controllers). When installed on a domain controller, configure the DHCP server with the credentials of the dedicated user account to prevent the server from inheriting, and possibly misusing, the power of the domain controller.

Configure a dedicated user account and configure the DHCP Server service with the account credentials under the following circumstances:

- A domain controller is configured to function as a DHCP server.
- The DHCP server is configured to perform DNS dynamic updates on behalf of DHCP clients.
- The DNS zones to be updated by the DHCP server are configured to allow only secure dynamic updates.

Once you have created a dedicated user account, you can configure DHCP servers with the user account credentials by using the DHCP console or by using the Netsh command (**netsh dhcp server set dnscredentials**).

**Note**

- If the supplied credentials belong to an object (such as a computer) that is a member of the DnsUpdateProxy security group, the next object to register the same name record in DNS will become the record owner.
- If you have specified credentials (user name, domain, and password) that the DHCP server uses when registering DHCP client computers in DNS, these credentials are not backed up with either synchronous or asynchronous backup. After a DHCP database is restored, new credentials must be configured.

**Controlling Update Access to Zones and Names**
Access to the DNS zones and resource records stored in Active Directory is controlled access control lists (ACLs). ACLs can be specified for the DNS Server service, an entire zone or for specific DNS names. By default, any authenticated Active Directory user can create the A or PTR resource records in any zone. Once an owner name has been created for a zone (regardless of the type of resource record), only the users or groups specified in the ACL for that name that have write permission are enabled to modify records corresponding to that name. While this approach is desirable in most scenarios, some special situations need to be considered separately.

**DNSAdmins group**
By default, the DNSAdmins group has full control of all zones and records in the Windows Server 2003 domain in which it is specified. In order for a user to be able to enumerate zones in a specific Windows Server 2003 domain, the user (or a group the user belongs to) must be enlisted in the DNSAdmin group.

It is possible that a domain administrator may not want to grant full control to all users listed in the DNSAdmins group.

Typically, this would be the result if a domain administrator wanted to grant full control for a specific zone and read only control for other zones in the domain to a set of users. To accomplish this, the domain administrator can create a separate group for each of the zones, and add specific users to each group. Then the ACL for each zone will contain a group with full control for that zone only. At the same time, all of the groups will be included in the DNSAdmins group, which can be configured to have read permissions only. As a result of the fact that a zone's ACL always contains the DNSAdmins group, all users enlisted in the zone-specific groups will have read permission for all the zones in the domain.

**Reserving names**
The default DNS Server service configuration of allowing any authenticated user to create a new name in a zone may not be sufficient for environments that require a high level of security. In such cases, the default ACL can be changed to allow for the creation of objects in a zone by certain groups or users only. Per-name administration of ACLs provides another solution to this problem. An administrator may reserve a name in a zone leaving the rest of the zone open for the creation of any new objects by all authenticated users. To accomplish this, an administrator creates a record for the reserved name and sets the appropriate list of groups or users in the ACL. As a result, only the users listed in the ACL will be able to register another record under the reserved name.

**Understanding Aging and Scavenging**
DNS servers running Windows Server 2003 support aging and scavenging features. These features are provided as a mechanism for performing cleanup and removal of stale resource records (RRs), which can accumulate in zone data over time.

With dynamic update, RRs are automatically added to zones when computers start on the network. However, in some cases, they are not automatically removed when computers leave the network. For example, if a computer registers its own host (A) RR at startup and is later improperly disconnected from the network, its host (A) RR might not be deleted. If your network has mobile users and computers, this situation can occur frequently.

If left unmanaged, the presence of stale RRs in zone data might cause some problems. The following are examples:

- If a large number of stale RRs remain in server zones, they can eventually take up server disk space and cause unnecessarily long zone transfers.
- DNS servers loading zones with stale RRs might use outdated information to answer client queries, potentially causing the client's to experience name resolution problems on the network.
- The accumulation of stale RRs at the DNS server can degrade its performance and responsiveness.
- In some cases, the presence of a stale RR in a zone could prevent a DNS domain name from being used by another computer or host device.

To solve these problems, the DNS Server service has the following features:

- Time stamping, based on the current date and time set at the server computer, for any RRs added dynamically to primary-type zones. In addition, time stamps are recorded in standard primary zones where aging/scavenging is enabled.
- For RRs that you add manually, a time stamp value of zero is used, indicating that they are not affected by the aging process and can remain without limitation in zone data unless you otherwise change their time stamp or delete them.
- Aging of RRs in local data, based on a specified refresh time period, for any eligible zones. Only primary type zones that are loaded by the DNS Server service are eligible to participate in this process.
- Scavenging for any RRs that persist beyond the specified refresh period. When a DNS server performs a scavenging operation, it can determine that RRs have aged to the point of becoming stale and remove them from zone data. Servers can be configured to perform recurring scavenging operations automatically, or you can initiate an immediate scavenging operation at the server.

  **Note**

  - By default, the aging and scavenging mechanism for the DNS Server service is disabled. It should only be enabled when all parameters are fully understood. Otherwise, the server could be accidentally configured to delete records that should not be deleted. If a record is accidentally deleted, not only will users fail to resolve queries for that record, but any user can create the record and take ownership of it, even on zones configured for secure

dynamic update.

The server uses the contents of each RR-specific time stamp, along with other aging/scavenging properties that you can adjust or configure, to determine when it scavenges records.

**Prerequisites for Aging and Scavenging**
Before the aging and scavenging features of DNS can be used, several conditions must be met:

1. Scavenging and aging must be enabled both at the DNS server and on the zone.

   By default, aging and scavenging of resource records is disabled.

2. Resource records must either be dynamically added to zones or manually modified to be used in aging and scavenging operations.

Typically, only those resource records added dynamically using the DNS dynamic update protocol are subject to aging and scavenging.

You can, however, enable scavenging for other resource records added through non-dynamic means. For records added to zones in this way, either by loading a text-based zone file from another DNS server or by manually adding them to a zone, a time stamp of zero is set. This makes these records ineligible for use in aging/scavenging operations.

In order to change this default, you can administer these records individually, to reset and permit them to use a current (non-zero) time stamp value. This enables these records to become aged and scavenged.

**Note**

- In the case of changing a zone from standard primary to Active Directory–integrated, you might want to enable scavenging of all existing resource records in the zone. To enable aging for all existing resource records in a zone, you can use the AgeAllRecords command, which is available through the dnscmd command-line tool.

**Aging and Scavenging Terminology**
The following list indicates new or revised terms that have been introduced to help specifically when discussing aging and scavenging.

**Current server time** The current date and time on the DNS server. This number can be expressed as an exact numeric value at any point in time.

**No-refresh interval** An interval of time, determined for each zone, as bounded by the following two events:

- The date and time when the record was last refreshed and its time stamp set.

- The date and time when the record next becomes eligible to be refreshed and have its time stamp reset.

This value is needed to decrease the number of write operations to the Active Directory database. By default, this interval is set to seven days. It should not be increased to an unreasonably high level, because the benefits of the aging and scavenging feature might either be lost or diminished.

**Record refresh** When a DNS dynamic update is processed for a resource record when only the resource record time stamp, and no other characteristics of the record, are revised. Refreshes generally occur for the following reasons:

- When a computer is restarted on the network and, if at startup, its name and IP address information are consistent with the same name and address information it used prior to being shut down, it sends a refresh to renew its associated resource records for this information.

- A periodic refresh is sent by the computer while it is running.

- The Windows XP and Windows Server 2003 DNS Client service renews DNS registration of client resource records every 24 hours. When this dynamic update occurs, if the dynamic update request does not cause modification to the DNS database, then it is considered to be a refresh and not a resource record update.

- Other network services make refresh attempts, such as: DHCP servers which renew client address leases, cluster servers which register and update records for a cluster, and the Net Logon service, which can register and update resource records used by Active Directory domain controllers.

**Record update** When a DNS dynamic update is processed for a resource record where other characteristics of the record in addition to its time stamp are revised. Updates generally occur for the following reasons:

- When a new computer is added to the network and, at startup, it sends an update to register its resource records for the first time with its configured zone.

- When a computer with existing records in the zone has a change in IP address, causing updates to be sent for its revised name-to-address mappings in DNS zone data.

- When the Net Logon service registers a new Active Directory domain controller.

**Refresh interval** An interval of time, determined for each zone, as bounded by the following two distinct events:

- The earliest date and time when the record becomes eligible to be refreshed and have its time stamp reset.

- The earliest date and time when the record becomes eligible to be scavenged and removed from the zone database.

This value should be large enough to allow all clients to refresh their records. By default, this interval is set to seven days. It should not be increased to an unreasonably high level, because the benefits of the aging and scavenging feature might either be lost or diminished.

**Resource record (RR) time stamp** A date and time value used by the DNS server to determine removal of the resource record when it performs aging and scavenging operations.

**Scavenging period** When automatic scavenging is enabled at the server, this period represents the time between repetitions of the automated scavenging process. The default value for this is seven days. To prevent deterioration of DNS server performance, the minimum allowed value for this is one hour.

**Scavenging servers** An optional advanced zone parameter that enables you to specify a restricted list of IP addresses for DNS servers that are enabled to perform scavenging of the zone. By default, if this parameter is not specified, all DNS servers that load a directory-integrated zone (also enabled for scavenging) attempt to perform scavenging of the zone. In some cases, this parameter can be useful if it is preferable that scavenging only be performed at some servers loading the directory-integrated zone. To set this parameter, you must specify the list of IP addresses for the servers enabled to scavenge the zone in the ScavengingServers parameter for the zone. This can be done using the dnscmd command, a command-line based tool for administering Windows DNS servers.

**Start scavenging time** A specific time, expressed as a number. This time is used by the server to determine when a zone becomes available for scavenging.

#### When Scavenging Can Start

Once all prerequisites for enabling the use of scavenging are met, scavenging can start for a server zone when the current server time is greater than the value of the start scavenging time for the zone.

The server sets the time value to start scavenging on a per-zone basis whenever any one of the following events occurs:

- Dynamic updates are enabled for the zone.

- A change in the state of the **Scavenge stale resource records** check box is applied. You can use the DNS console to modify this setting at either an applicable DNS server or one of its primary zones.

- The DNS server loads a primary zone enabled to use scavenging. This can occur when the server computer is started or when the DNS Server service is started.

- When a zone resumes service after having been paused.

When any of the previous events occur, the DNS server sets the value of start scavenging time by calculating the following sum:

Current server time + Refresh interval = Start scavenging time

This value is used as a basis of comparison during scavenging operations.

**Example of the aging and scavenging process for a sample record**
To understand the process of aging and scavenging at the server, consider the life span and successive stages of a single resource record, as it is added to a server and zone where this process is in effect and then aged and removed from the database.

1. A sample DNS host, "host-a.example.microsoft.com", registers its host (A) resource record at the DNS server for a zone where aging/scavenging is enabled for use.

2. When registering the record, the DNS server places a time stamp on this record based on current server time.

   After the record time stamp is written, the DNS server does not accept refreshes for this record for the duration of the zone no-refresh interval. It can, however, accept updates prior to that time. For example, if the IP address for "host-a.example.microsoft.com" changes, the DNS server can accept the update. In this case, the server also updates (resets) the record time stamp.

3. Upon expiration of the no-refresh period, the server begins to accept attempts to refresh this record.

   Once the initial no-refresh period ends, the refresh period immediately begins for the record. During this time, the server does not suppress attempts to refresh the record for its remaining life span.

4. During and after the refresh period, if the server receives a refresh for the record, it processes it.

   This resets the time stamp for the record based on the method described in step 2.

5. When subsequent scavenging is performed by the server for the "example.microsoft.com" zone, the record (and all other zone records) are examined by the server.

   Each record is compared to current server time on the basis of the following sum to determine whether the record should be removed:

   Record time stamp + **No-refresh interval** for zone + **Refresh interval** for zone

   - If the value of this sum is greater than current server time, no action is taken and the record continues to age in the zone.

   - If the value of this sum is less than current server time, the record is deleted both from any zone data currently loaded in server memory and also from the applicable DnsZone object store in Active Directory for the directory-integrated "example.microsoft.com" zone.

**Unicode Character Support**
Originally, Internet host names were restricted to the character set specified in RFCs 952 and 1123. These restrictions include limiting names to using uppercase and lowercase letters (A-"Z", a-z), numbers (0-9) and hyphens (-). In addition, the first character of the DNS name can be a number and names must be encoded and represented using US-ASCII-based characters.

These requirements were maintained when DNS was introduced as part of RFC 1035, one of the core DNS standards specifications. For use of DNS in international settings, this requirement has significant limitations where extended character sets are used for local naming standards.

To remove these limitations, Microsoft expands DNS character support beyond the RFC 1035 specification. The DNS service now provides enhanced default support for UTF-8, a Unicode transformation format.

**What is UTF-8?**
UTF-8 is the recommended character set for protocols evolving beyond the use of ASCII. The UTF-8 protocol provides for

support of extended ASCII characters and translation of UCS-2, a 16-bit Unicode character set that encompasses most of the world's writing systems. UTF-8 enables a far greater range of names than can be achieved using ASCII or extended ASCII encoding for character data.

Computers running Windows 2000, Windows XP, and Windows Server 2003 operating systems are UTF-8 aware. This means that when UTF-8 encoded characters are received or used as data by the server, the server can load and store this data in its zones. Although Windows-based DNS servers are UTF-8 aware, they remain compatible with other DNS servers that use traditional US-ASCII data encoding and current DNS standards.

**How the DNS Service Implements UTF-8**
To provide standards compatibility and interoperability with other DNS implementations, the DNS service uses uniform downcasing of any received character data. In this process, the DNS service converts all uppercase characters used in standard US-ASCII data to lowercase equivalent data for the following reasons:

- To maintain compatibility with current and existing DNS standards.
- To provide interoperability with DNS server implementations that do not recognize or support UTF-8 encoding.

To understand why uniform downcasing was chosen, several related points must first be considered from the current revised Internet standards for DNS. Several key points in the standards pertain directly to how character data is to be handled between DNS servers and other servers and clients. These include the following:

- Any binary string can be used in a DNS name. (RFC 2181)
- DNS servers must be able to compare names in a case-insensitive way. (RFC 1035)
- The original case for character data should be preserved whenever possible as the data is entered into the system. (RFC 1035)

Because case insensitivity is a required part of the core DNS standard and case preservation is an optional recommendation, uniform downcasing was chosen to provide an effective standards-compliant solution. By downcasing UTF-8 encoded names before transmission, other DNS servers (which are not UTF-8 aware) are able to receive and perform successful binary comparisons of the data and obtain the desired results.

**Considerations for Interoperability With UTF-8**
The DNS Server service can be configured to allow or disallow the use of UTF-8 characters on a per-server basis. Although other DNS server implementations that are not UTF-8 aware might be able to accept the transfer of a zone containing UTF-8 encoded names, these servers might not be able to write back those names to a zone file or reload those names from a zone file. Administrators should exercise caution when transferring a zone containing UTF-8 names to a DNS server that is not UTF-8-aware.

Some protocols place restrictions on the characters allowed in a name. In addition, names that are intended to be globally visible (RFC 1958) should contain ASCII-only characters, as recommended in RFC 1123.

The use of UTF-8 for transformation of Unicode characters is not noticeable for general users. Only where Network Monitor or another similar tool is used to analyze DNS-related traffic over the physical network are UTF-8 encoded characters observable.

In addition to DNS server support for the UTF-8 encoding format, the client resolver defaults to using the UTF-8 character encoding format.

Names encoded in UTF-8 format must not exceed the size limits clarified in RFC 2181, which specifies a maximum of 63 octets per label and 255 octets per name. Character count is insufficient to determine size because some UTF-8 characters exceed one octet in length.

The UTF-8 encoding protocol adapts to use with existing DNS protocol implementations that expect US-ASCII characters because representation of US-ASCII characters in UTF-8 is identical, byte for byte, to the US-ASCII representation. DNS client or server implementations that do not recognize UTF-8 characters always encode names in the US-ASCII format. Those names are correctly interpreted by the DNS Server service.

The DNS service provides the ability to configure name checking to allow or restrict the use of UTF-8 characters in DNS data.

By default, multibyte UTF-8 name checking is used, allowing the greatest tolerance when the DNS service processes characters. This is the preferred name-checking method for most privately operated DNS servers that are not providing name service for

Internet hosts.

**WINS Lookup Integration**
Support for using Windows Internet Name Service (WINS) is provided to look up DNS names that cannot be resolved by querying the DNS domain namespace. To accomplish WINS lookup, two specific resource record types are used and can be enabled for any zones loaded by the DNS service:

- The WINS resource record, which can be enabled to integrate WINS lookup into forward lookup zones
- The WINS-R resource record, which can be enabled to integrate node adapter status request for reverse lookup zones

**WINS Resource Record**
The WINS and DNS services are used to provide name resolution for the NetBIOS namespace and the DNS domain namespace, respectively. Although both DNS and WINS can provide a separate and useful name service to clients, WINS is mainly needed to provide support for older clients and programs that require support for NetBIOS naming.

However, the DNS service can work with WINS to provide combined name searches in both namespaces when resolving a DNS domain name not found in zone information. To provide this interoperability, a new record (the WINS record) was defined as part of the zone database file.

The WINS resource record is specific to computers running Windows NT 4.0 and earlier, Windows 2000, and Windows Server 2003 operating systems and can be attached only to the domain of origin for a zone. The presence of a WINS resource record can instruct the DNS service to use WINS to look up any forward queries for host names or names that are not found in the zone database. This functionality is particularly useful for name resolution required by clients that are not WINS-aware (for example, UNIX) for the names of computers not registered with DNS, such as Windows 95 or Windows 98 computers.

**How WINS Lookup Works**
The following is an example of a DNS client (host-b)querying its DNS server in an attempt to look up the address for another computer named "host-a.example.microsoft.com."

**WINS Lookup**

In Step 1, the client queries its preferred DNS server. In Steps 2 through 8, the normal process of recursion proceeds as the preferred DNS server queries other DNS servers in succession on behalf of the client. This process concludes at Step 8, when the DNS server for the example.microsoft.com zone is located through the previous chain of referral answers. At this point in the process, the server contacted is a DNS server either running Windows NT Server 4.0, Windows 2000, or Windows Server 2003.

When the DNS server for the example.microsoft.com zone receives the query for host-a, it looks in its configured zone to see if a matching address (A) resource record (RR) can be found. If no A record is found and the zone is enabled to use WINS lookup, the server does the following:

- The DNS server separates the host part of the name (host-a) from the fully qualified domain name contained in the DNS query.

  The host part of the name is the first label in the queried DNS domain name before a period is used in the name.

- The server then sends a NetBIOS name request to the WINS server using the host name, host-a.

- If the WINS server can resolve the name, it returns the IP address to the DNS server.
- The DNS server then compiles an A resource record using the IP address resolved through the WINS server and returns this record to the original preferred DNS server that was queried by the requesting client, host-b.
- The preferred DNS server then passes the query answer back to the requesting client.

**How WINS Reverse Lookup Works**

There is also a WINS-R record or WINS reverse lookup entry that can be enabled and added to reverse lookup zones. However, because the WINS database is not indexed by IP address, the DNS service cannot send a reverse name lookup to WINS to get the name of a computer given its IP address.

Because WINS does not provide reverse lookup capability, the DNS service instead sends a node adapter status request directly to the IP address implied in the DNS reverse query. When the DNS server gets the NetBIOS name from the node status response, it appends the DNS domain name back onto the NetBIOS name provided in the node status response and forwards the result to the requesting client.

**Note**

- WINS and WINS-R resource records are proprietary to the DNS Server service provided by Windows. You can prevent these resource records from being included in zone transfers to other DNS server implementations. For more information, see "How WINS Lookup Works" in this section.

**Network Ports Used By DNS**

During DNS resolution, DNS messages are sent from DNS clients to DNS servers or between DNS servers. Messages are sent over UDP and DNS servers bind to UDP port 53. When the message length exceeds the default message size for a User Datagram Protocol (UDP) datagram (512 octets), the first response to the message is sent with as much data as the UDP datagram will allow, and then the DNS server sets a flag indicating a truncated response. The message sender can then choose to reissue the request to DNS server using TCP (over TCP port 53). The benefit of this approach is that it takes advantage of the performance of UDP but also has a backup failover solution for longer queries.

In general, all DNS queries are sent from a high-numbered source port (above 1023) to destination port 53, and responses are sent from source port 53 to a high-numbered destination port. The following table lists the UDP and TCP ports used for different DNS message types.

**UDP and TCP Port Assignments for DNS Servers**

| Traffic Type | Source of Transmission | Source Port | Destination of Transmission | Destination Port |
|---|---|---|---|---|
| Queries from local DNS server | Local DNS server | Any port number above 1023 | Any remote DNS server | 53 |
| Responses to local DNS server | Any remote DNS server | 53 | Local DNS server | Any port number above 1023 |
| Queries from remote DNS server | Any remote DNS server | Any port number above 1023 | Local DNS server | 53 |
| Responses to remote DNS server | Local DNS server | 53 | Any remote DNS server | Any port number above 1023 |

**Note**

- The Windows Server 2003 DNS Server service supports Extension Mechanisms for DNS (EDNS0 as defined in RFC 2671), which allow DNS requestors to advertise the size of their UDP packets and facilitate the transfer of packets larger than 512 bytes. When a DNS server receives a request over UDP, it identifies the requestor's UDP packet size from the option (OPT) resource record and scales its response to contain as many resource records as are allowed in the maximum UDP packet size specified by the requestor.

- Windows Server 2003 DNS support for EDNS0 is enabled by default. It can be disabled using the registry. Locate the following registry subkey:
- HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters
- Add the entry **EnableEDNSProbes** to the subkey. Give the entry a DWORD value and set it to 0x0 to disable EDNS0.
- Use extreme caution when editing the registry Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system.

**Related Information**
The following resources contain additional information that is relevant to this section.

**RFCs for the DNS Server Service**
Request for Comments (RFCs) are an evolving series of reports, proposals for protocols, and protocol standards used by the Internet community. Domain Name System (DNS) specifications are based on approved RFCs published by the Internet Engineering Task Force (IETF) and other working groups.

The following RFCs can be found in the IETF RFC Database. These documents contain specifications used to design and implement the DNS Server service and DNS Client service.

- RFC 1034 -- Domain Names — Concepts and Facilities
- RFC 1035 -- Domain Names — Implementation and Specification
- RFC 1123 -- Requirements for Internet Hosts — Application and Support
- RFC 1886 -- DNS Extensions to Support IP Version 6
- RFC 1995 -- Incremental Zone Transfer in DNS
- RFC 1996 -- A Mechanism for Prompt Notification of Zone Changes (DNS NOTIFY)
- RFC 2136 -- Dynamic Updates in the Domain Name System (DNS UPDATE)
- RFC 2181 -- Clarifications to the DNS Specification
- RFC 2308 -- Negative Caching of DNS Queries (DNS NCACHE)
- RFC 2535 -- Domain Name System Security Extensions (DNSSEC)
- RFC 2671 -- Extension Mechanisms for DNS (EDNS0)
- RFC 2782 -- A DNS RR for specifying the location of services (DNS SRV)

**Internet Drafts for DNS**
The following Internet drafts contain specifications used to design and implement the DNS Server service and DNS Client service:

- Draft-skwan-utf8-dns-02.txt -- Using the UTF-8 Character Set in the Domain Name System
- Draft-ietf-dhc-dhcp-dns-08.txt -- Interaction between DHCP and DNS
- Draft-ietf-dnsind-tsig-11.txt -- Secret Key Transaction Signatures for DNS (TSIG)
- Draft-ietf-dnsind-tkey-00.txt -- Secret Key Establishment for DNS (TKEY RR)

- Draft-skwan-gss-tsig-04.txt -- GSS Algorithm for TSIG (GSS-TSIG)

**Other Specifications for DNS**

The following additional specification is used to design and implement the DNS Server service and DNS Client service. This specification is published by the ATM Forum. You can obtain this specification by downloading it from the ATM Forum FTP site.

- af-saa-0069.000.doc -- ATM Name System Specification version 1.0

**Obtaining DNS RFCs and Other Internet Draft Specifications**

You can obtain RFCs and other Internet drafts from the RFC Editor Web site. RFCs are classified as one of the following: approved Internet standards, proposed Internet standards (circulated in draft form for review), Internet best practices, or For Your Information (FYI) documents. Internet drafts are not assigned an RFC number but are specifications currently in the proposal stage and generally published by one of the IETF working groups, of which several groups focus on discussion of DNS-related topics.

### Note

- RFCs 1034 and 1035 define the original DNS standard protocol to support domain name services in a TCP/IP environment. These RFCs describe the protocols in a detailed manner, emphasizing the underlying ideas and techniques used in all DNS implementations.

**DNS Resource Records Reference**

A DNS database consists of one or more zone files used by the DNS server. Each zone holds a collection of structured resource records, the following of which are supported by the DNS Server service.

**Format of DNS Resource Records**

All resource records have a defined format that uses the same top-level fields, as described in the following table.

### Format of DNS Resource Records

| Field | Description |
|---|---|
| Owner | Indicates the DNS domain name that owns a resource record. This name is the same as that of the console tree node where a resource record is located. |
| Time to Live (TTL) | For most resource records, this field is optional. It indicates a length of time used by other DNS servers to determine how long to cache information for a record before expiring and discarding it.<br><br>For example, most resource records created by the DNS Server service inherit the minimum (default) TTL of 1 hour from the start of authority (SOA) resource record which prevents overlong caching by other DNS servers.<br><br>For an individual resource record, you can specify a record-specific TTL that overrides the minimum (default) TTL inherited from the SOA RR. TTL values of zero are not recommended as they increase DNS server utilization unnecessarily.<br><br>In the resource record examples below, the TTL field is omitted wherever it is optional. The TTL field is included in the syntax for each record to indicate where it may be added. |
| Class | Contains standard mnemonic text indicating the class of the resource record. For example, a setting of “IN” indicates that the resource record belongs to the Internet class, which is the only class supported by Windows Server 2003 DNS. This field is required. |
| Type | Contains standard mnemonic text indicating the type of resource record. For example, a mnemonic of “A” indicates that the resource record stores host address information. This field is required. |
| Record-specific data | A required, variable-length field that contains information describing the resource. The format of this information varies according to the type and class of the resource record. |

**DNS Resource Records (Alphabetical List)**

**A**

**Description:** Host address (A) resource record. Maps a DNS domain name to an Internet Protocol (IP) version 4 32-bit address. For more information, see RFC 1035.

**Syntax::**

*owner class ttl* **A** *IP_v4_address*

**Example:**

```
host1.example.microsoft.com.      IN A 127.0.0.1
```

**AAAA**

**Description:** IPv6 host address (AAAA) resource record. Maps a DNS domain name to an Internet Protocol (IP) version 6 128-bit address. For more information, see RFC 1886.

**Syntax:** *owner class ttl* **AAAA** *IP_v6_address*

**Example:**

```
ipv6_host1.example.microsoft.com.      IN AAAA 4321:0:1:2:3:4:567:89ab
```

**AFSDB**

**Description:** Andrew File System Database (AFSDB) resource record. Maps a DNS domain name in the *server_host_name* field to the host name for a server computer of a server subtype. The **subtype** field can have either of the following recognized and supported values:

- A value of **1** to indicate that the server is an AFS version 3.0 volume location server for the named AFS cell.
- A value of **2** to indicate that the server is an authenticated name server holding the cell-root directory node for the server that uses either Open Software Foundation's (OSF) DCE authenticated cell-naming system or HP/Apollo's Network Computing Architecture (NCA).

For more information, see RFC 1183.

**Syntax::**

*owner ttl class* **AFSDB** *subtype server_host_name*

**Example:**

```
example.microsoft.com.   AFSDB   1 afs-server1.example.microsoft.com.
```

**ATMA**

**Description:** Asynchronous Transfer Mode address (ATMA) resource record. Maps a DNS domain name in the *owner* field to an ATM address referenced in the *atm_address* field.

For more information, see "ATM Name System Specification Version 1.0" at the ATM Forum FTP site. At the ATM Forum FTP site, download **af-saa-0069.000.doc** or **af-saa-0069.000.rtf**.

**Syntax:** *owner ttl class* **ATMA** *atm_address*

**Example:**

```
atm-host   ATMA   47.0079.00010200000000000000.00a03e000002.00
```

**CNAME**

**Description:** Canonical name (CNAME) resource record. Maps an aliased or alternate DNS domain name in the **owner** field to a canonical or primary DNS domain name specified in the *canonical_name* field. The canonical or primary DNS domain name used in the data is required and must resolve to a valid DNS domain name in the namespace.

| |
|---|
| **Syntax:** *owner ttl class* **CNAME** *canonical_name* |
| **Example:**<br>`aliasname.example.microsoft.com.  CNAME  truename.example.microsoft.com.` |

**HINFO**

| |
|---|
| **Description:** Host information (HINFO) resource record. Specifies the type of CPU and operating system in the *cpu_type* and *os_type* fields, respectively, for the host DNS domain name in the **owner** field. Well-known CPU and operating system types that are most often used are noted in RFC 1700. This information can be used by application protocols such as FTP, which use special procedures when communicating with computers of a known CPU and operating system type. |
| **Syntax:** *owner ttl class* **HINFO** *cpu_type os_type* |
| **Example:**<br>`my-computer-name.example.microsoft.com.  HINFO  INTEL-386 WIN32` |

**ISDN**

| |
|---|
| **Description:** Integrated Services Digital Network (ISDN) resource record. Maps a DNS domain name to an ISDN telephone number. Telephone numbers used with this record should follow ITU-T E.163/E.164 international telephone numbering standards, which are compatible with current international phone numbering plans already in use. For more information, see RFC 1183. |
| **Syntax:** *owner ttl class* **ISDN** *isdn_address sub_address* |
| **Example:**<br>`my-isdn-host.example.microsoft.com.  ISDN  141555555539699 002` |

**KEY**

| |
|---|
| **Description:** Public key resource record. Contains a public key that is associated with a zone. In full DNSSEC implementation, resolvers and servers use KEY resource records to authenticate SIG resource records received from a signed zones. KEY resource records are signed by the parent zone, allowing a server that knows a parent zone's public key to discover and verify the child zone's key. Name servers or resolvers receiving resource records from a signed zone obtain the corresponding SIG record then retrieve the zone's KEY record. For more information, see RFC 2535. |
| **Syntax:** *owner class* **KEY** *protocol digital_signature_algorithm (DSA) public_key* |
| **Example:**<br>`widgets.microsoft.com IN KEY 0x0000 3 0` |

**MINFO**

| |
|---|
| **Description:** Mailbox mail list information (MINFO) resource record. Specifies (in *responsible_mailbox*) a domain mailbox name for a responsible person who maintains a mailing list or mailbox specified in the **owner** field. The *error_mailbox* field can also be used to specify a domain mailbox that receives error messages related to this mailing list or mailbox. Mailboxes specified for responsible contacts and error forwarding must be the same as valid mailbox (MB) records that already exist in the current zone. For more information, see RFC 1035. |
| **Syntax:** *owner ttl class* **MINFO** *responsible_mailbox error_mailbox* |
| **Example:**<br>`administrator.example.microsoft.com.  MINFO resp-mbox.example.microsoft.com err-mbox.example.microsoft.com` |

**MX**

| |
|---|
| **Description:** Mail exchanger (MX) resource record. Provides message routing to a mail exchanger host, as specified in *mail_exchanger_host*, for mail sent to the domain name specified in the **owner** field. A 2-digit preference value indicates preferred ordering if multiple exchanger hosts are specified. Each exchanger host must have a corresponding host (A) address resource record in a valid zone. For more information, see RFC 1035. |
| **Syntax:** *owner ttl class* **MX** *preference mail_exchanger_host* |
| **Example:**<br>`example.microsoft.com. MX 10 mailserver1.example.microsoft.com` |

**NS**

| |
|---|
| **Description:** Used to map a DNS domain name as specified in **owner** to the name of hosts operating DNS servers specified in the *name_server_domain_name* field. |
| **Syntax:** *owner ttl* IN **NS** *name_server_domain_name* |
| **Example:**<br>`example.microsoft.com.  IN NS nameserver1.example.microsoft.com` |

**NXT**

| |
|---|
| **Description:** Next resource record. NXT resource records indicate the nonexistence of a name in a zone by creating a chain of all of the literal owner names in that zone. They also indicate what resource record types are present for an existing name. For more information, see RFC 2535. |
| **Syntax:** *owner class* **NXT** *next_domain_name last_record_type NXT* |
| **Example:**<br>`east.widgets.microsoft.com. IN NXT ftp.widgets.microsoft.com. A NXT` |

**OPT**

| |
|---|
| **Description:** Option resource record. One OPT resource record can be added to the additional data section of either a DNS request or response. An OPT resource record belongs to a particular transport level message, such as UDP, and not to actual DNS data. Only one OPT resource record is allowed, but not required, per message. For more information, see RFC 2671. |
| **Syntax:** *name* **OPT** *class ttl rdlen rdata* |
| **Example:**<br>`null OPT IN 1280 0 0` |

**PTR**

| |
|---|
| **Description:** Pointer (PTR) resource record. Points from the name in **owner** to another location in the DNS namespace as specified by *targeted_domain_name*. Often used in special domains such as the in-addr.arpa domain tree to provide reverse lookups of address-to-name mappings. In most cases, each record provides information that points to another DNS domain name location, such as a corresponding host (A) address resource record in a forward lookup zone. For more information, see RFC 1035. |
| **Syntax:** *owner ttl class* **PTR** *targeted_domain_name* |
| **Example:**<br>`1.0.0.10.in-addr.arpa.  PTR host.example.microsoft.com.` |

**RP**

**Description:** Responsible Person (RP) resource record. Specifies the domain mailbox name for a responsible person in *mailbox_name*. This name is then mapped to a domain name in *text_record_name* for which (TXT) resource records exist in the same zone. When RP records are used in DNS queries, subsequent queries are used to retrieve associated text (TXT) resource record information. For more information, see RFC 1183.

**Syntax:** *owner ttl class* **RP** *mailbox_name text_record_name*

**Example:**

```
example.microsoft.com. RP admin.example.microsoft.com.
admin-info.example.microsoft.com.
admin-info.example.microsoft.com. TXT "Joe Administrator,
(555) 555-0110"
```

**SIG**

**Description:** Signature resource record. Encrypts an RRset to a signer's (RRset's zone owner) domain name and a validity interval. For more information, see RFC 2535.

**Syntax:**

*owner class* **SIG** *ttl signature_expiration signature_inception key_identifier signer_name{digital_signature}*

**Example:**

```
widgets.microsoft.com IN SIG 86400 19700101000000 19700101000000 49292

widgets.microsoft.com.{

AIYADP8d3zYNyQwW2EM4wXVFdslEJcUx/fxkfBeH1El4ixPFhpfHF
ElxbvKoWmvjDTCmfiYy2X+8XpFjwICHc398kzWsTMKlxovpz2FnCTM=

}
```

**SOA**

**Description:** Start of authority (SOA) resource record. Indicates the name of origin for the zone and contains the name of the server that is the primary source for information about the zone. It also indicates other basic properties of the zone. The SOA resource record is always first in any standard zone. It indicates the DNS server that either originally created it or is now the primary server for the zone. It is also used to store other properties such as version information and timings that affect zone renewal or expiration. These properties affect how often transfers of the zone are done between servers authoritative for the zone.

In the example below, the owner (primary DNS server) is specified as "@" because the domain name is the same as the origin of all data in the zone (example.microsoft.com.). This is a standard notation convention for resource records and is most often seen in the SOA record.

**Syntax:**

*owner class* **SOA** *name_server responsible_person (serial_number refresh_interval retry_interval expiration minimum_time_to_live)*

**Example:**

```
@   IN SOA     nameserver.example.microsoft.com.
postmaster.example.microsoft.com. (
1            ; serial number
3600         ; refresh   [1h]
600          ; retry     [10m]
86400        ; expire    [1d]
3600 )       ; min TTL   [1h]
```

**SRV**

**Description:** Service locator (SRV) resource record. Allows multiple servers providing a similar TCP/IP-based service to be located using a single DNS query operation. This record enables you to maintain a list of servers for a well-known server port and transport protocol type ordered by preference for a DNS domain name. For example, in Windows Server 2003 DNS, it provides the means to locate domain controllers that use Lightweight Directory Access Protocol (LDAP) service over TCP port 389.

The purposes of each of the specialized fields used in an SRV resource record are as follows:

**service** A symbolic name for the desired service. For well-known services, a reserved universal symbolic name such as "_telnet" or "_smtp" is defined in RFC 1700. If a well-known service name is not defined in RFC 1700, a local or user-preferred name can be used instead. Some widely used TCP/IP services, notably the Post Office Protocol (POP), do not have a single universal symbolic name. If RFC 1700 assigns a name for a service indicated in this field, the RFC-defined name is the only name that is legal to use. Only locally defined services can be named locally.

**protocol** Indicates the transport protocol type. Typically, this is either TCP or UDP, although any transport protocol named in RFC 1700 can be used.

**name** The DNS domain name referred to by this resource record. The SRV resource record is unique among other DNS record types in that it is not used to perform the search or query.

**priority** Sets the preference for a host specified in the **target** field. DNS clients that query for SRV resource records attempt to contact the first reachable host of the lowest numbered preference listed here. Although target hosts have the same stated preference value, they can be tried in random order. The range of preference values is 0 to 65535.

**weight** Can be used in addition to *preference* to provide a load-balancing mechanism where multiple servers are specified in the **target** field and are all set to the same level of preference. When selecting a target server host among those of equal preference, this value can be used to set an added level of preference that can be used to determine the exact order or balancing of selection for the target hosts used in an answered SRV query. When a non-zero value is used, servers of equal preference are tried in proportion to the weight of this value. The range of values is 1 to 65535. If load balancing is not needed, use a value of **0** in this field to make the record easier to read.

**port** The server port on the **target** host that provides the service indicated in the **service** field. The range of port numbers is 0 to 65535, although the number is often a well-known assigned service port number, as specified in RFC 1700. Unassigned ports can be used as needed.

**target** Specifies the DNS domain name of the host that provides the type of service being requested. For each host name used, a corresponding host address (A) resource record in the DNS namespace is required. A single period (**.**) can be used in this field to indicate authoritatively that the requested service specified in this SRV resource record is not available at this DNS domain name.

For more information, see the Internet draft "A DNS RR for specifying the location of services (DNS SRV)."

**Syntax:** service.protocol.name ttl class **SRV** preference weight port target

**Example:**

```
_ldap._tcp._msdcs    SRV 0 0   389 dc1.example.microsoft.com
SRV 10 0   389 dc2.example.microsoft.com
```

**TXT**

**Description:** Text (TXT) resource record. Maps a DNS domain name specified in the **owner** field to a string of characters in *text_string* serving as descriptive text. For more information, see RFC 1035.

**Syntax:**

*owner ttl class* **TXT** *text_string*

**Example:**

```
example.microsoft.com.    TXT  "This is an example of additional domain name
information."
```

**WKS**

| |
|---|
| **Description:** Well-known service (WKS) resource record. Describes the well-known TCP/IP services supported by a particular protocol on a specific IP address. WKS records provide TCP and UDP availability information for TCP/IP servers. If a server either supports both TCP and UDP for a well-known service or has multiple IP addresses that support a service, then multiple WKS records are used. For more information, see RFC 1035. |
| **Syntax:**<br><br>*owner ttl class* **WKS** *address protocol service_list* |
| **Example:**<br><br>`example.microsoft.com.  WKS 10.0.0.1 TCP ( telnet smtp ftp )` |

**X25**

| |
|---|
| **Description:** X.25 (X25) resource record. Maps a DNS domain name in the **owner** field to a Public Switched Data Network (PSDN) address number specified in *psdn_number*. PSDN numbers used with this record should follow the X.121 international numbering plan. For more information, see RFC 1183. |
| **Syntax:**<br><br>*owner ttl class* **X25** *psdn_number* |
| **Example:**<br><br>`example.microsoft.com.  X25 52204455506` |

**DNS Server Log Reference**

The following is a partial list of events recorded in the DNS server log. Event messages logged by the DNS Client service are logged in System log, and can also be viewed using Event Viewer at the applicable client computer. If you need to troubleshoot persistent problems, you can also enable for use advanced debugging options at the DNS server for obtaining a more detailed log of server activity. You can view this log by using the DNS console after the DNS Server service is installed on the server computer.

**Some Events Recorded in the DNS Server Log**

| Event ID | Description |
|---|---|
| 2 | The DNS server has started.<br><br>This message generally appears at startup when either the server computer is started or the DNS Server service is manually started. |
| 3 | The DNS server has shut down.<br><br>This message generally appears when either the server computer is shut down or the DNS Server service is stopped manually. |
| 408 | The DNS server could not open socket for address *IPaddress*. Verify that this is a valid IP address for the server computer.<br><br>If this is a valid IP address for the server computer, verify that no other application that would attempt to use the same DNS server port (such as another DNS server application) is running. By default, DNS uses TCP port 53. |

| | |
|---|---|
| 413 | The DNS server will send requests to other DNS servers on a port other than its default port (TCP port 53).<br><br>This DNS server is multihomed and has been configured to restrict DNS Server service to only some of its configured IP addresses. For this reason, there is no assurance that DNS queries made by this server to other remote DNS servers will be sent using one of the IP addresses enabled for the DNS server.<br><br>This might prevent query answer responses returned by these servers from being received on the DNS port that the server is currently configured to use. To avoid this problem, The DNS server sends queries to other DNS servers using an arbitrary non-DNS port, and the response is received regardless of the IP address used.<br><br>Typically, limiting the DNS server to using only its configured DNS port for sending queries to other DNS servers is the response to this event. This configuration is performed using the DNS console's server properties **Interfaces** tab as follows:<br><br>1. Either select **All IP addresses** to enable the DNS server to listen on all configured server IP addresses<br><br>2. Or, if you continue to select and use **Only the following IP addresses**, limit the **IP address** list to a single server IP address. |
| 414 | The server computer currently has no primary DNS suffix configured. Its DNS name is currently a single label host name. For example, its currently configured name is "host" rather than "host.example.microsoft".com or another fully qualified name.<br><br>While the DNS server has only a single label name, default resource records created for its configured zones use only this single label name when mapping the host name for this DNS server. This can lead to incorrect and failed referrals when clients and other DNS servers use these records to locate this server by name.<br><br>In general, the DNS server should be reconfigured with a full DNS computer name appropriate for its domain or workgroup use on your network. |
| 708 | The DNS server did not detect any zones of either primary or secondary type. It will run as a caching-only server but will not be authoritative for any zones. |
| 3150 | The DNS server wrote a new version of zone *zonename* to file *filename*. You can view the new version number in the DNS manager Zone Properties dialog box, Serial Number field.<br><br>This event should only appear if the DNS server is configured to operate as a root server. |
| 6527 | Zone *zonename* expired before it could obtain a successful zone transfer or update from a master server acting as its source for the zone. The zone has been shut down.<br><br>This event ID might appear when the DNS server is configured to host a secondary copy of the zone from another DNS server acting as its source or master server. It is always a good practice to verify that this server has network connectivity to its configured master server.<br><br>If the problem were to continue, one or more of the following options is avaialble:<br><br>1. Delete the zone and recreate it, specifying either a different master server, or an updated and corrected IP address for the same master server.<br><br>2. If zone expiration continues, consider adjusting the expire interval. |

For more information about all other messages not described in this topic, refer directly to the message text itself as it appears in the DNS server event log.

# DNS Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS Tools and Settings**

**In this section**

- DNS Tools
- DNS Registry Entries
- DNS Group Policy Settings
- DNS WMI Classes
- Related Information

**DNS Tools**

The following tools are associated with the Domain Name System (DNS).

**Dnscmd.exe: Dnscmd**

**Category**

This tool is included in the Microsoft Windows Server 2003 Support Tools.

**Version compatibility**

This tool runs on the Microsoft Windows 2000 Server and Windows Server 2003 operating systems.

Dnscmd is used to view the properties of DNS servers, zones, and resource records. In addition, Dnscmd is used to modify all aspects of the DNS Server service, including creating and deleting zones and resource records. Dnscmd can also be useful for developing scripts for configuring a DNS server.

**Dnslint.exe: DNSLint**

**Category**

This tool is a free download from Microsoft.

**Version compatibility**

This tool runs on Microsoft Windows XP, and the Windows 2000 Server and Windows Server 2003 operating systems.

DNSLint is a Microsoft Windows utility that can be used to help diagnose common DNS name resolution issues. It can be targeted to look for specific DNS record sets and ensure that they are consistent across multiple DNS servers. It can also be used to verify that DNS records used specifically for Active Directory directory service replication are correct.

**Dnsmgmt.msc: DNS Console**

**Category**

This tool is included in the Windows 2000 Server and Windows Server 2003 operating systems, and is installed when the DNS Server service is installed. This tool is also installed with either the Windows 2000 Server or Windows Server 2003 Administration Tools Pack (Adminpak.msi).

**Version compatibility**

This tool runs on the Windows 2000 Server and Windows Server 2003 operating systems. When installed from one of the administration tools packs, this tool can also run on Microsoft Windows 2000 Professional and Windows XP.

The DNS console is used to administer the DNS Server service. It can be used to modify all aspects of the DNS Server service, including creating and deleting zones and resource records, and forcing replication events between DNS server physical memory and DNS databases. The DNS console can also be used to perform diagnostics on the DNS infrastructure of a network.

**Eventvwr.exe: Event Viewer**

**Category**

This tool is included in all Windows server and client operating systems.

**Version compatibility**

This tool runs on Windows XP, and the Windows 2000 Server and Windows Server 2003 operating systems.

You can use Event Viewer to monitor events recorded in event logs. Typically, a computer stores the Application, Security, and System logs. It could also contain other logs, depending on the computer's role and the applications that are installed on it. For example, DNS servers write DNS-related events, such as any errors that occur while attempting to start the DNS Server service, to log files which can be read using Event Viewer.

**Ipconfig.exe: Ipconfig**
**Category**
This tool is included in all Windows server and client operating systems.

**Version compatibility**
This tool runs on all Windows server and client operating systems.

Ipconfig displays all current TCP/IP network configuration values and refreshes Dynamic Host Configuration Protocol (DHCP) and DNS settings. Used without parameters, Ipconfig displays IPv6 addresses or the IPv4 address, subnet mask, and default gateway for all adapters.

**Netmon.exe: Network Monitor**
**Category**
This tool is installed along with Windows Server 2003 and the Windows Server 2003 Administration Tools Pack.

**Version compatibility**
This tool runs on all Windows operating systems.

Network Monitor captures data about the packets on a network and logs them for subsequent analysis. The monitored data can be filtered many different ways including protocol, ports, physical addresses, and logical addresses. Network Monitor can be useful in many situations, such as when you are troubleshooting an environment that has a firewall between a DNS server and a client, or between two DNS servers.

Network Monitor comes in two versions: the Network Monitor that is provided as part of the Windows Server 2003 operating system, and the Network Monitor that is part of Microsoft Systems Management Server (SMS). The version of Network Monitor that is included with the Windows Server 2003 operating system only captures data about network packets being sent to or from the server on which you run Network Monitor; it also captures data about network broadcasts that are received. The Network Monitor that is included with SMS enables you to monitor all network packets on a network segment.

**Nslookup.exe: Nslookup**
**Category**
This tool is included in all Microsoft Windows server and client operating systems.

**Version compatibility**
This tool runs on all Windows server and client operating systems.

Nslookup is used to query DNS servers and to obtain detailed responses. The information obtained using Nslookup can be used to diagnose and solve name resolution problems, verify that resource records are added or updated correctly in a zone, and debug other server-related problems.

**DNS Registry Entries**
The following registry entries are associated with DNS.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, modify settings though the use of policy settings or through dedicated management tools, such as the DNS snap-in for the Microsoft Management Console (MMC), to accomplish tasks, rather than editing the registry directly. If you must edit the registry, use extreme caution.

### Note

- In Windows Server 2003, the location in the registry of the settings relating to DNS zones is different from the location used in Windows 2000 Server.
- In Windows 2000 Server, the location is:
- HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Zones

- In Windows Server 2003, the location is:
- HKEY_LOCAL_MACHINE\Software\Microsoft\WindowsNT\CurrentVersion\DNS Server\Zones

**DNS\Parameters**
The following registry entries are located under HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters.

**EDNSCacheTimeout**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

**Version**
Windows Server 2003

By default, the DNS server includes option (OPT) resource records indicating its User Datagram Protocol (UDP) maximum in responses to queries containing OPT resource records. The value of the registry key **EDNSCacheTimeout** determines how long the DNS server will keep information about the Extension Mechanisms for DNS (EDNS) versions supported by other DNS servers that have responded to a query with a OPT resource record. The value for the registry key is specified in seconds between 3,600 (1 hour) and 15,724,800 (182 days).

**EnableDirectoryPartitions**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

**Version**
Windows Server 2003

If you do not want the default DNS application directory partitions to be created automatically, you must disable the **EnableDirectoryPartitions** registry key. The values for this key are **0x0** (disable) and **0x1** (enable).

For more information about this registry entry, see the "Registry Reference" in the "Tools and Settings Collection."

**EnableEDNSProbes**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

**Version**
Windows Server 2003

The registry entry **EnableEDNSProbes** enables or disables the EDNS0 response for the DNS Server service. To configure the DNS server to include an OPT resource record only in response to EDNS0 requests containing OPT resource records, set the registry entry to a value of **0x1** (DWORD). In Microsoft Windows Server 2003 this setting is enabled by default. Setting the value to **0x0** (DWORD) will disable the feature.

**MaximumUdpPacketSize**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

**Version**
Windows Server 2003

The registry entry **MaximumUdpPacketSize** specifies the maximum UDP packet size advertised by the DNS server. The default value is 1,280 bytes. The value must be between 512 and 16,384 in decimal format (200 and 4,000 in hexadecimal format). UDP packets must travel through devices other than UDP hosts, such as routers, and some of these devices might not support UDP packets larger than 512 bytes. The maximum UDP packet length that is supported by all network devices should be determined, along with the path's Maximum Transmission Unit (MTU), before configuring this registry setting.

**RoundRobin**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

**Version**
Windows Server 2003

By default, DNS will perform round-robin rotation for all resource record types. The default setting for round-robin rotation is contained in the registry entry **RoundRobin** (REG_DWORD). By default, this entry's value is **1**, rotating all RR types except

those listed in the **DoNotRoundRobinTypes** registry entry. If the value of **RoundRobin** is set to **0**, then no resource record types will be round-robin rotated.

**DoNotRoundRobinTypes**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

**Version**
Windows Server 2003

By default, DNS will perform round-robin rotation for all resource record types. You can specify that certain resource record types are not to be round-robin rotated in the registry. The registry entry **DoNotRoundRobinTypes** (REG_SZ) allows a string value to be entered containing a list of resource record types. By modifying this entry, you turn off round-robin rotation for specific resource record types. For example, to prevent round-robin rotation for A, PTR, SRV, and NS record types, you would enter the following value for the registry entry: **a ptr srv ns**.

**DNSCache\Parameters**
The following registry entries are located under
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dnscache\Parameters.

**AlternateComputerNames**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dnscache\Parameters

**Version**
Windows Server 2003

The **AlternateComputerNames** registry entry specifies a list of alternate Fully Qualified Domain Names (FQDNs) for the computer. When the DNS Client service registers the host address (A) and pointer (PTR) resource records for the computer, it will also register the FQDNs specified in this key. This key is used by the Netdom.exe utility and is not typically modified by administrators.

**RegistrationRefreshInterval**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dnscache\Parameters

**Version**
Windows Server 2003

The **RegistrationRefreshInterval** registry entry specifies how often the DNS Client service will register the A DNS resource records for its host computer. The value for this registry key is specified in seconds.

**UpdateTopLevelDomainZones**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dnscache\Parameters

**Version**
Windows Server 2003

Windows XP and Windows 2000 with Service Pack 4 (SP4) and Windows Server 2003-based computers never try to dynamically update the root," "., zone.

The domain members and domain controllers in a domain with a single-label DNS name usually need to dynamically register DNS records in a single-label DNS zone that matches the DNS name of the domain. If an Active Directory forest root has a single-label DNS name, all domain controllers in the forest usually need to dynamically register DNS records in a single-label DNS zone that matches the DNS name of the forest root.

By default, Windows XP and Windows 2000 Service Pack 4 (SP4) and Windows Server 2003-based DNS clients do not attempt dynamic updates of any single-label DNS zone (.com, .net, .org, corp, for example). To enable such clients to attempt dynamic updates of a single-label DNS zones, set the **UpdateTopLevelDomainZones** (REG_DWORD) registry value to **0x1**.

These configuration changes should be applied to all domain controllers and members of an Active Directory domain with single-label DNS names. If a domain with a single-level domain name is a forest root, these configuration changes should be applied to all of the domain controllers in the forest, unless the separate zones _msdcs.*forest name*, _sites.*forest name*, _tcp.*forest name* and _udp.*forest name* are delegated from the *forest name* zone. You must restart the computer for the **UpdateTopLevelDomainZones** registry edit to take effect.

**Tcpip\Parameters**

The following registry entries are located under
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters.

**RegistrationEnabled (This registry entry is a global setting.)**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version**
Windows Server 2003

The **RegistrationEnabled** registry entry specifies that the DNS Client service should register all of the network connections of a computer in DNS. This is a global setting that is applied to all interfaces on a computer. If the need exists to apply this setting to an individual interface, see the registry entry for
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters \interfaces\[*interfaceGUID*}.

**SearchList**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters

**Version**
Windows Server 2003

The **SearchList** registry entry specifies the DNS suffix search list for the network connection used by the computer. For DNS clients, the DNS suffix search list extends or revises their DNS search capabilities. By adding additional suffixes to the list, the DNS client searches for short, unqualified computer names in more than one specified DNS domain. Then, if a DNS query fails, the DNS Client service can use this list to append other name suffix endings to the original name query and then repeat DNS queries to the DNS server for these alternate FQDNs. When the suffix search list is empty or unspecified, the primary DNS suffix of the computer is appended to short unqualified names, and a DNS query is used to resolve the resultant FQDN. If this query fails, the computer can try additional queries for alternate FQDNs by appending any connection-specific DNS suffix configured for network connections.

**Interfaces\{interfaceGUID}**
The following registry entries are located under
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\Interfaces\{*interfaceGUID*}.

**NameServer**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\Interfaces\{*interfaceGUID*}

**Version**
Windows Server 2003

The **NameServer** registry entry specifies the IP address of the DNS server that is used by the network connection of the computer.

**RegistrationEnabled (This is an interface-specific registry setting.)**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\Interfaces\{*interfaceGUID*}

**Version**
Windows Server 2003

The **RegistrationEnabled** registry entry specifies that the DNS Client service should register the computer's network connection in DNS. This entry is interface specific and can be set on any interfaces on a computer. The {*interfaceGUID*} portion of the registry path determines which interface the setting is applied to.

There is a global version of this setting that gets applied to all interfaces. Information about this setting can be found under the registry key HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\RegistrationEnabled.

For more information about this registry entry, see the "Registry Reference" in the Tools and Settings Collection.

**DNS Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with the DNS Client service.

### Group Policy Settings Associated With DNS Client Service

| Group Policy Name | Purpose |
|---|---|

| | |
|---|---|
| Primary DNS Suffix | Specifies the primary DNS suffix. |
| Dynamic Update | Specifies whether or not the DNS client should perform dynamic updates. |
| DNS Suffix Search List | Specifies the DNS server search list. |
| Primary DNS Suffix Devolution | Specifies whether DNS name devolution should be used in resolving names. |
| Register PTR Records | Specifies whether reverse lookup name registrations should be performed. |
| Registration Refresh Interval | Specifies the default refresh interval. |
| Replace Addresses In Conflicts | Specifies whether addresses in conflict should be replaced. |
| Register DNS records With Connection-specific DNS Suffix | Specifies whether DNS registration should be attempted for each network adapter. |
| TTL Set in the A and PTR Records | Specifies Time to Live (TTL) for dynamic registrations. |
| Update Security Level | Specifies the security level for updates. |
| Update Top Level Domain Zones | Specifies whether the computer sends dynamic updates to top level domain zones. |

For more information about Group Policy settings, see the "Group Policy Settings Reference" in the "Tools and Settings Collection."

**DNS WMI Classes**

The following table lists and describes the WMI classes that are associated with the DNS Server service.

**WMI Classes Associated With DNS Server Service**

| Microsoft DNS WMI Class | Description |
|---|---|
| MicrosoftDNS_Server | Describes a DNS server. Every instance of this class might be associated with one instance of class MicrosoftDNS_Cache, one instance of class MicrosoftDNS_RootHints, and multiple instances of class MicrosoftDNS_Zone. |
| MicrosoftDNS_Domain | Represents a domain in a DNS hierarchy tree. |
| MicrosoftDNS_Zone | Describes a DNS zone. Every instance of the class MicrosoftDNS_Zone must be assigned to exactly one DNS Server. Zones might be associated with multiple instances of the classes MicrosoftDNS_Domain and MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_Cache | Describes a cache existing on a DNS server (do not confuse this with a cache file that contains root hints). This class simplifies visualizing the containment of DNS objects, rather than representing a real object. The class, MicrosoftDNS_Cache, is a container for the resource records cached by the DNS server.<br><br>Every instance of the class MicrosoftDNS_Cache must be assigned to exactly one DNS server. It might be associated with multiple instances of MicrosoftDNS_Domain and MicrosoftDNS_ResourceRecord. |

| | |
|---|---|
| MicrosoftDNS_RootHints | Describes the RootHints stored in a cache file on a DNS server. This class simplifies visualizing the containment of DNS objects, rather than representing a real object. Class MicrosoftDNS_RootHints is a container for the resource records stored by the DNS server in a cache file.<br><br>Every instance of the class MicrosoftDNS_RootHints must be assigned to exactly one DNS server. It might be associated with multiple instances of the MicrosoftDNS_ResourceRecord class. |
| MicrosoftDNS_Statistic | Represents a single DNS server statistic. |
| MicrosoftDNS_ServerDomainContainment | Every instance of the class MicrosoftDNS_ServerDomainContainment might contain multiple instances of the class MicrosoftDNS_Domain. |
| MicrosoftDNS_DomainDomainContainment | Every instance of the MicrosoftDNS_DomainDomainContainment class might contain multiple other instances of MicrosoftDNS_Domain. |
| MicrosoftDNS_DomainResourceRecordContainment | Every instance of the class MicrosoftDNS_DomainResourceRecordComtainment might contain multiple instances of the MicrosoftDNS_ResourceRecord class. |
| MicrosoftDNS_ResourceRecord | Represents the general properties of a DNS RR. |
| MicrosoftDNS_AAAAType | Represents an IPv6 Address (AAAA), often pronounced quad-A, RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_AFSDBType | Represents an Andrew File System Database Server (AFSDB) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_ATMAType | Represents an ATM Address-to-Name (ATMA) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_AType | Represents an Address (A) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_CNAMEType | Represents a Canonical Name (CNAME) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_HINFOType | Represents a Host Information (HINFO) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_ISDNType | Represents an ISDN RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_KEYType | Represents a KEY RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MBType | Represents a Mailbox (MB) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MDType | Represents a Mail Agent for Domain (MD) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MFType | Represents a Mail Forwarding Agent for Domain (MF) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MGType | Represents an MG RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MINFOType | Represents an Mail Information (MINFO) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MRType | Represents a Mailbox Rename (MR) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MXType | Represents a Mail Exchanger (MX) RR. Subclass of MicrosoftDNS_ResourceRecord. |

| | |
|---|---|
| MicrosoftDNS_NSType | Represents a Name Server (NS) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_NXTType | Represents a Next (NXT) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_PTRType | Represents a Pointer (PTR) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_RPType | Represents a Responsible Person (RP) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_RTType | Represents a Route Through (RT) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_SIGType | Represents a Signature (SIG) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_SOAType | Represents a Start Of Authority (SOA) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_SRVType | Represents a Service (SRV) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_TXTType | Represents a Text (TXT) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_WINSRType | Represents a WINS-Reverse (WINSR) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_WINSType | Represents a WINS RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_WKSType | Represents a Well-Known Service (WKS) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_X25Type | Represents an X.25 (X25) RR. Subclass of MicrosoftDNS_ResourceRecord. |

For more information about many WMI classes, see the WMI SDK documentation on MSDN.

**Related Information**

The following resources contain additional information that is relevant to this section.

- Microsoft Platform SDK on MSDN for more information about WMI classes that are associated with the DNS Server service.
- "Group Policy Settings Reference" in the "Tools and Settings Collection" for information about Group Policy settings that are associated with the DNS Client service.
- "Registry Reference" in the "Tools and Settings Collection" for information about registry entries that are associated with DNS.

# WINS Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**WINS Technical Reference**
Windows Internet Name Service (WINS) is a NetBIOS name resolution service that allows client computers to register their NetBIOS names and IP addresses in a dynamic, distributed database and to resolve the NetBIOS names of network resources to their IP addresses.

WINS is needed in any Microsoft Windows network environment that includes operating systems or applications that rely on NetBIOS.

**In this subject**

- What Is WINS?
- How WINS Technology Works
- WINS Tools and Settings

# What Is WINS?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Role of WINS in the Network**

Although NetBIOS and NetBIOS names can be used with network protocols other than TCP/IP, WINS was designed specifically to support NetBIOS over TCP/IP (NetBT). WINS is required for any environment in which users access resources that have NetBIOS names. If you do not use WINS in such a network, you cannot connect to a remote network resource by using its NetBIOS name unless you use Lmhosts files, and you might be unable to establish file and print sharing connections.

The following figure illustrates the role of WINS for computers that use NetBIOS names. Typically, DHCP is used to assign IP addresses automatically.

**WINS Name Registration and Resolution**

In a typical scenario, the following occurs:

1. ClientA, which uses NetBIOS and is a WINS client, sends a name registration request to its configured primary WINS server (WINSA) when it starts up and joins the network. WINSA adds ClientA's NetBIOS name and IP address to the WINS database.

2. When ClientB needs to connect to ClientA by its name, it requests the IP address from the WINS server.

3. The WINS server locates the corresponding entry in its database and replies with ClientA's IP address.

**Summary of WINS Benefits**

WINS provides the following benefits over other NetBIOS name resolution methods:

- WINS name resolution reduces NetBIOS name query broadcast traffic because clients can query a WINS server directly instead of broadcasting queries.

- WINS enables the Computer Browser service to collect and distribute browse lists across IP routers.

- The WINS dynamic name-to-address database supports NetBIOS name registration and resolution in environments where DHCP-enabled clients are configured for dynamic TCP/IP address allocation.

- The WINS database also supports centralized management and replicates name-to-address mappings to other WINS servers.

- WINS and DNS can be used in the same environment to provide combined name searches in both namespaces.

**WINS and DNS**

WINS and DNS are both name resolution services for TCP/IP networks. While WINS resolves names in the NetBIOS namespace, DNS resolves names in the DNS domain namespace. WINS primarily supports clients that run older versions of Windows and applications that use NetBIOS. Windows 2000, Windows XP, and Windows Server 2003 use DNS names in addition to NetBIOS names. Environments that include some computers that use NetBIOS names and other computers that use domain names must include both WINS servers and DNS servers.

# How WINS Technology Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- NetBIOS Overview
- WINS Architecture
- WINS Protocol
- WINS Processes and Interactions
- Related Information

Windows Internet Name Service (WINS) is a name resolution service that maps NetBIOS names to IP addresses in networks that use NetBIOS over TCP/IP (NetBT). As such, the primary purpose of WINS is to support clients that run older versions of Windows and applications that use NetBIOS.

In earlier versions of Microsoft operating systems, NetBIOS names were required for locating network resources. In Microsoft Windows NT 4.0, for example, clients used NetBIOS to locate Windows NT 4.0 domain controllers, as well as for file and print sharing. Therefore, WINS is required for name resolution in network environments that include computers running Windows versions earlier than Windows 2000.

WINS is not required in a network that consists entirely of computers running Windows 2000, Windows XP, Windows Server 2003, or other TCP/IP-based systems, such as most versions of UNIX, that fully support the use of Domain Name System (DNS) names. If NetBIOS and, consequently, WINS are eliminated from such an environment, however, any applications and services that depend on NetBIOS, such as the Computer Browser service, will not function. Organizations that need to continue to support older versions of Windows still rely on NetBIOS and WINS.

WINS can be used in conjunction with DNS, which resolves domain names, to connect to any network resource by referencing the resource's user-friendly name. Used in conjunction with Dynamic Host Configuration Protocol (DHCP), WINS supports dynamic IP address assignments, thus eliminating the administrative burden of maintaining static IP addresses.

This section describes how WINS works in a properly configured environment, which includes the following:

- NetBT is enabled.
- DNS is configured correctly.
- DHCP is configured correctly.
- The network, including routers, is configured to handle name resolution traffic.
- WINS-configured servers are designed with sufficient CPU, memory, and hard disk space to handle WINS activity.

The following sections describe WINS components, how they fit in a network environment, and how NetBIOS name resolution processes work.

**NetBIOS Overview**

An understanding of NetBIOS is essential to understanding WINS. In the OSI reference model, NetBIOS is a session-layer protocol. Applications use this protocol to communicate over NetBIOS-compatible transports. NetBIOS and applications that use NetBIOS can run over both TCP/IP and Internetwork Packet Exchange (IPX). When it runs over TCP/IP, NetBIOS is commonly referred to as NetBT.

RFCs 1001 and 1002 define the functions and features of three NetBIOS services in a TCP/IP environment: name service, session service, and datagram service. The name service encompasses registering NetBIOS names, renewing and releasing

names, and resolving NetBIOS names to IP addresses. WINS is the Microsoft implementation of a NetBIOS name server (NBNS), as defined by the RFCs. The other two services are beyond the scope of this section.

**NetBIOS Names**

RFCs 1001 and 1002 provide for 16-byte NetBIOS names. The first 15 characters of a NetBIOS name are user-definable. Windows reserves the sixteenth character for a name suffix.

The user-definable portion of a NetBIOS name cannot begin with an asterisk (*). Use of extended characters, the underscore (_) and period (.) in particular, can result in name resolution errors in environments that also use DNS name resolution. NetBIOS names are not case-sensitive.

The name suffix, the final byte of a NetBIOS name reserved by Windows, specifies the resource type. A WINS client can use the suffix to identify the specific service it needs to access. That is, a WINS client can construct the NetBIOS name based on a computer, user, or domain name and append the suffix to locate a specific resource on that computer. For example, the Messenger service has a suffix of 0x03. To send a message to COMPUTER42, the client sends a message to the Messenger service on COMPUTER42 by specifying the following NetBIOS name:

```
COMPUTER42      [03]
```

In the full 16-character name notation, the first 15 characters are padded with spaces, if necessary. A NetBIOS name can be a unique name, which means it maps to a single IP address, or a group name, which means it maps to multiple IP addresses. For example, each computer that runs Windows Server 2003 has a Server service for sharing files and a Workstation service for accessing the files shared by the Server service. These services each have a unique NetBIOS name, so client computers can locate the appropriate server and use the file-sharing service. On the other hand, the domain controllers within a single domain share a group name.

The following table describes some of the NetBIOS name suffixes used by Windows Server 2003. The suffixes are listed in hexadecimal format. Other applications, such as Microsoft Exchange and Microsoft Systems Management Server (SMS), register NetBIOS names with different suffixes.

**Common Windows NetBIOS Name Suffixes**

| 15-Character Name | Suffix (Hexadecimal) | Type | Usage |
|---|---|---|---|
| *ComputerName* | 00 | Unique | Registered by the Workstation service on a WINS client. Typically, this name is called the NetBIOS computer name. |
| *DomainName* | 00 | Group | Registered by the Workstation service for receiving browser broadcasts from LAN Manager-based computers. |
| *MSBROWSE* | 01 | Group | Registered by the master browse server for each subnet. |
| *ComputerName* | 03 | Unique | Registered by the Messenger service on a WINS client. This name is usually appended to the NetBIOS computer name and to the name of the logged-on user. (The Messenger service is not related to Windows Messenger.) |
| *UserName* | 03 | Unique | Identifies the Messenger service for the logged-on user. User names are registered in the WINS database by the Messenger service. |
| *ComputerName* | 1B | Unique | Registered by each Windows Server 2003 domain controller running as the domain master browse server. This name record is used to allow remote browsing of domains. When a WINS server is queried for this name, a WINS server returns the IP address of the computer that registered this name. |
| *DomainName* | 1B | Unique | Registered by each Primary Domain Controller (PDC) that is running as the domain master browser. This name is used to support remote browsing of domains. When a WINS server is queried for this name, it returns the IP address of the computer that registered the name. |
| *DomainName* | 1C | Group | Registered for use by domain controllers within the domain. This NetBIOS name can include up to 25 IP addresses: one for the PDC and 24 for backup domain controllers (BDCs). |

| | | | |
|---|---|---|---|
| *DomainName* | 1D | Unique | Registered only by a master browse server. There is only one master browse server per subnet. Backup browse servers use this name to communicate with the master browse server to retrieve the list of available servers from the master browse server. WINS servers always return a positive registration response for *DomainNname*[1D], even though they do not add this name to the WINS database. Therefore, when a WINS server is queried for D*omainName*[1D], the server always responds with a broadcast address, which forces the client to broadcast to resolve the name. |
| *DomainName* | 1E | Group | Registered for any computers configured to be network browse servers. This is a normal group name. Any computers configured to be network browse servers can broadcast to this name and listen for broadcasts to this name to elect a master browse server. A statically-mapped group name uses this name to register itself on the network. When a WINS server receives a name query for a name ending with [1E], the WINS server always returns the network broadcast address for the local network of the requesting client. The client can then use this address to broadcast to the group members. |
| *ComputerName* | 1F | Unique | Registered by the Network Dynamic Data Exchange (NetDDE) services; appears only if the NetDDE services are started on the computer. |
| *ComputerName* | 20 | Unique | Registered by the Server service on the WINS client. The WINS client uses this service to share folders and printers on the network. |
| *GroupName* | 20 | Group | A special group (also called Internet group) name is registered with WINS servers to identify groups of computers for administrative purposes. For example, “printers” could be a registered group name used to identify an administrative group of print servers. |
| *ComputerName* | BE | Unique | Registered by the Network Monitoring Agent service and appears only if the service is started on the WINS client computer. If the computer name has fewer than 15 characters, plus symbols (**+**) are added to expand the name to 15 characters. |
| *ComputerName* | BF | Unique | Registered by the Network Monitoring Utility (included with Microsoft Systems Management Server). If the computer name has fewer than 15 characters, plus symbols (**+**) are added to expand the name to 15 characters. |

The NetBIOS namespace is flat, which means that names can be used only once within a network. By contrast, DNS uses fully qualified domain names (FQDNs), which combine a host name with the hierarchical name of its domain. For example, a NetBIOS name of WINSserver01 might be an FQDN of WINSserver01.reskit.com.

Being able to use a NetBIOS name only once within a network can be a restriction with imposing implications for large networks. Using a NetBIOS scope, as described in RFC 1001, is one solution to this situation. A character string, known as the scope identifier, works something like a domain name in DNS and defines the population of computers across which a registered NetBIOS name is known. The scope identifier is appended to NetBIOS names during name services processes. However, the meaning of scope varies based on the NetBIOS node. For example, the scope for B-node includes all the NetBIOS nodes in the local subnet, the scope for P-node includes all the NetBIOS nodes in the routed network that use the same NetBIOS name service, and the scope for M-node and H-node is an intersection of the B-node and P-node scopes. (NetBIOS nodes are defined later in this section.) This situation causes name resolution problems in environments that use more than one type of NetBIOS node. Because only NetBIOS nodes that use the same scope ID can resolve each other’s names, the use of different scope IDs can create communication problems. Therefore, use of the scope identifier is discouraged in Windows Server 2003.

**NetBIOS Nodes**

Client computers use NetBIOS name services to register, renew, and release names and to query and resolve IP addresses for network resources. NetBIOS session and datagram services use these name services to locate resources. For example, if a user wants to map a network drive to a file share on a remote computer by using Windows Explorer, the user types the remote computer name and share name in the **Map Network Drive** window. Windows Explorer uses NetBIOS name services to obtain the remote computer's IP address and then establishes a NetBIOS session over which a file-sharing session is established to access the shared resource.

NetBIOS name services are carried out either by using IP broadcasts or by using a NetBIOS name server. Broadcasts are appropriate in single-subnet local area networks (LANs), but rapidly cause administrative problems in multiple-subnet networks. A NetBIOS name server is the desirable alternative for larger networks. To allow for various sizes of networks, RFCs

1001 and 1002 use the concept of node type to determine the specific method a computer uses to perform name services. The following table describes the four NetBIOS node types.

**NetBIOS Node Types**

| Name Resolution Node | Description |
|---|---|
| B-node | Broadcast node. The client computer sends IP broadcast messages to all the computers on the subnet. The computer that has the requested name sends back a confirmation with its IP address. This is the default mode for non-WINS clients. |
| P-node | Point-to-point node. The client computer only communicates with a NetBIOS name server (in Windows Server 2003-based networks, this is the WINS server) to register names and resolve names to IP addresses. |
| M-node | Mixed node. The client computer uses a mix of B-node and P-node communications to register and resolve NetBIOS names: it first attempts to resolve a name by using broadcasts, and if that is unsuccessful it queries a WINS server. |
| H-node | Hybrid node. The client computer uses a hybrid of B-node and P-node: it first queries a WINS server, and if that is unsuccessful it sends broadcasts. |

The default node type for Windows-based WINS clients is B-node. When a computer is configured to use a WINS server, whether manually or through DHCP, it becomes H-node. The other NetBIOS node types are configured through DHCP by configuring the **WINS/NBT Node Type** option for a DHCP client.

Because B-node is based on broadcasts, it does not scale beyond a single subnet. Configuring routers to forward NetBIOS broadcasts also does not scale well and is not recommended. To address these limitations of RFC-compliant B-node, Microsoft extended B-node for name service operations. Microsoft's extension, known as modified B-node, adds the following two name lookup facilities:

**NetBIOS name cache**
An in-memory cache of recently resolved NetBIOS names that can be searched before attempting other name resolution methods.

**LMHosts file**
A flat file, located in *systemroot*\System32\Drivers\Etc, that contains a static list of NetBIOS names and their IP addresses. This file does not exist by default.

**WINS Architecture**
The WINS service is Microsoft's implementation of a NetBIOS name server. WINS consists of two primary components: WINS servers and WINS clients. Each WINS server includes a dynamic database of NetBIOS name-to-IP address mappings. WINS clients communicate with a WINS server to register their NetBIOS names in the WINS database and to query the WINS database to resolve the IP addresses associated with other NetBIOS names. A special kind of WINS client is the WINS proxy. WINS proxies support NetBIOS name services in a limited way for client computers that are not WINS-enabled. The following figure illustrates how WINS components fit in a network environment.

**WINS Component Configuration**

This example shows two subnets (Subnet 1 and Subnet 2) that include WINS clients. The third subnet (Subnet 3) includes B-node clients and a WINS proxy to act on the behalf of the B-node clients during name service requests. There are two WINS servers, each of which contains a WINS database. The WINS components illustrated in the figure are described in the following table.

**WINS Components**

| Component | Description |
|---|---|
| WINS server | A computer that provides the WINS name registration and resolution service. A WINS server replicates the WINS database to other WINS servers so that complete name-to-address resolution information is available, regardless of which WINS server a WINS client uses. |
| WINS client | Any WINS-enabled computer that communicates with a WINS server to register, refresh, or release its NetBIOS name or to resolve the NetBIOS name of another computer. |
| WINS proxy | A WINS client computer that is configured to act on the behalf of other, non-WINS-enabled computers, allowing these computers limited participation in name registration, release, and resolution processes. |
| WINS database | A dynamically updated list of NetBIOS names and their associated IP addresses, including IP addresses assigned by DHCP. In networks that have multiple WINS servers, the servers exchange database updates through replication. |

**WINS Servers**

A WINS server handles name registration requests from WINS clients by registering their names and IP addresses, provided the requested unique name is not in active use. It also responds to NetBIOS name queries submitted by clients by returning the IP address of a queried name if it is listed in the WINS database. Either local clients (on the same subnet as the WINS server) or remote clients (across a router from the server) can register with a WINS server.

When a WINS-enabled client starts on the network, it sends its name and IP address in a registration request directly to its configured primary WINS server. The WINS server that registers the NetBIOS name of the client in its database is said to be the owner of the WINS name entry.

WINS servers can replicate the contents of their databases to other WINS servers.

**Primary and Secondary WINS Servers**

WINS servers can act as either a primary WINS server or a secondary WINS server to a client. The difference between primary and secondary WINS servers is simply the priority in which clients contact them. A primary WINS server is the first server a client contacts to perform its NetBIOS name service operations. A client contacts a secondary WINS server only when a primary WINS server is unable to fulfill the request, for example if it is unavailable when the client makes the request or unable to resolve a name for the client.

If a primary WINS server fails to fulfill a request, the client makes the same request of its secondary WINS server. If more than two WINS servers are configured for the client, the client tries the additional secondary WINS servers until the list is exhausted or one of the WINS servers successfully responds to the request. After a client uses a secondary WINS server, it periodically tries to switch back to its primary WINS server for future name service requests.

**WINS Clients**
WINS clients are computers that are configured to make direct use of a WINS server. WINS clients attempt to register their names with a WINS server when they start or join the network. Thereafter, they query the WINS server to resolve NetBIOS names as needed. WINS clients communicate with WINS servers to:

- Register client names in the WINS database.
- Refresh client names in the WINS database.
- Release client names from the WINS database.
- Resolve names by obtaining name-to-IP address mappings from the WINS database.

Most WINS clients typically have more than one NetBIOS name that they must register for use with the network. These names are used to publish various types of network services, such as the Messenger or Workstation services, that each computer can use to communicate with other computers on the network.

WINS client computers are configured with either static or dynamic IP addresses. Clients that use static IP addresses are manually configured with a set of specific WINS servers. Clients that use dynamic IP addresses use the **WINS/NBNS Servers** option in DHCP to specify the WINS servers.

For Windows 2000, Windows XP, and Windows Server 2003, WINS clients can be configured with up to 12 secondary WINS servers. This feature is useful in an environment in which there are many mobile clients, many NetBIOS-based resources, and services are used often. In such an environment, updates to the WINS database might not be replicated throughout the network of WINS servers at the time of a request, and it can be helpful for clients to be able to query more than two WINS servers. Clients use the additional server addresses only if the primary and secondary servers fail to respond.

WINS clients running any of the following versions of Windows can communicate with a WINS server running Windows Server 2003:

- 32-bit versions of the Windows Server 2003 family
- 64-bit versions of Windows Server 2003, Datacenter Edition and Windows Server 2003, Enterprise Edition
- 32-bit versions of Windows XP Professional and Windows XP Home Edition
- 64-bit version of Windows XP Professional
- Windows Millennium Edition
- Windows 2000 Professional; Windows 2000 Server; Windows 2000 Advanced Server; and Windows 2000 Datacenter Server
- Windows NT Workstation 4.0 and Windows NT Server 4.0
- Windows 98
- Linux and UNIX clients (with Samba installed)

Clients that are not WINS-enabled can participate in name registration and resolution processes in a limited way by using WINS proxies.

**WINS Proxies**
A WINS proxy is a WINS client that can perform limited NetBIOS name services, such as registration, release, and resolution, on behalf of other non-WINS clients that are on a routed TCP/IP network.

Typically, older NetBIOS clients that are not, or cannot be, configured to use WINS are B-node clients. These computers use broadcasts to register their NetBIOS names on the network and to resolve NetBIOS name queries. Computers configured for B-node cannot use WINS directly because WINS servers do not respond to broadcasts. A WINS proxy can listen on the local subnet for B-node name query broadcasts and respond for the names that are not on the local subnet. WINS proxies

communicate with a WINS server by using unicast datagrams.

RCF 1001 recommends against using B-node name resolution in a routed network, but in practice, the B-node NetBIOS node type is sometimes useful and sometimes cannot be removed or updated. Microsoft designed WINS proxies to support B-node clients in a routed network.

**WINS Database**

The WINS database resides on the WINS server. It stores NetBIOS name-to-IP address mappings for the network. WINS clients use this mapping information to connect with other network resources. NetBIOS names are registered in the WINS database whenever a network resource becomes available for use, for example when a computer starts up. Therefore, the contents of the WINS database change over time as computers join and leave the network.

The size of the WINS database depends on the number of WINS clients in the network and the number of NetBIOS names each uses. Unique name entries typically are 42 bytes. Internet group entries can include up to 25 addresses and, therefore, are longer entries. The databases on all WINS servers in a network are about equal in size. All the databases have the same number of NetBIOS name entries, except for those pending replication.

The actual size of the database, however, can be much larger than the number of entries, because space is not automatically reclaimed when unused records are deleted. WINS database compaction recovers the unused space. Windows Server 2003 provides both dynamic and manual database compaction. The manual database compaction is most efficient, but requires the database to be offline. The dynamic database compaction runs during idle time after a database update and allows the database to remain online.

The use of multiple WINS servers in a NetBIOS environment provides redundancy and load balancing. When multiple WINS servers are used, updates to a WINS database replicate among the WINS servers designated as replication partners until the updates are in all the WINS databases in the network. Although each name entry is eventually replicated to all other WINS databases, a name entry is said to be owned by the WINS server that originated the entry.

WINS servers running Windows Server 2003 can replicate with WINS servers running earlier versions of Windows.

**WINS Database Files**

The Windows Server 2003 WINS database uses the Extensible Storage Engine (ESE). This database imposes no limit on the number of records that a WINS server can store or replicate.

WINS uses the Jet database format for storing its data. Jet produces the J*n*.log and other files by default in the *systemroot*\System32\Wins folder. The files that are created and used by the database on each WINS server are described in the following table.

**WINS Server Database Files**

| File | Description |
|---|---|
| J50.log and J50*xxxxx*.log | A log of all WINS database transactions. This file is used by WINS to recover data if necessary.<br><br>Log files maintain a specific size of 1024 KB. When WINS tries to write more transactions to the log than the file size can accommodate, it renames the current log file and creates a new one. The new log file has a file name in the format J*n*.log, where *n* is a decimal number, such as J50.log. The format of the renamed log file is Jet*xxxxx*.log, where each *x* denotes a hexadecimal number from 0 to F. Renamed log files are maintained in the same folder as the current log file.<br><br>All entries in the log file are written to the database and the log is deleted every three hours, when the WINS database is successfully backed up, and when the WINS Server service is shut down properly. |
| J50.chk | A checkpoint file that indicates the location of the last information successfully written from the transaction logs to the database. During data recovery, the checkpoint file indicates where recovery begins. The checkpoint file is updated every time data is written to the database file (Wins.mdb). |

| | |
|---|---|
| Wins.mdb | The WINS database, which contains two tables: the IP address-to-owner ID mapping table and the name-to-IP address mapping table.<br><br>The name-to-IP address mapping table stores NetBIOS names and the IP addresses assigned to them. These entries are created during name registration requests and during replication. This table includes a clustered index (logical order of the key values is the same as the physical order of the rows in the table) on the name field for quick record retrieval during name queries. The primary index is built by concatenating owner ID and version ID in ascending order for quick retrieval of records that fall within a range of version IDs.<br><br>The IP address-to-owner ID mapping table contains a row for each WINS server that has entries in the name-to-IP address mapping table. A row contains the IP address of the WINS server and its identifier, which is the owner ID field for the name entries it owns. This table is used to build the owner-to-version table that determines which replication partners have the latest updates. |
| Winstmp.mdb | A temporary file that is created by the WINS service. This file functions as a swap file during index maintenance operations and can remain in the *systemroot*\System32\Wins folder after a system failure. |
| Res#.log | These are reserved log files, which function in emergencies when the server runs out of disk space. If a server attempts to create another transaction log file and there is insufficient disk space, the server flushes any outstanding transactions into these reserved log files. The service then shuts down and logs an event to Event Viewer. |

To increase speed and efficiency of data storage, current transactions are written to log files rather than directly to the database. Therefore, the most current view of the data includes both the database and any transactions in the log files. Both the database and the log files are used for recovery if the WINS service abruptly or unexpectedly stops. If the service stops in an unexpected manner, the log files are automatically used to re-create the correct state of the WINS database.

**Name Data**

Name entries in the name-to-IP address mapping table include data used during name query requests, as well as data used to age and replicate the entries. Data used for name service requests or for aging and replicating entries is described in the following table.

**Name Data**

| Data | Description |
|---|---|
| Name | The NetBIOS name. |
| Address | The IP address associated with the name.<br><br>A unique name has a single IP address. A special group entry can have multiple IP addresses. |
| Name type | The type of name.<br><br>A name is classified by how it is added to the WINS database:<br><br>• Static (the name is manually added to the WINS database)<br><br>• Dynamic (the name is automatically added to the WINS database during NetBIOS name registration)<br><br>A name is also classified as one of the following:<br><br>• Unique name<br><br>• Normal group<br><br>• Special group, also known as an Internet group<br><br>• Multihomed (a computer that uses multiple IP addresses) |

| | |
|---|---|
| State | The status of the NetBIOS name entry, which can be one of the following:<br>• Active (name is in active use)<br>• Released (network node has shut down, name is not in use)<br>• Extinct, also known as tombstone (name was not reregistered, is ready for deletion) |
| Owner ID | The ID of the WINS server that owns the entry. The owner is the WINS server that first added the entry to the WINS database.<br>WINS automatically assigns and increments an integer value to represent owner IDs at the local server. These owner IDs are mapped to the WINS server IP addresses. Owner IDs are used internally at the local server, and their values differ from WINS server to WINS server. |
| Version ID | A counter that indicates which name entry updates need to be replicated. |
| Time stamp | A date and time stamp that is updated when a NetBIOS name entry is updated. WINS uses specific time intervals to determine when to renew or delete name entries from the database. WINS calculates the time stamp from the current date and time plus a time interval. |

**WINS Time Intervals**

Name entries in the WINS database have time stamps that determine when specific aging activities are to take place. WINS uses four configurable time intervals to calculate the time stamps. The following table describes the four time intervals.

**WINS Time Intervals**

| Time Interval | Description |
|---|---|
| Renew interval (also known as the Time-to-Live [TTL]) | Specifies when a client must refresh its name. The default is six days.<br>During a name registration request, the entry is time-stamped with the sum of the current time and this interval value. If a name entry is not refreshed before this time stamp expires, WINS releases the name entry. |
| Extinction interval (also known as tombstone interval) | Specifies the interval between when an entry is marked as released and when it is marked as extinct. The default depends on the renew interval and, if the WINS server has replication partners, on the maximum replication time interval, which is the configurable amount of time between pull replications. The maximum allowable value is six days.<br>When an entry is marked as extinct, the entry is time-stamped with the sum of the current time and the extinction time-out on the WINS server that is configured as the pulling replication partner (the partner that requests replication). |
| Extinction time-out (also known as tombstone time-out) | Specifies the interval between when an entry is marked extinct and when the entry is finally deleted (scavenged) from the database. The default depends on the renew interval and, if the WINS server has replication partners, on the maximum replication time interval. The default is six days. |
| Verification interval | Specifies the interval after which a WINS server must verify that old names it does not own are still active. The default value is 24 days.<br>When an active entry is replicated, it is time-stamped with the sum of the current time and the verification interval on the WINS server requesting replication (pull partner). |

The Windows Server 2003 defaults provided for these values take the following into consideration:

- Minimized level of network traffic
- Minimized load on WINS servers
- Various configurations in which WINS servers might be deployed

- Minimized window between replications
- Exceptional conditions, such as long weekends and large volumes in worst-case scenarios

**Server Clocks**
Replication and scavenging (database cleanup) algorithms rely on a reasonably consistent system clock. Setting the system clock forward or backward affects these algorithms. However, because time stamps are always entered locally, the WINS servers do not need to be time-synchronized.

**WINS Protocol**
The WINS protocol is based on, and is compatible with, the protocols defined for NetBIOS name services specified in RFCs 1001 and 1002. Therefore, WINS is compatible with any other implementation of these RFCs. That is, another RFC-compliant implementation of the client can communicate with a WINS server. Similarly, a Microsoft TCP/IP client can communicate with other implementations of an NBNS. To provide scalability for larger networks, however, the WINS implementation of NBNS supports replication of the WINS database between WINS servers. WINS replication is Microsoft proprietary technology, so WINS replication is not compatible with other NBNS implementations. This section briefly describes the format of NetBIOS packets and the ports used by NetBIOS.

**NetBIOS name services packets**
NetBIOS name service packets consist of messages sent between a WINS client and a WINS server. These message packets are similar in structure to DNS packets, but with additional types and codes for NetBIOS. The high-level format of name services packets is described in the following table.

**Name Services Packet Format**

| Message Section | Description |
|---|---|
| Name service header | Fixed length, 12 octets. This section contains information about the type of message and counts for the other records included in the message. |
| Question entries<br><br>or<br><br>Answer resource records | Variable length, optional. Length is defined in the header. This section contains the NetBIOS name for name registration, refresh, and release messages.<br><br>Variable length, optional. Length is defined in the header. This section contains the resource records returned in response to a request. |
| Authority resource records | This section is not used in Windows Server 2003. |
| Additional resource records | Variable length, optional. Length is defined in the header. This section contains other resource records that are not provided as a direct reply to a request. |

Each name service packet contains a header and one or more additional entries. The sections included for a packet depend on the message. The format of name service packets used by Windows Server 2003 is compatible with the specification provided in RFC 1002. For a detailed description of packet fields, see RFC 1002.

**WINS ports**
The ports listed in the following table are used by specific WINS services.

**WINS Port Assignments**

| Service Name | UDP | TCP |
|---|---|---|
| NetBIOS name service | 137 (client and server) | |
| WINS replication | | 42 |
| WINS replication partner automatic discovery | 42 | |

The WINS client and WINS Server services listen on User Datagram Protocol (UDP) port 137. UDP is an unreliable transport protocol in that it does not establish a session or connection between the sender and the receiver. Because of this, it is possible for more requests than responses to be sent. That is, a client might need to send a request multiple times before it receives a

response. However, a client never receives more than one response to a request.

**WINS Processes and Interactions**

WINS clients communicate with WINS servers for NetBIOS name services. WINS servers communicate with other WINS servers for WINS database replication. WINS servers also periodically run a process to identify and clean up extinct names in the WINS database.

NetBIOS name services include four types of processes between a WINS client and a WINS server. The following table briefly describes these processes, which are discussed in more detail in the following sections.

**NetBIOS Name Service Processes**

| Name Service Process | Description |
|---|---|
| Name registration | Name registration is a WINS client requesting the use of a NetBIOS name on the network. WINS validates that the NetBIOS name is not in active use and then adds it to the WINS database.<br><br>When a NetBIOS name is registered in the WINS database, other computers can resolve that name and use the resulting IP address to communicate with the network resource.<br><br>Names typically are registered when a NetBIOS application starts, such as when a computer or service starts up, or when a user logs on to the network. |
| Name renewal | Each NetBIOS name registered in the WINS database has a specified TTL. Before this time expires, the name is refreshed. |
| Name release | When a NetBIOS application shuts down, such as when a computer or service is stopped or a user logs off the network, the name is released by the WINS client and is marked as released in the WINS database. |
| Name resolution | When an application needs to communicate with a NetBIOS application on another NetBIOS node, the NetBIOS name for the other node is resolved to its IP address. |

Clients that are not configured to use WINS can also participate in these processes to a limited extent by using a WINS proxy. The remainder of this section describes what happens during typical and WINS proxy name service processes, the scavenge process, and the replication process.

**Name Registration**

Before a NetBIOS name can be resolved in a WINS environment, it must be registered with a WINS server. For example, when a WINS client starts up, it sends a name registration request to the WINS server for each NetBIOS name it uses. A name registration request can be for a unique name (maps to a single IP address) or for a group name (maps to multiple IP addresses).

As illustrated in the following figure, a WINS client (ClientC) sends a name registration request directly to its configured WINS server, WINSA.

**Name Registration**

In this example, ClientC sends a name registration request to its configured primary WINS server, WINSA. WINSA adds an entry for ClientC, with its IP address, in the WINS database and sends a positive reply back to ClientC.

Registering a unique NetBIOS name by using a WINS server works as follows:

1. When a network resource starts up, the WINS client sends a name registration request, which includes the NetBIOS name

and IP address, to its configured WINS server.

2. The WINS server checks to see if the name has already been registered, and if so, whether it is in active use. The WINS server sends a Wait for Acknowledgment (WACK) message to the WINS client while it attempts to determine whether the name can be registered.

3. If the name is not in use, the server adds the NetBIOS name and IP address to the WINS database and sends the client a positive name registration reply, which includes a TTL value that determines when the name will expire.

4. If the name is in active use, the WINS server does not add the name and address to the WINS database and sends the WINS client a negative name registration reply.

The precise process for registering NetBIOS names depends on the client's node type. B-node clients use broadcasts instead of WINS servers to register names. M-node and H-node clients combine the use of broadcasts and WINS P-node clients use only WINS.

Because WINS servers do not respond to broadcasts, the actions described in this section do not apply to broadcast registration. The following table describes the results of WINS server replies.

**WINS Server Replies**

| Server Reply | Result |
|---|---|
| No reply | If the WINS client has one or more secondary servers configured, it tries each server. If the WINS client does not receive an immediate response from a WINS server, it can try the server up to three times. If the WINS client does not receive a reply from any of its configured WINS servers, name registration fails and the application can display an error to the user. |
| Positive reply | The name can be resolved by other computers for communication and no other network resource can use the same name (if the name is unique). |
| Negative reply | The name registration fails. Windows Server 2003 processes, such as the Server service, write an error event to the system event log. |

**Name Conflicts**

During a NetBIOS name registration request, a WINS server verifies that the requested name is not a duplicate of a NetBIOS name already in use in the network. The WINS server first determines whether the name exists in the WINS database. If the name is already registered, the WINS server determines whether the name is in active use or whether it is available. A variety of factors determine whether the name is available.

In some cases, a WINS server can determine from the database entry whether a NetBIOS name is active. If the WINS server cannot determine in this way whether the name is active, it might need to challenge the name. To challenge a name, the WINS server sends a name query request to the WINS client that registered the name. If the name is active, the WINS client that registered the name sends a name query response and is said to defend the name.

The following factors influence the action taken by a WINS server when resolving a name conflict:

- Whether the name is a unique name or a group name.

- The state of the registered name. A registered name can be active, released, or extinct.

- Whether the name is owned by the WINS server handling the registration request or another WINS server.

- Whether the IP address is the same or different from the IP address specified in the name registration request.

- Whether the name is statically or dynamically added to the WINS database.

**Names with different IP addresses**

If a WINS client sends a name registration request for a unique name that already exists in the WINS database, but with a different IP address, the WINS server first checks the status of the existing name. If the name is in a released or extinct state, the

WINS server treats the request as a new registration and sends a positive name registration reply to the WINS client requesting the name.

If the database status of the existing name is active, the WINS server determines whether the unique name is still in use by sending a challenge to the WINS client that registered the name, as illustrated in the following figure.

**Name Challenge**

In this example, the following steps take place:

1. A WINS client (ClientA at IP address 192.168.0.17) sends a name registration request to its configured primary WINS server (WINSA).

2. WINSA finds the unique name "ClientA" with a different IP address in the WINS database. WINSA sends a Wait for Acknowledgement (WACK) message to the requesting WINS client. The WACK message includes the estimated time of the wait in the TTL field.

   WINSA then sends a name query request to the WINS client at IP address 192.168.0.20. WINSA waits 500 milliseconds between challenges, and if ClientA is multihomed, WINSA tries each IP address. If WINSA receives no response from the first challenge, it makes two additional attempts.

3. The name ClientA is still in active use, so the WINS client sends a name query response back to WINSA.

4. WINSA then sends a negative name registration response back to the requesting WINS client. If the registered name "ClientA" was no longer in active use, no name query response would be sent, and WINSA could send a positive name registration response to the requesting WINS client.

**Names with the same IP address**

If a WINS client sends a name registration request for a unique name with the same IP address as one that already exists in the WINS database, the action a WINS server takes depends on the status and ownership of the existing name, as follows:

- If the registered name has a status of active and is owned by the WINS server handling the new registration request, the WINS server sends a positive name registration reply to the WINS client making the request.

- If the registered name has a released or extinct status, or if it is owned by a different WINS server, the WINS server treats it as a new registration: it sends a positive name registration reply to the WINS client making the request and takes ownership of the name.

**Group names**

Group names are handled differently than unique names. A group name can be a normal group name or a special (also known as Internet) group name. Normal group names can have many associated IP addresses, but the member addresses are not stored in the WINS database. WINS responds to a name query for a normal group name with the limited broadcast address 255.255.255.255. Routers do not forward packets addressed to the limited broadcast address, so special groups were

developed to support communications between subnets.

Special groups are used for special, user-defined administrative groups. For example, a special group can be used to group resources such as file servers or printers. Special groups are associated with multiple IP addresses.

A WINS server handles name conflicts for a group name as follows:

- If a WINS client sends a unique name registration request that conflicts with a registered normal group name, a WINS server always sends a negative name registration reply.

- If a WINS client sends a name registration request for a special group name, a WINS server always sends a positive name registration reply, adding the requested name as an additional member of the group. In this situation, if the existing name has a state of released or extinct, the name registration request is treated as a new registration.

- If a WINS client sends a name registration request for a *DomainName*[1D] name, a WINS server always returns a positive registration response, even though the WINS server does not add this name to the WINS database. When a WINS client queries a WINS server for this type of name, the server responds with a broadcast address, which forces the WINS client to broadcast to resolve the name.

**Static names**

In addition to supporting dynamic name registration, WINS supports static name registration for computers that do not directly communicate with WINS. Static names are added manually to the WINS database with the WINS Microsoft Management Console (MMC) snap-in or with the **netsh wins server add name** command. Static names do not automatically age and drop from the WINS database like dynamically-added names do. Static names remain in the database indefinitely unless there is manual intervention.

If a WINS client sends a name registration request for an existing static name, a WINS server by default always sends a negative name registration reply. This behavior can be overridden to always send a positive name registration reply.

**Positive Name Registration Replies**

When a WINS server sends a WINS client a positive name registration reply for a name that does not yet exist, it adds the name entry to the WINS database as follows:

- Calculates time stamp by adding current time to the renew interval

- Takes ownership

- Sets state to active

- Assigns a new version ID

When a WINS server sends a WINS client a positive name registration reply for a name and IP address that already exist in the WINS database, it updates the name entry in the WINS database. The following table describes the database updates for unique, dynamic name registrations.

### Note

- A WINS server does not update existing database records for normal group entries or static entries because the server returns negative name registration replies for these types of name conflicts (unless the default behavior for group entries is overridden).

### Name Registration Database Updates

| State of Name | Server Action |
|---|---|
| Owned and active | Updates time stamp |
| Replica and active | Updates time stamp, takes ownership, increments version ID |
| Released | Updates time stamp, makes active, increments version ID |

| | |
|---|---|
| Owned and extinct | Updates time stamp, makes active, increments version ID |
| Replica and extinct | Updates time stamp, takes ownership, makes active, increments version ID |

The time stamp is calculated as the sum of the current time and the renew interval. Changes that increment the version ID are replicated to all other WINS servers.

**Burst Handling**

High-volume (burst) server loads occur when a large number of WINS clients simultaneously attempt to register their names with a WINS server, such as when power is restored after an outage. A WINS server can use burst mode to respond positively to client requests before it processes and updates the WINS database.

Burst mode uses a configurable burst-queue size as a threshold value. This value specifies how many name registration and name renewal (also known as refresh) requests a WINS server processes normally before it starts burst-mode handling. By default, the value is 500. When the number of name registration and refresh requests exceeds the threshold value, a WINS server initiates burst mode.

During burst mode, a WINS server immediately responds to registration and refresh requests with a positive response that includes a very small TTL. The TTL value included in the response varies for different clients to distribute the actual registration load over time. This process slows the refresh and retry rate for new WINS clients and regulates the amount of WINS client network traffic.

For example, if the burst queue size is 500 entries and more than 500 requests are active, the WINS server replies immediately to the next 100 WINS registration and refresh requests by sending immediate positive responses, with a starting TTL value of 5 minutes. For each additional round of 100 client requests, the WINS server adds 5 minutes to the TTL, up to a maximum of 50 minutes. If WINS client traffic still arrives at burst levels, the WINS server responds to the next round of 100 client requests starting again with a TTL value of 5 minutes. The WINS server continues to increment the TTL until it reaches its maximum intake of 25,000 requests. At 25,000 requests, the WINS server begins dropping requests.

During burst handling, name release requests are queued along with name registration and refresh requests. When the queue becomes full, however, release requests are silently dropped. In this case, the names are released when their TTL expires.

Name query requests are queued indefinitely during burst handling.

**Name Renewal**

Dynamic NetBIOS names are not owned permanently. When a WINS server successfully registers a name, it sends the WINS client a positive name registration reply with a TTL value that specifies the life span of the name. The default TTL value in Windows Server 2003 is six days. It is the responsibility of the WINS client to renew the name before the TTL expires.

If the WINS client does not renew the NetBIOS name before the TTL expires, the state of the name is changed to released, and the WINS server eventually deletes the name from the WINS database, as described later. Static names do not expire, so they do not need to be renewed.

To renew a name, a WINS client sends a name refresh request to the WINS server. The WINS server treats name refresh requests similarly to name registration requests, by sending a name refresh reply that includes a new TTL. The following figure illustrates a renewal request.

### Name Renewal

In this example, the WINS client, ClientC, sends a name refresh request to its configured primary server, WINSA. WINSA updates the database entry for ClientC to reflect an active state and sends a positive name refresh reply to ClientC with a new TTL.

WINS clients attempt to renew their NetBIOS names when one-half of the TTL value is reached or when the computer or the service restarts.

If the WINS server does not respond to the name refresh request, the WINS client continues to try the primary WINS server every 10 minutes for one hour, and then tries the secondary WINS server every 10 minutes for one hour. The process of trying first the primary server for an hour and then the secondary server for an hour continues until the name expires or the WINS server responds and renews the name.

**Name Release**

A NetBIOS name is released when it is no longer in active use by the WINS client that registered it. The owning WINS server does not respond to or resolve name queries for these names, unless the WINS client again registers the name.

Names can be released actively or passively. Expired names that are not renewed are released passively. WINS clients actively release their NetBIOS names when NetBIOS applications terminate properly, such as when a computer is shut down or a service is stopped, as shown in the following illustration.

**Name Release**

In this illustration, the following occurs:

1. When the computer, ClientC, shuts down properly, it sends a name release request to the WINS server, WINSA.

2. WINSA changes the state of ClientC's name entry in the WINS database to released, time-stamps the entry with the sum of the current time and the extinction interval, and takes ownership of the of name entry.

   **Note**

   - For active releases in Windows 98, the WINS server makes itself the owner of the name entry, if it is not already. In Windows NT 4.0 and later, if the WINS client sends a name release request to a different WINS server than it registered with, the WINS server changes the name entry to extinct instead of released, as described later in this section.

3. WINSA sends a positive name release response back to ClientC.

When a name entry is changed to the released state, the version ID is not updated and the change is not replicated to other WINS servers.

Released name entries are handled differently if the WINS server releasing the name is not the owner of the name entry, as described in the following table.

**Released Name Handling**

| Server Is Owner of Name Entry | Server Is Not Owner of Name Entry |
|---|---|
| State set to release | State set to extinct |
| Time stamp calculated from current time plus extinction interval | Time stamp calculated from current time plus extinction interval plus extinction time-out |
| Release status information is not replicated to other WINS servers | Extinct status information is replicated to other WINS servers |

The different approach for non-owners prevents inconsistencies between primary and secondary WINS servers, because released name entries are not replicated to other servers while extinct name entries are replicated.

If a network resource does not shut down properly, or the WINS client is unable to contact the WINS server during shutdown, the name might not be automatically released.

The released state simplifies WINS name registration for WINS clients that shut down and then restart. If a name is released, the WINS server does not challenge the name when the network resource restarts. If a proper shut down did not occur and the name is not released, the WINS server challenges the name on the next registration request if the IP address is different, as can happen when a DHCP-enabled laptop changes subnets. In such a case, the challenge fails (because the client cannot defend the old IP address) and the registration succeeds, but the registration requires extra processing.

**Name Extinction and Deletion**

When a name entry in the WINS database is marked released and the name is not reregistered, its state progresses to extinct. The name entry is marked with a series of time intervals that determine when the entry changes from released to extinct, and when it can be deleted from the database. The scavenge process checks the time intervals and makes these changes. This process runs automatically, based on the relationship between the configurable renewal and extinction intervals.

**Name extinction**

In general, name entries pass through the states described in the following table.

**Progression of Inactive States**

| Current State of Name Entry | Resulting Status of Name Entry |
|---|---|
| Active state, TTL interval elapsed, WINS server is the owner of the name entry | Released |
| Active state, TTL interval elapsed, WINS server is not the owner of the name entry | Extinct |
| Released state, extinction interval is not elapsed | Released |
| Released state, extinction interval is elapsed | Extinct |
| Extinct state, extinction time-out is not elapsed | Extinct, not ready for deletion |
| Extinct state, extinction time-out is elapsed | Extinct, deleted during scavenging |

Because changing a name entry to the extinct state results in replication, rapid synchronization of WINS databases occurs. The extinct state prevents inconsistencies from lingering. For example, if the primary WINS server of a WINS client is unavailable when the client shuts down, the name release request is directed to the secondary WINS server. If the primary WINS server is available again when the client restarts, the client registers and continues to renew with the primary WINS server, which has not recorded any change in the status of the client, while the secondary WINS server still reflects the released state of the name entry.

**Name deletion**

Extinct name entries that have expired extinction time-out intervals are automatically deleted from the WINS database by the scavenge process. Because changing the status to extinct causes name entries to be replicated, replication typically ensures that the name entries are extinct in all copies of the WINS database before any of the entries are deleted, thus ensuring that the name entries are deleted from all copies of the database.

Under certain abnormal conditions, however, names no longer in use can remain in the database. For example, if an extinct entry is deleted before it is replicated, the active state of the record in the replica databases never changes. This might happen if a replication copy of the database is not reachable during the extinction time-out period.

When an active entry is replicated, it is time-stamped on the pulling server (the WINS server requesting the replication) with the sum of the current time and the verification interval. The default verification interval is 24 days. If the scavenge process determines that there are entries with an expired verification interval, the WINS server sends a name query to the WINS server that owns the name entry to determine whether the version ID is still valid. The following table describes the possible courses of action based on the owning WINS servers response.

**Verification Interval Evaluation**

| Owning WINS Server Response | Action Taken |
|---|---|
| Negative response (name entry is invalid) | Name entry is deleted |

| | |
|---|---|
| Positive response (name entry is valid) | Time stamp is updated |
| No response | Name entry left intact until next verification interval or until an administrator manually scavenges it |

The scavenge process determines which name entries need to be updated or deleted based on ownership, state, and time stamp. This process releases name entries when appropriate, deletes extinct name entries, and verifies whether names are still in use after the verification interval expires. The scavenge process runs periodically based on a scavenging time interval. The scavenging time interval starts at WINS server startup and is half the renew interval (by default, 72 hours). If a WINS server is stopped and restarted before 72 hours have elapsed, the scavenging time interval is reset. If a WINS server is stopped on a daily basis, scavenging does not occur. Scavenging can also be initiated manually.

The following table summarizes the changes the scavenge process makes to name entries in the WINS database.

**Changes to Name Entries During Scavenging**

| Pre-Scavenge State | Post-Scavenge State |
|---|---|
| Owned, active state, renew interval not expired | Unchanged |
| Owned, active state, renew interval expired | Marked released |
| Owned, released state, extinction interval not expired | Unchanged |
| Owned, released state, extinction interval expired | Marked extinct |
| Owned, extinct state, extinction time-out not expired | Unchanged |
| Owned, extinct state, extinction time-out expired | Deleted |
| Replica, extinct state, extinction time-out expired | Deleted |
| Replica, active state, verification interval not expired | Unchanged |
| Replica, active state, verification interval expired, owner challenged, positive response (name entry exists in owner's database) | Time stamp updated (current time plus verification interval) |
| Replica, active state, verification interval expired, owner challenged, negative response (name does not exist in owner's database) | Deleted |
| Replica, active state, verification interval expired, owner challenged, no response received | Unchanged |

During the first scavenging run, all the actions described in the previous table are performed except for deleting name entries. Name entries are not deleted until at least three days after WINS server startup. This delay allows sufficient time for replicating the entries that are ready to be deleted.

In addition to the database cleanup that occurs during the scavenge process, database consistency checks verify name entries in the local database and update name entries as necessary to match the owner entry. Version ID consistency checks verify that owner version IDs are higher than replica version IDs at other WINS servers.

**Name Resolution**

When a computer needs to communicate with another network resource that uses a NetBIOS name, the computer must first acquire the network resource's IP address before communications can be established. Name resolution is the process of obtaining the IP address for a NetBIOS name.

As the following figure illustrates, the WINS client sends the NetBIOS name to a WINS server, the WINS server sends the IP address back to the client, and then the client uses the IP address to connect to the remote computer.

**Name Resolution**

In this figure, ClientA, a WINS client, needs to connect to ClientB. ClientA sends a name query request for the NetBIOS name ClientB to its primary WINS server, WINSA. WINSA finds ClientB in the WINS database and returns the IP address 192.168.1.17 to ClientA, and ClientA then connects to ClientB.

The precise steps for resolving a NetBIOS name depend on the client's NetBIOS node type. B-node clients broadcast the name request to the local subnet. P-node clients use a WINS server only. M-node clients first try broadcasting, and if that is unsuccessful, they use a WINS server. H-node clients first try a WINS server, and if that is unsuccessful, they try broadcasting. This section focuses on the WINS server part of the process.

WINS clients running Windows 2000, Windows XP, or Windows Server 2003 are configured by default to use DNS first to resolve names that are longer than 15 characters or that have periods (.) within the name. If the client is configured to use a DNS server, DNS is used again as a final option if a WINS query is unsuccessful for names that are less than 15 characters and that do not have periods.

For NetBIOS name resolution, a WINS client typically performs the following progression of steps until either the name is resolved or all methods have failed to return an IP address:

1. Client checks its local NetBIOS name cache of remote names. Recently resolved NetBIOS names (up to 16, by default) are held in this cache for 10 minutes.

2. Client sends the NetBIOS name query request to its configured primary WINS server. If the primary WINS server fails to respond, either because it is not available or because it does not have an entry for the name, the client tries to contact all other configured WINS servers in the order they are listed in its configuration.

3. If the client uses H-node, it broadcasts the NetBIOS name query to the local subnet up to three times. (If the client uses M-node, it performs this step before contacting the WINS server (step 2). If the client uses P-node, it does not perform this step.)

4. Client checks the Lmhosts file, if Lmhosts is enabled in the **WINS** tab of the advanced TCP/IP properties.

5. Client converts the NetBIOS name to a host name by removing the last byte and any spaces at the end of the NetBIOS name.

6. Client checks to see if the host name corresponding to the converted NetBIOS name matches the local host name.

7. Client checks the DNS client resolver cache.

8. Client tries a DNS server, if it is configured for one.

If the WINS server resolves the name query request, the WINS server sends a positive name query reply that includes the requested IP address to the client. When the client receives the reply, it uses the address to establish a connection to the desired network resource.

If the WINS server cannot resolve the name query request or if the request is for a unique name that is in a released or extinct state, it sends a negative name query reply to the client. If none of these steps can resolve the name, Windows returns an error.

**Name Queries for Normal Groups**
A normal group name does not have an IP address associated with it, so when a WINS server receives a name query request for a registered normal group name, it cannot return a specific address. Instead, the WINS server returns the limited broadcast address (255.255.255.255). The WINS client then issues a broadcast to its local subnet to resolve the name.

If the request is for a normal group name that is in a released or extinct state, a WINS server sends a positive name query reply and also sends the limited broadcast address (255.255.255.255).

**Name Queries for Special Groups**
A special group can have multiple IP addresses (up to 25) associated with it. When a WINS server receives a name query request for a special group, it returns all the IP addresses for which the TTL has not expired.

### Note

- The WINS server sends as many addresses as it can fit into a UDP message. Because special groups are limited to 25 addresses, all the addresses fit into the UDP message.

**WINS Proxy Name Services**
When a WINS proxy is located on a subnet that includes B-node clients, the WINS proxy can mediate B-node name services requests for registration, release, and resolution by taking the following actions:

- Perform a name lookup during name registration and send a negative name registration reply if it finds the name in its local cache of remote names or in the WINS database.
- Delete the B-node client name from its cache of remote names, when a client releases its name.
- Attempt to resolve a B-node name query request by using information from either its local cache of remote names or from the WINS server.

**Proxy Support for Name Registration Requests**
When a B-node client broadcasts a name registration request, the WINS proxy receives the broadcast and then does a name lookup for names that do not exist on the local subnet. First it uses its local cache of remote NetBIOS names, and if the name is not in the cache, the WINS proxy sends a name query request to the WINS server. If the unique name is found in the WINS database, the proxy sends a negative name registration reply to the B-node client.

**Proxy Support for Name Release**
When a B-node network resource shuts down, WINS proxies simply delete the name from the local name cache in response to the name release request.

**Proxy Support for Name Resolution**
WINS proxies support NetBIOS name resolution for B-node clients. They receive B-node name query broadcasts and respond for names that are not found on the local subnet.

The following figure illustrates how a WINS proxy resolves names for non-WINS clients.

### WINS Proxy Name Resolution

In this example, the WINS proxy (ClientB) performs the following steps to resolve names for the B-node client (ClientA):

1. ClientA broadcasts a NetBIOS name query request to the local subnet (Subnet 1).

2. ClientB receives the broadcast and checks its cache of remote names for the requested NetBIOS name. The WINS proxy always differentiates name queries for local names from remote names. It compares the address of names it resolves to its own address by using the subnet mask, and if the two match, the WINS proxy does not respond to the name query.

3. If ClientB locates the NetBIOS name in its cache, ClientB sends a positive name query reply to ClientA with the IP address.

4. In this example, ClientB cannot locate the NetBIOS name in its cache, so ClientB sends a name query request to the WINS server, WINSA, and enters the requested name in its cache of remote names in a “resolving” state. If ClientB receives another query for the same name before the WINSA responds, ClientB does not query WINSA again.

5. If WINSA cannot resolve the name, it sends a negative name query reply to ClientB, which in turn sends a negative name query reply to ClientA.

6. In this example, WINSA can resolve the name, so it sends a positive name query reply with the IP address to ClientB. ClientB updates the cache entry with the IP address and changes the state to resolved.

   By default, WINS proxies cache remote name mappings resolved by the WINS server for 6 minutes.

7. ClientB sends a positive name query response to ClientA and uses the name mapping in its cache to respond to subsequent NetBIOS name queries broadcast from any B-node clients on the subnet. A WINS proxy sends reply messages only if the response is already in its cache.

### Note

- When a WINS proxy responds to a query for a multihomed client or for a group record that contains a list of IP addresses, it returns only the first address to the B-node client.

**Replication**

Typically, large environments include multiple WINS servers. When multiple WINS servers are used, they can be configured to replicate, or copy, records from one WINS database to other WINS databases. Replication keeps all the WINS databases synchronized and ensures that the names registered on one WINS server are available on all WINS servers. Replication supports the following:

- Reduced name services traffic over WANs

- Redundancy

- Load balancing

- Scalability

For a WINS server to replicate data, it must be configured with at least one other WINS server as its replication partner. Replication partners are WINS servers that are configured to have a replication relationship with each other.

There are three types of replication partners, as described in the following table.

**Types of Replication Partners**

| Type of Partner | Description |
|---|---|
| Push | A WINS server that is configured to notify its pull partner when there are updated entries in the WINS database that are available for replication. Push partners initiate replication. |
| Pull | A WINS server that is configured to request the updated WINS database entries that are ready for replication. |
| Push/pull | A WINS server that is configured to act both as a push partner and a pull partner. This is the default configuration. |

A WINS server can be configured to discover its replication partners automatically (known as autodiscovery) or it can be manually configured for specific replication partners. WINS servers periodically announce their presence on the network. The WINS announcements are sent on a multicast address that is reserved for WINS (224.0.1.24). WINS servers that are configured for automatic discovery listen for the announcements and find other WINS servers on the network. Any WINS server discovered this way is automatically added to the replication partners list as a push/pull partner.

Regardless of whether servers are configured for one-way replication (push only or pull only) or for two-way replication (push/pull), the primary and secondary WINS servers for a client must have a push and pull relationship to each other to ensure that WINS functions properly if the primary server fails.

The following figure illustrates how replication works. Two WINS servers, WINSA and WINSB, are configured to be replication partners.

**WINS Database Replication**

In this figure, a WINS client (ClientA) on Subnet 1 registers its name with its primary WINS server, WINSA, and its name is updated in the WINSA database. Another WINS client (ClientB) on Subnet 3 registers its name with its primary WINS server, WINSB, and its name is updated in the WINSB database. If, after replication, ClientA sends a name query request to WINSA to find an IP address for ClientB, ClientB will be in the WINSA database.

WINS replication is always incremental, which means that only changed records, rather than all records, are replicated.

**Persistent Connections**

By default WINS uses persistent connections between replication partners. When they use persistent connections, WINS servers do not disconnect from their replication partners each time replication is completed and, therefore, avoid the overhead and delays of establishing a new connection each time replication begins. Typically when WINS servers are interconnected through high-speed LAN links, it is preferable to keep connections open.

Persistent connections increase the speed of replication because a server can immediately send updates to its partners, making replication more consistent. The bandwidth used by persistent connections is minimal because the connection is usually idle.

Persistent connections can be used with push partners and pull partners, either with a specific partner or with all the replication partners of a WINS server.

**Version ID**
Every name entry in a WINS database has a version ID field. This field is incremented whenever a change that is to be replicated takes place. That is, the version ID for a name is incremented whenever that name is registered, changed from a released to an active state, or changed to an extinct state.

The value in version ID reflects the total number of replicable changes that occurred to owned entries for that particular WINS server. The value is incremented by hexadecimal 1 every time a replicable change occurs. For example, if WINSA is the owner for ClientA, which has a version ID of 4B3, and for ClientB, which has a version ID of 4C2, ClientB was the fifteenth replicated change in the WINSA database after the ClientA change.

The number of changes in version ID is one way that WINS determines when to trigger replication between two servers.

**Push Partners**
A push partner is a WINS server that is configured to push or notify other WINS servers when it has database updates that are ready to be replicated. Push partners initiate replication. They notify replication partners when it is time for the partners to pull updates, but they do not send any updates.

A push partner can be configured to use any of the following events to trigger the push notification:

- WINS server startup.
- An IP address change in a name-to-address mapping in the database.
- A specified number of version ID changes occur. This number is the number of local changes and does not include changes pulled from other partners. WINS can use this number as a threshold for determining how many changes must be made to the database before it starts push replication to its partners. This number can apply globally to all partners to which it pushes or individually to specific partners.

When persistent connections are used for push replication and the number of version ID changes for triggering replication is set to 0 (the default), the push partner sends a push trigger notifying its replication partners every time an update occurs. In this situation, push replication is not dependent on the number of times version ID changes but occurs at every update. (An update is defined here as a change that increments the highest version ID in the local WINS database for records the server owns.) If the number of version ID changes is greater than 0, the frequency of push notifications is reduced.

If persistent connections are not used for push replication, push replication is dependent on the number of times the version ID changes. If this number is set to zero, push replication never occurs, except if it is set to occur at service startup or when IP addresses change. If the number of version ID changes is greater than 0 when persistent connections are not used, the frequency of push notifications is increased.

For example, suppose that the highest version ID for server WINSA is 1C4. WINSA is also set to push to its replication partners when there have been two updates in its database. Suppose also that the following four sets of database changes are then made to the WINS database at WINSA:

1. ClientA refreshes its previously registered name but keeps the same IP address.
2. ClientB registers its name, creating a new dynamic name-to-address mapping in the database.
3. ClientC reregisters a previously released name and changes its IP address.
4. A pull replication occurs at a specified interval with another WINS server.

When these changes are entered into the database, the highest version ID for WINSA is 1C6 because two of the changes — update 2 (registering a new name) and update 3 (changing an IP address) — cause the version ID for that server to be incremented.

After these changes occur, WINSA then sends a push notification to its replication partners.

**Pull Partners**
A pull partner is a WINS server that is configured to pull, or request replication of, updated WINS database entries from other

WINS servers (those configured as its push partners) at a configured interval. Push replication can occur in response to a specified event, in response to a manual request by an administrator, or in response to a push trigger.

A pull partner pulls or requests entries that have a higher version ID than the last entry it received from its configured replication partner.

A pull partner can be configured to use either of the following events to trigger the request for replication:

- WINS server startup
- A user-specified amount of elapsed time, which can apply globally to all the partners from which it pulls or individually to specific partners

When the specified time has elapsed, the pull partner sends a replication request to its configured partners. The partners respond with incremental updates, if any have occurred since the last replication.

Database updates are not physically replicated until a pull partner sends a replication request in response to the notification sent by a push partner. Therefore, pull replication can be viewed as the single process used to replicate data between WINS databases.

The IP address-to-owner ID table in the WINS database is used during the replication process. In addition, all WINS servers maintain an internal push partner owner-to-version mapping table. During WINS initialization, a WINS server scans the name-to-IP address mapping table to find the highest version ID for each owner in the IP address-to-owner ID table. The WINS server uses the information to build the push partner owner-to-version table, which maps the owner IDs to their highest version IDs. The WINS server maintains this table in memory and never commits it to the database. WINS uses the push partner owner-to-version table to determine the state of the database at any point before or after replication.

During replication, the WINS server updates the push partner owner-to-version table with the highest version IDs sent by its push partners. The WINS server then scans the version ID field in the name-to-IP address table to find the highest version ID for each owner and compares the results with the numbers in the push partner owner-to-version table to determine which push partner has the latest data for each owner. The WINS server also updates its IP address-to-owner ID table with additional owners obtained from its push partners.

The following figure illustrates how WINS manages replication. In this example, four WINS servers (WINSA, WINSB, WINSC, and WINSD) are all configured as push/pull partners for a central server, WINSH.

**Example of Pull Replication**

Before replication begins in this example, the owner-to-version table at WINSA contains the highest version IDs for all the owners in its database. Assume that these values are the values shown in the following table.

**WINSA Owner-to-Version Table**

| Owner | Name | Highest Version ID |
|---|---|---|

| | | |
|---|---|---|
| 192.168.1.5 | WINSA | 1F |
| 192.168.2.5 | WINSH | 125 |
| 192.168.3.5 | WINSB | 31 |
| 192.168.4.5 | WINSC | 100 |
| 192.168.5.5 | WINSD | 200 |

In reality, pull replication can occur dynamically between WINSH and WINSA, WINSB, WINSC, and WINSD at various times, so the table might not remain static for long. To simplify the details of an individual pull replication cycle, however, the example below focuses on what might happen when WINSA replicates its database with WINSH.

In this example, the following changes occur in the replicated WINS network:

1. Assume that first WINSB, WINSC, and WINSD each replicate with WINSH, based on the highest version ID.

    a. WINSB has added or updated one new record since its last replication cycle, which is replicated at WINSH.

    b. WINSC has the same version ID and does not have any records to be replicated at WINSH.

    c. WINSD has updated 20 records since its last replication cycle, which are replicated at WINSH.

2. Assume that after WINSB, WINSC, and WINSD replicate with WINSH, WINSH sends a push trigger to WINSA, initiating replication. WINSA then pulls the updated owner-to-version information from WINSH.

3. WINSA responds by pulling entries from WINSH.

    WINSA determines which updates it needs to pull based on the difference between its locally-held highest version ID for each owner and the corresponding highest version IDs provided by WINSH. WINSA specifies the range of records to be pulled and replicated by comparing version IDs. In this example, WINSA pulls updates that occurred on WINSH with a version ID greater than 125, updates that occurred on WINSB with a version ID greater than 31, and updates that occurred on WINSD with a version ID greater than 200.

If another pull replication to the same partner is already queued, WINS treats the later request as further down in the queue and discards it in favor of keeping the one that is higher in the queue.

**Accepting and Blocking Replication Partners**
WINS servers can be configured to accept updates only from specific replication partners (known as persona grata) or to block updates from specific replication partners (known as persona non grata) during replication. A WINS server can be configured for only one of these options. These options apply either during push-pull replication or during pull replication.

**Accepting replication partners**
When a WINS server is configured to accept specific replication partners, only updates from WINS servers that are included in the list are replicated. For example, accepting replication from specific partners might be useful when WINS servers are configured in a hub-and-spokes pattern, where a central server is the hub and other distributed servers are the spokes. By including only the IP addresses for the hubs in the list, you can replicate updates only between the hubs, without including the spokes.

If a WINS server is configured to accept updates from specific partners and no list of accepted WINS servers is provided, no updates are replicated. Accepting updates only from specific partners is a new WINS feature in Windows Server 2003.

**Blocking replication partners**
When a WINS server is configured to block specific replication partners, only updates from WINS servers that are not in the list are replicated. For example, blocking replication partners is useful when a WINS server is removed from service. After a WINS server is removed from service, name entries it owns can continue to be replicated to other servers. Replication of these records can occur for one of the following reasons:

- Static entries that were originally added to the now inactive WINS server replicate indefinitely to the other active WINS servers in the network until the entries are deleted manually.

- Dynamic entries that were originally added to the now inactive WINS server are not immediately deleted from the WINS database. WINS must check with the owner server before it deletes dynamic entries. If a database entry cannot be verified as expired because the owner server is no longer in use, other WINS server's retain the entry until it can be verified.

The blocking replication partners option can prevent replication of name entries from inactive WINS servers.

If a WINS server is configured to block updates and no list of blocked WINS servers is provided, updates are replicated for all WINS servers.

**Owner ID and Time Stamp During Replication**
WINS replicates only name entries in the active and extinct states. During replication, the fields for these database entries are copied, with the exception of owner ID and time stamp.

The owner ID is obtained from the local owner ID-to-version ID mapping table because the value that is used locally to represent a specific WINS server differs from server to server. For example, WINSD might be represented as owner ID 2 on WINSB and as owner ID 3 on WINSA.

When a name entry is replicated, it is given a new time stamp. Active name entries are time-stamped with the sum of the local current time and the verification interval. Extinct name entries are time-stamped with the sum of the local current time and the extinction time-out.

**Name Conflicts During Replication**
Although name conflicts are usually handled at the time of name registration, it is possible for the same name to be registered at two different WINS servers. This situation might happen if a WINS client registers the same name at a second WINS server before the updates from the first WINS server replicate to the second. In this case, WINS resolves the conflict at replication time.

Conflicts at replication can be between two unique name entries, between a unique name entry and a group name entry, or between two group name entries.

**Conflicts between unique name entries**
When two unique names conflict, WINS resolves the conflict based on three factors:

- State of the entries (active, released, or extinct)
- Ownership of the entries
- Same or different IP addresses

This section describes how WINS resolves conflicts between unique names.

**Conflicts between two replicas**
When two replicas conflict, the new replica overwrites the existing replica, regardless of whether the addresses match. The only exception to this rule is if the existing replica is active and the new replica is extinct. If the existing replica is active, the new replica is extinct, and different WINS servers own the replicas, then the new replica does not overwrite the existing replica. If the existing replica is active, the new replica is extinct, and the same WINS server owns both, the new extinct replica overwrites the existing active replica.

**Conflicts between owned entries and replicas with the same IP address**
The replica replaces the owned entry unless the owned entry is active and the replica is extinct. In this case, WINS increments the version ID of the owned entry so that it replicates during the next iteration.

**Conflicts between owned entries and replicas with different IP addresses**
The replica replaces the owned entry unless the owned entry is active. If the owned entry is active and the replica is extinct, WINS increments the version ID of the owned entry so that it replicates during the next iteration. If both the owned entry and the replica are active, the server receiving the replica challenges the client that registered the owned entry to determine whether the client still uses the name. If it does still use the name, WINS sends the client designated in the replica a name conflict demand. This message puts the client in a conflict state, which forces the client to put the name in a conflict state. A name in a conflict state is marked and the name is no longer used.

**Conflicts between unique entries and group entries**
When a unique entry and a group entry conflict, WINS keeps the group entry. If the WINS server owns the unique entry and the entry is not in a released or extinct state, the WINS server requests the client named in the unique entry to release the

name.

**Conflicts between two special group entries**
When there is a conflict between two special groups, the new replica replaces the existing entry unless the existing entry is active. If the existing entry is active, WINS increments its version ID so that it replicates at the next iteration. If the new replica is also active, the WINS server updates the member list of the existing entry with any new members from the replica. If the list of active members grows to more than 25, the extra members are not added but are dropped silently.

**Conflicts involving multihomed entries**
If one of the name entries involved in a name conflict is for a multihomed node, the conflict is resolved in one of the following ways:

- If a multihomed replica conflicts with an extinct or released entry in the database, WINS replaces the existing entry in the database with the replica, unless the existing entry is a normal group and is in a released state. This is the same as the other scenarios in which a single-address entry conflicts with a released normal group entry.

- If a multihomed replica that is extinct conflicts with an active existing entry and both entries are owned by the same server, WINS replaces the active existing entry. If the active existing entry is a replica owned by a different server, WINS does not replace the existing entry. If the active existing entry is owned by the local WINS server and is a unique entry, WINS increments the version ID of the existing record to force replication.

- If an active multihomed replica conflicts with an active, unique, multihomed replica in the local database with the same owner, WINS replaces the existing entry. If the owner is different, WINS does not replace it. If the entry in the database is owned by the local WINS server, and if the members of the record (a single member in the case of a unique record) are a subset of the members of the replica, WINS changes the time stamp of the existing entry and increments its version ID to force replication. If the members of the replica are not a subset, the WINS server challenges the addresses in the existing entry. If there are no responses to the challenges, WINS replaces the existing entry. If there is at least one response to the challenges, WINS notifies the client to release the name from all addresses before it replaces the existing entry with the replica.

- If a multihomed replica conflicts with an existing active group entry, WINS increments the version ID of the existing entry to force replication.

- If a single-address replica conflicts with an existing inactive multihomed entry, WINS replaces the existing entry with the replica. If the replica conflicts with an existing active multihomed entry and both entries are owned by the same owner, WINS replaces the existing entry with the replica. If the existing multihomed entry is a replica owned by a different server, WINS does not replace it. If, however, the existing multihomed entry is owned by the local WINS server and the new replica is a unique record, then WINS challenges the clients that use the addresses in the multihomed record. If there are no responses to the challenges, WINS replaces the existing entry. If there is at least one response to the challenges, WINS sends requests for the name to the addresses in the existing entry and then updates the existing entry. The address in the unique replica, if present in the member list, is ignored in this situation.

**WINS Convergence Time**
There is a latency period between the time a database entry is updated at one WINS server and the time the entry is replicated to all other WINS servers in the network. This latency period is known as the convergence time for the WINS system. Convergence time can be computed as the sum of the configured replication periods from one server to the next over the longest path. The following figure illustrates a replication configuration and indicates the replication periods between nodes. This figure is not intended to be a realistic configuration, but merely to illustrate a longest replication path.

**WINS Convergence**

In this figure, the longest replication path is from WINSB to WINSA to WINSC. A name registration request from one of the WINS clients causes the WINSB database to be updated. Changes to the WINSB database are replicated to WINSA every hour, and changes are replicated from WINSA to WINSC every two hours. Therefore, the convergence time for the name registration request in this example is three hours.

The convergence time can vary among different types of name services. For example, name registration requests that occur at one server replicate to the server's replication partner at the next replication event. Name release requests, however, are not replicated. NetBIOS names are released when a network resource shuts down. Because it is common for these names to be reused with the same IP address when the network resource is restarted, replicating the name releases unnecessarily increases the network load of replication. Since these name service requests are not replicated, however, a NetBIOS name can be in the release state in one WINS database and still be in the active state in all other WINS databases.

In addition, some changes can take place and not be reflected in any of the WINS databases. For example, if a WINS client shuts down improperly, as in the case of an unexpected power outage, it is unable to send a name release request to its primary WINS server, and the registered names are not marked as released in the WINS database.

**Replication and Name Services Summary**

The following table describes typical events that might occur in a NetBIOS network, the name service operations they invoke, the resulting WINS database updates, and whether or not the changed name entry is replicated. These scenarios assume that the WINS server handling the name service request is the owner for the name entry and that each name service request results in a positive response.

**Typical WINS Scenarios**

| Event | Name Service Request / WINS Process | WINS Database Updates | Replication |
|---|---|---|---|
| Computer starts up | Name registration | • Name added to database<br>• State set to active<br>• Owner ID set<br>• Version ID incremented<br>• Renew interval set | Yes |
| Computer shuts down | Release | • State set to released<br>• Owner ID set<br>• Extinction interval set | No |
| Computer restarts, same name and IP address | Name registration | • State set to active<br>• Owner ID set<br>• Version ID incremented<br>• Renew interval set | Yes |

| | | | |
|---|---|---|---|
| Computer stays up, renew interval nears | Name refresh | • Name added to database<br>• State set to active<br>• Owner ID set<br>• Version ID incremented<br>• Renew interval set | Yes |
| Computer shuts down and restarts on different subnet with different primary WINS server, same name but different IP address | Name registration, which is challenged | • State remains active (release from shutdown not replicated)<br>• Owner ID set<br>• Version ID incremented<br>• Renew interval set | Yes |
| Computer shuts down and stays down, extinction interval expires | Database scavenge | • State set to extinct<br>• Version ID incremented<br>• Extinction time-out set | Yes |
| Computer remains shut down, extinction time-out expires | Database scavenge | • Entry deleted during scavenging | No |

**Related Information**

The following resources contain additional information that is relevant to this section.

- "How DHCP Technology Works"
- "How DNS Works"

For more information about WINS, see the following RFCs in the IETF RFC Database.

- RFC 1002, "Protocol Standard for a NetBIOS Service on a TCP/UDP Transport: Detailed Specifications."

# WINS Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- WINS Tools
- WINS Registry Settings
- DHCP Options for WINS
- Network Ports Used by WINS

The "WINS Tools" section describes tools that are useful for configuring, managing, and monitoring WINS servers and databases. Some of the tools are specific to WINS, while others are not.

The "WINS Registry Settings" section describes registry entries that are useful in specific circumstances and need to be set directly by using Regedit.exe. Registry entries that are not described in this section are modified by the tools described in the "WINS Tools" section.

The "DHCP Options for WINS" section describes the DHCP options that relate specifically to WINS.

The "Network Ports Used by WINS" section lists the ports that WINS uses for specific purposes.

**WINS Tools**
The following tools are associated with WINS.

**Jetpack.exe: Jetpack**
**Category**
The Jetpack tool is included as part of the operating system.

**Version compatibility**
Jetpack runs on Windows NT 4.0, Windows 2000, and the Windows Server 2003 family.

This tool compacts the WINS database while the database is offline. (Database compaction also runs as an automatic background process during idle time after a database update while the server is online. Dynamic compaction, however, does not reclaim as much space as offline compaction.)

Jetpack copies database information to a temporary database, deletes the original WINS database, and then renames the temporary database to the original name.

**Nbtstat.exe: Nbtstat**
**Category**
The **Nbtstat** tool is included as part of the operating system.

**Version compatibility**
**Nbtstat** runs on, and can target, computers running Windows NT 4.0, Windows 2000, Windows XP, and the Windows Server 2003 family.

This tool displays NetBIOS over TCP/IP (NetBT) protocol statistics, NetBIOS name tables for both the local computer and remote computers, and the NetBIOS name cache. It can be used to refresh the NetBIOS name cache and to release and reregister the names registered with WINS during troubleshooting.

To find more information about Nbtstat.exe, see "Command Line References" in the "Tools and Settings Collection."

**Netsh.exe: Netsh**
**Category**
The **Netsh** commands for WINS are included as part of the operating system.

**Version compatibility**
The **Netsh** commands for WINS run on, and can target, computers running the Windows Server 2003 family and Windows 2000 Server. There are some functional differences between the commands on Windows Server 2003 and Windows 2000

Server.

This tool provides a command-line alternative to the WINS Microsoft Management Console (MMC) snap-in for administering WINS servers. Command-line management can be advantageous in the following ways:

- Commands run in interactive mode can more efficiently manage WINS servers across slow wide area network (WAN) links.
- Commands run in batch mode can automate recurring tasks for managing many servers.

The **Netsh** extension that supports WINS server administration is available from the **wins>** prompt, which is available from the **netsh>** prompt.

The **server** command is available at the **netsh wins>** prompt for switching to a specific server context. The following table describes the commands available at the **netsh wins server>** prompt for administering a WINS server.

To find more information about **Netsh** commands for WINS, see "Command Line References" in the "Tools and Settings Collection."

**Network Connections**
**Category**
Network Connections is included as part of the operating system.

**Version compatibility**
Network Connections runs on Windows 2000, Windows XP, and the Windows Server 2003 family.

Network Connections is used to configure WINS clients for the following:

- Manually configure primary and secondary WINS servers (if DHCP option 44 is not used to configure the IP addresses of WINS servers)
- Enable Lmhosts lookup
- Enable or disable NetBT

These configuration options are available from the **WINS** tab in the advanced Internet Protocol (TCP/IP) properties for a connection.

**Wins.dll: WINS Replication Network Monitor Parser**
**Category**
WINS Replication Network Monitor Parser is included with Windows Server 2003 Resource Kit tools.

**Version compatibility**
WINS Replication Network Monitor Parser runs on Windows 2000 Server and the Windows Server 2003 family.

The WINS Replication Network Monitor Parser tool is a DLL that parses WINS data from within Network Monitor, a feature of Microsoft Windows. This tool is useful as a way to view and troubleshoot network issues related to WINS replication.

To find more information about WINS Replication Network Monitor Parser, see "Resource Kit Tools" in the "Tools and Settings Collection."

**Winsmgmt.msc: WINS Microsoft Management Console Snap-in**
**Category**
The WINS MMC snap-in is included with the Windows Server 2003 family and Windows 2000 Server, and it is installed when the WINS Server service is installed. It is also included in the Windows Server 2003 Administration Tools Pack.

**Version compatibility**
The WINS snap-in runs on, and can target, computers running Windows 2000, Windows XP, and the Windows Server 2003 family.

The WINS snap-in configures and manages WINS servers and databases by supporting the functions described in the following table.

| Function | Options |
|---|---|

| | |
|---|---|
| Configures server properties | • Frequency for updating server statistics<br>• Database backup settings<br>• Time intervals for aging and deleting name entries in the database<br>• Database consistency-checking settings<br>• Logging settings<br>• Burst handling settings<br>• Database path and name<br>• Starting version ID value<br>• LAN Manager compatibility |
| Configures database replication properties | • General properties, such as which WINS servers are used for replication and how static mappings are handled<br>• Push partner properties, such as when push replication is initiated and whether persistent connections are used<br>• Pull partner properties, such as when pull replication is initiated, how many attempts are made, and whether persistent connections are used<br>• Blocking or accepting replication only from specific partners<br>• Automatic discovery of replication partners |
| Manages WINS servers | • Add and delete WINS servers<br>• Add, remove, and configure replication partners<br>• Start and stop WINS service<br>• Display server statistics |

| | |
|---|---|
| Manages WINS databases | • Manually initiate replication<br>• Display database records<br>• Manually initiate the scavenge (database cleanup) process<br>• Initiate backup or restore<br>• Manually delete records<br>• Delete owners<br>• Initiate database consistency checks, which verify local database records against records in the owner databases<br>• Initiate version ID consistency checks, which verify that owner version IDs are higher than replica version IDs at other WINS servers<br>• Create static name mappings<br>• Import Lmhosts files<br>• Verify name records |

**WINS Registry Entries**
The following registry entries are associated with WINS and might need to be modified to customize a WINS client or WINS server configuration. Additional registry entries associated with WINS are modified by options in the WINS snap-in and **Netsh** commands. These tools should be used to update registry entries whenever possible.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The registry entries associated with WINS are under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters. These registry entries are used by NetBT and are used to configure WINS clients.

**BcastNameQueryCount**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters\

**Version**
The BcastNameQueryCount entry is included in Windows NT 4.0, Windows 2000, Windows XP, and the Windows Server 2003 family.

The BcastNameQueryCount entry specifies the number of times that NetBT broadcasts a unique name query if no response is received.

For more information about BcastNameQueryCount, see "Registry Reference" in the "Tools and Settings Collection."

**BcastQueryTimeout**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters\

**Version**
The BcastQueryTimeout entry is included in Windows NT 4.0, Windows 2000, Windows XP, and the Windows Server 2003 family.

The BcastQueryTimeout entry specifies the time in milliseconds between successive broadcast queries for a unique name.

For more information about BcastQueryTimeout, see "Registry Reference" in the "Tools and Settings Collection."

**CacheTimeout**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters\

**Version**
The CacheTimeout entry is included in Windows NT 4.0, Windows 2000, Windows XP, and the Windows Server 2003 family.

The CacheTimeout entry specifies the time in milliseconds that NetBT caches NetBIOS names.

For more information about CacheTimeout, see "Registry Reference" in the "Tools and Settings Collection."

**EnableProxy**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters\

**Version**
The EnableProxy entry is included in Windows NT 4.0, Windows 2000, Windows XP, and the Windows Server 2003 family.

The EnableProxy entry configures a computer to act as a WINS proxy for B-node clients on the local subnet.

**NodeType**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters\

**Version**
The NodeType entry is included in Windows NT 4.0, Windows 2000, Windows XP, and the Windows Server 2003 family.

The NodeType entry specifies the method NetBT uses to register and resolve NetBIOS names. The default NodeType is B-node. Configuring a client to use a WINS server sets this entry to H-node. The registry entry can be modified with Regedit.exe for M-node or P-node.

For more information about NodeType, see "Registry Reference" in the "Tools and Settings Collection."

**Size/Small/Medium/Large**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters\

**Version**
The Size/Small/Medium/Large entry is included in Windows NT 4.0, Windows 2000, Windows XP, and the Windows Server 2003 family.

The Size/Small/Medium/Large entry specifies the maximum number of entries that can be held in the NetBIOS name cache of recently resolved NetBIOS names.

**ScopeID**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters\

**Version**
The ScopeID entry is included in Windows NT 4.0, Windows 2000, Windows XP, and the Windows Server 2003 family.

The ScopeID entry sets the NetBIOS scope, which is an optional, additional qualifier for NetBIOS names. Use of the scope identifier is discouraged.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WINS**
The registry entries under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WINS\Parameters are used to configure WINS servers. Most of these registry entries are set by using the WINS snap-in or the WINS **Netsh** commands. The registry entries described in this section need to be modified by using Regedit.exe.

**DataFiles**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WINS\Parameters\

**Version**
The DataFiles entry is included in Windows NT 4.0, Windows 2000, and the Windows Server 2003 family.

The DataFiles subkey contains a list of files that contain static name records. WINS uses these files to initialize and reinitialize the local database. This subkey does not exist in the registry by default. This subkey and its entries are needed if static name records are used.

**InitTimePause**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WINS\Parameters\

**Version**
The InitTimePause entry is included in Windows NT 4.0, Windows 2000, and the Windows Server 2003 family.

The InitTimePause registry entry determines whether WINS starts in a paused state and remains in that state until the first replication is complete. While in a paused state, WINS does not accept any name service requests.

This registry entry can be used in conjunction with the WINS snap-in option for triggering push or pull replication at system startup to restore a WINS database by using replication.

**DHCP Options for WINS**
When Dynamic Host Configuration Protocol (DHCP) is used to dynamically assign IP addresses in a WINS environment, you can use DHCP options to define the primary and secondary WINS servers and the name resolution method used by DHCP clients. The following table lists the DHCP options that are associated with WINS.

### DHCP Options Associated with WINS

| DHCP Option | Description |
|---|---|
| 44 | Identifies the WINS servers to be used by DHCP clients. |
| 46 | Defines the NetBIOS Node Type: B-node, P-node, M-node, or H-node. This option typically does not need to be set because WINS clients are automatically set to H-node when they are configured with WINS servers. |
| 47 | Identifies the NetBIOS scope ID to be used by the DHCP client. Using NetBIOS scope IDs is not recommended. |

For more information about DHCP options, see "DHCP Tools and Settings."

**Network Ports Used by WINS**
The ports listed in the following table are used by specific WINS services.

### WINS Port Assignments

| Service Name | UDP | TCP |
|---|---|---|
| NetBIOS Name Service | 137 (client and server) | |
| WINS replication | | 42 |
| WINS replication partner automatic discovery | 42 | |

# Network Configuration Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Configuration**
Network configuration is vital to the proper operation of any network infrastructure. Administrators must be able to configure IP addresses as well as other configuration information, such as options configured by using Dynamic Host Configuration Protocol (DHCP) or the Windows Time service. These services offer administrators scalable solutions to configure client computers on the network.

**Network Configuration Components**
Microsoft Windows Server 2003 provides DHCP and the Windows Time service for network configuration.

**DHCP**
DHCP is a client/server protocol that automatically provides an IP host with its IP address and other related configuration information such as the subnet mask and default gateway. RFC 2131 and RFC 2132 define DHCP as an Internet Engineering Task Force (IETF) standard based on the Bootstrap Protocol (BOOTP), with which it shares many implementation details. DHCP allows hosts to obtain all necessary TCP/IP configuration information from a DHCP server.

All Microsoft Windows Server 2003 products (including Standard Edition, Enterprise Edition, Web Edition, and Datacenter Edition) include a DHCP Server service, which is an optional networking component. All Windows clients include the DHCP Client as part of TCP/IP, including Windows Server 2003, Windows XP, Windows 2000, Windows NT 4.0, Windows Millennium Edition (Windows Me), and Windows 98.

DHCP simplifies the administrative management of IP address configuration by automating this process for network clients. The DHCP servers, which are computers running the DHCP Server service, allocate IP addresses and related TCP/IP configuration settings to DHCP-enabled clients on the network. DHCP relay agents help forward DHCP messages between DHCP clients and DHCP servers.

**Windows Time Service**
The Windows Time service (W32Time) in Windows Server 2003 synchronizes the date and time for all computers running on a Windows Server 2003 network. Time synchronization is critical for the proper operation of many Windows services and line-of-business applications. The Windows Time service uses the Network Time Protocol (NTP) to synchronize computer clocks on the network so that an accurate clock value, or time stamp, can be assigned to network validation and resource access requests. The service integrates NTP and time providers, making it a reliable and scalable time service for enterprise administrators.

**Network Configuration Scenarios**
Every device on a TCP/IP-based network must have a unique unicast IP address to access the network and its resources. Without DHCP, IP addresses must be configured manually on each computer on the network, changes must be tracked so that unused addresses can be reused by other computers, and computers must be manually reconfigured each time they move between subnets.

DHCP allows this entire process to be automated and centrally managed. The DHCP server maintains a pool of IP addresses and leases an address to any DHCP-enabled client when it starts on the network. Because the IP addresses are dynamic (leased) rather than static (permanently assigned), addresses no longer in use are automatically returned to the pool for reallocation.

DHCP also allows the network administrator to centrally manage additional configuration settings by specifying DHCP options, which pass additional information to the DHCP client when it obtains a lease.

The Windows Time service is essential to the successful operation of Kerberos authentication. It is therefore essential for authentication based on Active Directory. Any application that uses Kerberos, including most security services, relies on time synchronization between the computers that are participating in the authentication request. Active Directory domain controllers must also have synchronized clocks to help ensure accurate data replication.

Although Windows Time service was originally designed to provide clock synchronization for Kerberos authentication, many current applications use timestamps to ensure transactional consistency, to record the time of important events, and other time-sensitive information.

# DHCP Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP Technical Reference**
Microsoft Windows Server 2003 includes Dynamic Host Configuration Protocol (DHCP), a TCP/IP standard that enables the centralized management of IP addresses and other optional configuration information for client computers on a network.

DHCP simplifies IP address configuration by automating the process for clients on a network. DHCP servers, allocate IP addresses and related TCP/IP configuration settings to DHCP-enabled clients on the network. DHCP relay agents are used to forward initial DHCP messages between DHCP clients and DHCP servers if the clients and servers are not on the same IP broadcast subnet.

The DHCP Server service for Windows Server 2003 is based on Internet Engineering Task Force (IETF) standards. DHCP specifications are defined in Requests for Comments (RFCs) published by the Dynamic Host Configuration working group of the IETF. The following RFCs specify the core DHCP standards that Windows Server 2003 DHCP supports:

- RFC 2131: Dynamic Host Configuration Protocol
- RFC 2132: DHCP Options and BOOTP Vendor Extensions

Before you can understand DHCP you must have a working knowledge of TCP/IP networks. Specifically, you must understand how subnets work within a TCP/IP network. You should also review and understand the terms listed in "What Is DHCP?."

# What Is DHCP?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What is DHCP?**

Dynamic Host Configuration Protocol (DHCP) is a client/server protocol that automatically provides an Internet Protocol (IP) host with its IP address and other related configuration information such as the subnet mask and default gateway. RFCs 2131 and 2132 define DHCP as an Internet Engineering Task Force (IETF) standard based on Bootstrap Protocol (BOOTP), a protocol with which DHCP shares many implementation details. DHCP allows hosts to obtain necessary TCP/IP configuration information from a DHCP server.

The Microsoft Windows Server 2003 operating system includes a DHCP Server service, which is an optional networking component. All Windows-based clients include the DHCP client as part of TCP/IP, including Windows Server 2003, Microsoft Windows XP, Windows 2000, Windows NT 4.0, Windows Millennium Edition (Windows Me), and Windows 98.

**Note**

- It is necessary to have an understanding of basic TCP/IP concepts, including a working knowledge of subnets before you can fully understand DHCP. For more information about TCP/IP, see "TCP/IP Technical Reference."

**Benefits of DHCP**

In Windows Server 2003, the DHCP Server service provides the following benefits:

- **Reliable IP address configuration.** DHCP minimizes configuration errors caused by manual IP address configuration, such as typographical errors, or address conflicts caused by the assignment of an IP address to more than one computer at the same time.

- **Reduced network administration.** DHCP includes the following features to reduce network administration:

    - Centralized and automated TCP/IP configuration.

    - The ability to define TCP/IP configurations from a central location.

    - The ability to assign a full range of additional TCP/IP configuration values by means of DHCP options.

    - The efficient handling of IP address changes for clients that must be updated frequently, such as those for portable computers that move to different locations on a wireless network.

    - The forwarding of initial DHCP messages by using a DHCP relay agent, thus eliminating the need to have a DHCP server on every subnet.

**Why use DHCP**

Every device on a TCP/IP-based network must have a unique unicast IP address to access the network and its resources. Without DHCP, IP addresses must be configured manually for new computers or computers that are moved from one subnet to another, and manually reclaimed for computers that are removed from the network.

DHCP enables this entire process to be automated and managed centrally. The DHCP server maintains a pool of IP addresses and leases an address to any DHCP-enabled client when it starts up on the network. Because the IP addresses are dynamic (leased) rather than static (permanently assigned), addresses no longer in use are automatically returned to the pool for reallocation.

The network administrator establishes DHCP servers that maintain TCP/IP configuration information and provide address configuration to DHCP-enabled clients in the form of a lease offer. The DHCP server stores the configuration information in a database, which includes:

- Valid TCP/IP configuration parameters for all clients on the network.

- Valid IP addresses, maintained in a pool for assignment to clients, as well as excluded addresses.
- Reserved IP addresses associated with particular DHCP clients. This allows consistent assignment of a single IP address to a single DHCP client.
- The lease duration, or the length of time for which the IP address can be used before a lease renewal is required.

A DHCP-enabled client, upon accepting a lease offer, receives:

- A valid IP address for the subnet to which it is connecting.
- Requested DHCP options, which are additional parameters that a DHCP server is configured to assign to clients. Some examples of DHCP options are Router (default gateway), DNS Servers, and DNS Domain Name. For a full list of DHCP options, see "DHCP Tools and Settings."

**Terms and Definitions**

The following table lists common terms associated with DHCP.

**DHCP Terms and Definitions**

| Term | Definition |
|---|---|
| DHCP server | A computer running the DHCP Server service that holds information about available IP addresses and related configuration information as defined by the DHCP administrator and responds to requests from DHCP clients. |
| DHCP client | A computer that gets its IP configuration information by using DHCP. |
| Scope | A range of IP addresses that are available to be leased to DHCP clients by the DHCP Server service. |
| Subnetting | The process of partitioning a single TCP/IP network into a number of separate network segments called subnets. |
| DHCP option | Configuration parameters that a DHCP server assigns to clients. Most DHCP options are predefined, based on optional parameters defined in Request for Comments (RFC) 2132, although extended options can be added by vendors or users. |
| Option class | An additional set of options that can be provided to a DHCP client based on its computer class membership. The administrator can use option classes to submanage option values provided to DHCP clients. There are two types of options classes supported by a DHCP server running Windows Server 2003: vendor classes and user classes. |
| Lease | The length of time for which a DHCP client can use a DHCP-assigned IP address configuration. |
| Reservation | A specific IP address within a scope permanently set aside for leased use by a specific DHCP client. Client reservations are made in the DHCP database using the DHCP snap-in and are based on a unique client device identifier for each reserved entry. |
| Exclusion/exclusion range | One or more IP addresses within a DHCP scope that are not allocated by the DHCP Server service. Exclusions ensure that the specified IP addresses will not be offered to clients by the DHCP server as part of the general address pool. |
| DHCP relay agent | Either a host or an IP router that listens for DHCP client messages being broadcast on a subnet and then forwards those DHCP messages directly to a configured DHCP server. The DHCP server sends DHCP response messages directly back to the DHCP relay agent, which then forwards them to the DHCP client. The DHCP administrator uses DHCP relay agents to centralize DHCP servers, avoiding the need for a DHCP server on each subnet. Also referred to as a *BOOTP relay agent*. |

| | |
|---|---|
| Unauthorized DHCP server | A DHCP server that has not explicitly been authorized. Sometimes referred to as a *rogue DHCP server*.<br><br>In a Windows Server 2003 domain environment, the DHCP Server service on an unauthorized server running Windows Server 2003 fails to initialize. The administrator must explicitly authorize all DHCP servers running Windows Server 2003 that operate in an Active Directory service domain environment. At initialization time, the DHCP Server service in Windows Server 2003 checks for authorization and stops itself if the server detects that it is in a domain environment and the server has not been explicitly authorized. |
| Automatic Private IP Addressing (APIPA) | A TCP/IP feature in Windows XP and Windows Server 2003 that automatically configures a unique IP address from the range 169.254.0.1 through 169.254.255.254 with a subnet mask of 255.255.0.0 when the TCP/IP protocol is configured for automatic addressing, the **Automatic private IP address** alternate configuration setting is selected, and a DHCP server is not available. The APIPA range of IP addresses is reserved by the Internet Assigned Numbers Authority (IANA) for use on a single subnet, and IP addresses within this range are not used on the Internet. |
| Superscope | A configuration that allows a DHCP server to provide leases from more than one scope to clients on a single physical network segment. |
| Multicast IP addresses | Multicast IP addresses allow multiple clients to receive data that is sent to a single IP address, enabling point-to-multipoint communication. This type of transmission is often used for streaming media transmissions, such as video conferencing. |
| Multicast Scope | A range of multicast IP addresses that can be assigned to DHCP clients. A multicast scope allows dynamic allocation of multicast IP addresses for use on the network by using the MADCAP protocol, as defined in RFC 2730. |
| BOOTP | An older protocol with similar functionality; DHCP is based on BOOTP. BOOTP is an established protocol standard used for configuring IP hosts. BOOTP was originally designed to enable boot configuration for diskless workstations. Most DHCP servers, including those running Windows Server 2003, can be configured to respond to both BOOTP requests and DHCP requests. |

# How DHCP Technology Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How DHCP Works**

DHCP provides an automated way to distribute and update IP addresses and other configuration information on a network. A DHCP server provides this information to a DHCP client through the exchange of a series of messages, known as the DHCP conversation or the DHCP transaction. If the DHCP server and DHCP clients are located on different subnets, a DHCP relay agent is used to facilitate the conversation.

### Note

- It is necessary to have an understanding of basic TCP/IP concepts, including working knowledge of subnets before you can have a full understanding of DHCP. For more information about TCP/IP, see "TCP/IP Technical Reference."

### In this section

- DHCP Architecture
- DHCP Protocols
- DHCP Processes and Interactions

**DHCP Architecture**

The DHCP architecture consists of DHCP clients, DHCP servers, and DHCP relay agents on a network. The clients interact with servers using DHCP messages in a DHCP conversation to obtain and renew IP address leases.

**DHCP Client Functionality**

A *DHCP client* is any network-enabled device that supports the ability to communicate with a DHCP server in compliance with RFC 2131, for the purpose of obtaining dynamic leased IP configuration and related optional information.

DHCP provides support for client computers running any of the following Microsoft operating systems:

- Windows NT version 4.0
- Windows 2000
- Windows XP
- Windows Server 2003
- Windows 98
- Windows Millennium Edition

**Automatic IP Configuration**

DHCP supports Automatic Private IP Addressing (APIPA), which enables computers running Windows 2000, Windows XP, and Windows Server 2003 to configure an IP address and subnet mask if a DHCP server is unavailable at system startup and the **Automatic private IP address** Alternate Configuration setting is selected. This feature is useful for clients on small private networks, such as a small-business office or a home office.

The DHCP Client service on a computer running Windows XP and Windows Server 2003 uses the following process to auto-configure the client:

1. The DHCP client attempts to locate a DHCP server and obtain an IP address and configuration.
2. If a DHCP server cannot be found or does not respond after one minute, the DHCP client checks the settings on the

**Alternate Configuration** tab of the properties of the TCP/IP protocol.

If **Automatic private IP address** is selected, the DHCP client auto-configures its IP address and subnet mask by using a selected address from the Microsoft-reserved Class B network, 169.254.0.0, with the subnet mask 255.255.0.0. The DHCP client tests for an address conflict to ensure that the IP address is not in use on the network. If a conflict is found, the client selects another IP address. The client retries auto-configuration up to 10 times.

If **User Configured** is selected, the DHCP client configures a static IP address configuration. The DHCP client tests for an address conflict to ensure that the IP address is not already in use on the network. If a conflict is found, the DHCP client indicates the error condition to the user.

3. When the DHCP client succeeds in self-selecting an address, it configures its network interface with the IP address. The client then continues to check for a DHCP server in the background every five minutes. If a DHCP server responds, the DHCP client abandons its self-selected IP address and uses the address offered by the DHCP server (and any other DHCP option information that the server provides) to update its IP configuration settings.

If the DHCP client obtained a lease from a DHCP server on a previous occasion, and the lease is still valid (not expired) at system startup, the client tries to renew its lease. If, during the renewal attempt, the client fails to locate any DHCP server, it attempts to ping the default gateway listed in the lease, and proceeds in one of the following ways:

- If the ping is successful, the DHCP client assumes that it is still located on the same network where it obtained its current lease, and continues to use the lease as long as the lease is still valid. By default the client then attempts, in the background, to renew its lease when 50 percent of its assigned lease time has expired.

- If the ping fails, the DHCP client assumes that it has been moved to a network where a DHCP server is not available. The client then auto-configures its IP address by using the settings on the **Alternate Configuration** tab. When the client is auto-configured, it attempts to locate a DHCP server and obtain a lease every five minutes.

**Local Storage**
Windows Server 2003 DHCP supports local storage, which allows clients to store DHCP information on their own hard disks. Local storage is useful because it enables the client to store its last leased IP address, so that when the client starts it first attempts to renew the lease of its previous IP address. Local storage also enables a client to be shut down and restarted and it will use its previously leased address and configuration, even if the DHCP server is unreachable or offline at the time that the client computer is restarted.

**DHCP Server Responsibilities**
The DHCP servers maintain scopes, reservations, and options as set by the administrator.

**Scopes**
A scope must be properly defined and activated before DHCP clients can use the DHCP server for automatic TCP/IP configuration. A DHCP scope is an administrative collection of IP addresses and TCP/IP configuration parameters that are available for lease to DHCP clients of a specific subnet. The network administrator creates a scope for each subnet.

A scope has the following properties:

- A scope name, assigned when the scope is created.

- A range of possible IP addresses from which to include or exclude addresses used in DHCP lease offers.

- A unique subnet mask, which determines the network ID for an IP address in the scope.

- Lease duration values.

Each DHCP scope can have a single continuous range of IP addresses. To use several address ranges within a single scope you must first define the entire address range for the scope, and then set exclusion ranges.

**Lease Durations**
When a scope is created, the lease duration is set to eight days by default. However there are situations when the administrator might want to change the lease duration. The following are examples of adjusting the lease duration due to individual network

consideration:

- An organization has a large number of IP addresses available and configurations that rarely change. The administrator increases the lease duration to reduce the frequency of lease renewal exchanges between clients and the DHCP server. Because the DHCP clients are renewing their leases less frequently, DHCP-related network traffic is reduced.

- A limited number of IP addresses are available and client configurations change frequently or clients move often in or out of the network. The administrator reduces the lease duration. This increases the rate at which unused addresses are returned to the available address pool for reassignment.

For example, consider the ratio between connected computers and available IP addresses. If 40 computers share 254 available addresses, the demand for reusing addresses is low. A long lease time, such as a few months, might be appropriate in such a situation. However, if 230 computers must share the same address pool, demand for available addresses is greater, and a shorter lease time, for example a few days, is more appropriate.

**Note**

- Although it is possible to configure a client with infinite lease duration, use infinite lease durations with caution. Even relatively stable environments have a certain amount of client turnover. At a minimum, computers might be added and removed, moved from one office to another, or network adapters might be replaced. If a client with an infinite lease is removed from the network without releasing its lease, the DHCP server is not notified, and the IP address is not automatically reused. Also, when using an infinite lease, options set on the DHCP server are not automatically updated on the DHCP client, because the client is never required to renew its lease and obtain the new options. It is recommended that reservations be used rather than infinite lease durations.

**Exclusion Ranges**

When you create a new scope, immediately exclude the addresses of existing statically configured computers from the scope. By using exclusion ranges, you can exclude specific IP address ranges within a scope so that those addresses are not offered to clients. Assign IP addresses within exclusion ranges to computers or devices that must have a static IP address, such as servers, firewalls, or routers.

You can use excluded IP addresses on your network by manually configuring these addresses at computers that do not use DHCP to obtain an address, or by configuring reservations for these addresses.

**Reservations**

You can reserve IP addresses for assignment to specified computers or devices on the network. Reservations ensure that a specified hardware device on a subnet always receives the same IP address lease. Use reservations for DHCP-enabled devices that must always have the same IP address on your network, such as servers that do not support Domain Name System (DNS) dynamic update.

**Note**

- If multiple DHCP servers are each configured with scopes that cover addresses that must be reserved, the reservations must be specified on each DHCP server. Otherwise, the client might receive an IP address from one of the DHCP servers that does not contain the reservation, and therefore might not receive the IP address reserved for the client.

**Superscopes**

A superscope allows a DHCP server to provide leases from more than one scope to clients on a single physical subnet. Before you can create a superscope, you must use the DHCP Microsoft Management Console (MMC) snap-in to define at least one of the scopes to be included in the superscope. Scopes added to a superscope are called *member scopes*. Superscopes can resolve DHCP Server service issues in several different ways; these issues include situations in which:

- Support is needed for DHCP clients on a single physical network segment — such as a single Ethernet LAN segment — where multiple logical IP networks are used. When more than one logical IP network is used on a physical network, these configurations are also known as *multinets*. In a situation where multinets are used, clients might not be able to communicate directly with each other, because the clients might be on different logical subnets, even if they are on the same physical network segment. In this case, routing must be enabled to allow the clients to communicate with each other. Also, a router or BOOTP/DHCP relay agent must be configured on the subnet to allow DHCP messages to travel between the logical subnets.

- Support is needed for DHCP clients that are in a multinet located on the other side of BOOTP relay agents.
- Clients need to be migrated to a new scope.

**Interactions between Client and Server**
DHCP servers and DHCP clients communicate through a series of DHCP messages. To obtain a lease, the DHCP client initiates a conversation with a DHCP server using a series of these DHCP messages.

**DHCP Messages**
The following list includes the eight types of messages that can be sent between DHCP clients and servers. For more information about the structure and specifics of each of these packets, see "DHCP Message Format" later in this section.

**DHCPDiscover**
Broadcast by a DHCP client when it first attempts to connect to the network. The DHCPDiscover message requests IP address information from a DHCP server.

**DHCPOffer**
Broadcast by each DHCP server that receives the client DHCPDiscover message and has an IP address configuration to offer to the client. The DHCPOffer message contains an unleased IP address and additional TCP/IP configuration information, such as the subnet mask and default gateway. More than one DHCP server can respond with a DHCPOffer message. The client accepts the best offer, which for a Windows DHCP client is the first DHCPOffer message that it receives.

**DHCPRequest**
Broadcast by a DHCP client after it selects a DHCPOffer. The DHCPRequest message contains the IP address from the DHCPOffer that it selected. If the client is renewing or rebinding to a previous lease, this packet might be unicast directly to the server.

**DHCPAck**
Broadcast by a DHCP server to a DHCP client acknowledging the DHCPRequest message. At this time, the server also forwards any options. Upon receipt of the DHCPAck, the client can use the leased IP address to participate in the TCP/IP network and complete its system startup. This message is typically broadcast, because the DHCP client does not officially have an IP address that it can use at this point. If the DHCPAck is in response to a DHCPInform, then the message is unicast directly to the host that sent the DHCPInform message.

**DHCPNack**
Broadcast by a DHCP server to a DHCP client denying the client's DHCPRequest message. This might occur if the requested address is incorrect because the client moved to a new subnet or because the DHCP client's lease has expired and cannot be renewed.

**DHCPDecline**
Broadcast by a DHCP client to a DHCP server, informing the server that the offered IP address is declined because it appears to be in use by another computer.

**DHCPRelease**
Sent by a DHCP client to a DHCP server, relinquishing an IP address and canceling the remaining lease. This is unicast to the server that provided the lease.

**DHCPInform**
Sent from a DHCP client to a DHCP server, asking only for additional local configuration parameters; the client already has a configured IP address. This message type is also used by DHCP servers running Windows Server 2003 to detect unauthorized DHCP servers.

**DHCP Lease Process**
A DHCP-enabled client obtains a lease for an IP address from a DHCP server. Before the lease expires, the DHCP client must renew the lease or obtain a new lease. Leases are retained in the DHCP server database for a period of time after expiration. By default, this grace period is four hours and cleanup occurs once an hour for a DHCP server running Windows Server 2003. This protects a clients lease in case the client and server are in different time zones, the internal clocks of the client and server computers are not synchronized, or the client is off the network when the lease expires.

**Obtaining a New Lease**
A DHCP client initiates a conversation with a DHCP server when it is seeking a new lease, renewing a lease, rebinding, or restarting. The DHCP conversation consists of a series of DHCP messages passed between the DHCP client and DHCP servers. The following figure shows an overview of this process when the DHCP server and DHCP client are on the same subnet.

### DHCP Lease Process Overview

1. The DHCP client requests an IP address by broadcasting a DHCPDiscover message to the local subnet.

2. The client is offered an address when a DHCP server responds with a DHCPOffer message containing an IP address and configuration information for lease to the client. If no DHCP server responds to the client request, the client sends DHCPDiscover messages at intervals of 0, 4, 8, 16, and 32 seconds, plus a random interval of between -1 second and 1 second. If there is no response from a DHCP server after one minute, the client can proceed in one of two ways:

   - If the client is using the Automatic Private IP Addressing (APIPA) alternate configuration, the client self-configures an IP address for its interface.

   - If the client does not support alternate configuration, such as APIPA, or if IP auto-configuration has been disabled, the client network initialization fails.

   In both cases, the client begins a new cycle of DHCPDiscover messages in the background every five minutes, using the same intervals as before (0, 4, 8, 16, and 32 seconds), until it receives a DHCPOffer message from a DHCP server.

3. The client indicates acceptance of the offer by selecting the offered address and broadcasting a DHCPRequest message in response.

4. The client is assigned the address and the DHCP server broadcasts a DHCPAck message in response, finalizing the terms of the lease.

When the client receives acknowledgment, it configures its TCP/IP properties by using the DHCP option information in the reply, and completes its initialization of TCP/IP.

In rare cases, a DHCP server might return a negative acknowledgment to the client. This can happen if a client requests an invalid or duplicate address. If a client receives a negative acknowledgment (DHCPNack), the client must begin the entire lease process again.

When the DHCP client and the DHCP server are on the same IP broadcast subnet, the DHCPDiscover, DHCPOffer, DHCPRequest, and DHCPAck messages are sent to identify clients by means of IP-level broadcasts sent to the limited broadcast address and the media access control (MAC) broadcast address.

When the DHCP server and DHCP client are not on the same subnet either a router or a host on the DHCP client's subnet must act as a DHCP relay agent to support the forwarding of DHCP messages between the DHCP client and the DHCP server.

**Renewing a Lease**

The DHCP client first attempts to renew its lease when 50 percent of the original lease time, known as *T1*, has passed. At this point the DHCP client sends a unicast DHCPRequest message to the DHCP server that originally granted its lease. If the server is available, and the lease is still available, the server responds with a unicast DHCPAck message and the lease is renewed.

If the original DHCP server is available, but the client's current lease is no longer available, the DHCP server responds with a DHCPNack message, and the client immediately starts the process to obtain a new lease. This can happen if the client has changed subnets or if the DHCP server cannot fulfill the lease request for some other reason.

If there is no response from the DHCP server, the client waits until 87.5 percent of the lease time has passed (known as *T2*). At T2, the client enters the rebinding state, and broadcasts a DHCPRequest message to attempt to renew the lease from any available DHCP server. If no DHCP server is available by the time the lease expires, the client immediately unbinds itself from the existing lease and starts the process to obtain a new lease, beginning with a DHCPDiscover message.

**Preventing Address Conflicts**
Windows Server 2003 DHCP has both server-side and client-side conflict detection to prevent duplicate IP addresses on your network.

**Client Conflict Detection**
Client computers running Windows Server 2003, Windows XP, Windows 2000, Windows NT 4.0, Windows Millennium Edition, and Windows 98 automatically check to determine if an IP address is already in use before using it.

After the DHCP client receives a lease from the DHCP server, the client sends an Address Resolution Protocol (ARP) request to the address that it has been assigned. If a reply to the ARP request is received, the client has detected a conflict and sends a DHCPDecline message to the DHCP server. The DHCP server attaches a BAD_ADDRESS value to the IP address in the scope for the length of the lease. The client then begins the lease process again, and is offered the next available address in the scope.

### Note

- ARP requests do not traverse routers. Clients use ARP requests rather than pings (ICMP Echo messages) because pings require the sender to have an IP address.

**Server Conflict Detection**
If your network includes older DHCP clients that do not perform conflict detection themselves, you can enable conflict detection on the DHCP server. By default, the Windows Server 2003 DHCP Server service does not perform any conflict detection.

To detect conflicts, the DHCP server pings (sends an ICMP Echo message to) an IP address before offering that address to clients in a new lease. The DHCP server only pings addresses that have not been successfully and previously leased. If a client requests a lease on an IP address that it already had or is requesting a renewal, the DHCP server does not ping the IP address.

If conflict detection is enabled, an administrator-defined number of pings are sent. The server waits 1 second for a reply. Because the time required for a client to obtain a lease is equal to the number of pings used, choose this value carefully because it directly impacts the overall performance of the server. In general, one ping is sufficient.

If a response to the ping is received, a conflict is registered and that address is not offered to clients requesting a lease from the server. The DHCP server then attaches a BAD_ADDRESS value to that IP address in the scope. The DHCP server then tries to lease the next available address. If the duplicate address is removed from the network, the BAD_ADDRESS value attached to the IP address can be deleted from the scope's list of active leases, and then the address returns to the pool. Addresses are marked as BAD_ADDRESS for the length of the lease for which the scope is configured. If the BAD_ADDRESS entry is not manually removed, it will automatically be removed after a period of time equal to the lease time for the scope.

### Note

- In general, use server conflict detection only as a troubleshooting aid when you suspect that duplicate IP addresses are in use on your network. Each additional conflict detection attempt adds to the time needed to negotiate leases for DHCP clients.

**DHCP Options**
*DHCP options* are additional configuration parameters that a DHCP server assigns to clients. Options can also be used for DHCP communication between the server computer and client computers.

The most specific options take precedence over the least specific options. This simplifies DHCP management and allows a flexible administration that can range from per-server default settings to common settings for a specific subnet and individualized client settings when needed for special circumstances. In most cases, the option values are specified in the **Options** dialog box on the DHCP server, scope, or reservation.

DHCP options can be configured for specific values and enabled for assignment and distribution to DHCP clients based on:

- **Server options.** These options apply globally for all scopes and classes defined at each DHCP server and any clients that it services. Configured server option values always apply unless they are overridden by options assigned to other scope, class, or client reservation.

- **Scope options.** These options apply to any clients that obtain a lease within that particular scope. Configured scope option values always apply to all computers obtaining a lease in a given scope unless they are overridden by options assigned to class or client reservation.

- **Class options.** These options apply to any clients that specify that particular DHCP Class ID value when obtaining a scope lease. Configured class option values always apply to all computers configured as members in a specified DHCP option class unless they are overridden by options assigned to a client reservation.

- **Reserved client options.** These options apply only to the client corresponding to the reservation. Reserved client option values override all other server, scope, or class assigned option values.

Options are typically applied at each DHCP server at the server or scope level. To precisely manage or customize option settings for a group or class of computers, specify either a user or vendor class assignment that overrides the broader server or scope option defaults.

For special requirements, such as clients with special functions, assign options for specific reserved clients.

Options can also be used to separate and distribute appropriate options for clients with similar or special configuration needs. For example, DHCP clients on the same floor of a building can be configured with the same DHCP Class ID value to assign them membership in the same option class. You can then distribute additional or varied option data to that class during the lease process, overriding any scope or globally provided default options.

**Note**

- Statically configured values on a client override any DHCP options of any type or level.

Many options are predefined on a DHCP server running Windows Server 2003. Other standard DHCP options can be added as needed to support any other DHCP client software that recognizes or requires the use of these additional options. The DHCP Server service running on Windows Server 2003 supports all options defined in RFC 2132, although most DHCP clients use or support only a small subset of the available RFC-specified options.

The following table contains a list of default DHCP options requested by DHCP clients running Windows Server 2003 and Windows XP. For a complete reference of DHCP options, see "DHCP Tools and Settings."

**Default DHCP Options**

| Option Code | Option Name |
|---|---|
| 1 | Subnet mask |
| 3 | Router |
| 6 | DNS servers |
| 15 | DNS domain name |
| 44 | WINS/NBNS servers |
| 46 | WINS/NetBT node type |
| 47 | NetBIOS scope ID |
| 51 | Lease time |
| 58 | Renewal (T1) time value |
| 59 | Rebinding (T2) time value |
| 31 | Perform router discovery |
| 33 | Static route |
| 43 | Vendor-specific information |
| 249 | Classless static routes |

**DHCP Option Parameters**

DHCP servers can be configured to provide optional data that fully configures TCP/IP on a client. Some of the most common

DHCP option types configured and distributed by the DHCP server during the lease process include parameters for the default gateway, DNS, and WINS.

Clients can be configured with:

- **Information options.** You can explicitly configure these options and any associated values provided to clients.
- **Protocol options.** You can implicitly configure these options used by the DHCP Server service based on server and scope property settings.

You can use the DHCP snap-in to configure these properties and set them for an entire scope or for a single, reserved client scope.

**Information Options**

The following table lists the most common types of DHCP information options that can be configured for DHCP clients. These options can be enabled and configured for each scope that you configure on a DHCP server. Depending on your network infrastructure, some of these options can be configured as server options, such as DNS domain name.

**Common Information Options**

| Code | Description |
|---|---|
| 3 | Router |
| 6 | DNS server |
| 15 | DNS domain name |
| 44 | WINS/NBNS servers |

Clients can request these DHCP options, and can use the values to set their TCP/IP configurations for the duration of the lease.

**Protocol Options**

The following table shows protocol options that DHCP clients can be configured to use when communicating with a DHCP server to obtain or renew a lease.

**Common Protocol Options**

| Code | Description |
|---|---|
| 51 | Lease time |
| 53 | DHCP message type |
| 55 | Special option type used to communicate a parameter request list to the DHCP server |
| 58 | Renewal time value (T1) |
| 59 | Rebind time value (T2) |

The values provided to clients for lease time, T1, and T2 are taken from the scope settings on the DHCP server. The value provided for DHCP message type is automatically set depending on which packet of the DHCP conversation is being sent.

**Option Classes**

Option classes allow quick introduction of custom applications for enterprise networks. DHCP option classes provide a way to easily configure network clients with the parameters necessary to meet the special requirements of custom applications. Equipment from multiple vendors on a network can also use different option code numbers for different functions. The options used to support vendor classes — the vendor class identifier and the vendor-specific option — are defined in the Internet DHCP options standard reference, RFC 2132.

Windows Server 2003 includes two types of option classes: vendor-defined and user-defined. These classes can be configured on your servers to offer specialized client support in the following ways:

- Add and configure vendor-defined classes for managing DHCP options assigned to clients identified by vendor type.

- Add and configure user-defined classes for managing DHCP options assigned to clients that need a similar DHCP option configuration.

After options classes are defined on a DHCP server, scopes on the server can be configured to assign options for specific user-defined and vendor-defined option classes.

**Vendor Classes**
Vendor-defined option classes can be used by DHCP clients to identify the client's vendor type and configuration when obtaining a lease from the DHCP server. The client can include the vendor class ID option (option code 60) when it requests or selects a lease from a DHCP server to identify its vendor class during the lease process.

The vendor class identifier information is a string of character data interpreted by the DHCP servers. Vendors can choose to define specific vendor class identifiers to convey particular configuration or other identification information about a client. For example, the identifier might encode the client's hardware or software configuration. Most vendor types are derived from standard reserved hardware and operating system-type abbreviation codes listed in RFC 1700.

When vendor options are specified, the server performs the following additional steps to provide a lease to the client:

- The server verifies that the vendor class identified by the client request is a recognized class defined on the server.

  If the vendor class is recognized, the server checks to see if any additional DHCP options are configured for this class in the active scope.

  If the vendor class is not recognized, the server ignores the vendor class identified in the client request, and returns options allocated to the default vendor class (which includes all DHCP Standard options).

- If the scope contains options configured specifically for use with clients in this vendor-defined class, the server returns those options using the vendor-specific option type (option code 43) as part of its acknowledgment message.

In most cases, the default vendor class — the DHCP Standard option class — provides a default vendor class for any Windows DHCP clients or other DHCP clients that do not specify a vendor class ID. In some cases, you might define additional vendor classes for other DHCP clients, such as printers or some types of UNIX clients. When you add other vendor classes for these purposes, make sure that the vendor class identifier you use to configure the class at the server matches the identifier used by clients for your third-party vendor.

**User Classes**
User classes allow DHCP clients to differentiate themselves by specifying what type of client they are, such as desktop or server computer. For computers running Windows Server 2003, Windows XP, and Windows 2000, you can define specific user class identifiers to convey information about a client's software configuration, its physical location in a building, or about its user preferences. For example, an identifier can specify that DHCP clients are members of a user class called "2nd floor, West", which has need for a specific set of router, DNS, and WINS server settings. An administrator can then configure the DHCP server to include different option values depending on the user class of client receiving the lease.

Windows Server 2003 user classes can be used as follows:

- DHCP client computers can include the DHCP user class option when sending DHCP request messages to the DHCP server. This can specifically identify the client as part of a user class on the server.

- DHCP servers running the Windows 2000 Server or Windows Server 2003 DHCP Server service can recognize and interpret the DHCP user class option from clients and provide additional options (or a modified set of DHCP options) based on the client's user class identity.

For example, shorter leases can be assigned to wireless clients. Or perhaps a particular set of clients might need a specific set of routes, a specific DNS server, or a specific default gateway.

**Note**

- If user classes are not specified, default settings, such as server options or scope options, are assigned.

A user class can be either a default or custom user class. Microsoft provides three default user classes, as described in the

following table.

**Default User Classes Provided by Windows DHCP**

| Class Type | Class ID String | Description |
|---|---|---|
| Default User Class | (Unspecified) | This class is typically used by most DHCP clients. Clients that are included in this class:<br>• DHCP clients that cannot be configured with a user class or a user class ID. This is true for most Windows-based DHCP clients prior to Windows 2000.<br>• Clients running Windows Server 2003, Windows XP, or Windows 2000 configured with a class ID unknown to the DHCP server.<br>• Clients that do not otherwise specify a user class ID. |
| Default Routing and Remote Access class | RRAS.Microsoft | This class is used by the Windows 2000 Server or Windows Server 2003 DHCP Server service to classify clients making a PPP-type connection through a remote access server. Typically, this class includes most dial-up networking clients that use DHCP to obtain a lease, including remote access clients that cannot be configured with a Routing and Remote Access user class or a Routing and Remote Access user class ID.<br>See "DHCP and Routing and Remote Access" later in this topic for details about the interaction between a Routing and Remote Access server and a DHCP server and how DHCP servers identify remote access clients. |
| Default BOOTP class | BOOTP | This class is used by the Windows 2000 Server or Windows Server 2003 DHCP Server service to classify any clients recognized as BOOTP clients. |

Use the Microsoft default user classes to isolate specific configuration details for clients with special needs, such as older clients or clients that use BOOTP or Routing and Remote Access. For example, you might want to include and assign special BOOTP option types (such as option codes 66 and 67) for clients that are BOOTP type, or shorten the lease time for remote access clients.

You can also add and configure custom user classes for use by DHCP clients running Windows 2000, Windows XP, and Windows Server 2003. For a custom user class to work properly, the client must use the same custom identifier when requesting options as was used when the class was defined on the DHCP server

The user class option field permits only one ASCII text string to be used for identifying clients. This means each client computer can be identified only as a member of a single user class by the DHCP server. You can use additional user classes to make new hybrids from your other user classes to accommodate clients that need configuration for multiple user classes. For example, if you have two user classes, one called "mobile" with short lease times assigned and another called "engineer" with an option assigned to configure a high-performance server for its clients, you can make a new hybrid user class called "mobile-engineer" that contains both special option value settings.

**MADCAP and Multicast DHCP**

Multicast Address Dynamic Client Allocation Protocol (MADCAP) is modeled after the DHCP standard. MADCAP assists in simplifying and automating configuration of multicast groups on your network, but it is not required for the operation of multicast groups or for the DHCP Server service. Multicast scopes provide only multicast address configuration and do not support or use other DHCP-assignable options.

Multicast scopes configured on the DHCP server define ranges of IP multicast addresses. Similar to allocating unicast IP addresses, IP multicast addresses are allocated to MADCAP clients. A MADCAP address is configured separately from a primary IP address. Computers that use either static or dynamic IP configuration through a DHCP server can be MADCAP clients.

In Windows Server 2003, the DHCP Server service supports both DHCP and MADCAP, although these services function separately. Clients of one do not depend on the use or configuration of the other.

Clients that do not support the MADCAP service or are unable to contact and obtain multicast configuration from a MADCAP server can be configured in other ways so that they participate in either permanent or temporary multicast groups on the network.

In all TCP/IP networks, each computer requires a unique primary unicast IP address for each network interface. You must assign this required primary unicast IP address before you can configure a computer to support and use secondary IP addresses such as multicast IP addresses.

**DHCP Protocols**

In Windows Server 2003, the DHCP Server service includes support for the Dynamic Host Configuration Protocol (DHCP), the Multicast Address Dynamic Client Allocation Protocol (MADCAP), and the Bootstrap Protocol (BOOTP).

**DHCP**

DHCP servers communicate with DHCP clients by using a series of DHCP messages. The format of DHCP messages is based on the message format used with the BOOTP protocol.

RFC 2131 defines the format for each message sent between a DHCP client and a DHCP server. The following table shows the possible fields in the DHCP messages.

**DHCP Message Fields**

| Field Name | Friendly Name | Field Length (Octets) | Description |
|---|---|---|---|
| op | Message Type | 1 | Message type |
| htype | Hardware Address Type | 1 | Hardware address type. Defined at http://www.iana.org/assignments/arp-parameters |
| hlen | Hardware Address Length | 1 | Hardware address length in octets |
| hops | Hops | 1 | Value is set to zero by DHCP clients. Optionally used to count the number of relay agents that forwarded the message. |
| xid | Transaction ID | 4 | A random number used to associate messages and responses between a client and a server. |
| secs | Seconds | 2 | Seconds elapsed since client began address acquisition or renewal process. |
| flags | Flags | 2 | Flags set by client. The Broadcast flag is set if the client cannot receive unicast IP datagrams (for example, before it is configured with an IP address). |
| ciaddr | Client IP Address | 4 | This field is only filled in if the client has an IP address and can respond to ARP requests. |
| yiaddr | Your IP Address | 4 | Address given to the DHCP client by the DHCP server |
| siaddr | DHCP Server IP Address | 4 | IP address of the server that is offering a lease |
| giaddr | Gateway IP Address | 4 | DHCP relay agent IP address |
| chaddr | Client Hardware Address | 16 | Client hardware address |
| sname | Server Host Name | 64 | Optional server host name. Not used in Windows Server 2003 |

| | | | |
|---|---|---|---|
| file | Boot File Name | 128 | The name of the file containing the boot image for a BOOTP client |
| options | Options | variable | Optional parameters field. In the DHCP protocol packet, each option begins with a single octet tag, which holds the option code, and a second octet, which describes the option data length, in bytes. For a complete list of the DHCP options available by default on a DHCP server running on Windows Server 2003, see "DHCP Tools and Settings." |

For a complete view of how these fields are used in each DHCP message, see RFC 2131 or use a network monitoring tool, such as Netmon, to view the DHCP messages.

**MADCAP**

Windows Server 2003 includes a Multicast Address Dynamic Client Allocation Protocol (MADCAP) Server service to support dynamic assignment and configuration of IP multicast addresses on TCP/IP-based networks.

Whereas DHCP unicast scopes provide client configurations by allocating ranges of IP addresses for point-to-point communication between two networked computers, multicast scopes provide ranges for multicast IP addresses. These addresses are reserved for multicast operation using directed transmission from one point to multiple points.

A multicast address is shared by many computers. A group of TCP/IP computers can use a single multicast IP address to send directed communication to all computers with which they share the use of the group address. An IP datagram that is sent to the multicast address is forwarded to all members of that multicast group.

**Dynamic Membership**

Multicast addresses support dynamic membership, allowing individual computers to join or leave the multicast group at any time. The size of the group is not limited, and computers can be members of multiple groups. In addition, any computer that uses TCP/IP can send datagrams to any multicast group.

**Multicast Address Ranges**

You can permanently reserve multicast group addresses or temporarily assign and use them. A permanent group is made by permanently reserving a multicast IP address (224.0.0.0 to 239.255.255.255) with the Internet Assigned Numbers Authority (IANA). The reserved address then becomes a well-known address, indicating a specific multicast group that exists regardless of whether group member computers are present on the network. Any multicast IP address that is not permanently reserved with the IANA can then be used dynamically to assign and form temporary multicast groups. These temporary groups can exist as long as one or more computers on the network are configured with the group's address and actively share in its use.

**BOOTP**

Bootstrap Protocol (BOOTP) is a computer configuration protocol developed before DHCP. DHCP improves on BOOTP and resolves specific limitations that BOOTP had as a computer configuration service. RFC 951 defines BOOTP.

Whereas BOOTP configures diskless workstations with limited boot capabilities, DHCP configures networked computers, that have local hard drives and full boot capabilities.

Likewise, although both BOOTP and DHCP allocate IP addresses to clients during startup, they use different methods of allocation. BOOTP typically provides fixed allocation of a single IP address for each client, permanently reserving this address in the BOOTP server database. DHCP typically provides dynamic, leased allocation of available IP addresses, reserving each DHCP client address temporarily in the DHCP database.

Because of the relationship between BOOTP and DHCP, both protocols share some defining characteristics. BOOTP and DHCP use nearly identical request messages and reply messages. Both protocols enclose each protocol message in a single User Datagram Protocol (UDP) datagram of 576 bytes. Message headers are the same for both BOOTP and DHCP, except for the final message header field that carries optional data. For BOOTP, this optional field is called the *vendor-specific area* and is limited to 64 bytes. For DHCP, this optional field is called the *options field* and is at least 312 bytes long.

Both BOOTP and DHCP use the same reserved protocol ports for sending and receiving messages between servers and clients. Both BOOTP and DHCP servers use UDP port 67 to listen for and receive client request messages. BOOTP and DHCP clients typically reserve UDP port 68 for accepting message replies from either a BOOTP server or DHCP server.

Because DHCP and BOOTP messages use nearly identical format types and packet structures, and use the same well-known service ports, BOOTP or DHCP relay agent programs usually treat BOOTP and DHCP messages as the same message type and do not differentiate between them.

BOOTP clients do not rebind or renew configuration with the BOOTP server except when the system restarts, whereas DHCP clients do not require a system restart to rebind or renew configuration with the DHCP server. Instead, clients automatically enter the rebinding state at defined intervals to renew their leased address allocation with the DHCP server. This process occurs in the background and is transparent to the user.

BOOTP uses a two-phase bootstrap configuration process in which clients contact BOOTP servers to perform address determination and boot file name selection, and clients also contact Trivial File Transfer Protocol (TFTP) servers to perform file transfer of their boot image. DHCP uses a single-phase boot configuration process whereby a DHCP client negotiates with a DHCP server to determine its IP address and obtain any other initial configuration details it needs for network operation.

Because BOOTP clients contact TFTP servers to perform file transfer of their boot image and Windows Server 2003 does not provide a TFTP file service, you need a third-party TFTP server to support BOOTP clients that must boot from an image file (usually diskless workstations). You also need to configure your DHCP server to provide supported BOOTP/DHCP options.

**DHCP Options Supported for BOOTP Clients**

To obtain other options, BOOTP clients must specify DHCP option code 55 (the Options Request List parameter) in the BOOTP request. BOOTP clients that do not specify option 55 can still retrieve the options listed in the following table from DHCP servers running Windows NT Server 4.0 or later, if they are configured on the server.

**DHCP Options for BOOTP Clients**

| Code | Option Name |
|---|---|
| 1 | Subnet Mask |
| 3 | Router |
| 4 | Time Server |
| 5 | Name Server |
| 9 | LPR Server |
| 12 | Computer Name |
| 15 | Domain Name |
| 17 | Root Path |
| 42 | NTP Servers |
| 44 | WINS Server |
| 45 | NetBIOS over TCP/IP Datagram Distribution Server |
| 46 | NetBIOS over TCP/IP Node Type |
| 47 | NetBIOS over TCP/IP Scope |
| 48 | X Window System Font Server |
| 49 | X Window System Display Manager |
| 69 | SMTP Server |
| 70 | POP3 Server |

DHCP servers running Windows Server 2003 return the options in the order listed above and return as many options as can fit in a single datagram response. For more information about individual DHCP options, see "DHCP Tools and Settings."

**Note**

- When configuring client reservations for use with BOOTP clients, remember that DHCP options can apply equally to DHCP and BOOTP clients.

**BOOTP Table**

Each record in the BOOTP table has three fields of information that is returned to the BOOTP client:

- **Boot Image**. Identifies the generic file name (such as "unix") of the requested boot file, based on the BOOTP client's hardware type.

- **File Name**. Identifies the full path of the boot file (such as "/etc/vmunix") that the BOOTP server returns to the client by using TFTP.

- **File Server**. Identifies the name of the TFTP server used to store the boot file.

To add entries in the BOOTP table, use the DHCP snap-in.

**DHCP Processes and Interactions**
In Windows Server 2003, the DHCP Server service interacts with several other services, including the Active Directory directory service, DNS, and the Routing and Remote Access service.

**Detecting Unauthorized DHCP Servers**
An unauthorized DHCP server on a network can cause a variety of problems, such as the leasing of incorrect IP addresses and options. To protect against this type of problem, when a DHCP server running Windows 2000 or Windows Server 2003 starts on the network, it first attempts to determine if it is authorized to service clients. There are different methods used depending on how the network is configured.

**Unauthorized Domain Member DHCP Servers**
A domain member DHCP server queries Active Directory. The DHCP server compares its IP address and server name to the list of authorized DHCP servers. If either the server name or IP address is found on the list of authorized DHCP servers, the server is authorized as a DHCP server. If no match is found, the server is not authorized in Active Directory, the server does not respond to DHCP traffic, and a system event is logged.

### Note

- This process of authorizing DHCP servers is useful for only DHCP servers running Windows 2000 or Windows Server 2003. This process cannot be used for DHCP servers running Windows NT Server 4.0, or servers running non-Windows-based DHCP Server services. Only a member of the Enterprise Admins group can authorize or unauthorize a DHCP server in Active Directory.

**Unauthorized Workgroup DHCP Servers**
A Windows Server 2003 workgroup member DHCP server uses the following process to detect other DHCP servers currently running on the reachable network and to determine if it is authorized to provide service.

1. When the DHCP Server service starts, it sends a DHCPInform request message to the reachable network, using the local limited broadcast address (255.255.255.255), to locate other DHCP servers on the network.

   This message includes several vendor-specific option types that are known and supported by other DHCP servers running Windows Server 2003. These other DHCP servers will respond with a DHCPAck containing information indicating if they are authorized domain member or workgroup member servers.

2. When queried, other DHCP servers running Windows 2000 and Windows Server 2003 reply with DHCPAck messages to acknowledge and answer with workgroup or domain membership information.

3. If an Active Directory domain member DHCP server is found, then the workgroup member server determines that it is not authorized and does not service clients. If other workgroup servers are found, the workgroup member server determines that it is authorized to service clients, and begins service. It then performs the check again at one-hour intervals.

**DHCP and DNS**
Domain Name System (DNS) servers provide name resolution for network clients. DNS resolves a fully qualified domain name (FQDN) to its corresponding IP address.

Although DHCP provides a powerful mechanism for automatically configuring client IP addresses, prior to Windows 2000, the DHCP Server service did not notify DNS to update the DNS records on behalf of the client. Specifically, DHCP did not map the client name to an IP address and did not update IP address-to-name mappings using DNS dynamic update.

Without a way for DHCP to interact with DNS, the information maintained by DNS for a DHCP client might be incorrect. For example, a client can acquire its IP address from a DHCP server, but the DNS records might not reflect the IP address acquired

nor provide a mapping from the new IP address to the FQDN.

**DNS Dynamic Updates**

In Windows 2000 and Windows Server 2003, DHCP servers and clients can register record updates if the DNS server supports DNS dynamic updates. In Windows 2000 Server and Windows Server 2003, the DNS service supports DNS dynamic updates.

A DHCP server running Windows Server 2003 can register with a DNS server and update pointer (PTR) and address (A) resource records on behalf of its DHCP-enabled clients by using the DNS dynamic update protocol.

The ability to register A and PTR resource records lets a DHCP server act as a DNS registration proxy for clients using Windows NT 4.0, Windows 98, or Windows Millennium Edition, and possibly other clients that are not able to register the updates on their own, as shown in the following figure.

**DHCP Server Performing DNS Dynamic Update on Behalf of DHCP Client**

DHCP clients running Windows 2000, Windows XP, and Windows Server 2003 interact with DNS differently than DHCP clients running earlier versions of Windows. DHCP clients running Windows XP, Windows 2000, or Windows Server 2003 typically update their own dynamic forward lookup names, as shown in the following figure.

**DHCP Client and DHCP Server Performing DNS Dynamic Update**

An additional DHCP option code (option code 81) enables the return of a client's FQDN to the DHCP server. If implemented, the DHCP server can dynamically update an individual computer's resource records on a DNS server by using the DNS dynamic update protocol.

For more information about DNS dynamic updates, see "DNS Technical Reference."

**Secure DNS Dynamic Updates**

By itself, DNS dynamic update is not secure; any client can modify DNS records. When secure DNS dynamic update is configured, the authoritative name server accepts updates only from clients and servers that are authorized to make DNS dynamic updates to the appropriate objects in Active Directory. Secure DNS dynamic update is available only on Active Directory–integrated zones.

Secure DNS dynamic update protects zones and resource records from being modified by unauthorized users by allowing you to specify the users and groups that can modify zones and resource records. By default, Windows Server 2003, Windows XP Professional, and Windows 2000 clients attempt unsecured DNS dynamic updates first. If that request fails, they attempt secure updates.

When using multiple DHCP servers and secure DNS dynamic updates, add each of the DHCP servers as members of the DnsUpdateProxy global security group so that any DHCP server can perform a secure DNS dynamic update for any record. Otherwise, when a DHCP server performs a secure DNS dynamic update for a record, that DHCP server is the only computer that can update the record.

**DHCP and Routing and Remote Access**

The Windows Server 2003 DHCP Server service interacts with the Windows Server 2003 Routing and Remote Access Server service in two specific ways. When Routing and Remote Access is used to provide remote access to PPP clients, the remote access server obtains IP addresses from the DHCP server, which it then assigns to the PPP clients.

DHCP also interacts with routers when DHCP clients and DHCP servers are on different subnets from each other. In this

situation, a router that can act as a DHCP relay agent must be present on the subnet of the DHCP client. You can use the Windows Server 2003 Routing and Remote Access service to act as a DHCP relay agent.

**Configuration of PPP Clients**

When the Routing and Remote Access service is configured to use DHCP to obtain IP addresses for TCP/IP based clients, the Routing and Remote Access service instructs the DHCP Client service to obtain 10 IP addresses from a DHCP server when the first PPP client connects. The Routing and Remote Access service uses the first IP address obtained from DHCP for the Internal interface, which is a logical interface that represents the connections to all PPP-based clients. Subsequent addresses are assigned to TCP/IP-based PPP clients as they connect. After the PPP client disconnects, the now-unassigned IP address is reused for a future PPP connection.

The remote access server uses the IP addresses from these leases to configure PPP clients, but discards all options contained in the leases.

When all 10 IP addresses are used, the Routing and Remote Access service obtains another block of 10 IP addresses from the DHCP server.

With a Windows NT 4.0–based remote access server, DHCP-allocated addresses are recorded and reused when the remote access service is restarted. In Windows Server 2003 and Windows 2000 Server, the Routing and Remote Access service releases all DHCP-allocated IP addresses by using DHCPRelease messages each time the service is stopped.

If the DHCP server becomes unavailable, the DHCP Client service on the Routing and Remote Access server assigns APIPA addresses to TCP/IP-based PPP clients. APIPA addresses for remote access connectivity work only if the network to which the remote access client is attached is also using APIPA addresses (which is not a recommended configuration). If the local network is not using APIPA addresses, remote access clients can only obtain point-to-point remote access connectivity.

The Routing and Remote Access service uses a specific LAN interface to obtain DHCP-allocated IP addresses for remote access clients. You can select which LAN interface to use on the **IP** tab of the **Properties** dialog box of a server in the **Routing and Remote Access** snap-in. If the Routing and Remote Access server has more than one LAN interface installed, the Routing and Remote Access Server Setup Wizard prompts you to select the LAN interface.

**Options for PPP Clients**

Although the remote access server running Windows Server 2003 discards all options from the leases it obtains from the DHCP server, PPP clients do receive specific configuration information, such as WINS server and DNS server assignments, from the settings of the remote access server as part of the negotiation of the PPP connection. However, clients running Windows 2000, Windows XP, or Windows Server 2003 can receive additional configuration information from the DHCP server, by using a DHCPInform message after the connection has been established. These options are available only if the VPN server has the DHCP Relay Agent routing protocol component configured with the IP address of the DHCP server.

The following three figures show the three steps of the remote access server obtaining leases from the DHCP server.

First, when the first PPP client connects to the remote access server, the remote access server obtains 10 IP addresses from the DHCP server as shown in the following figure.

**Remote Access Server Obtains IP Addresses**

Next, the remote access server uses Internet Protocol Control Protocol (IPCP) to configure the IP address of the client, as well as assign the DNS server and WINS server settings that are configured on the selected interface of the remote access server, as shown in the following figure.

**Remote Access Server Configures PPP Client**

After the remote access client has an IP address, it sends a unicast DHCPInform message to request options from the DHCP server to the remote access server. The remote access server must also be configured with the DHCP Relay Agent routing

protocol component. The remote access server, acting in its role as a DHCP relay agent, then sends the DHCPInform message to the DHCP server. The DHCP server responds with the options in a DHCPAck message, which is sent back to the remote access server. Finally, the DHCP relay agent on the remote access server sends the DHCPAck message to the remote access client, as shown in the following figure.

**PPP Client Obtains DHCP Options**

The following table lists the DHCP options that are requested by the client in the DHCPInform message.

**DHCP Options Requested in DHCPInform Message**

| Code | Description |
|---|---|
| 1 | Subnet mask |
| 6 | DNS servers |
| 15 | DNS domain name |
| 43 | Vendor-specific information |
| 44 | WINS/NBNS servers |
| 249 | Classless static routes |

**DHCP Relay Agents**

A DHCP relay agent is a hardware device or software program that can pass DHCP or BOOTP messages between DHCP clients and servers, according to the RFC 2131 specification for DHCP. DHCP relay agents act as proxies, forwarding messages from a subnet to one or more DHCP servers. Some DHCP messages are sent as broadcasts, so without relay agents and the ability to pass DHCP and BOOTP messages across routers, every subnet on a network must have its own DHCP server.

Most routers support acting as a DHCP relay agent. Alternatively, if a router cannot function as a DHCP relay agent, a computer that can function as a DHCP relay agent must be configured on each subnet to which the router is connected.

In cases where it is impractical or impossible to configure routers to act as a DHCP relay agent, you can configure a computer running Windows Server 2003 or Windows 2000 Server, to act as a relay agent by enabling the Routing and Remote Access service and installing the DHCP Relay Agent routing protocol component.

**How Relay Agents Work**

The following figure shows how Client C on Subnet 2 obtains a DHCP address lease from DHCP Server 1 on Subnet 1.

**Using a Relay Agent**

1. DHCP Client C broadcasts a DHCPDiscover message on Subnet 2 as a UDP datagram over well-known UDP port 67, which is the port reserved and shared for BOOTP and DHCP server communication.

2. The relay agent, in this case a DHCP relay-enabled router, examines the Gateway IP Address field (also known as the giaddr field) in the DHCP message header. If the field has an IP address of 0.0.0.0, the agent fills the Gateway IP Address field with the IP address assigned to the interface on which the DHCPDiscover was received, and forwards the

DHCPDiscover message as a unicast message to the DHCP server on Subnet 1.

3. When DHCP Server 1 receives the DHCPDiscover message, it examines the Gateway IP Address field to determine if the packet was relayed. The DHCP server then determines whether it can supply an IP address lease to clients on the subnet indicated by the address in the Gateway IP Address field.

   For example, if the Gateway IP Address field has an IP address of 192.168.45.2, the DHCP server checks its DHCP scopes for a scope range that includes 192.168.45.2 (the gateway IP address in the packet). To find a match, the DHCP server determines whether the IP address 192.168.45.2 matches the network ID of each scope. It determines the network ID of each scope by ANDing any IP address in the scope with its corresponding subnet mask. In this case, the DHCP server checks to see which scope includes addresses for Subnet 2. If a scope exists that matches this criterion, the DHCP server selects an available address from the matched scope to use in an IP address lease offer response to the client.

4. DHCP Server 1 sends a DHCPOffer message directly to the relay agent identified in the Gateway IP Address field.

5. The relay agent relays the DHCPOffer message to the DHCP client.

   Depending on the value of the Broadcast flag in the DHCPOffer message (which was copied from the DHCPDiscover message), the DHCP relay agent either unicasts or broadcasts the DHCPOffer message.

6. By using a similar process, a DHCPRequest message is relayed from client to server, and a DHCPAck message is relayed from server to client.

For more information about the DHCP relay agent, see "How the DHCP Relay Agent Works" in How Unicast IPv4 Routing Protocols and Services Work.

# DHCP Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP Tools and Settings**

**In this section**

- DHCP Tools
- DHCP Options
- Related information

**DHCP Tools**

The following tools are associated with DHCP.

**DHCP Snap-in**

The DHCP snap-in allows you to perform a variety of administrative tasks for your DHCP servers:

- Create and manage scopes, including superscopes and multicast scopes.
- Create and manage properties for scopes, such as options, reservations, and exclusion ranges.
- Review active leases for each scope.

**Category**

The DHCP snap-in Microsoft Management Console (MMC) appears as an administrative tool after you install DHCP from Add/Remove Windows Components in Control Panel. The DHCP snap-in can also be added to Windows Server 2003 or Windows XP by installing the Windows Server 2003 Administrative Tools Pack. This allows remote administration of DHCP servers running Windows 2000 Server or Windows Server 2003 from a Windows XP-based workstation.

**Version Compatibility**

The Windows Server 2003 DHCP snap-in is compatible with DHCP servers running Windows Server 2003 and Windows 2000.

**Netsh**

Netsh is a command-line scripting tool that allows you to display or modify the network configuration of a computer. Netsh also provides a scripting feature that allows you to run a group of commands in batch mode against a specified computer. Netsh can also save a configuration script in a text file for archival purposes or for reuse in configuring other servers.

Commands in the **netsh dhcp** context provide a command-line method to help with the administration of DHCP servers and provides an equivalent alternative to console-based management. All commands in **netshdhcp** context can also be executed against a specified remote server.

**Category**

Netsh is a command-line tool.

**Version compatibility**

You can use netsh commands with Windows 2000 Server and Windows Server 2003.

**Network Monitor**

You can use the Network Monitor tool or a commercial packet analyzer (also known as a network sniffer), to capture and view packets such as DHCP messages.

In Windows 2000 Server and Windows Server 2003, Network Monitor is installed as an optional management and monitoring component by using Add or Remove Programs in Control Panel. After it is installed, you can run Network Monitor from the Administrative Tools folder.

**Category**

Network Monitor is available in Microsoft Systems Management Server or with Windows 2000 Server and Windows Server 2003.

**Version compatibility**
You can use Network Monitor to capture and view packets in Windows XP, Windows 2000, or Windows Server 2003.

**DHCP Options**
This section lists the predefined options available for use with the Microsoft Windows Server 2003 DHCP service. These options are defined according to the updated standards reference for DHCP options in RFC 2132, "DHCP Options and BOOTP Vendor Extensions."

Use the DHCP Microsoft Management Console (MMC) snap-in to specifically configure each option value, and enable the option for assignment and distribution to DHCP clients based on server, scope, class, or client-specific levels of preference.

In this section:

- **Basic options.** These options were originally defined in RFC 1497 and relisted in RFC 2123.
- **IP host options.** These options affect the operation of the IP layer, on a per-host basis.
- **IP interface options.** These options affect operation of the IP layer on a per-interface basis.
- **Link layer options.** These options affect operation of the data-link layer on a per-interface basis.
- **TCP options.** These options affect operation of the TCP layer on a per-interface basis.
- **Application layer options.** These options affect the application layer operations on a per-interface basis.
- **NetBIOS over TCP/IP options.** These options are used to support NetBIOS over TCP/IP.
- **Vendor-specific options.** These options are specified for vendor class use..
- **User class options.** These options are specified for user class use.
- **DHCP extensions.** These options are used to implement default protocol interaction and system behavior between servers and clients.
- **Administrator-defined options.** These options are not preconfigured in Windows Server 2003, but can be defined by an administrator.
- **Microsoft options.** These options are only available for use with supported Microsoft DHCP clients, such as computers running Windows Server 2003 or Windows XP.

**Note**

- For all DHCP options that use a list of IP addresses as the value data, the IP addresses are always used in order of preference by the DHCP client. For example, the first address in the list is used first.

**Basic Options**
The following sections list the basic DHCP options originally defined in RFC 1497 and updated in RFC 2132, for use with DHCP and the Boot Protocol (BOOTP) service. The BOOTP service refers to options as vendor extensions.

The DHCP service supports configuration and distribution of any options assigned using the DHCP Manager snap-in. By default, Microsoft DHCP-enabled clients require and provide storage and interpretation for options 1 (Subnet Mask), 3 (Router), 6 (DNS Servers), and 15 (DNS Domain Name).

**Pad Option**
A single octet of zero ("00") used for padding. This option differs from most DHCP options in that it does not use a length or value field. This option used to ensure that subsequent DHCP options are aligned on word boundaries the same as they appear in the DHCP packet. This option does not require configuration.

**Code**
0

**Length**
Not used.

**Value**
Not used.

### Structure of Pad Option

| Code |
| --- |
| 0 |

**End Option**
A single octet of decimal 255 (“FF”) used to indicate the end of a DHCP options area in DHCP messages. This option differs from most DHCP options because it does not use a length or value field. Typically, it is used at the end of the options field to indicate that there is no more option data in a DHCP message. It can also be used within the message, in connection with vendor-specific information (option 43), to indicate the end of an encapsulated vendor-specific options subfield. This option does not require configuration.

**Code**
255

**Length**
Not used.

**Value**
Not used.

### Structure of End Option

| Code |
| --- |
| 255 |

**Subnet Mask**
This option specifies the subnet mask of the client subnet, as described in RFC 950. The value for this option is taken from the **Subnet Mask** field, as defined in the **DHCP ScopeProperties** dialog box in DHCP Manager. A DHCP client running Windows XP or Windows Server 2003 requests this option.

**Code**
1

**Length**
Fixed, 4 octets.

**Value**
Unsigned 32-bit (4 octet) integer representing the subnet mask for an IP address provided in a DHCP message.

### Structure of Subnet Mask

| Code | Length | Subnet Mask |
| --- | --- | --- |
| 1 | 4 | *subnet mask in binary format* |

**Time Offset**
This option specifies an offset value (in seconds) from the Coordinated Universal Time (UTC) that applies to the client subnet. This value is configurable as a signed 32-bit integer. Positive offset values indicate a subnet location east of the zero meridian. Negative offset values indicate a subnet location west of the zero meridian.

**Code**
2

**Length**
Fixed, 4 octets.

**Value**
Signed 32-bit integer used for offset of UTC.

**Structure of Time Offset**

| Code | Length | Time Offset |
|---|---|---|
| 2 | 4 | *time* |

**Router**
This option specifies a list of IP addresses for routers on the client subnet. When more than one router is assigned, the client interprets and uses the addresses in the specified order. This option is normally used to assign a default gateway to DHCP clients on a subnet. A DHCP client running Windows XP or Windows Server 2003 requests this option.

**Code**
3

**Length**
Variable. Minimum length of 4 octets; octet length increases in multiples of 4 for each router address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each assigned router.

**Structure of Router**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 3 | *n* | *IP address in binary format* | *IP address in binary format* |

**Time Server**
This option specifies a list of IP addresses for time servers, as defined in RFC 868, that are available to the client. When more than one time server is assigned, the client interprets and uses the addresses in the specified order.

**Code**
4

**Length**
Variable. Minimum length of 4 octets; octet length increases in multiples of 4 for each time server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each assigned time server.

**Structure of Time Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 4 | *n* | *IP address in binary format* | *IP address in binary format* |

**IEN Name Server**
This option specifies a list of IP addresses for Internet Engineering Note (IEN) name servers available to the client. When more than one server is assigned, the client interprets and uses the addresses in the specified order.

**Code**
5

**Length**
Variable. Minimum length of 4 octets; octet length increases in multiples of 4 for each IEN name server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each assigned IEN name server.

**Structure of IEN Name Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 5 | *n* | *IP address in binary format* | *IP address in binary format* |

**DNS Servers**
This option specifies a list of IP addresses for DNS name servers available to the client. When more than one server is assigned, the client interprets and uses the addresses in the specified order. A DHCP client running Windows XP and Windows Server 2003 requests this option.

**Code**
6

**Length**
Variable. Minimum length of 4 octets; octet length increases in multiples of 4 for each Domain Name System (DNS) server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each assigned DNS server.

**Structure of DNS Servers**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 6 | *n* | *IP address in binary format* | *IP address in binary format* |

**Log Server**
This option specifies a list of IP addresses for Massachusetts Institute of Technology Lab for Computer Science (MIT-LCS) User Datagram Protocol (UDP) log servers available to the client. When more than one server is assigned, the client interprets and uses the addresses in the specified order.

**Code**
7

**Length**
Variable. Minimum length of 4 octets; octet length increases in multiples of 4 for each log server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each assigned log server.

**Structure of Log Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 7 | *n* | *IP address in binary format* | *IP address in binary format* |

**Cookie Server**
This option specifies a list of IP addresses for cookie servers, as defined in RFC 865, available to the client. When more than one server is assigned, the client interprets and uses the addresses in the specified order.

**Code**
8

**Length**
Variable. Minimum length of 4 octets; octet length increases in multiples of 4 for each cookie server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each assigned cookie server.

**Structure of Cookie Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 8 | *n* | *IP address in binary format* | *IP address in binary format* |

**LPR Server**
This option specifies a list of IP addresses for line printer (LPR) servers, as defined in RFC 1179, available to the client. When more than one server is assigned, the client interprets and uses the addresses in the specified order.

**Code**
9

**Length**
Variable. Minimum length of 4 octets; octet length increases in multiples of 4 for each LPR server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each assigned LPR server.

**Structure of LPR Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 9 | *n* | *IP address in binary format* | *IP address in binary format* |

**Impress Server**
This option specifies a list of IP addresses for Imagen Impress servers available to the client. When more than one server is assigned, the client interprets and uses the addresses in the specified order.

**Code**
10

**Length**
Variable. Minimum length of 4 octets; octet length increases in multiples of 4 for each Impress server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each assigned Impress server.

**Structure of Impress Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 10 | *n* | *IP address in binary format* | *IP address in binary format* |

**Resource Location Server**
This option specifies a list of IP addresses for resource location servers, as defined in RFC 887, available to the client. When more than one server is assigned, the client interprets and uses the addresses in the specified order.

**Code**
11

**Length**
Variable. Minimum length of 4 octets; octet length increases in multiples of 4 for each resource location server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each assigned resource location server.

**Structure of Resource Location Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 11 | *n* | *IP address in binary format* | *IP address in binary format* |

**Host Name**
This option specifies a host name for the client. In some cases, this name can also be fully qualified by appending the name value provided here with the DNS domain name, as specified in DHCP option 15. For Windows clients, this option is not supported for use when configuring the client's host name, which is set for computers running Windows XP or Windows Server 2003 on the **Computer Name** tab in the **System Properties** dialog box on the client computer.

**Code**
12

**Length**
Length varies depending on data in value. Minimum length is 1 octet. Maximum length is limited to 63 characters, or one octet for each character used in the host name configured for use with this option.

**Value**
ASCII character text.

**Structure of Host Name**

| Code | Length | Host Name |
|---|---|---|
| 12 | *n* | *name* |

**Boot File Size**
This option specifies the size of the default boot image file for the client.

**Code**

13

**Length**
Fixed, 2 octets.

**Value**
Unsigned 16-bit integer to indicate the number of 512-octet blocks needed to make up the boot file.

**Structure of Boot File Size**

| Code | Length | File Size |
|---|---|---|
| 13 | 02 | *16-bit integer* |

**Merit Dump File**
This option specifies the path name of a file to which the client's core memory image should be dumped in the event the client terminates abnormally. Data used for a value is in ASCII character text format. The length of the value field depends on the number of characters used in the path specified. For example, if the path entered has 20 characters, the value field for this option should also be 20 octets in length.

**Code**
14

**Length**
Length varies depending on data in value. Minimum length is 1 octet.

**Value**
ASCII character text.

**Structure of Merit Dump File**

| Code | Length | Dump File Path |
|---|---|---|
| 14 | *n* | *path name* |

**DNS Domain Name**
This option specifies the domain name that the DHCP client should use when resolving unqualified domain names with the Domain Name System (DNS). For DHCP clients running Windows 2000, Windows XP, and Windows Server 2003, the DNS Domain Name option becomes the connection-specific DNS name assigned to the DHCP-configured interface. The connection-specific DNS name is used to construct fully qualified domain names (FQDNs) that are registered using DNS dynamic update. The length of the value field depends on the number of characters used in the DNS domain name specified. For example, if the domain name has 20 characters, the value field for this option is 20 octets in length. A DHCP client running Windows XP or Windows Server 2003 requests this option.

**Code**
15

**Length**
Length varies depending on data in value. Minimum length is 1 octet.

**Value**
ASCII character text.

**Structure of DNS Domain Name**

| Code | Length | Domain Name |
|---|---|---|
| 15 | *n* | *domain name* |

**Swap Server**
This option specifies the IP address of the client's swap server.

**Code**
16

**Length**
Length is fixed at 4 octets.

**Value**
A single IP address for the client's swap server (unsigned 32-bit integer).

### Structure of Swap Server

| Code | Length | Swap Server Address |
|---|---|---|
| 16 | 4 | *IP address in binary format* |

**Root Path**
This option specifies the path of the client's root disk. The path value is formatted as ASCII text. The length of the value field depends on the number of characters used in the root path specified. For example, if the root path entered has 20 characters, the value field for this option is 20 octets in length.

**Code**
17

**Length**
Length varies depending on data in value. Minimum length is 1 octet.

**Value**
ASCII character text.

### Structure of Root Path

| Code | Length | Root Disk Path |
|---|---|---|
| 17 | *n* | *path name* |

**Extensions Path**
This option specifies an extension path file that can be retrieved using Trivial File Transfer Protocol (TFTP). The file contains information to be interpreted as the 64-octet vendor-extension field within a BOOTP response. To allow more than 64 octets of BOOTP vendor extension information, this option can be enabled. When enabled, the length of the specified extension path file is not constrained in size and all references in the extensions file to tag 18 (such as instances of the BOOTP Extensions Path field) are ignored.

**Code**
18

**Length**
Length varies depending on data in value. Minimum length is 1 octet.

**Value**
ASCII character text.

### Structure of Extension Path

| Code | Length | Extensions Path |
|---|---|---|
| 18 | *n* | *file name* |

**IP Host Options**
The following sections describe the DHCP options that affect the operation of the IP layer, on a per-host basis.

**IP Forwarding Enable/Disable**
This option specifies whether the DHCP client should enable or disable forwarding of datagrams at the IP layer.

**Code**
19

**Length**
Length is fixed at 1 octet.

**Value**
Accepted values for this option are:

- 1 = Enable IP forwarding

- 0 = Disable IP forwarding

**Structure of IP Forwarding Enable/Disable**

| Code | Length | Value |
|---|---|---|
| 19 | 1 | 0 \| 1 |

**Non-Local Source Routing Enable/Disable**
This option specifies whether the DHCP client enables or disables the forwarding at the IP layer of datagrams that contain source routing information and were sent by a non-local host.

**Code**
20

**Length**
Length is fixed at 1 octet.

**Value**
Accepted values for this option are:

- 1 = Enable forwarding of datagrams from non-local sources
- 0 = Disable forwarding of datagrams from non-local sources

**Structure of Non-Local Source Routing Enable/Disable**

| Code | Length | Value |
|---|---|---|
| 20 | 1 | 0 \| 1 |

**Policy Filter**
This option specifies policy filters for non-local source routing on the client. The filters consist of a list of IP address and mask pairs specifying destination and mask pairs for which incoming datagrams should be source-route filtered. The client discards any source routed datagram with a next-hop address that does not match one of the filters. For further information about policy filtering as it applies to this option, see RFC 1122 in the IETF RFC Database.

**Code**
21

**Length**
Variable. Minimum length is 8 octets for a single destination and mask pair. Length increases in multiples of 8 octets for each additional pair used.

**Value**
Two consecutive, unsigned 32-bit integers indicating a paired value, consisting of an IP address followed by a subnet mask.

**Structure of Policy Filter**

| Code | Length | Address 1 | Subnet Mask 1 | Address N | Subnet Mask N |
|---|---|---|---|---|---|
| 21 | *n* | *IP address in binary format* | *subnet mask in binary format* | *IP address in binary format* | *subnet mask in binary format* |

**Maximum Datagram Reassembly Size**
This option specifies the maximum size datagram that the client needs to be prepared to reassemble.

**Code**
22

**Length**
Fixed, 2 octets.

**Value**
Unsigned 16-bit integer specifying the maximum datagram size for reassembly. The minimum size for a datagram is 576

octets.

**Structure of Maximum Datagram Reassembly Size**

| Code | Length | File Size |
|---|---|---|
| 22 | 2 | *16-bit integer* |

**Default IP Time-To-Live**
This option specifies the default Time-To-Live (TTL) that the client uses for the datagrams it sends.

**Code**
23

**Length**
Fixed, 1 octet.

**Value**
A number (in seconds) between 1 and 255.

**Structure of Default IP Time-To-Live**

| Code | Length | TTL |
|---|---|---|
| 23 | 1 | *TTL value in seconds* |

**Path MTU Aging Time-out**
This option specifies the time-out for aging Path Maximum Transmission Unit (MTU) values. Values are found by the Path MTU discovery process, as defined in RFC 1191.

**Code**
24

**Length**
Fixed, 4 octets.

**Value**
A number (in seconds) that specifies a time-out value.

**Structure of Path MTU Aging Time-out**

| Code | Length | Time-out |
|---|---|---|
| 24 | 4 | *time-out value in seconds* |

**Path MTU Plateau Table**
This option specifies a table of MTU sizes to use when performing Path MTU discovery, as defined in RFC 1191.

**Code**
25

**Length**
Variable. Minimum length is 2 octets and increases in multiples of 2.

**Value**
A table formatted as a list of 16-bit unsigned integers, ordered from smallest to largest. The minimum tabled MTU value cannot be smaller than **68**.

**Structure of Path MTU Plateau Table**

| Code | Length | MTU Size 1 | MTU Size N |
|---|---|---|---|
| 25 | *n* | *MTU size in binary format* | *MTU size in binary format* |

**IP Interface Options**
The following sections describe the DHCP options that affect operation of the IP layer on a per-interface basis.

**Interface MTU**

This option specifies the MTU size that can be used on a specified host adapter interface.

**Code**
26

**Length**
Fixed, 2 octets.

**Value**
A 16-bit unsigned integer specifying the interface MTU. The minimum value for the MTU is **68**.

**Structure of Interface MTU**

| Code | Length | MTU |
|---|---|---|
| 26 | 2 | *interface MTU* |

**All Subnets Are Local**
This option specifies whether the client assumes that all subnets within the client's internetwork use the same MTU size as the local subnet on which the client is connected.

**Code**
27

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option are:

- 1 = Clients assume all subnets are local and share the same MTU size
- 0 = Clients assume some subnets are not local and that smaller MTU sizes might be in use on remote subnets

**Structure of All Subnets Are Local**

| Code | Length | Value |
|---|---|---|
| 27 | 1 | 0 \| 1 |

**Broadcast Address**
This option specifies the broadcast address used on the client's subnet.

**Code**
28

**Length**
Fixed, 4 octets.

**Value**
Typically, the limited broadcast IP address (255.255.255.255), but can be modified using legal values for broadcast addresses, as specified in section 3.2.1.3 of RFC 1122.

**Structure of Broadcast Address**

| Code | Length | Broadcast Address |
|---|---|---|
| 28 | 4 | *broadcast address in binary format* |

**Perform Mask Discovery**
This option specifies whether the client uses Internet Control Message Protocol (ICMP) for subnet mask discovery.

**Code**
29

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option are:

- 1 = Client performs subnet mask discovery
- 0 = Client does not perform subnet mask discovery

### Structure of Perform Mask Discovery

| Code | Length | Value |
|---|---|---|
| 29 | 1 | 0 \| 1 |

**Mask Supplier**
This option specifies whether the client responds to subnet mask requests using ICMP.

**Code**
30

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option are:

- 1 = Client responds to subnet mask requests
- 0 = Client does not respond to subnet mask requests

### Structure of Mask Supplier

| Code | Length | Value |
|---|---|---|
| 30 | 1 | 0 \| 1 |

**Perform Router Discovery**
This option specifies whether the client solicits routers using the router discovery method in RFC 1256. A DHCP client running Windows XP or Windows Server 2003 requests this option.

**Code**
31

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option are:

- 1 = Client performs router discovery
- 0 = Client does not perform router discovery

### Structure of Perform Router Discovery

| Code | Length | Value |
|---|---|---|
| 31 | 1 | 0 \| 1 |

**Router Solicitation Address**
This option specifies the IP address to which the client submits router solicitation requests.

**Code**
32

**Length**
Fixed, 4 octets.

**Value**
Unsigned 32-bit integer representing an IP address.

### Structure of Router Solicitation Address

| Code | Length | Address |
|---|---|---|
| 32 | 4 | *IP address in binary format* |

**Static Routes**
This option specifies a list of classful static routes that the DHCP client automatically adds to its IP routing table. Multiple routes to the same destination are listed in descending order of priority. The default route of 0.0.0.0 is an illegal destination for a static route. To configure the default route, use the Router DHCP option to assign a default gateway. A DHCP client running Windows XP or Windows Server 2003 requests this option.

**Code**
33

**Length**
Variable. Minimum length of 8 octets; octet length increases in multiples of 8 for each additional static route provided with this option.

**Value**
A list of IP address pairs. Each set of 8 octets provides two consecutive IP addresses pairing the destination (as a classful network ID) and a router address (the IP address of the router interface on the subnet to which this scope-specific option is configured) used for each route. The first 4 octets specify the destination classful network ID, and the second 4 octets specify the router IP address.

### Structure of Static Routes

| Code | Length | Destination 1 | Router 1 | Destination N | Router N |
|---|---|---|---|---|---|
| 33 | *n* | *IP address in binary format* | *IP address in binary format* | *IP address in binary format* | *IP address in binary format* |

**Classless Static Route**
This option specifies a list of classful static routes that the client automatically adds to its IP routing table. A DHCP client running Windows XP or Windows Server 2003 requests this option. The Classless Static Route can be used to configure split tunneling for remote access virtual private network (VPN) clients running Windows XP and Windows Server 2003. For more information, see "VPN Technical Reference."

**Code**
249

### Note

- This is the same as option 121, as defined in RFC 3442.

**Length**
Variable. Minimum length of 5 octets; maximum octet length depends on the nature and number of the classless static routes. Each route entry includes a destination descriptor and a router and can vary from a minimum of 5 octets in length to maximum 9 octets in length. For more information about how classless static routes are constructed using a destination descriptor, see RFC 3442 in the IETF RFC Database.

**Value**
The destination descriptor and the router IP address. The value is encoded. For the encoding scheme, see RFC 3442.

### Structure of Classless Static Route

| Code | Length | Destination 1 | Router 1 | Destination N | Router N |
|---|---|---|---|---|---|
| 249 | *n* | *Destination descriptor, as defined in RFC 3442* | *IP address in binary format* | *Destination descriptor, as defined in RFC 3442* | *IP address in binary format* |

**Link Layer Options**
The following sections describe the DHCP options that affect operation of the data link layer on a per-interface basis.

**Trailer Encapsulation**
This option specifies whether the client negotiates the use of trailers, as described in RFC 893, when using the Address Resolution Protocol (ARP).

**Code**
34

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option are:

- 1 = Client attempts to use trailer
- 0 = Client does not attempt to use trailers

### Structure of Trailer Encapsulation

| Code | Length | Value |
|---|---|---|
| 34 | 1 | 0 \| 1 |

**ARP Cache Time-Out**
This option specifies the time-out for ARP cache entries.

**Code**
35

**Length**
Fixed, 4 octets.

**Value**
An unsigned 32-bit integer specifying a time-out value, in seconds.

### Structure of ARP Cache Time-Out

| Code | Length | Time |
|---|---|---|
| 35 | 4 | *time-out value in seconds* |

**Ethernet Encapsulation**
This option specifies whether the client uses Ethernet II (RFC 894) or IEEE 802.3 (RFC 1042) encapsulation (if the interface is Ethernet).

**Code**
36

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option are:

- 1 = Client uses RFC 1042 encapsulation
- 0 = Client uses RFC 894 encapsulation

### Structure of Ethernet Encapsulation

| Code | Length | Value |
|---|---|---|

| | | |
|---|---|---|
| 36 | 1 | 0 \| 1 |

**TCP Options**
The following sections describe the DHCP options that affect operation of the TCP layer on a per-interface basis.

**TCP Default TTL**
This option specifies the default TTL that the client uses when sending TCP segments.

**Code**
37

**Length**
Fixed, 1 octet.

**Value**
An unsigned 8-bit integer specifying a Time-To-Live (TTL) value in seconds. The minimum TTL value is **1**.

### Structure of TCP Default TTL

| Code | Length | TTL |
|---|---|---|
| 37 | 1 | *TTL value in seconds* |

**TCP Keep-Alive Interval**
This option specifies the interval the client waits before sending a keep-alive message on a TCP connection. A value of **0** indicates that the client should not send keep-alive messages on connections unless specifically requested by an application.

**Code**
38

**Length**
Fixed, 4 octets.

**Value**
An unsigned 32-bit integer that specifies a keep-alive interval, in seconds.

### Structure of TCP Keep-Alive Interval

| Code | Length | Time |
|---|---|---|
| 38 | 4 | *keep-alive interval in seconds* |

**TCP Keep-Alive Garbage**
This option specifies whether or not the client sends TCP keep-alive messages with an octet of garbage data for compatibility with older implementations.

**Code**
39

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option are:

- 1 = Client sends keep-alive garbage octet
- 0 = Client does not send keep-alive garbage octet

### Structure of TCP Keep-Alive Garbage

| Code | Length | Value |
|---|---|---|
| 39 | 1 | 0 \| 1 |

**Application Layer Options**

The following sections describe the DHCP options that affect the application layer operations on a per-interface basis. These are miscellaneous options used to configure programs and services.

**NIS Domain Name**
This option specifies the Network Information Service (NIS) domain name as an ASCII string.

**Code**
40

**Length**
Length varies depending on data in value. Minimum length is 1 octet.

**Value**
ASCII character text.

### Structure of NIS Domain Name

| Code | Length | NIS Domain Name |
|---|---|---|
| 40 | *n* | *NIS domain name* |

**NIS Servers**
This option lists the IP addresses in order of preference for Network Information Service (NIS) servers available to the client.

**Code**
41

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each NIS server.

### Structure of NIS Servers

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 41 | *n* | *IP address in binary format* | *IP address in binary format* |

**NTP Servers**
This option lists the IP addresses in the order of preference for Network Time Protocol (NTP) servers available to the client.

**Code**
42

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server address listed.

**Value**
Unsigned 32-bit integer representing the IP address of each NTP server.

### Structure of NTP Servers

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 42 | *n* | *IP address in binary format* | *IP address in binary format* |

**X Window System Font Servers**
This option lists the IP addresses in the order of preference for X Window System font servers available to the client.

**Code**
48

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server address listed.

**Value**
Unsigned 32-bit integer representing each server IP address.

**Structure of X Window System Font Servers**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 48 | *n* | *IP address in binary format* | *IP address in binary format* |

**X Window System Display Manager Servers**
This option lists the IP addresses in the order of preference for X Window System display manager servers available to the client.

**Code**
49

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server address listed.

**Value**
Unsigned 32-bit integer representing each server IP address.

**Structure of X Window System Display Manager Servers**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 49 | *n* | *IP address in binary format* | *IP address in binary format* |

**NIS+ Domain Name**
This option specifies the name of the client's Network Information Service Plus (NIS+) domain name as an ASCII string.

**Code**
64

**Length**
Length varies depending on the data in its value. Minimum length is 1 octet.

**Value**
ASCII character text.

**Structure of NIS+ Domain Name**

| Code | Length | NIS+ Domain Name |
|---|---|---|
| 64 | *n* | *NIS+ domain name* |

**NIS+ Servers**
This option lists the IP addresses in the order of preference for Network Information Service Plus (NIS+) servers available to the client.

**Code**
65

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server address listed.

**Value**
Unsigned 32-bit integer representing IP address of NIS+ servers.

**Structure of NIS+ Servers**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 65 | *n* | *IP address in binary format* | *IP address in binary format* |

**Mobile IP Home Agents**
This option lists the IP addresses in the order of preference for mobile IP home agents available to the client.

**Code**
68

**Length**

Variable. Minimum length is 0 octets. A length of 0 octets signifies that no mobile IP home agents are available. Octet length increases in multiples of 4 for each mobile IP home agent address listed.

**Value**
Unsigned 32-bit integer representing IP address of a mobile IP home agent.

**Structure of Mobile IP Home Agents**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 68 | *n* | *IP address in binary format* | *IP address in binary format* |

**Simple Mail Transfer Protocol (SMTP) Server**
This option lists the IP addresses in order of preference for SMTP servers available to the client.

**Code**
69

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server IP address listed.

**Value**
Unsigned 32-bit integers representing IP addresses of servers.

**Structure of Simple Mail Transfer Protocol (SMTP) Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 69 | *n* | *IP address in binary format* | *IP address in binary format* |

**Post Office Protocol 3 (POP3) Server**
This option lists the IP addresses in order of preference for POP3 servers available to the client.

**Code**
70

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server IP address listed.

**Value**
Unsigned 32-bit integers representing IP addresses of servers.

**Structure of Post Office Protocol 3 (POP3) Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 70 | *n* | *IP address in binary format* | *IP address in binary format* |

**Network News Transport Protocol Server**
This option lists the IP addresses in order of preference for NNTP servers available to the client.

**Code**
71

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server IP address listed.

**Value**
Unsigned 32-bit integers representing IP addresses of servers.

**Structure of Network News Transport Protocol Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 71 | *n* | *IP address in binary format* | *IP address in binary format* |

**Default World Wide Web Server**
This option lists the IP addresses in order of preference for default Web servers available to the client.

**Code**
72

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server IP address listed.

**Value**
Unsigned 32-bit integers representing IP addresses of servers.

**Structure of Default World Wide Web Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 72 | *n* | *IP address in binary format* | *IP address in binary format* |

**Default FFinger Server**
This option lists the IP addresses in order of preference for default Finger servers available to the client.

**Code**
73

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server IP address listed.

**Value**
Unsigned 32-bit integers representing IP addresses of servers.

**Structure of Default Finger Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 73 | *n* | *IP address in binary format* | *IP address in binary format* |

**Default Internet Relay Chat Server**
This option lists the IP addresses in order of preference for default IRC servers available to the client.

**Code**
74

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server IP address listed.

**Value**
Unsigned 32-bit integers representing IP addresses of servers.

**Structure of Default Internet Relay Chat Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 74 | *n* | *IP address in binary format* | *IP address in binary format* |

**StreetTalk Server**
This option lists the IP addresses in order of preference for StreetTalk servers available to the client.

**Code**
75

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server IP address listed.

**Value**
Unsigned 32-bit integers representing IP addresses of servers.

**Structure of StreetTalk Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|

| | | | |
|---|---|---|---|
| 75 | *n* | *IP address in binary format* | *IP address in binary format* |

**StreetTalk Directory Assistance Server**
This option lists the IP addresses in order of preference for StreetTalk Directory Assistance (STDA) servers available to the client.

**Code**
76

**Length**
Variable. Minimum length is 4 octets; octet length increases in multiples of 4 for each server IP address listed.

**Value**
Unsigned 32-bit integers representing IP addresses of servers.

**Structure of StreetTalk Directory Assistance Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 76 | *n* | *IP address in binary format* | *IP address in binary format* |

**NetBIOS over TCP/IP Options**
The following options are used to support NetBIOS over TCP/IP. All Microsoft-based DHCP clients and DHCP servers can recognize and support the use of these options.

**WINS/NBNS Servers**
This option lists the IP addresses for NetBIOS name servers (NBNSes) on the network. In Windows, a Windows Internet Name Service (WINS) server is an NBNS. A DHCP client running Windows XP or Windows Server 2003 requests this option.

**Code**
44

**Length**
Variable. Minimum length is 4 octets; length can be increased by multiples of 4 for each address listed.

**Value**
Each 4 octets in this field contains an NBNS server IP address, specified as an unsigned 32-bit integer.

**Structure of WINS/NBNS Servers**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 44 | *n* | *IP address in binary format* | *IP address in binary format* |

**NetBIOS over TCP/IP Datagram Distribution Server**
This option lists the IP addresses for NetBIOS datagram distribution (NBDD) servers.

**Code**
45

**Length**
Variable. Minimum length is 4 octets; length can be increased only by multiples of 4.

**Value**
Each 4 octets in this field contains an NBDD server IP address, specified as an unsigned 32-bit integer.

**Structure of NetBIOS over TCP/IP Datagram Distribution Server**

| Code | Length | Address 1 | Address N |
|---|---|---|---|
| 45 | *n* | *IP address in binary format* | *IP address in binary format* |

**NetBIOS over TCP/IP Node Type**
Configures the client node type for NetBIOS over TCP/IP (NetBT) clients, as described in RFCs 1001and 1002. On multihomed computers, the node type is assigned for the computer, not to individual network adapters. A DHCP client running Windows XP or Windows Server 2003 requests this option.

**Code**

46

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option are:

- 1 = b-node
- 2 = p-node
- 4 = m-node
- 8 = h-node

**Structure of NetBIOS over TCP/IP Node Type**

| Code | Length | Value |
|---|---|---|
| 46 | 1 | 1 \| 2 \| 4 \| 8 |

**NetBIOS over TCP/IP Scope ID**
This option specifies a string representing the NetBIOS over TCP/IP scope ID for the client, as specified in RFCs 1001 and 1002. On multihomed computers, the node type is assigned for the computer, not to individual network adapters. A DHCP client running Windows XP or Windows Server 2003 requests this option. The use of NetBIOS scope IDs is not recommended.

**Code**
47

**Length**
Variable. Minimum length is 1 octet. Octet length is equal to the number of characters used in NetBIOS scope ID.

**Value**
This option specifies the NetBIOS over TCP/IP scope identifier used by the client. The format used for these scope IDs is described in RFCs 1001 and 1002. For character-set restrictions, see the RFCs.

**Structure of NetBIOS over TCP/IP Scope ID**

| Code | Length | NetBIOS Scope |
|---|---|---|
| 47 | *n* | *scope identifier* |

**Vendor-Specific Options**
This section describes reserved DHCP options specified for vendor class use. The vendor-specific options are specified in RFC 2132. Vendor classes can be used by the DHCP service and DHCP clients running Windows 2000, Windows XP, and Windows Server 2003. For any other DHCP clients, default classes provided by the DHCP service can be used to group and classify non-identifying clients at the DHCP server.

The Windows Server 2003 DHCP snap-in provides a default vendor class called *DHCP Standard*. This class can be used to group and classify clients that do not identify a vendor class to the DHCP service.

**Vendor-Specific Information**
This option is used by clients and servers to exchange vendor-specific information. Servers not equipped to interpret the information ignore it. Clients that expect but do not receive the information attempt to operate without it.

In some cases, a vendor uses this option to send more than one information item; therefore, this option can serve as a subfield for encapsulating vendor-specific options. When encapsulating options, DHCP servers maintain the same syntax (the same sequence of code, length, and value fields) for each encapsulated option as it would normally appear in the full standard options field. The following exceptions are for the encapsulated, vendor-specific subfield:

- A “Magic cookie” field cannot be used.
- All standard option codes — other than the padding option (0) or the end option (255) — can be redefined, but should

conform to the code, length, value syntax sequence described in RFC 2131.

- If present, the end option (255) signifies the end of the encapsulated vendor options, but not the end of the encapsulated vendor-specific subfield. If no end option is present, the end for the encapsulated vendor-specific subfield is taken from its stated length. For more information, see RFC 2132 in the IETF RFC Database.

**Code**
43

**Length**
Variable. Minimum length is 1 octet.

**Value**
An object of *n* octets (where *n* is equal to the length specified with this option). The definition of values stored for this option is vendor specific, and values provided here are presumed to be interpreted by vendor-specific code on DHCP clients and the DHCP server.

**Structure of Vendor-Specific Information**

| Code | Length | Value |
|---|---|---|
| 43 | *n* | *vendor-specific information* (which can include subfield *bytes 1-n*) |

When this option uses an encapsulated vendor-specific subfield, the information bytes 1–*n* have the following format.

| Code | Length | Data Item |
|---|---|---|
| T1 | *n* | *d1*, *d2*, ...*dn* |
| T2 | *n* | *d1*, *d2*, *dn* |

**Vendor Class Identifier**
Can be used by DHCP clients to identify their vendor type and configuration when communicating with DHCP servers. Vendors can define their own specific identifier values, like conveying a particular hardware or operating system configuration.

For Windows Server 2003, all computers that function either as DHCP servers or DHCP clients can use and support this option. When vendor classes are used, the DHCP server responds to identifying clients by using option 43, the reserved option for returning vendor-specific information to the client.

DHCP servers that do not automatically interpret this option are expected to ignore it. For earlier, Windows-based clients and other clients that do not support this option, the DHCP service classifies these clients as part of the default vendor class — the DHCP Standard option class — predefined for Windows-based DHCP servers.

**Code**
60

**Length**
Variable. Minimum is 1 octet; Length varies according to *n* (the number of octets used as an identifier).

**Value**
A value of *n* octets, which can be interpreted by DHCP servers that support vendor-specific classification of clients.

**Structure of Vendor Class Identifier**

| Code | Length | Value |
|---|---|---|
| 60 | *n* | *vendor class identifier* |

**User Class Options**
This section describes reserved DHCP options specified for user classes. User classes can be used by the DHCP service and DHCP-enabled client computers running Windows Server 2003. For other DHCP clients, default classes provided by the DHCP service can be used to group and classify non-identifying clients at the DHCP server.

**User Class Information**
A DHCP client can use this option to identify the user class of which it is a member when communicating with the DHCP server. The information contained in this option is a Network Virtual Terminal (NVT) ASCII text object that represents the user class ID.

You can use the DHCP snap-in to define specific user classes. When user classes are created, each class sets an identifying string of information to be used by the DHCP service to classify identifying clients. Also, a default user class is created for classifying clients that are unable to support a user class ID.

User classes can be helpful for separating client computers that have a shared or common need for similar software configuration or user preferences. For example, an identifier can specify that a particular DHCP client be a member of the class "accounting auditors," who have special service needs, such as a particular database server.

Computers running Windows Server 2003 support sending or using this option. Legacy DHCP clients do not send a class ID and cannot recognize DHCP user class IDs. Such client's are assigned to the Default User Class, a user class predefined for immediate use in the DHCP snap-in. Other user classes must be manually created.

**Code**
77

**Length**
Variable. Minimum is 2 octets.

**Value**
ASCII character text.

**Structure of User Class Information**

| Code | Length | User Class Information |
|---|---|---|
| 77 | *n* | *c1*, *c2*, *c3*, *c4 ...cn* |

**DHCP Extensions**
The following options are specific to DHCP and are used to implement default protocol interaction and system behavior between servers and clients. Some of these options are implicitly set when you configure server and scope properties using the DHCP snap-in.

**Requested IP Address**
This option can be used by clients when sending a DHCPDiscover message to request a specific IP address from the DHCP server.

**Code**
50

**Length**
Fixed, 4 octets.

**Value**
Single, unsigned 32-bit integer representing a requested IP address.

**Structure of Requested IP Address**

| Code | Length | Requested IP Address |
|---|---|---|
| 50 | *4* | *IP address in binary format* |

**IP Address Lease Time**
This option is used to negotiate and exchange lease-time information between DHCP clients and servers in two possible ways. First, the option can be used in a DHCPDiscover or DHCPRequest message sent by a client to request a lease time for its IP address. Second, the option can be used in a DHCPOffer message sent by a server to specify a lease time for the client. This option is configured on the **Scope Properties** dialog box.

**Code**
51

**Length**
Fixed, 4 octets.

**Value**
Single, unsigned 32-bit integer representing a clients lease time (in seconds).

**Structure of IP Address Lease Time**

| Code | Length | Lease Time |
|---|---|---|
| 51 | 4 | *lease time in seconds* |

**Option Overload**
Used in messages sent by a DHCP server to indicate that either of the standard message fields in a DHCP packet for *server_host_name* (**sname**) and *boot_file_name* (**file**) can be used to hold options (a condition also known as *overloaded*).

When this option is used, it extends the options area in each packet by indicating that unused space for one or both of these two standard fields should be allocated to the area used to carry DHCP options.

**Code**
52

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option include:

- 1 = **File** field is overloaded
- 2 = **Sname** field is overloaded
- 3 = Both **file** and **sname** fields are overloaded

### Structure of Option Overload

| Code | Length | Value |
|---|---|---|
| 52 | 1 | 1 \| 2 \| 3 |

**TFTP Server Name**
This option specifies the host name of the Trivial File Transfer Protocol (TFTP) server when the *server_host_name* (**sname**) field in a DHCP message is overloaded and used for carrying additional DHCP options.

**Code**
66

**Length**
Variable depending on data in value. Minimum length is 1 octet.

**Value**
ASCII character text.

### Structure of TFTP Server Name

| Code | Length | TFTP Server |
|---|---|---|
| 66 | *n* | *TFTP server host name* |

**Boot File Name**
This option specifies the name of a boot image file on the TFTP server when the *boot_file_name* (**file**) field in a DHCP message is overloaded and used for carrying additional DHCP options.

**Code**
67

**Length**
Variable depending on data in value. Minimum length is 1 octet.

**Value**
ASCII character text.

### Structure of Boot File Name

| Code | Length | Boot File Name |
|---|---|---|
| 67 | *n* | *boot image file name* |

**DHCP Message Type**
This option is required for use in all DHCP messages to convey the type of message being sent.

**Code**
53

**Length**
Fixed, 1 octet.

**Value**
Accepted values for this option are:

- 1 = DHCP Discover message (DHCPDiscover)
- 2 = DHCP Offer message (DHCPOffer)
- 3 = DHCP Request message (DHCPRequest)
- 4 = DHCP Decline message (DHCPDecline)
- 5 = DHCP Acknowledgment message (DHCPAck)
- 6 = DHCP Negative Acknowledgment message (DHCPNak)
- 7 = DHCP Release message (DHCPRelease)
- 8 = DHCP Informational message (DHCPInform)

### Structure of DHCP Message Type

| Code | Length | Value |
|---|---|---|
| 53 | 1 | 1 \| 2 \| 3 \| 4 \| 5 \| 6 \| 7 \| 8 |

**Server Identifier**
This option is used in DHCPOffer and DHCPRequest messages, and might appear in DHCP Acknowledgment messages (DHCPAck, DHCPNak). The server identifier is the IP address of a selected DHCP server.

This option is used in three possible ways. First, servers include this option in DHCPOffer messages so that clients can distinguish between multiple lease offers. Second, clients include this option in DHCPRequest messages to select a lease and indicate which offer is accepted from multiple lease offers. Third, clients can use the contents of this option for unicast transmission of DHCPRequest messages to specific DHCP servers to renew a current lease.

**Code**
54

**Length**
Fixed, 4 octets.

**Value**
A single, unsigned 32-bit integer representing the IP address that identifies the DHCP server.

### Structure of Server Identifier

| Code | Length | Address |
|---|---|---|
| 54 | 4 | *IP address in binary format* |

**Parameter Request List**

Used by a DHCP client to request specific option values from the DHCP server. Each option is requested and listed by a single octet value containing a valid or recognized DHCP option Code for the server.

For clients that use this option, the list can be ordered by preference. Although the DHCP server is not required to return options in the order they are requested it does attempt to insert the requested options in the requested order.

**Code**
55

**Length**
Variable. Minimum of 1 octet; length increases by 1 octet for each option code included in the request list.

**Value**
List of 8-bit values, each representing an option code between 0 and 255.

**Structure of Parameter Request List**

| Code | Length | Option Codes |
|---|---|---|
| 55 | *n* | *c1*, *c2*...*cn* |

**Optional Message**
Can be used by both the DHCP server and DHCP clients in the following ways:

- A server can use this option to provide and embed an error message in a DHCP Negative Acknowledgment (DHCPNak) message in the event of a failure.
- A client can use this option in a DHCPDecline message to indicate why it declined offered parameters.

The message consists of a variable-length ASCII text string, which the receiving computer can then either log or display.

**Code**
56

**Length**
Minimum of 1 octet. Length depends on the length of the sent message.

**Value**
ASCII character text.

**Structure of Optional Message**

| Code | Length | Text |
|---|---|---|
| 56 | *n* | *c1*, *c2*...*cn* |

**Maximum Message Size**
Used by client to specify the maximum length for a DHCP message it can accept. A client can include this option in DHCPDiscover or DHCPRequest messages; however, it does not include this option in DHCPDecline messages.

**Code**
57

**Length**
Fixed, 2 octets.

**Value**
A 16-bit integer indicating the maximum size, in octets, for a DHCP message. The minimum value for this option is **576**.

**Structure of Maximum Message Size**

| Code | Length | Value |
|---|---|---|
| 57 | 2 | *maximum size* |

**Renewal Time Value (T1)**

The time value of this option is typically 50 percent of the client's lease time. To adjust the value, change the length of the client lease in the client scope properties or the per-user class on the DHCP server. You can also change the value by using the Netsh tool.

**Code**
58

**Length**
Fixed, 4 octets.

**Value**
A 32-bit unsigned integer indicating the number of seconds before the client begins to renew its address lease with the DHCP server.

**Structure of Renewal Time Value (T1)**

| Code | Length | T1 Interval |
|---|---|---|
| 58 | 4 | *renewal interval in seconds* |

**Rebinding Time Value (T2)**
The time value of this option is typically 87.5 percent of the full configured duration (lease time) for a client's lease. To adjust the value, change the length of the client lease in the properties for the client's scope or per-user class on the DHCP server. You can also change the value by using the Netsh tool.

**Code**
59

**Length**
Fixed, 4 octets.

**Value**
A 32-bit unsigned integer indicating the number of seconds before the client enters the rebinding state (if it has not renewed its current address lease with the DHCP server).

**Structure of Rebinding Time Value (T2)**

| Code | Length | T2 Interval |
|---|---|---|
| 59 | 4 | *rebinding interval in seconds* |

**Client Unique Identifier**
This option is used by clients to specify their unique identifier to the server. This option is most useful for reserved clients. When a reserved client contacts the server, the DHCP service checks and matches the client identifier value to a corresponding identifier used to configure an address reservation in the server's database. When a matching reservation is found, the DHCP server returns the reserved address and its related parameters to the correct client.

Each clients identifier must be unique among all other client identifiers used on the DHCP client's local subnet and any remote subnets reachable using DHCP relay. Vendors and system administrators are responsible for choosing client identifiers that meet this requirement for uniqueness. One way to ensure unique values is to use the client's media access control (MAC) address as the client identifier value. Media access control addresses are encoded in the client's network adapter hardware, and are assigned to hardware manufacturers in such a way as to ensure that they are unique for each device.

**Code**
61

**Length**
Variable length; minimum length is 2 octets.

**Value**
A series of 2 or more octets treated as a single value by the DHCP server. Servers can interpret and use this value to uniquely identify clients. The client identifier can consist of type-value pairs similar to the DHCP Header fields "htype" and "chaddr," which are defined by the DHCP protocol.

**Structure of Client Unique Identifier**

| Code | Length | Type | Client Identifier |
|---|---|---|---|
| 61 | *n* | *t1* | *i1*, *i2*...*in* |

**Administrator-Defined Options**
This section describes DHCP options that are reserved and specified for use by RFC 2132, but are not predefined for use in the DHCP snap-in. Administrators can add these options to support DHCP clients that recognize these options.

**Proxy Autodiscovery for Internet Explorer 5**
This option points to the configuration file that the client uses for automatic configuration of Internet Explorer 5.*x* and Internet Explorer 6. The configuration file can be a .pac, .jvs, .js, or .ins file created by a system or Web administrator when deploying Internet Explorer 5.*x* on an intranet. It might include settings for other Internet Explorer configurable options, such as which home page to use, or settings for locating and using a proxy server.

The option is communicated between Internet Explorer client computers and the DHCP server using the DHCPInform message. DHCPInform is currently supported for DHCP servers running Windows Server 2003 and DHCP clients running Windows 2000, Windows XP, and Windows Server 2003.

The use of additional DHCP configuration is supported by Internet Explorer 5.*x* and Internet Explorer 6, but not earlier versions, because those use different methods for automatic detection and configuration of proxy server settings.

You can add and configure an alias (CNAME) resource record at the DNS server to support Internet Explorer proxy server auto-discovery and configuration features.

**Code**
252

**Length**
Variable

**Value**
A URL that points to the configuration file that the client should use for automatic configuration of Internet Explorer 5.*x* and Internet Explorer 6.

**Structure of Proxy Autodiscovery for Internet Explorer 5**

| Code | Length | Value |
|---|---|---|
| 252 | *n* | *URL name* |

**Microsoft Options**
This section describes reserved DHCP options defined by Microsoft. These options are only available for use with supported Windows-based DHCP clients, such as computers running Windows Server 2003.

The Microsoft options are provided as encapsulated vendor-specific data fields within the vendor-specific information option.

Currently, administrators can assign these options are by using the DHCP snap-in through the following vendor classes: Microsoft options and Microsoft Windows 2000 options.

**Disable NetBIOS over TCP/IP (NetBT)**
This option can be used to selectively enable or disable NetBT for DHCP-enabled computers running Windows Server 2003, Windows XP, and Windows 2000. By default, if this option is not present, Windows Server 2003, Windows XP, and Windows 2000 enable the use of NetBT for network connections that are configured to use TCP/IP. Earlier Windows-based clients require NetBT and do not support this option.

**Code**
1

**Length**
4 octets

**Value**
Accepted values for this option are:

- 1= NetBT remains enabled
- 2=Disable NetBT for DHCP clients

**Structure of Disable NetBIOS over TCP/IP (NetBT)**

| Code | Length | NetBT |
|---|---|---|
| 001 | 4 | 1 \| 2 |

**Release DHCP Lease on Shutdown**
This option can be used to control whether DHCP-enabled computers running Windows 2000, Windows XP, or Windows Server 2003 sends a DHCPRelease message to the DHCP server when a shutdown occurs. It is actually implemented and interpreted as a bit-masked value by the DHCP Client service. By default, these clients do not send DHCPRelease messages on proper shutdown.

**Code**
2

**Length**
4 octets

**Value**
Accepted values for this option are:

- 1 = DHCP clients send a DHCPRelease message on proper shutdown
- 0 = DHCP clients do not send a DHCPRelease message on proper shutdown

**Structure of Release DHCP Lease on Shutdown**

| Code | Length | Release |
|---|---|---|
| 002 | 4 | 0 \| 1 |

**Default Router Metric Base**
This option can be used to set the default base metric for DHCP clients running Windows Server 2003. When this option is set, the DHCP Client service uses the value configured here as the base metric for its default gateways.

**Code**
3

**Length**
4 octets

**Value**
This value represents a specified router metric base to be used for all default gateway routes used by DHCP-enabled clients running Windows Server 2003. This value can be assigned as an integer representing a cost metric ranging from 1 through 9,999. It is used in calculating the fastest, most reliable, and least expensive routes. If a value is not specified, a default of either one (1) or the currently set interface-specific metric is used.

**Structure of Default Router Metric Base**

| Code | Length | Route Metric |
|---|---|---|
| 003 | *4* | *Router metric base* |

# DNS registration changes for Windows Server 2003 based DHCP Servers

Updated: August 19, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This article describes the DNS registration changes for DHCP Servers that are running Windows Server® 2003.

**Overview**

When the DHCP Server role is installed on a domain controller, the DHCP Server inherits the security permissions of the domain controller. To prevent possible misuse of the domain controller's elevated permissions, DHCP Servers that are installed on Windows Server 2003 do not register DNS records on behalf of the clients that are associated with the DHCP Server unless the DHCP Server is explicitly configured with DNS credentials. This behavior prevents a potential escalation of privilege to clients of the DHCP Server.

**Configuring DNS credentials on a DHCP Server that is running Windows Server 2003**

Follow these steps to configure the DNS credentials of a DHCP Server that is installed on a domain controller running the Windows Server 2003 operating system:

1. Start the DHCP management console. Click **Start**, then click **Run** and type **dhcpmgmt.msc**.

2. In the DHCP navigation pane, expand the server node and right-click **IPv4**, and then click **Properties**.

3. In the resulting dialog box, click the **Advanced** tab, and then click **Credentials**.

4. In the **DNS dynamic update credentials** dialog box, enter the DNS credentials (User name, Domain, and Password) for the account that is used by the DHCP Server for DNS registrations.

| **Note** |
| --- |
| These credentials should belong to a member of the DnsAdmins or the DnsUpdateProxy group. |

**Related information**

For more information about creating and adding a user account as a member of a group by using the Active Directory® Users and Groups console, see Changing group memberships.

# Windows Time Service Technical Reference

Updated: August 17, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 Foundation, Windows Server 2008 R2, Windows Server 2008 R2 Foundation

**Windows Time Service Technical Reference**

**In this guide**

- Where to Find Windows Time Service Configuration Information
- What is the Windows Time Service?
- Importance of Time Protocols
- How the Windows Time Service Works
- Windows Time Service Tools and Settings

| **Note** |
| --- |
| In Windows Server® 2003 and Microsoft Windows 2000 Server, the directory service is named Active Directory® directory service. In Windows Server 2008 R2 and Windows Server 2008, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

The Windows® Time service, also known as W32Time, synchronizes the date and time for all computers running in an AD DS domain. Time synchronization is critical for the proper operation of many Windows services and line-of-business applications. The Windows Time service uses the Network Time Protocol (NTP) to synchronize computer clocks on the network so that an accurate clock value, or time stamp, can be assigned to network validation and resource access requests. The service integrates NTP and time providers, making it a reliable and scalable time service for enterprise administrators.

| **Important** |
| --- |
| The W32Time service is not a full-featured NTP solution that meets time-sensitive application needs and is not supported by Microsoft as such. For more information, see Microsoft Knowledge Base article 939322, Support boundary to configure the Windows Time service for high-accuracy environments (http://go.microsoft.com/fwlink/?LinkID=179459). |

**Where to Find Windows Time Service Configuration Information**

This guide does **not** discuss configuring the Windows Time service. There are several different topics on Microsoft TechNet and in the Microsoft Knowledge Base that do explain procedures for configuring the Windows Time service. If you require configuration information, the following topics should help you locate the appropriate information.

- To configure the Windows Time service for the forest root primary domain controller (PDC) emulator, see:
    - Configure the Windows Time service on the PDC emulator in the forest root domain (http://go.microsoft.com/fwlink/?LinkId=91969)
    - Configuring a time source for the forest (http://go.microsoft.com/fwlink/?LinkId=111146)
    - Microsoft Knowledge Base article 816042, How to configure an authoritative time server in Windows Server (http://go.microsoft.com/fwlink/?LinkID=60402), which describes configuration settings for computers running Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, and Windows Server 2003 R2.
    - Microsoft Knowledge Base article 216734, How to configure an authoritative time server in Windows 2000 (http://go.microsoft.com/fwlink/?LinkID=23042), which describes configuration settings for computers running

Windows 2000 Server.

- To configure the Windows Time service on any domain member client or server, or even domain controllers that are not configured as the forest root PDC emulator, see Configure a client computer for automatic domain time synchronization (http://go.microsoft.com/fwlink/?LinkId=91376).

| **Warning** |
| --- |
| Some applications may require their computers to have high-accuracy time services. If that is the case, you may choose to configure a manual time source, but be aware that the Windows Time service was not designed to function as a highly accurate time source. Ensure that you are aware of the support limitations for high-accuracy time environments as described in Microsoft Knowledge Base article 939322, Support boundary to configure the Windows Time service for high-accuracy environments (http://go.microsoft.com/fwlink/?LinkID=179459). |

- To configure the Windows Time service on any Windows-based client or server computers that are configured as workgroup members instead of domain members see Configure a manual time source for a selected client computer (http://go.microsoft.com/fwlink/?LinkId=91377).

- To configure the Windows Time service on a host computer that runs a virtual environment, see Microsoft Knowledge Base article 816042, How to configure an authoritative time server in Windows Server (http://go.microsoft.com/fwlink/?LinkID=60402). If you are working with a non-Microsoft virtualization product, be sure to consult the documentation of the vendor for that product.

- To configure the Windows Time service on a domain controller that is running in a virtual machine, it is recommended that you partially disable time synchronization between the host system and guest operating system acting as a domain controller. This enables your guest domain controller to synchronize time for the domain hierarchy, but protects it from having a time skew if it is restored from a Saved state. For more information, see Microsoft Knowledge Base article 976924, You receive Windows Time Service event IDs 24, 29, and 38 on a virtualized domain controller that is running on a Windows Server 2008–based host server with Hyper-V (http://go.microsoft.com/fwlink/?LinkID=192236) and Deployment Considerations for Virtualized Domain Controllers (http://go.microsoft.com/fwlink/?LinkID=192235).

- To configure the Windows Time service on a domain controller acting as the forest root PDC emulator that is also running in a virtual computer, follow the same instructions for a physical computer as described in Configure the Windows Time service on the PDC emulator in the Forest Root Domain (http://go.microsoft.com/fwlink/?LinkId=91969).

- To configure the Windows Time service on a member server running as a virtual computer, use the domain time hierarchy as described in (Configure a client computer for automatic domain time synchronization (http://go.microsoft.com/fwlink/?LinkId=91376).

**What is the Windows Time Service?**

The Windows Time service (W32Time) provides network clock synchronization for computers without the need for extensive configuration.

The Windows Time service is essential to the successful operation of Kerberos version 5 authentication and, therefore, to AD DS-based authentication. Any Kerberos-aware application, including most security services, relies on time synchronization between the computers that are participating in the authentication request. AD DS domain controllers must also have synchronized clocks to help to ensure accurate data replication.

The Windows Time service is implemented in a dynamic link library called W32Time.dll. W32Time.dll is installed by default in the **%Systemroot%\System32** folder during operating system setup and installation.

W32Time.dll was originally developed for Windows 2000 Server to support a specification by the Kerberos V5 authentication protocol that required clocks on a network to be synchronized. Starting with Windows Server 2003, W32Time.dll provided increased accuracy in network clock synchronization over the Windows 2000 Server operating system and, in addition, supported a variety of hardware devices and network time protocols by means of time providers. Although originally designed to provide clock synchronization for Kerberos authentication, many current applications use timestamps to ensure transactional consistency, to record the time of important events, and other business-critical, time-sensitive information. These applications benefit from time synchronization between computers that is provided by the Windows Time service.

**Importance of Time Protocols**

Time protocols communicate between two computers to exchange time information and then use that information to synchronize their clocks. With the Windows Time service time protocol, a client requests time information from a server and synchronizes its clock based on the information that is received.

The Windows Time service uses NTP to help synchronize time across a network. NTP is an Internet time protocol that includes the discipline algorithms necessary for synchronizing clocks. NTP is a more accurate time protocol than the Simple Network Time Protocol (SNTP) that is used in some versions of Windows; however, W32Time continues to support SNTP to enable backward compatibility with computers running SNTP-based time services such as Windows 2000.

# How the Windows Time Service Works

Updated: March 12, 2015

Applies To: Windows SBS 2003, Windows SBS 2008, Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 Foundation, Windows Server 2008 R2, Windows Server 2008 R2 Foundation, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Windows Time Service Architecture
- Windows Time Service Time Protocols
- Windows Time Service Processes and Interactions
- Network Ports Used by Windows Time Service

**Note**

This topic explains only how the Windows Time service (W32Time) works. For information about how to configure Windows Time service, see the list of topics in the section Where to Find Windows Time Service Configuration Information.

**Note**

In Windows Server® 2003 and Microsoft Windows 2000 Server, the directory service is named Active Directory® directory service. In Windows Server 2008 and later versions, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to AD DS, but the information is also applicable to Active Directory.

Although the Windows Time service is not an exact implementation of the Network Time Protocol (NTP), it uses the complex suite of algorithms that is defined in the NTP specifications to ensure that clocks on computers throughout a network are as accurate as possible. Ideally, all computer clocks in an AD DS domain are synchronized with the time of an authoritative computer. Many factors can affect time synchronization on a network. The following factors often affect the accuracy of synchronization in AD DS:

- Network conditions
- The accuracy of the computer's hardware clock
- The amount of CPU and network resources available to the Windows Time service

**Important**

The W32Time service is not a full-featured NTP solution that meets time-sensitive application needs and is not supported by Microsoft as such. For more information, see Microsoft Knowledge Base article 939322, Support boundary to configure the Windows Time service for high-accuracy environments (http://go.microsoft.com/fwlink/?LinkID=179459).

Computers that synchronize their time less frequently, such as computers running Windows XP Home Edition, computers with intermittent network connections, or computers that are not joined to a domain, are configured by default to synchronize with time.windows.com. Because they do not synchronize their clock frequently and because the factors that affect time accuracy may not be known, it is impossible to guarantee time accuracy on computers that have intermittent or no network connections.

An AD DS forest has a predetermined time synchronization hierarchy. The Windows Time service synchronizes time between computers within the hierarchy, with the most accurate reference clocks at the top. If more than one time source is configured on a computer, Windows Time uses NTP algorithms to select the best time source from the configured sources based on the computer's ability to synchronize with that time source. The Windows Time service does not support network synchronization

from broadcast or multicast peers. For more information about these NTP features, see RFC 1305 in the IETF RFC Database.

Every computer that is running the Windows Time service uses the service to maintain the most accurate time. In most cases, it is not necessary to configure the Windows Time service. Computers that are members of a domain act as a time client by default. In addition, the Windows Time service can be configured to request time from a designated reference time source, and can also be configured to provide time to clients.

The degree to which a computer's time is accurate is called a stratum. The most accurate time source on a network (such as a hardware clock) occupies the lowest stratum level, or stratum one. This accurate time source is called a reference clock. An NTP server that acquires its time directly from a reference clock occupies a stratum that is one level higher than that of the reference clock. Resources that acquire time from the NTP server are two steps away from the reference clock, and therefore occupy a stratum that is two higher than the most accurate time source, and so on. As a computer's stratum number increases, the time on its system clock may become less accurate. Therefore, the stratum level of any computer is an indicator of how closely that computer is synchronized with the most accurate time source.

When the W32Time Manager receives time samples, it uses special algorithms in NTP to determine which of the time samples is the most appropriate for use. The time service also uses another set of algorithms to determine which of the configured time sources is the most accurate. When the time service has determined which time sample is best, based on the above criteria, it adjusts the local clock rate to allow it to converge toward the correct time. If the time difference between the local clock and the selected accurate time sample (also called the time skew) is too large to correct by adjusting the local clock rate, the time service sets the local clock to the correct time. This adjustment of clock rate or direct clock time change is known as clock discipline.

**Windows Time Service Architecture**

The Windows Time service consists of the following components:

- Service Control Manager
- Windows Time Service Manager
- Clock Discipline
- Time providers

The following figure shows the architecture of the Windows Time service.

**Windows Time Service Architecture**

The Service Control Manager is responsible for starting and stopping the Windows Time service. The Windows Time Service Manager is responsible for initiating the action of the NTP time providers included with the operating system. The Windows Time Service Manager controls all functions of the Windows Time service and the coalescing of all time samples. In addition to providing information about the current system state, such as the current time source or the last time the system clock was updated, the Windows Time Service Manager is also responsible for creating events in the event log.

The time synchronization process involves the following steps:

- Input providers request and receive time samples from configured NTP time sources.
- These time samples are then passed to the Windows Time Service Manager, which collects all the samples and passes them to the clock discipline subcomponent.

- The clock discipline subcomponent applies the NTP algorithms which results in the selection of the best time sample.
- The clock discipline subcomponent adjusts the time of the system clock to the most accurate time by either adjusting the clock rate or directly changing the time.

If a computer has been designated as a time server, it can send the time on to any computer requesting time synchronization at any point in this process.

**Windows Time Service Time Protocols**
Time protocols determine how closely two computers' clocks are synchronized. A time protocol is responsible for determining the best available time information and converging the clocks to ensure that a consistent time is maintained on separate systems.

The Windows Time service uses the Network Time Protocol (NTP) to help synchronize time across a network. NTP is an Internet time protocol that includes the discipline algorithms necessary for synchronizing clocks. NTP is a more accurate time protocol than the Simple Network Time Protocol (SNTP) that is used in some versions of Windows; however W32Time continues to support SNTP to enable backward compatibility with computers running SNTP-based time services, such as Windows 2000.

**Network Time Protocol**
Network Time Protocol (NTP) is the default time synchronization protocol used by the Windows Time service in the operating system. NTP is a fault-tolerant, highly scalable time protocol and is the protocol used most often for synchronizing computer clocks by using a designated time reference.

NTP time synchronization takes place over a period of time and involves the transfer of NTP packets over a network. NTP packets contain time stamps that include a time sample from both the client and the server participating in time synchronization.

NTP relies on a reference clock to define the most accurate time to be used and synchronizes all clocks on a network to that reference clock. NTP uses Coordinated Universal Time (UTC) as the universal standard for current time. UTC is independent of time zones and enables NTP to be used anywhere in the world regardless of time zone settings.

**NTP Algorithms**
NTP includes two algorithms, a clock-filtering algorithm and a clock-selection algorithm, to assist the Windows Time service in determining the best time sample. The clock-filtering algorithm is designed to sift through time samples that are received from queried time sources and determine the best time samples from each source. The clock-selection algorithm then determines the most accurate time server on the network. This information is then passed to the clock discipline algorithm, which uses the information gathered to correct the local clock of the computer, while compensating for errors due to network latency and computer clock inaccuracy.

The NTP algorithms are most accurate under conditions of light-to-moderate network and server loads. As with any algorithm that takes network transit time into account, NTP algorithms might perform poorly under conditions of extreme network congestion. For more information about the NTP algorithms, see RFC 1305 in the IETF RFC Database.

**NTP Time Provider**
The Windows Time service is a complete time synchronization package that can support a variety of hardware devices and time protocols. To enable this support, the service uses pluggable time providers. A time provider is responsible for either obtaining accurate time stamps (from the network or from hardware) or for providing those time stamps to other computers over the network.

The NTP provider is the standard time provider included with the operating system. The NTP provider follows the standards specified by NTP version 3 for a client and server, and can interact with SNTP clients and servers for backward compatibility with Windows 2000 and other SNTP clients. The NTP provider in the Windows Time service consists of the following two parts:

- **NtpServer output provider.** This is a time server that responds to client time requests on the network.
- **NtpClient input provider.** This is a time client that obtains time information from another source, either a hardware device or an NTP server, and can return time samples that are useful for synchronizing the local clock.

Although the actual operations of these two providers are closely related, they appear independent to the time service. Starting with Windows 2000 Server, when a Windows computer is connected to a network, it is configured as an NTP client. Also, computers running the Windows Time service only attempt to synchronize time with a domain controller or a manually specified time source by default. These are the preferred time providers because they are automatically available, secure

sources of time.

**NTP Security**
Within an AD DS forest, the Windows Time service relies on standard domain security features to enforce the authentication of time data. The security of NTP packets that are sent between a domain member computer and a local domain controller that is acting as a time server is based on shared key authentication. The Windows Time service uses the computer's Kerberos session key to create authenticated signatures on NTP packets that are sent across the network. NTP packets are not transmitted inside the Net Logon secure channel. Instead, when a computer requests the time from a domain controller in the domain hierarchy, the Windows Time service requires that the time be authenticated. The domain controller then returns the required information in the form of a 64-bit value that has been authenticated with the session key from the Net Logon service. If the returned NTP packet is not signed with the computer's session key or is signed incorrectly, the time is rejected. All such authentication failures are logged in the Event Log. In this way, the Windows Time service provides security for NTP data in an AD DS forest.

Generally, Windows time clients automatically obtain accurate time for synchronization from domain controllers in the same domain. In a forest, the domain controllers of a child domain synchronize time with domain controllers in their parent domains. When a time server returns an authenticated NTP packet to a client that requests the time, the packet is signed by means of a Kerberos session key defined by an interdomain trust account. The interdomain trust account is created when a new AD DS domain joins a forest, and the Net Logon service manages the session key. In this way, the domain controller that is configured as reliable in the forest root domain becomes the authenticated time source for all of the domain controllers in both the parent and child domains, and indirectly for all computers located in the domain tree.

The Windows Time service can be configured to work between forests, but it is important to note that this configuration is not secure. For example, an NTP server might be available in a different forest. However, because that computer is in a different forest, there is no Kerberos session key with which to sign and authenticate NTP packets. To obtain accurate time synchronization from a computer in a different forest, the client needs network access to that computer and the time service must be configured to use a specific time source located in the other forest. If a client is manually configured to access time from an NTP server outside of its own domain hierarchy, the NTP packets sent between the client and the time server are not authenticated, and therefore are not secure. Even with the implementation of forest trusts, the Windows Time service is not secure across forests. Although the Net Logon secure channel is the authentication mechanism for the Windows Time service, authentication across forests is not supported.

**Hardware Devices That Are Supported by the Windows Time Service**
Hardware-based clocks such as GPS or radio clocks are often used as highly accurate reference clock devices. By default, the Windows Time service NTP time provider does not support the direct connection of a hardware device to a computer, although it is possible to create a software-based independent time provider that supports this type of connection. This type of provider, in conjunction with the Windows Time service, can provide a reliable, stable time reference.

Hardware devices, such as a cesium clock or a Global Positioning System (GPS) receiver, provide accurate current time by following a standard to obtain an accurate definition of time. Cesium clocks are extremely stable and are unaffected by factors such as temperature, pressure, or humidity, but are also very expensive. A GPS receiver is much less expensive to operate and is also an accurate reference clock. GPS receivers obtain their time from satellites that obtain their time from a cesium clock. Without the use of an independent time provider, Windows time servers can acquire their time by connecting to an external NTP server, which is connected to a hardware device by means of a telephone or the Internet. Organizations such as the United States Naval Observatory provide NTP servers that are connected to extremely reliable reference clocks.

Many GPS receivers and other time devices can function as NTP servers on a network. You can configure your AD DS forest to synchronize time from these external hardware devices only if they are also acting as NTP servers on your network. To do so, configure the domain controller functioning as the primary domain controller (PDC) emulator in your forest root to synchronize with the NTP server provided by the GPS device. To do so, see Configure the Windows Time service on the PDC emulator in the Forest Root Domain (http://go.microsoft.com/fwlink/?LinkId=91969).

**Simple Network Time Protocol**
The Simple Network Time Protocol (SNTP) is a simplified time protocol that is intended for servers and clients that do not require the degree of accuracy that NTP provides. SNTP, a more rudimentary version of NTP, is the primary time protocol that is used in Windows 2000. Because the network packet formats of SNTP and NTP are identical, the two protocols are interoperable. The primary difference between the two is that SNTP does not have the error management and complex filtering systems that NTP provides. For more information about the Simple Network Time Protocol, see RFC 1769 in the IETF RFC Database.

**Time Protocol Interoperability**
The Windows Time service can operate in a mixed environment of computers running Windows 2000, Windows XP, and Windows Server 2003, because the SNTP protocol used in Windows 2000 is interoperable with the NTP protocol in Windows XP and Windows Server 2003.

The time service in Windows NT Server 4.0, called TimeServ, synchronizes time across a Windows NT 4.0 network. TimeServ is an add-on feature available as part of the *Microsoft Windows NT 4.0 Resource Kit* and does not provide the degree of reliability of time synchronization that is required by Windows Server 2003.

The Windows Time service can interoperate with computers running Windows NT 4.0 because they can synchronize time with computers running Windows 2000 or Windows Server 2003; however, a computer running Windows 2000 or Windows Server 2003 does not automatically discover Windows NT 4.0 time servers. For example, if your domain is configured to synchronize time by using the domain hierarchy–based method of synchronization and you want computers in the domain hierarchy to synchronize time with a Windows NT 4.0 domain controller, you have to configure those computers manually to synchronize with the Windows NT 4.0 domain controllers.

Windows NT 4.0 uses a simpler mechanism for time synchronization than the Windows Time service uses. Therefore, to ensure accurate time synchronization across your network, it is recommended that you upgrade any Windows NT 4.0 domain controllers to Windows 2000 or Windows Server 2003.

**Windows Time Service Processes and Interactions**

The Windows Time service is designed to synchronize the clocks of computers on a network. The network time synchronization process, also called time convergence, occurs throughout a network as each computer accesses time from a more accurate time server. Time convergence involves a process by which an authoritative server provides the current time to client computers in the form of NTP packets. The information provided within a packet indicates whether an adjustment needs to be made to the computer's current clock time so that it is synchronized with the more accurate server.

As part of the time convergence process, domain members attempt to synchronize time with any domain controller located in the same domain. If the computer is a domain controller, it attempts to synchronize with a more authoritative domain controller.

Computers running Windows XP Home Edition or computers that are not joined to a domain do not attempt to synchronize with the domain hierarchy, but are configured by default to obtain time from time.windows.com.

To establish a computer running Windows Server 2003 as authoritative, the computer must be configured to be a reliable time source. By default, the first domain controller that is installed on a Windows Server 2003 domain is automatically configured to be a reliable time source. Because it is the authoritative computer for the domain, it must be configured to synchronize with an external time source rather than with the domain hierarchy. Also by default, all other Windows Server 2003 domain members are configured to synchronize with the domain hierarchy.

After you have established a Windows Server 2003 network, you can configure the Windows Time service to use one of the following options for synchronization:

- Domain hierarchy-based synchronization
- A manually-specified synchronization source
- All available synchronization mechanisms
- No synchronization.

Each of these synchronization types is discussed in the following section.

**Domain Hierarchy–Based Synchronization**

Synchronization that is based on a domain hierarchy uses the AD DS domain hierarchy to find a reliable source with which to synchronize time. Based on domain hierarchy, the Windows Time service determines the accuracy of each time server. In a Windows Server 2003 forest, the computer that holds the primary domain controller (PDC) emulator operations master role, located in the forest root domain, holds the position of best time source, unless another reliable time source has been configured. The following figure illustrates a path of time synchronization between computers in a domain hierarchy.

**Time Synchronization in an AD DS Hierarchy**

**Reliable Time Source Configuration**

A computer that is configured to be a reliable time source is identified as the root of the time service. The root of the time service is the authoritative server for the domain and typically is configured to retrieve time from an external NTP server or hardware device. A time server can be configured as a reliable time source to optimize how time is transferred throughout the domain hierarchy. If a domain controller is configured to be a reliable time source, Net Logon service announces that domain controller as a reliable time source when it logs on to the network. When other domain controllers look for a time source to synchronize with, they choose a reliable source first if one is available.

**Time Source Selection**

The time source selection process can create two problems on a network:

- Additional synchronization cycles.
- Increased volume in network traffic.

A cycle in the synchronization network occurs when time remains consistent between a group of domain controllers and the same time is shared between them continuously without a resynchronization with another reliable time source. The Windows Time service's time source selection algorithm is designed to protect against these types of problems.

A computer uses one of the following methods to identify a time source to synchronize with:

- If the computer is not a member of a domain, it must be configured to synchronize with a specified time source.
- If the computer is a member server or workstation within a domain, by default, it follows the AD DS hierarchy and synchronizes its time with a domain controller in its local domain that is currently running the Windows Time service.

If the computer is a domain controller, it makes up to six queries to locate another domain controller to synchronize with. Each query is designed to identify a time source with certain attributes, such as a type of domain controller, a particular location, and whether or not it is a reliable time source. The time source must also adhere to the following constraints:

- A reliable time source can only synchronize with a domain controller in the parent domain.
- A PDC emulator can synchronize with a reliable time source in its own domain or any domain controller in the parent

domain.

If the domain controller is not able to synchronize with the type of domain controller that it is querying, the query is not made. The domain controller knows which type of computer it can obtain time from before it makes the query. For example, a local PDC emulator does not attempt to query numbers three or six because a domain controller does not attempt to synchronize with itself.

The following table lists the queries that a domain controller makes to find a time source and the order in which the queries are made.

**Domain Controller Time Source Queries**

| Query Number | Domain Controller | Location | Reliability of Time Source |
|---|---|---|---|
| 1 | Parent domain controller | In-site | Prefers a reliable time source but it can synchronize with a non-reliable time source if that is all that is available. |
| 2 | Local domain controller | In-site | Only synchronizes with a reliable time source. |
| 3 | Local PDC emulator | In-site | Does not apply.<br><br>A domain controller does not attempt to synchronize with itself. |
| 4 | Parent domain controller | Out-of-site | Prefers a reliable time source but it can synchronize with a non-reliable time source if that is all that is available. |
| 5 | Local domain controller | Out-of-site | Only synchronizes with a reliable time source. |
| 6 | Local PDC emulator | Out-of-site | Does not apply.<br><br>A domain controller does not attempt to synchronize with itself. |

**Note**

- A computer never synchronizes with itself. If the computer attempting synchronization is the local PDC emulator, it does not attempt Queries 3 or 6.

Each query returns a list of domain controllers that can be used as a time source. Windows Time assigns each domain controller that is queried a score based on the reliability and location of the domain controller. The following table lists the scores assigned by Windows Time to each type of domain controller.

**Score Determination**

| Domain Controller Status | Score |
|---|---|
| Domain controller located in same site | 8 |
| Domain controller marked as a reliable time source | 4 |
| Domain controller located in the parent domain | 2 |
| Domain controller that is a PDC emulator | 1 |

When the Windows Time service determines that it has identified the domain controller with the best possible score, no more queries are made. The scores assigned by the time service are cumulative, which means that a PDC emulator located in the same site receives a score of nine.

If the root of the time service is not configured to synchronize with an external source, the internal hardware clock of the computer governs the time.

**Manually-Specified Synchronization**

Manually-specified synchronization enables you to designate a single peer or list of peers from which a computer obtains time. If the computer is not a member of a domain, it must be manually configured to synchronize with a specified time source. A computer that is a member of a domain is configured by default to synchronize from the domain hierarchy, manually-specified synchronization is most useful for the forest root of the domain or for computers that are not joined to a domain. Manually specifying an external NTP server to synchronize with the authoritative computer for your domain provides reliable time. However, configuring the authoritative computer for your domain to synchronize with a hardware clock is actually a better solution for providing the most accurate, secure time to your domain.

Manually-specified time sources are not authenticated unless a specific time provider is written for them, and they are therefore vulnerable to attackers. Also, if a computer synchronizes with a manually-specified source rather than its authenticating domain controller, the two computers might be out of synchronization, causing Kerberos authentication to fail. This might cause other actions requiring network authentication to fail, such as printing or file sharing. If only the forest root is configured to synchronize with an external source, all other computers within the forest remain synchronized with each other, making replay attacks difficult.

**All Available Synchronization Mechanisms**
The "all available synchronization mechanisms" option is the most valuable synchronization method for users on a network. This method allows synchronization with the domain hierarchy and may also provide an alternate time source if the domain hierarchy becomes unavailable, depending on the configuration. If the client is unable to synchronize time with the domain hierarchy, the time source automatically falls back to the time source specified by the **NtpServer** setting. This method of synchronization is most likely to provide accurate time to clients.

**Stopping Time Synchronization**
There are certain situations in which you will want to stop a computer from synchronizing its time. For example, if a computer attempts to synchronize from a time source on the Internet or from another site over a WAN by means of a dial-up connection, it can incur costly telephone charges. When you disable synchronization on that computer, you prevent the computer from attempting to access a time source over a dial-up connection.

You can also disable synchronization to prevent the generation of errors in the event log. Each time a computer attempts to synchronize with a time source that is unavailable, it generates an error in the Event Log. If a time source is taken off of the network for scheduled maintenance and you do not intend to reconfigure the client to synchronize from another source, you can disable synchronization on the client to prevent it from attempting synchronization while the time server is unavailable.

It is useful to disable synchronization on the computer that is designated as the root of the synchronization network. This indicates that the root computer trusts its local clock. If the root of the synchronization hierarchy is not set to **NoSync** and if it is unable to synchronize with another time source, clients do not accept the packet that this computer sends out because its time cannot be trusted.

The only time servers that are trusted by clients even if they have not synchronized with another time source are those that have been identified by the client as reliable time servers.

**Disabling the Windows Time Service**
The Windows Time service (W32Time) can be completely disabled. If you choose to implement a third-party time synchronization product that uses NTP, you must disable the Windows Time service. This is because all NTP servers need access to User Datagram Protocol (UDP) port 123, and as long as the Windows Time service is running on the Windows Server 2003 operating system, port 123 remains reserved by Windows Time.

**Network Ports Used by Windows Time Service**
The Windows Time service communicates on a network to identify reliable time sources, obtain time information, and provide time information to other computers. It performs this communication as defined by the NTP and SNTP RFCs.

### Port Assignments for the Windows Time Service

| Service name | UDP | TCP |
|---|---|---|
| NTP | 123 | N/A |
| SNTP | 123 | N/A |

# Windows Time Service Tools and Settings

Updated: May 23, 2012

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 Foundation, Windows Server 2008 R2, Windows Server 2008 R2 Foundation

**In this section**

- Windows Time Service Tools
- Windows Time Service Registry Entries
- Windows Time Service Group Policy Settings
- Network Ports Used by the Windows Time Service
- Related Information

**Note**

This topic contains information only about tools and settings for Windows Time service (W32Time). If you only want to synchronize time for a domain-joined client computer, see Configure a client computer for automatic domain time synchronization. For additional topics about how to configure Windows Time service, see the list of topics in the section Where to Find Windows Time Service Configuration Information.

**Caution**

You should not use the **Net time** command to configure or set time when the Windows Time service is running.

Also, on older computers that run Windows XP or earlier, the command **Net time /querysntp** displays the name of a Network Time Protocol (NTP) server with which a computer is configured to synchronize, but that NTP server is used only when the computer's time client is configured as NTP or AllSync. That command has since been deprecated.

Most domain member computers have a time client type of NT5DS, which means that they synchronize time from the domain hierarchy. The only typical exception to this is the domain controller that functions as the primary domain controller (PDC) emulator operations master of the forest root domain, which is usually configured to synchronize time with an external time source. To view the time client configuration of a computer, run the **W32tm /query /configuration** command from an elevated Command Prompt in starting in Windows Server 2008, and Windows Vista®, and read the **Type** line in the command output. For more information, see How Windows Time Service Works (http://go.microsoft.com/fwlink/?LinkId=117753). You can run the command **reg query HKLM\SYSTEM\CurrentControlSet\Services\W32Time\Parameters** and read the value of **NtpServer** in the command output.

**Important**

The W32Time service is not a full-featured NTP solution that meets time-sensitive application needs and is not supported by Microsoft as such. For more information, see Microsoft Knowledge Base article 939322, Support boundary to configure the Windows Time service for high-accuracy environments (http://go.microsoft.com/fwlink/?LinkID=179459).

**Windows Time Service Tools**

The following tools are associated with the Windows Time service.

**W32tm.exe: Windows Time**

**Category**

This tool is installed as part of Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server® 2008 R2 default installations.

**Version compatibility**

This tool works on Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2 default installations.

W32tm.exe is used to configure Windows Time service settings. It can also be used to diagnose problems with the time service. W32tm.exe is the preferred command line tool for configuring, monitoring, or troubleshooting the Windows Time service.

The following tables describe the parameters that are used with W32tm.exe.

**W32tm.exe Primary Parameters**

| **Parameter** | **Description** |
|---|---|
| W32tm /? | W32tm command line help |
| W32tm /register | Registers the time service to run as a service and adds default configuration to the registry. |
| W32tm /unregister | Unregisters the time service and removes all configuration information from the registry. |
| w32tm /monitor<br><br>[/domain:<domain name>]<br>[/computers:<name>[,<name>[,<name>...]]]<br>[/threads:<num>] | domain – specifies which domain to monitor. If no domain name is given, or neither the domain nor computers option is specified, the default domain is used. This option might be used more than once.<br><br>computers – monitors the given list of computers. Computer names are separated by commas, with no spaces. If a name is prefixed with a '*', it is treated as a PDC. This option might be used more than once.<br><br>threads – specifies the number of computers to analyze simultaneously. The default value is 3. Allowed range is 1-50. |
| w32tm /ntte <NT time epoch> | Convert an NT system time, in (10^-7)s intervals from 0h 1-Jan 1601, into a readable format. |
| w32tm /ntpte <NTP time epoch> | Convert an NTP time, in (2^-32)s intervals from 0h 1-Jan 1900, into a readable format. |
| w32tm /resync<br><br>[/computer:<computer>]<br><br>[/nowait]<br><br>[/rediscover]<br><br>[/soft] | Tells a computer that it should resynchronize its clock as soon as possible, throwing out all accumulated error statistics.<br><br>computer:<computer> – Specifies the computer that should resynchronize. If not specified, the local computer will resynchronize.<br><br>nowait – do not wait for the resynchronize to occur; return immediately. Otherwise, wait for the resynchronize to complete before returning.<br><br>rediscover – Redetect the network configuration and rediscover network sources, then resynchronize.<br><br>soft – resynchronize using existing error statistics. Not useful, provided for compatibility. |
| w32tm /stripchart<br><br>/computer:<target><br><br>[/period:<refresh>]<br><br>[/dataonly]<br><br>[/samples:<count>] | Display a strip chart of the offset between this computer and another computer.<br><br>computer:<target> – the computer to measure the offset against.<br><br>period:<refresh> – the time between samples, in seconds. The default is 2s.<br><br>dataonly – display only the data without graphics.<br><br>samples:<count> – collect <count> samples, then stop. If not specified, samples will be collected until **Ctrl+C** is pressed. |

| | |
|---|---|
| w32tm /config<br><br>[/computer:<target>]<br><br>[/update]<br><br>[/manualpeerlist:<peers>]<br><br>[/syncfromflags:<source>]<br><br>[/LocalClockDispersion: <seconds>]<br><br>[/reliable:(YES\|NO)]<br><br>[/largephaseoffset: <milliseconds>] | computer:<target> – adjusts the configuration of <target>. If not specified, the default is the local computer.<br><br>update – notifies the time service that the configuration has changed, causing the changes to take effect.<br><br>manualpeerlist:<peers> – sets the manual peer list to <peers>, which is a space-delimited list of DNS and/or IP addresses. When specifying multiple peers, this option must be enclosed in quotes.<br><br>syncfromflags:<source> – sets what sources the NTP client should synchronize from. <source> should be a comma separated list of these keywords (not case sensitive):<br><br>MANUAL – include peers from the manual peer list.<br><br>DOMHIER – synchronize from a domain controller (DC) in the domain hierarchy.<br><br>LocalClockDispersion:<seconds> – configures the accuracy of the internal clock that W32Time will assume when it can't acquire time from its configured sources.<br><br>reliable:(YES\|NO) – set whether this computer is a reliable time source.<br><br>This setting is only meaningful on domain controllers.<br><br>YES – this computer is a reliable time service.<br><br>NO – this computer is not a reliable time service.<br><br>largephaseoffset:<milliseconds> – sets the time difference between local and network time which W32Time will consider a spike. |
| w32tm /tz | Display the current time zone settings. |
| w32tm /dumpreg<br><br>[/subkey:<key>]<br><br>[/computer:<target>] | Display the values associated with a given registry key.<br><br>The default key is HKLM\System\CurrentControlSet\Services\W32Time<br><br>(the root key for the time service).<br><br>subkey:<key> – displays the values associated with subkey <key> of the default key.<br><br>computer:<target> – queries registry settings for computer <target> |
| w32tm /query [/computer: <target>] {/source \| /configuration \| /peers \| /status} [/verbose] | This parameter was first made available in the Windows Time client versions of Windows Vista, and Windows Server 2008.<br><br>Display a computer's Windows Time service information.<br><br>**computer:<target>** – Query the information of **<target>**. If not specified, the default value is the local computer.<br><br>**Source** – Display the time source.<br><br>**Configuration** – Display the configuration of run time and where the setting comes from. In verbose mode, display the undefined or unused setting too.<br><br>**peers** – Display a list of peers and their status.<br><br>**status** – Display Windows Time service status.<br><br>**verbose** – Set the verbose mode to display more information. |

| | |
|---|---|
| w32tm /debug {/disable \| {/enable /file:<name> /size: <bytes> /entries:<value> [/truncate]}} | This parameter was first made available in the Windows Time client versions of Windows Vista, and Windows Server 2008.<br><br>Enable or disable the local computer Windows Time service private log.<br><br>**disable** – Disable the private log.<br><br>**enable** – Enable the private log.<br><br>• **file:<name>** – Specify the absolute file name.<br><br>• **size:<bytes>** – Specify the maximum size for circular logging.<br><br>• **entries:<value>** – Contains a list of flags, specified by number and separated by commas, that specify the types of information that should be logged. Valid numbers are 0 to 300. A range of numbers is valid, in addition to single numbers, such as 0-100,103,106. Value 0-300 is for logging all information.<br><br>**truncate** – Truncate the file if it exists. |

For more information about **W32tm.exe**, see Help and Support Center in Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2.

**Windows Time Service Registry Entries**

The following registry entries are associated with the Windows Time service.

This information is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system.

When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**Warning**

Some of the preset values that are configured in the System Administrative template file (System.adm) for the Group Policy object (GPO) settings are different from the corresponding default registry entries. If you plan to use a GPO to configure any Windows Time setting, be sure that you review Preset values for the Windows Time service Group Policy settings are different from the corresponding Windows Time service registry entries in Windows Server 2003 (http://go.microsoft.com/fwlink/?LinkId=186066). This issue applies to Windows Server 2008 R2, Windows Server 2008, Windows Server 2003 R2, and Windows Server 2003.

Many registry entries for the Windows Time service are the same as the Group Policy setting of the same name. The Group Policy settings correspond to the registry entries of the same name located in:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time**.

There are several registry keys at this registry location. The Windows Time settings are stored in values across all of these keys.

**Note**

Many of the values in the W32Time section of the registry are used internally by W32Time to store information. These values should not be manually changed at any time. Do not modify any of the settings in this section unless you are familiar with the setting and are certain that the new value will work as expected. The following registry entries are located under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time**

Some of the parameters are stored in clock ticks in the registry and some are in seconds. To convert the time from clock ticks to seconds:

- 1 minute = 60 sec
- 1 sec = 1000 ms

- 1 ms = 10,000 clock ticks on a Windows system, as described at DateTime.Ticks Property.

For example, 5 minutes would become 5*60*1000*10000 = 3000000000 clock ticks.

**AllowNonstandardModeCombinations**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpServer**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry indicates that non-standard mode combinations are allowed in synchronization between peers. The default value for domain members is 1. The default value for stand-alone clients and servers is 1.

**AllowNonstandardModeCombinations**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry indicates that non-standard mode combinations are allowed in synchronization between clients and servers. The default value for domain members is 1. The default value for stand-alone clients and servers is 1.

**AnnounceFlags**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls whether this computer is marked as a reliable time server. A computer is not marked as reliable unless it is also marked as a time server.

- 0x00 Not a time server
- 0x01 Always time server
- 0x02 Automatic time server
- 0x04 Always reliable time server
- 0x08 Automatic reliable time server

The default value for domain members is 10. The default value for stand-alone clients and servers is 10.

**CompatibilityFlags**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the following compatibility flags and values:

- DispersionInvalid: 0x00000001
- IgnoreFutureRefTimeStamp: 0x00000002
- AutodetectWin2K: 0x80000000
- AutodetectWin2KStage2: 0x40000000

The default value for domain members is 0x80000000. The default value for stand-alone clients and servers is 0x80000000.

**CrossSiteSyncFlags**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry determines whether the service chooses synchronization partners outside the domain of the computer. The options and values are:

- None: 0
- PdcOnly: 1
- All: 2

This value is ignored if the NT5DS value is not set. The default value for domain members is 2. The default value for stand-alone clients and servers is 2.

**DllName**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the location of the DLL for the time provider.

The default location for this DLL on both domain members and stand-alone clients and servers is %windir%\System32\W32Time.dll.

**DllName**
Registry path

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpServer**

Version

Windows Server 2003 Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the location of the DLL for the time provider.

The default location for this DLL on both domain members and stand-alone clients and servers is %windir%\System32\W32Time.dll.

**Enabled**

**Registry path**

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry indicates if the NtpClient provider is enabled in the current Time Service.

- Yes 1
- No 0

The default value on domain members is 1. The default value on stand-alone clients and servers is 1.

**Enabled**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpServer**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry indicates if the NtpServer provider is enabled in the current Time Service.

- Yes 1
- No 0

The default value on domain members is 1. The default value on stand-alone clients and servers is 1.

**EventLogFlags**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls the events that the time service logs.

- Time Jump: 0x1
- Source Change: 0x2

The default value on domain members is 2. The default value on stand-alone clients and servers is 2.

**EventLogFlags**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the events logged by the Windows Time service.

- 0x1 reachability changes
- 0x2 large sample skew (This is applicable to Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2 only)

The default value on domain members is 0x1. The default value on stand-alone clients and servers is 0x1.

**FrequencyCorrectRate**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls the rate at which the clock is corrected. If this value is too small, the clock is unstable and overcorrects. If the value is too large, the clock takes a long time to synchronize. The default value on domain members is 4. The default value on stand-alone clients and servers is 4.

| **Note** |
| --- |
| 0 is an invalid value for the FrequencyCorrectRate registry entry. On Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2computers, if the value is set to 0 the Windows Time service will automatically change it to 1. |

**HoldPeriod**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls the period of time for which spike detection is disabled in order to bring the local clock into synchronization quickly. A spike is a time sample indicating that time is off a number of seconds, and is usually received after good time samples have been returned consistently. The default value on domain members is 5. The default value on stand-alone clients and servers is 5.

**InputProvider**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry indicates if the NtpClient provider is enabled.

- Yes 1
- No 0

The default value on domain members is 1. The default value on stand-alone clients and servers is 1.

**InputProvider**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpServer**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry indicates if the NtpServer provider is enabled.

- Yes 1

- No 0

The default value on domain members is 1. The default value on stand-alone clients and servers is 1.

**LargePhaseOffset**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies that a time offset greater than or equal to this value in $10^{-7}$ seconds is considered a spike. A network disruption such as a large amount of traffic might cause a spike. A spike will be ignored unless it persists for a long period of time. The default value on domain members is 50000000. The default value on stand-alone clients and servers is 50000000.

**LargeSampleSkew**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows Server 2003 and Windows Server 2008

This entry specifies the large sample skew for logging in seconds. To comply with Security and Exchange Commission (SEC) specifications, this should be set to three seconds. Events will be logged for this setting only when EventLogFlags is explicitly configured for 0x2 large sample skew. The default value on domain members is 3. The default value on stand-alone clients and servers is 3.

**LastClockRate**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry is maintained by W32Time. It contains reserved data that is used by the Windows operating system, and any changes to this setting can cause unpredictable results. The default value on domain members is 156250. The default value on stand-alone clients and servers is 156250.

**LocalClockDispersion**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls the dispersion (in seconds) that you must assume when the only time source is the built-in CMOS clock. The default value on domain members is 10. The default value on stand-alone clients and servers is 10.

**MaxAllowedPhaseOffset**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
