Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the maximum offset (in seconds) for which W32Time attempts to adjust the computer clock by using the

clock rate. When the offset exceeds this rate, W32Time sets the computer clock directly. The default value for domain members is 300. The default value for stand-alone clients and servers is 1.

In order for W32Time to set the computer clock gradually, the offset must be less than the MaxAllowedPhaseOffset value and satisfy the following equation at the same time:

|CurrentTimeOffset| / (PhaseCorrectRate*UpdateInterval) < SystemClockRate / 2

The CurrentTimeOffset is measured in clock ticks, where 1ms = 10,000 clock ticks on a Windows system.

SystemClockRate and PhaseCorrectRate are also measured in clock ticks. To get the SystemClockRate, you can use the following command and convert it from seconds to clock ticks using the formula of seconds*1000*10000:

```
W32tm /query /status /verbose
ClockRate: 0.0156000s
```

SystemclockRate is the rate of the clock on the system. Using 156000 seconds as an example, the SystemclockRate would be = 0.0156000 * 1000 * 10000 = 156000 clock ticks.

MaxAllowedPhaseOffset is also in seconds. To convert it to clock ticks, multiply MaxAllowedPhaseOffset*1000*10000.

The following two examples show how to apply

Example 1: Time differs by 4 minutes (For example, your time is 11:05 AM and the time sample received from a peer and believed to be correct is 11:09 AM).

phasecorrectRate = 1

UpdateInterval = 30000 (clock ticks)

systemclockRate = 156000 (clock ticks)

MaxAllowedPhaseOffset = 10min = 600 seconds = 600*1000*10000=6000000000 clock ticks

|currentTimeOffset| = 4mins = 4*60*1000*10000 = 2400000000 ticks

Is CurrentTimeOffset < MaxAllowedPhaseOffset?

2400000000 < 6000000000 = TRUE

AND does it satisfy the above equation? (|CurrentTimeOffset| / (PhaseCorrectRate*UpdateInterval) < SystemClockRate / 2)

Is 2,400,000,000 / (30000*1) < 156000/2

Is 100,000 < 78,000

NO/FALSE

Therefore W32tm would set the clock back immediately.

| **Note** |
| --- |
| In this case, if you want to set the clock back slowly, you would need to adjust the values of PhaseCorrectRate or updateInterval in the registry as well to ensure the equation results in TRUE. |

Example 2: Time differs by 3 minutes.

phasecorrectRate = 1

UpdateInterval = 30000 (clock ticks)

systemclockRate = 156000 (clock ticks)

MaxAllowedPhaseOffset = 10min = 600 seconds = 600*1000*10000=6000000000 clock ticks

currentTimeOffset = 3mins = 3*60*1000*10000 = 1800000000 clock ticks

Is CurrentTimeOffset < MaxAllowedPhaseOffset?

1800000000 < 6000000000 = TRUE

AND does it satisfy the above equation? (|CurrentTimeOffset| / (PhaseCorrectRate*UpdateInterval) < SystemClockRate / 2)

Is 3 mins (1,800,000,000) / (30000*1) < 156000/2

Is 60,000 < 78,000

YES/TRUE

In this case the clock will be set back slowly.

**MaxClockRate**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry is maintained by W32Time. It contains reserved data that is used by the Windows operating system, and any changes to this setting can cause unpredictable results. The default value for domain members is 155860. The default value for stand-alone clients and servers is 155860.

**MaxNegPhaseCorrection**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the largest negative time correction in seconds that the service makes. If the service determines that a change larger than this is required, it logs an event instead. Special case: 0xFFFFFFFF means always make time correction. The default value for domain members is 0xFFFFFFFF. The default value for stand-alone clients and servers is 54,000 (15 hrs).

**MaxPollInterval**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the largest interval, in $\log_2$ seconds, allowed for the system polling interval. Note that while a system must poll according to the scheduled interval, a provider can refuse to produce samples when requested to do so. The default value for domain controllers is 10. The default value for domain members is 15. The default value for stand-alone clients and servers is 15.

**MaxPosPhaseCorrection**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2.

This entry specifies the largest positive time correction in seconds that the service makes. If the service determines that a change larger than this is required, it logs an event instead. Special case: 0xFFFFFFFF means always make time correction. The default value for domain members is 0xFFFFFFFF. The default value for stand-alone clients and servers is 54,000 (15 hrs).

**MinClockRate**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry is maintained by W32Time. It contains reserved data that is used by the Windows operating system, and any changes to this setting can cause unpredictable results. The default value for domain members is 155860. The default value for stand-alone clients and servers is 155860.

**MinPollInterval**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the smallest interval, in $\log_2$ seconds, allowed for the system polling interval. Note that while a system does not request samples more frequently than this, a provider can produce samples at times other than the scheduled interval. The default value for domain controllers is 6. The default value for domain members is 10. The default value for stand-alone clients and servers is 10.

**NtpServer**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Parameters**

**Version**
Windows Server 2003 and Windows Server 2008

This entry specifies a space-delimited list of peers from which a computer obtains time stamps, consisting of one or more DNS names or IP addresses per line. Each DNS name or IP address listed must be unique. Computers connected to a domain must synchronize with a more reliable time source, such as the official U.S. time clock.

- 0x01 SpecialInterval
- 0x02 UseAsFallbackOnly
- 0x04 SymmetricActive

  For more information about this mode, see Windows Time Server: 3.3 Modes of Operation (http://go.microsoft.com/fwlink/?LinkId=208012).

- 0x08 Client

There is no default value for this registry entry on domain members. The default value on stand-alone clients and servers is time.windows.com,0x1.

| **Note** |
| --- |
| For more information on available NTP Servers, see Microsoft Knowledge Base article 262680 (http://go.microsoft.com/fwlink/?LinkId=186067) |

**PhaseCorrectRate**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls the rate at which the phase error is corrected. Specifying a small value corrects the phase error quickly, but might cause the clock to become unstable. If the value is too large, it takes a longer time to correct the phase error.

The default value on domain members is 1. The default value on stand-alone clients and servers is 7.

| Note |
| --- |
| 0 is an invalid value for the PhaseCorrectRate registry entry. On Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2computers, if the value is set to 0, the Windows Time service automatically changes it to 1. |

**PollAdjustFactor**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls the decision to increase or decrease the poll interval for the system. The larger the value, the smaller the amount of error that causes the poll interval to be decreased. The default value on domain members is 5. The default value on stand-alone clients and servers is 5.

**ResolvePeerBackOffMaxTimes**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the maximum number of times to double the wait interval when repeated attempts to locate a peer to synchronize with fail. A value of zero means that the wait interval is always the minimum. The default value on domain members is 7. The default value on stand-alone clients and servers is 7.

**ResolvePeerBackOffMinutes**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the initial interval to wait, in minutes, before attempting to locate a peer to synchronize with. The default value on domain members is 15. The default value on stand-alone clients and servers is 15.

**ServiceDll**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Parameters**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry is maintained by W32Time. It contains reserved data that is used by the Windows operating system, and any changes to this setting can cause unpredictable results. The default location for this DLL on both domain members and stand-alone clients and servers is %windir%\System32\W32Time.dll.

**ServiceMain**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Parameters**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry is maintained by W32Time. It contains reserved data that is used by the Windows operating system, and any changes to this setting can cause unpredictable results. The default value on domain members is SvchostEntry_W32Time. The default value on stand-alone clients and servers is SvchostEntry_W32Time.

**SpecialPollInterval**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the special poll interval in seconds for manual peers. When the SpecialInterval 0x1 flag is enabled, W32Time uses this poll interval instead of a poll interval determine by the operating system. The default value on domain members is 3,600. The default value on stand-alone clients and servers is 604,800.

**SpecialPollTimeRemaining**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\TimeProviders\NtpClient**

**Version**
Windows Server 2003 and Windows Server 2008

This entry is maintained by W32Time. It contains reserved data that is used by the Windows operating system. It specifies the time in seconds before W32Time will resynchronize after the computer has restarted. Any changes to this setting can cause unpredictable results. The default value on both domain members and on stand-alone clients and servers is left blank.

**SpikeWatchPeriod**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry specifies the amount of time that a suspicious offset must persist before it is accepted as correct (in seconds). The default value on domain members is 900. The default value on stand-alone clients and workstations is 900.

**Type**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Parameters**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry Indicates which peers to accept synchronization from:

- **NoSync.** The time service does not synchronize with other sources.
- **NTP.** The time service synchronizes from the servers specified in the **NtpServer.** registry entry.
- **NT5DS.** The time service synchronizes from the domain hierarchy.
- **AllSync.** The time service uses all the available synchronization mechanisms.

The default value on domain members is **NT5DS.** The default value on stand-alone clients and servers is **NTP.**

**UpdateInterval**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows XP, Windows Vista, Windows 7, Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2.

This entry specifies the number of clock ticks between phase correction adjustments. The default value for domain controllers is 100. The default value for domain members is 30,000. The default value for stand-alone clients and servers is 360,000.

| **Note** |
| --- |
| 0 is an invalid value for the UpdateInterval registry entry. On computers running Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2, if the value is set to 0 the Windows Time service automatically changes it to 1. |

The following three registry entries are not a part of the W32Time default configuration but can be added to the registry to obtain increased logging capabilities. The information logged to the System Event log can be modified by changing value for the EventLogFlags setting in the Group Policy Object Editor. By default, the time service creates a log in Event Viewer every time that it switches to a new time source.

| **Warning** |
| --- |
| Some of the preset values that are configured in the System Administrative template file (System.adm) for the Group Policy object (GPO) settings are different from the corresponding default registry entries. If you plan to use a GPO to configure any Windows Time setting, be sure that you review Preset values for the Windows Time service Group Policy settings are different from the corresponding Windows Time service registry entries in Windows Server 2003 (http://go.microsoft.com/fwlink/?LinkId=186066). This issue applies to Windows Server 2008 R2, Windows Server 2008, Windows Server 2003 R2, and Windows Server 2003. |

The following registry entries must be added in order to enable W32Time logging:

**FileLogEntries**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls the amount of entries created in the Windows Time log file. The default value is none, which does not log any Windows Time activity. Valid values are 0 to 300. This value does not affect the event log entries normally created by Windows Time.

**FileLogName**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls the location and file name of the Windows Time log. The default value is blank, and should not be changed unless **FileLogEntries** is changed. A valid value is a full path and file name that Windows Time will use to create the log file. This value does not affect the event log entries normally created by Windows Time.

**FileLogSize**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W32Time\Config**

**Version**
Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2

This entry controls the circular logging behavior of Windows Time log files. When **FileLogEntries** and **FileLogName** are defined, this entry defines the size, in bytes, to allow the log file to reach before overwriting the oldest log entries with new entries. Any positive number is valid, and 3000000 is recommended. This value does not affect the event log entries normally created by Windows Time.

**Windows Time Service Group Policy Settings**

You can configure most W32Time parameters by using the Group Policy Object Editor. This includes configuring a computer to be an NTPServer or NTPClient, configuring the time synchronization mechanism, and configuring a computer to be a reliable time source.

| **Note** |
| --- |
| Group Policy settings for the Windows Time service can be configured on Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2 domain controllers and can be applied only to computers running Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, and Windows Server 2008 R2. |

You can find the Group Policy settings used to configure W32Time in the Group Policy Object Editor snap-in in the following locations:

- Computer Configuration\Administrative Templates\System\Windows Time Service

  Configure **Global Configuration Settings** here.

- Computer Configuration\Administrative Templates\System\Windows Time Service\Time Providers

  Configure **Windows NTP Client** settings here.

  Enable **Windows NTP Client** here.

  Enable **Windows NTP Server** here.

| **Warning** |
| --- |
| Some of the preset values that are configured in the System Administrative template file (System.adm) for the Group Policy object (GPO) settings are different from the corresponding default registry entries. If you plan to use a GPO to configure any Windows Time setting, be sure that you review Preset values for the Windows Time service Group Policy settings are different from the corresponding Windows Time service registry entries in Windows Server 2003 (http://go.microsoft.com/fwlink/?LinkId=186066). This issue applies to Windows Server 2008 R2, Windows Server 2008, Windows Server 2003 R2, and Windows Server 2003. |

The following table lists the global Group Policy settings that are associated with the Windows Time service and the pre-set value associated with each setting. For more information about each setting, see the corresponding registry entries in "Windows Time Service Registry Entries" earlier in this subject. The following settings are contained in a single GPO called **Global Configuration Settings**.

**Global Group Policy Settings Associated with Windows Time**

| Group Policy Setting | Pre-Set Value |
| --- | --- |
| AnnounceFlags | 10 |
| EventLogFlags | 2 |
| FrequencyCorrectRate | 4 |
| HoldPeriod | 5 |
| LargePhaseOffset | 1280000 |
| LocalClockDispersion | 10 |
| MaxAllowedPhaseOffset | 300 |
| MaxNegPhaseCorrection | 54,000 (15 hours) |
| MaxPollInterval | 15 |

| | |
|---|---|
| MaxPosPhaseCorrection | 54,000 (15 hours) |
| MinPollInterval | 10 |
| PhaseCorrectRate | 7 |
| PollAdjustFactor | 5 |
| SpikeWatchPeriod | 90 |
| UpdateInterval | 100 |

The following table lists the available settings for the **Configure Windows NTP Client** GPO and the pre-set values that are associated with the Windows Time service. For more information about each setting, see the corresponding registry entries in "Windows Time Service Registry Entries" earlier in this subject.

**NTP Client Group Policy Settings Associated with Windows Time**

| Group Policy Setting | Default Value |
|---|---|
| NtpServer | time.windows.com,0x1 |
| Type | Default options:<br>• **NTP.** Use on computers that are not joined to a domain.<br>• **NT5DS.** Use on computers that are joined to a domain. |
| CrossSiteSyncFlags | 2 |
| ResolvePeerBackoffMinutes | 15 |
| ResolvePeerBackoffMaxTimes | 7 |
| SpecialPollInterval | 3600 |
| EventLogFlags | 0 |

**Network Ports Used by the Windows Time Service**

Windows Time follows the NTP specification, which requires the use of UDP port 123 for all time synchronization communication. This port is reserved by Windows Time and remains reserved at all times. Whenever the computer synchronizes its clock or provides time to another computer, that communication is performed on UDP port 123.

| **Note** |
|---|
| If you have a computer with multiple network adapters (also called a multihomed computer), you cannot selectively enable the Windows Time service based on the network adapter. |

# Network Access Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Access Technologies**

Network access is a critical component of any organization's network infrastructure. Administrators have to dynamically enable and control network access for employees, vendors, business partners, and entire branch offices that are in a variety of physical locations and that are using many different types of devices. Enabling network access, while maintaining security, is an enormous challenge for administrators. You can use the Microsoft Windows Server 2003 operating system to implement a comprehensive network access solution that can include the following variety of technologies:

- Secure access to wireless local area networks (WLANs)
- Secure remote access to intranets over the Internet
- Services that provide centralized network connection authentication, authorization, and accounting
- Tools and services that support the creation and distribution of components to manage secure client-side network access

**Network Access Technologies Architecture**

In Windows Server 2003, there are four network access technology components:

- 802.11 wireless
- Virtual private networks (VPNs)
- Internet Authentication Service (IAS)
- Connection Manager

The following figure shows the components of a network access technology infrastructure. In this example, the Connection Manager service profile initiates remote access client connections to dial-up or VPN-based remote access servers. The remote access servers act as Remote Authentication Dial-In User Service (RADIUS) clients and send the access requests to an IAS server for authentication and authorization. Similarly, the 802.11 wireless client requests access from the wireless access point, which sends the access requests to an IAS server.

The IAS server receives and processes the access requests and queries a user account database to verify access client credentials.

**Network Access Technology Architecture**

**Network Access Technologies Components**
The following network access technologies provide a range of options for secure client access to an organization's network.

**802.11 Wireless**
The WLAN protocol, 802.11, and associated technologies, such as the 802.1X protocol, are IEEE standards supported by Microsoft to provide secure wireless networking that allows you to extend your core network infrastructure to roaming wireless clients.

The IEEE 802.11 wireless standard defines the specifications for the physical layer and the media access control (MAC) sublayer for wireless communications. The 802.1X standard defines port-based network access control used to provide authenticated network access for Ethernet networks. Although this standard was originally designed for wired Ethernet networks, it has been adapted for use on 802.11 wireless LANs.

Until the recent development and wide adoption of WiFi, also known as 802.11b, network clients needed to be physically connected to a LAN to obtain high-speed network access to the LAN.

For more information, see 802.11 Wireless Technical Reference.

**VPN**
A VPN is the extension of a private network that encompasses secure links across shared or public networks, such as the Internet, so that remote clients can securely connect to an organization's network resources. VPN technology also enables remote offices to securely connect to each other so that they can share resources and information over the Internet. A VPN connection uses secure authentication and data encryption to preserve the privacy and integrity of data as it traverses the Internet.

For more information, see VPN Technical Reference.

**IAS**
IAS is the Microsoft implementation of the RADIUS standard defined by the Internet Engineering Task Force (IETF) in RFCs 2138 and 2139. IAS performs centralized authentication, authorization, auditing, and accounting of users who are connecting to a wireless or wired local area network (LAN), using a remote access connection to connect to a private intranet. A server running IAS can be configured to perform a RADIUS server role or a RADIUS proxy role.

Configured as a RADIUS server, an IAS server accepts connection requests from access clients and performs connection authentication and authorization for many types of network access, including wireless, wired, and remote access dial-up and VPN connections. You can use an IAS server to authenticate users in databases on domain controllers running Windows NT Server version 4.0, Windows 2000 Server, or Windows Server 2003. Configured as a RADIUS proxy, an IAS proxy server forwards authentication and accounting messages to a RADIUS server. When used as a RADIUS proxy, an IAS proxy server is a central switching or routing point through which RADIUS access and accounting messages flow.

**Connection Manager**
You can use Connection Manager to create and distribute customized remote access client connections, called service profiles. Service profiles are used to automatically configure remote access clients so they can connect to servers that are running the Routing and Remote Access service or other dial-up or VPN servers by using administrator-defined connection settings. By customizing remote access connections and controlling how users remotely connect to a network, administrators can simplify

their remote access solution, reduce the organizational resources dedicated to assisting remote users, and increase the security of remote connections to the private intranet.

For more information, see Connection Manager Technical Reference.

**Network Access Technologies Scenarios**

The four network access technologies in this section can be deployed in a variety of configurations to meet the specific needs of your environment. When an access client attempts to connect to a wireless access point or a remote access server, the wireless access point or remote access server acts as a RADIUS client and communicates with an IAS server for authentication and authorization to complete the network connection. Connection Manager profiles can be used to automate client-side remote access client configuration

# Connection Manager Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connection Manager Technical Reference**
Connection Manager is a suite of components that provides administrators with the ability to create and distribute customized remote access connections, called service profiles, and to create, distribute, and automatically update customized phone books. Connection Manager service profiles appear as network connections on client computers, and profiles can be used to connect to remote networks through servers that are running Routing and Remote Access, Internet Authentication Service (IAS), or remote access and virtual private networking technologies from companies other than Microsoft.

Administrators can manually customize and distribute remote access connections to a network, allow users to manually create remote access connections, or both. However, these methods are not easy to document or maintain, and user interfaces and connection properties vary widely. In addition, access requirements are more difficult, if not impossible, to enforce. With the Connection Manager suite, administrators can create and maintain one or more remote access connections customized specifically for access to their networks. Administrators can provide their users with a branded, customized connection experience that is the same on all supported operating systems and for which the administrator has already configured all of the connection properties. By customizing remote access connections and controlling how users remotely connect to a network, administrators who use the Connection Manager suite can simplify their remote access solutions, reduce the organizational resources dedicated to assisting remote users, and decrease the risk that remote connections pose to the network.

# What Is Connection Manager?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Connection Manager?**

**In this section**

- Connection Manager Components
- Common Connection Manager Scenarios
- Connection Manager Dependencies
- Related Information

The Connection Manager suite of components provides administrators with the ability to create and maintain customized remote access connections and customized phone books of access numbers so that users can connect to a network using administrator-defined connection features. Administrators can distribute these customized remote access connections, called service profiles, by using a variety of methods, and they can customize the user interface with text and graphics that are unique to their organizations. Connection Manager service profiles appear in the connections folder on client computers, have their own distinct and brandable user interface, and can be used to connect to remote networks through servers that are running Routing and Remote Access, Internet Authentication Service (IAS), or remote access and virtual private networking technologies from companies other than Microsoft.

By customizing remote access connections and controlling how users remotely connect to a network, administrators who use the Connection Manager suite can simplify their remote access solutions, reduce the organizational resources dedicated to assisting remote users, and decrease the risk that remote connections pose to the network. The Connection Manager suite includes phone book services, so access numbers can be updated every time a user connects to the network without any action required by the user, regardless of the location of the user. Using the Connection Manager suite also helps organizations that have users in multiple geographic locations because administrators can ensure that local access numbers and virtual private network (VPN) servers are listed first. Administrators can create service profiles in multiple languages, providing a similar connection experience for all users regardless of language.

Although administrators can allow users to manually create remote access connections to a network, this method has major disadvantages for large networks with many remote access users. These disadvantages include:

- The procedure for manually configuring remote access connections varies between Microsoft Windows operating systems. Administrators and support personnel would require separate procedures for supporting users on each operating system.
- The procedure for troubleshooting manually configured remote access connections varies between Windows operating systems. Administrators and support personnel would require multiple troubleshooting procedures.
- If any dial-up access numbers change, either the administrator or the user must reconfigure the connection by manually typing the new number. Administrators must manually inform users of access number changes.
- Administrators do not have access to user-configured remote access connections, so enforcing network access requirements (such as the use of antivirus software) on remote computers is difficult.

The Connection Manager suite helps administrators solve these and other issues. Administrators can create connections that have a consistent user interface across all Windows operating systems, use specific authentication protocols, check for required programs, verify registry settings, update files and phone books, or perform any combination of these tasks. Using the Connection Manager suite provides numerous benefits that manually creating connections does not. These benefits include:

**Branding**

Administrators can customize the user interface to identify their organizations. Customizable elements include graphics, icons, and messages. Administrators can also customize online Help and phone books, and they can include support resources that

are unique to their network needs.

**Connection support**
Administrators can customize individual aspects of the user connection, such as by providing routing table updates, by configuring user proxy settings for use during the connection, and by specifying what authentication protocols are used or what VPN protocol to try first when a connection is attempted. Administrators can also provide choices for users, such as a list of VPN servers that users can choose from when they make a connection. Users can save their favorite connection settings. Connection settings are saved based on user logon credentials, so multiple users on the same computer can share a service profile without having to share or re-create their settings.

**Customizable program and application functionality**
Administrators can incorporate custom functionality, including installing and running programs to enhance the connection experience for users. These programs can run automatically at various points during the connection process, such as when users disconnect or when an error occurs.

**Integrated support for access numbers and phone books**
Administrators can specify what phone books and access numbers are available to users. Businesses can contract access number support with multiple large Internet service providers (ISPs) and distribute these access numbers in their phone books. Administrators can configure service profiles to update phone books automatically when users connect to the organization network, eliminating the need for manually maintaining and updating lists of access numbers.

**Logging**
Administrators can configure whether connection attempts are logged by default on user computers and whether users can turn logging on or off. Log files can be used to troubleshoot connection problems.

**Platform support**
Administrators can create service profiles that provide a similar connection experience to users whose computers are running different Windows operating systems. Alternatively, administrators can create service profiles that require a specific Windows operating system to connect to the organization network.

**Connection Manager Components**
The Connection Manager suite consists of Connection Manager, the Connection Manager Administration Kit, and Connection Point Services. Connection Point Services itself consists of Phone Book Administrator and Phone Book Service.

**Connection Manager**
Connection Manager is client connection software that administrators can customize and distribute to users. The customized and distributed Connection Manager software, including all additional programs and applications that administrators include with it, composes a service profile. A service profile consists of all of the files that Connection Manager needs to install itself and then enable users to connect to the network. Administrators can maximize or minimize the identification of the service or organization, depending on what they include in a service profile.

**Connection Manager Administration Kit**
The Connection Manager Administration Kit (CMAK) is a wizard that guides administrators as they create and customize a Connection Manager service profile and then builds the service profile as a compressed, self-installing executable that administrators can distribute to users. Although using the CMAK wizard to build custom service profiles is simple, creating the custom elements requires careful planning and development.

**Phone Book Administrator**
Phone Book Administrator (PBA) is a tool to create and maintain phone book files for use with Connection Manager service profiles. Each phone book is a collection of points of presence (POPs) provided by either the administrator or one or more ISPs with which the organization has contracted to provide Internet access to its users. Each POP provides a local access number and connection settings for a specific region within a country or dependency. PBA compresses and publishes these phone books to a server running Phone Book Service. Administrators who do not intend to include phone books in their service profiles do not need to install PBA.

**Phone Book Service**
Phone Book Service (PBS) is an Internet Information Services (IIS) extension. When a service profile that is configured to check for phone book updates establishes a connection, Connection Manager queries the PBS server for a phone book update. PBS compares the version of the phone book that the service profile is using with the most recent files in the phone book database and then sends any updates to the service profile. Administrators who do not intend to include phone books in their service profiles do not need to install PBS.

**Common Connection Manager Scenarios**
Connection Manager is designed so that administrators can customize it to meet a wide variety of business needs. The following are some of the most common Connection Manager scenarios. Although the scenarios are fictional, administrators who set up and maintain remote access solutions commonly encounter the problems that the scenarios detail.

**Businesses with many remote or traveling users**
A sales company has many representatives who work in the field and who frequently need to make remote access connections to the corporate network. Long-distance charges are prohibitive, and the company does not want the expense of maintaining a large dial-up remote access solution. VPN connections across the Internet are more cost-effective but present more difficulties for inexperienced users. The best solution would be for users to connect to the Internet by dialing a local access number and then make VPN connections to the corporate network. This type of connection is known as a double-dial connection.

The company contracts with several large ISPs to provide local numbers for dial-up access to the Internet across the sales area of the company. The company imports the POP data from the ISPs into a single phone book using PBA and publishes the phone book to a PBS server on the perimeter network. Then the company configures a service profile that allows sales representatives to connect to the Internet by picking a local access number wherever they might be and then seamlessly makes a VPN connection to the corporate network. The company installs the service profile on all corporate laptops and also makes the service profile available for download on the corporate intranet.

**Businesses with specific requirements for network access**
A technology company is increasingly worried about security but wants to continue to allow remote access connections for traveling users and for employees who work from home. The company wants to use Layer Two Tunneling Protocol over Internet Protocol security (L2TP/IPSec) VPN connections, but it is concerned about the ability of their users who are not joined to the corporate domain to get the appropriate certificates that these connections require. Additionally, the company has issued multiple requests for its employees to upgrade the operating systems on their home computers and to run current antivirus software on those computers, but evidence strongly suggests that not all employees have complied. The best solution would be to grant full access to the corporate network only to those remote access connections that comply with the company's requirements, restricting other connections to a quarantined network that has access only to the software that compliance requires.

The company configures a certification authority on their corporate intranet and configures Routing and Remote Access on a server that is running Microsoft Windows Server 2003. Remote access policies are configured for Point-to-Point Tunneling Protocol (PPTP) connections, L2TP connections, and for quarantining all remote access connections that do not meet company requirements for operating system, connection software, and antivirus software. An administrator writes a custom action script and uses the Connection Manager suite and the Windows Server 2003 Resource Kit Tools to create a Connection Manager service profile. This profile checks for required programs, registry settings, and files; quarantines the remote access connection until compliance has been verified; and requests and installs a certificate for an L2TP/IPSec connection. The administrator makes the service profile available for download on the corporate intranet and the quarantine network, and the administrator burns the profile onto CD-ROMs for distribution to new employees.

**Businesses that want to brand their connections**
An ISP has access points and customers all over the world. The customer base uses a diverse set of operating systems, including many versions of Windows operating systems. The company wants to provide a branded, distinctive service to all of its customers, including its own icons, graphics, customized online Help, and troubleshooting steps. The company also wants to reduce the amount of training necessary for its support personnel to troubleshoot customer connections. The best solution would be to provide distinctively branded connections that resemble each other as much as possible in usage and appearance, regardless of operating system and language.

For its Windows users, the company creates phone books in each language that it supports and then publishes them to PBS servers. The company then creates a dial-up service profile in each language that it supports, makes the profiles available on its public Web site, and mails floppy disks with the appropriate service profile to its existing customers.

**Connection Manager Dependencies**
Because Connection Manager is designed to be customizable, the actual dependencies and requirements of individual service profiles vary widely. However, each component of the Connection Manager suite has some consistent dependencies.

**Connection Manager**
Connection Manager requires one of the following operating systems:

- Microsoft Windows 98
- Microsoft Windows 2000
- Microsoft Windows Millennium Edition
- Microsoft Windows XP
- Microsoft Windows Server 2003

Connection Manager also requires a supported version of Internet Explorer to be installed on the same computer. Internet Explorer does not have to be set as the default browser, and the user does not have to use Internet Explorer. Supported versions of Internet Explorer include:

- Internet Explorer 4.01
- Internet Explorer 5
- Internet Explorer 5.5
- Internet Explorer 6

Connection Manager requires the following protocols and interfaces:

- Point-to-Point Protocol (PPP)
- TCP/IP
- Telephony Application Programming Interface (TAPI) for dial-up connections
- PPTP or L2TP for VPN connections

**Connection Manager Administration Kit**
The Connection Manager Administration Kit (CMAK) must be installed on a supported operating system. Although the operating system is the only specific requirement, creating a service profile that meets particular needs might require additional programs or files to be available on the computer on which CMAK is installed. These programs and files include those that the administrator wants to use in custom actions or as additional files.

CMAK must be installed on one of the following operating systems:

- Windows Server 2003
- Windows XP Professional with the Windows Server 2003 Administration Tools Pack

**Phone Book Service**
Phone Book Service (PBS) is an Internet Information Services (IIS) extension. It depends on the following components:

- Internet Information Services
- World Wide Web (WWW)
- File Transfer Protocol (FTP)
- TCP/IP

PBS must be installed on a server running Windows Server 2003.

**Phone Book Administrator**
Phone Book Administrator (PBA) depends on the following components:

- FTP
- TCP/IP

PBA can be installed on either Windows Server 2003 or Windows XP Professional.

**Connection Manager Logical Diagram**

The following figure illustrates how a simple Connection Manager deployment works and how phone books are updated.

**Sample Connection Manager Deployment**

# How Connection Manager Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Connection Manager Works**

**In this section**

- Connection Manager Terminology
- Connection Manager Architecture
- Connection Manager Protocols
- Connection Manager Interfaces
- Connection Manager Physical Structure
- Connection Manager Processes and Interactions
- Network Ports Used by Connection Manager
- Related Information

Connection Manager is a suite of components that provides administrators with the ability to create and distribute customized remote access connections and to create, distribute, and automatically update customized phone books. Connection Manager service profiles appear as network connections on client computers, and profiles can be used to connect to remote networks through servers running Routing and Remote Access, Internet Authentication Service (IAS), or remote access and virtual private networking technologies from companies other than Microsoft.

This section provides an in-depth view of how Connection Manager works in an optimal environment. Connection Manager can perform well in many environments; it is designed to be customized for individual network needs. However, for the purpose of this section, an optimal environment is defined as follows:

- Telephone and network infrastructure is in place, address space has been leased, domain names have been registered, and an Internet presence has been established.
- The Active Directory directory service and Group Policy are configured correctly on the network, and appropriate Group Policy settings and permissions are applied.
- Domain Name System (DNS) servers are configured correctly on the network.
- Dynamic Host Configuration Protocol (DHCP) servers are configured correctly on the network.
- Remote access servers are configured correctly and deployed properly on the network.
- Routers are configured correctly on the network.
- Remote Authentication Dial-in User Service (RADIUS) authentication is being used, and it is configured correctly on the network.
- Firewalls and filters are configured correctly on all parts of the network, including between the intranet, the perimeter network, and the Internet.
- Internet Information Services (IIS) is configured correctly.

- A local account (not a domain account) with minimal permissions has been created for posting phone books. This account is disabled except when phone books are being posted.
- File Transfer Protocol (FTP) anonymous access is disabled. FTP is disabled for all accounts except the one that is used to post phone books.
- The FTP service is started immediately before a phone book is posted, and the service is stopped immediately after the phone book has been posted.
- Permissions for the Phone Book Service (PBS) folder and for the PBSData folder in the FTP virtual root have been set appropriately.
- All remote access computers are running the Microsoft Windows XP Professional operating system.
- The Internet service providers (ISPs) with which the organization has contracted service provide phone books or point of presence (POP) data in a database form that administrators can easily import into phone books.

**Connection Manager Terminology**
Before you review Connection Manager components and processes, it is helpful to understand the terminology. The following subsections provide a brief introduction and illustration of the Connection Manager suite and a glossary of terms.

**Connection Manager Components**
Connection Manager refers to both a component and a suite of components. The Connection Manager component is customizable remote access connection software. The Connection Manager suite supports the creation, distribution, and maintenance of customized remote access connections and phone books. The Connection Manager suite consists of the Connection Manager component, the Connection Manager Administration Kit component, and Connection Point Services. Connection Point Services itself consists of Phone Book Administrator and Phone Book Service. Unlike Connection Manager, there is no program named Connection Point Services.

**Connection Manager**
Connection Manager is client connection software that administrators can customize and distribute to users. Administrators can customize many aspects of a Connection Manager service profile, including interface elements, authentication protocols, and programs that run at specific points during the connection. A Connection Manager service profile is compressed into a self-installing, self-extracting executable that can be easily distributed. Most Connection Manager service profiles fit on 3.5-inch disks.

Connection Manager 1.3 is the most recent version; older versions do not have all of the functionality discussed in the Windows Server 2003 Technical Reference. Connection Manager 1.3 is included with the Microsoft Windows Server 2003 and Windows XP operating systems. Service profiles that are created for these operating systems do not need to include Connection Manager 1.3. Service profiles that are created for the Microsoft Windows 2000, Windows Millennium Edition, and Windows 98 operating systems should include Connection Manager 1.3 with the service profile.

**Connection Manager Administration Kit**
To create a Connection Manager service profile, administrators need the Connection Manager Administration Kit (CMAK), which includes:

- a wizard for creating and customizing a Connection Manager service profile and building the service profile as a compressed, self-installing executable
- customizable templates for online Help
- default graphics
- pre-configured custom actions
- customizable templates for service-profile files

Administrators can perform additional customization using a plain-text editor (such as Notepad) to edit service-profile files and then using the CMAK wizard to re-build the service profile. Although using the CMAK wizard is simple, creating a service

profile that exactly meets the needs of a particular network or business environment requires careful planning and development.

CMAK 1.3 is the most recent version, and it is included with Windows Server 2003. Earlier versions of CMAK do not have all of the functionality discussed in the Windows Server 2003 Technical Reference.

**Phone Book Service**
Phone Book Service (PBS) is an Internet Information Services (IIS) extension. For service profiles that are configured to use and check for updated phone books, Connection Manager queries the PBS server after it connects to the Internet. PBS compares the phone book version reported by Connection Manager with the most recent version file. When appropriate, it passes the appropriate update file to the Connection Manager service profile. Administrators who do not intend to include phone books in their service profiles do not need to install PBS.

The most recent version of PBS is included with Windows Server 2003. Earlier versions of PBS do not have all of the functionality discussed in the Windows Server 2003 Technical Reference.

**Phone Book Administrator**
Phone Book Administrator (PBA) is a tool to create, maintain, and post phone book files for use with Connection Manager service profiles. Each phone book is a collection of POPs. Each POP provides a local access number and connection settings for a specific region within a country or dependency. PBA compresses phone books into .cab files, which administrators can post to the PBS server using FTP.

The most recent version of PBA is included with Windows Server 2003 and Windows XP Professional. Earlier versions of PBA do not have all of the functionality discussed in the Windows Server 2003 Technical Reference. Although administrators can use the Windows Server 2003 version of PBS with earlier versions of PBA, the Windows Server 2003 version of PBA is not compatible with earlier versions of PBS.

**Connection Manager Glossary of Terms**
The following terms describe the components and elements of Connection Manager:

**.cab file**
The file name extension for a cabinet file. A cabinet file is a compressed data file that contains phone book information or installation information for Connection Manager. Phone books have two types of .cab files, Full.cab and Delta.cab. Full.cab files contain full phone books. Delta.cab files contain only changes to the phone book. PBA creates a Delta.cab file the first five times that an administrator changes information in a phone book. If the administrator makes a sixth set of changes, PBA creates a Full.cab file.

**.cmp file**
The file name extension for a connection profile file. Every service profile has at least one .cmp file, named *ServiceProfileName*.cmp. The .cmp files contain user-related information. By editing this file, administrators can provide a first-time-only population of user information. Because users can overwrite this information, any settings that administrators specify are available the first time the service profile is used.

**.cms file**
The file name extension for a service provider file. Every service profile has at least one .cms file, named *ServiceProfileName*.cms. The service provider file specifies the configuration of the phone book and most of the other functions of a service profile. Most advanced customization for a service profile is done by editing the .cms file for a particular service profile, by using either the **Advanced Customization** page of the CMAK wizard or a plain-text editor.

**.inf file**
The file name extension for an information file. Every service profile has one .inf file. The .inf file specifies installation information for service profiles. Administrators can configure some setup and uninstallation information in an .inf file, but they should thoroughly test the installation after making any changes. Information files cannot be edited from the **Advanced Customization** page of the CMAK wizard; they must be edited with a plain-text editor.

**.pbk file**
The file name extension for a phone book file. A phone book file is a text file that contains lists of POP information. Phone book files are compressed before they are transferred to the server.

**.pbr file**
The file name extension for a region file. A region file is a text file that helps categorize POPs. A POP can reference one of many geographical regions listed in the region file.

**.sed file**
The file name extension for a connection extraction file. Every service profile has one .sed file. The .sed file contains the instructions for building a self-extracting executable (.exe) file for service profiles. Administrators should never edit any .sed file.

**.ver file**
The file name extension for a version file. Every time that a phone book is updated, the version file is incremented.

**advanced customization**
The process of manually editing service-profile files to achieve specific results. Administrators can use the CMAK wizard to customize most features of Connection Manager service profiles. However, some features require administrators to edit the service profile files, changing how Connection Manager handles certain functions. Administrators can edit these files either by using the **Advanced Customization** page of the CMAK wizard or by building the service profile, editing the service-profile files using a plain-text editor, and then rebuilding the service profile. This process is called advanced customization.

**component profile**
A service profile that is merged into another service profile. Administrators can merge much of the information in existing service profiles into a new service profile by using the CMAK wizard.

**custom action**
An additional program that starts seamlessly at a specified point during the remote access connection. A custom action can be a dynamic-link library (DLL) file; an executable file such as a .bat, .exe, or .cmd file; or a shell-executable file, such as a .txt or .doc file. Custom actions can run at any of nine points during the connection.

**dial-up connection**
A remote access connection that uses a modem to connect to a network.

**direct connection**
A remote access connection that uses a technology such as a digital subscriber line (DSL) or a cable modem to connect to a network.

**disconnect action**
A custom action that runs immediately before the connection ends. Disconnect actions run even if Connection Manager did not initialize the disconnection. For example, if a disruption in telephone service terminates a connection, Connection Manager will attempt to run the disconnect actions specified in the service profile after the unexpected termination.

**double-dial connection**
A remote access connection that first uses a modem to connect to an ISP and then makes a VPN connection to a specific network.

**key**
The generic term for an entry in a Connection Manager service-profile file. All valid entries in service-profile files have key names. Each key must have an appropriate value to be valid.

**monitored action**
A custom action that runs after a connection is established and, for a VPN connection, after the tunnel is established. Each monitored action runs every time the user connects to the service, whether through a dial-up connection, a direct connection, or a double-dial connection. All monitored actions must be .exe files because monitored actions run asynchronously. Connection Manager monitors the status of all monitored actions and starts the disconnect sequence when the last monitored action closes.

**on-cancel action**
A custom action that runs as soon as users click **Cancel** during a connection attempt. On-cancel actions do not run when users click the **Cancel** button to close Connection Manager.

**on-error action**
A custom action that runs whenever an error occurs during a connection.

**phone book**
A collection of one or more POP entries, with each POP supplying a telephone number that provides dial-up access to an intranet or an ISP. Phone books give users complete POP information, so when they travel they can connect to different Internet access points rather than being restricted to a single POP.

**post-connect action**
A custom action that runs after a connection is established and, for a VPN connection, after the tunnel is established. Each post-connect action runs every time the user connects, whether through a dial-up connection or a direct connection.

**pre-connect action**
A custom action that runs as soon as users click **Connect.** These actions run before Connection Manager establishes a connection to the service.

**pre-dial action**
A custom action that runs after users click **Connect** but before the computer starts to dial the connection to the service. Pre-

connect actions run before pre-dial actions.

**pre-init action**
A custom action that runs as soon as users start Connection Manager. These actions run before the Connection Manager logon screen appears.

**pre-tunnel action**
A custom action that runs after a connection with the ISP is established but before a tunnel to the VPN server is established. This type of action is available only if the service profile is configured for VPN connections, and it will run only when users are using the VPN connection option.

**section**
A header within service-profile files. Section names are always contained within brackets. Some section names are preset; others can be added by administrators.

**service profile**
A customized Connection Manager remote access connection used to connect to an ISP, a corporate network, or other network. Service profiles are occasionally referred to as Connection Manager profiles.

**service-profile files**
The collective term for all files needed to build a Connection Manager profile, including but not limited to the .inf, .sed, .cms, and .cmp files.

**top-level profile**
A profile that contains information from other service profiles. Administrators can merge much of the information in existing service profiles into a new service profile by using the CMAK wizard.

**value**
The data required to configure a key in service-profile files.

**Connection Manager Architecture**
The following figure illustrates how the components of the Connection Manager suite work together. This figure illustrates a Connection Manager service profile that is configured to use phone books. VPN-only service profiles, which do not use phone books, require neither PBA nor PBS.

**Overall Architecture for Connection Manager**

The following table describes the components of the Connection Manager architecture.

**Connection Manager Architecture Components**

| Component | Description |
|---|---|
| Phone Book Administrator (PBA) | Used to create and maintain phone books that Connection Manager uses. |

| | |
|---|---|
| Connection Manager Administration Kit (CMAK) | Used to create Connection Manager service profiles. |
| Phone Book Service (PBS) | Used to distribute phone books to Connection Manager. |
| Connection Manager | Used to connect to a remote network. In the architecture in the previous figure, the service profile first connects to an ISP using a POP from its phone book. Then the service profile makes a VPN connection to the remote network. |
| Remote access server | Used to provide remote access. For example, a remote access server might be a computer that is running Windows Server 2003 and Routing and Remote Access. |

**Connection Manager Protocols**

Administrators can customize Connection Manager service profiles to use specific protocols. For example, administrators can specify the use of data-link protocols such as Point-to-Point Tunneling Protocol (PPTP) and transport protocols such as NetBEUI. Additionally, programs that administrators include for custom actions could use a variety of protocols. The following table shows the protocols that the Connection Manager suite uses by default.

### Connection Manager Protocols

| Component | Description |
|---|---|
| Point-to-Point Protocol (PPP) | A data-link layer protocol for transmitting data across point-to-point links. PPP allows remote access technologies (including Connection Manager) and devices to interoperate. |
| TCP/IP | A protocol suite that provides communication across interconnected networks such as the Internet. |
| Hypertext Transfer Protocol (HTTP) | An application-layer protocol that specifies the client/server interaction between Web browsers and Web servers. Connection Manager service profiles use HTTP to communicate with PBS servers. |
| File Transfer Protocol (FTP) | An application-layer protocol that is used to transfer files between hosts on a TCP/IP network. FTP is used to post phone books to PBS servers. |

**Connection Manager Interfaces**

By default, Connection Manager service profiles use some remote access application programming interfaces (APIs) and Telephony Application Programming Interface (TAPI). Administrators can customize service profiles to use any of the remote access APIs documented on Microsoft Developer Network (MSDN). In addition to using remote access APIs, Connection Manager has its own set of macros, DLL parameters, and registry key values for use with custom actions.

**Macros**

Administrators can use some command-line macros in custom actions to pass arguments. When these macros are used, Connection Manager replaces them with the actual run-time information for the parameter. The following table describes the command-line macros that custom actions support.

### Connection Manager command-line macros

| Macro | Description |
|---|---|
| %ServiceName% | The service name of the profile. |
| %UserPrefix% | The user-name prefix used for this connection. |
| %UserSuffix% | The user-name suffix used for this connection. |
| %UserName% | The user name without any realm user-name prefix or suffix. |
| %Profile% | The location and file name of the active connection profile (.cmp) file. |
| %ServiceDir% | The path to the profile directory. |

| | |
|---|---|
| %Domain% | The Active Directory domain for the connection. |
| %InetUserName% | The user name for the Internet connection. |
| %ConnectionType% | A value that identifies the connection type: 0, 1, or 2.<br>0 = dial-up<br>1 = direct<br>2 = double-dial |
| %DialRasPhoneBook% | The full path to the phone book file. |
| %TunnelRasPhoneBook% | The full path to the phone book file used for the VPN portion of this connection. |
| %DialRasEntry% | The service name or remote access entry name for the dial-up connection. |
| %TunnelRasEntry% | The service name or remote access entry name for the tunnel connection. |
| %AutoRedial% | A Boolean value that is 1 if this dial attempt is an automatic redial or 0 if not an automatic redial. |
| %PopName% | The description for the phone number in the phone book. |
| %ErrorCode% | The Win32 error code. |
| %LastErrorSource% | The origin of the last error. |
| %CurrentFavorite% | The connection settings that the user saved in the **Settings Saved As** box. |
| %TunnelServerAddress% | The IP or DNS address of the VPN server, if any. |
| %ClientIPAddress% | The IP address of the computer on which the Connection Manager profile is installed. |
| %ServerIPAddress% | The IP address of the remote access server, if any. |
| %Interactive% | A Boolean value that is used in a custom action to determine whether to display a user interface. Administrators can incorporate this macro in a custom action to display an interactive user interface (such as an error message). Administrators should use this macro only with programs that can either complete (if Connection Manager is running in an interactive state) or that are able to take other action, such as failing gracefully without an error message (if Connection Manager is running in a non-interactive state). This macro was designed to be used in conjunction with the **Program interacts with the user** check box. For example, if the **Program interacts with the user** check box is cleared, the %interactive% macro should be added to the custom action parameters so that the custom action can behave according to the state in which Connection Manager is running. Using this macro might require modification to the custom action itself. |

When parameters are specified, Connection Manager reads the parameter string and passes it to the **pszCommandLine** parameter of the DLL or sends the string as part of the command line to an executable (available through the Windows API **GetCommandLine**).

If the custom action is a DLL, the first token of the parameter string is the function entry point to call. This token is removed from the parameters before the string is passed to the DLL (so the **pszCommandLine** string does not start with the DLL entry point name as the first parameter). When creating the DLL, administrators must ensure that the exported name of the DLL matches the name specified as the first parameter, because name decoration can result in different names. (For example, in C++, name decoration can cause the exported name to be different from the actual function name.)

Connection Manager cannot denote a null pointer in a string, so it passes the string NULL (which it passes for all undefined parameters). Use quotes only when a parameter contains spaces. When using an executable other than a DLL, the function name is not required.

**DLL Parameters**

The following table describes the DLL parameters that Connection Manager supports. DLLs only run synchronously; Connection Manager starts the action and then waits for the function to return before continuing. The first argument is the function name within the DLL to call. Administrators specify the argument in the Parameters box in the **Add/Edit Custom Actions** page of the CMAK wizard.

**Connection Manager DLL Parameters**

| Parameter | Description |
|---|---|
| hWndParent | Handle to the Connection Manager logon dialog box or NULL; used as the parent window for any user interface that the custom action displays. |
| hinstDll | Handle to the instance of this DLL. |
| pszCommandLine | String pointer to the command-line arguments. |
| dwReserved | Reserved for future use. |

The syntax for each of these custom actions is:

```
HRESULT WINAPI function
    [IN] HWND hWndParent
    [IN] HINSTANCE hinstDll
    [IN] LPCSTR pszCommandLine
    [IN] DWORD dwReserved
```

Custom action DLLs often have a comment that appears while they run. These comments have the form **Running Custom Action** *Description*, and they are specified in the **Description** box on the **Add/EditCustom Actions** page of the CMAK wizard. The Connection Manager interface is frozen and does not accept input while this type of action runs.

Custom action DLLs require a return value. If the return value is less than 0, the DLL call fails. (SUCCEEDED macro returns False.) In this case, an error message (including the return value) appears in the form "**Custom Action** *Description* **failed** *ReturnValue*." If a pre-init, pre-dial, pre-connect, pre-tunnel, or post-connect DLL action fails, the connection attempt is ended.

The DLL is unloaded after the function call. For DLLs that require extended times for the program to run, administrators should implement WM_PAINT messages in the DLL to ensure that user actions do not disrupt graphics.

Administrators should provide the exact name of exported functions when they build custom action DLLs. When using a language that changes the exported name (such as C++), administrators should use a .def file to preserve the exported function names.

**Registry key values**

For the most part, administrators do not need to set registry keys for use with Connection Manager. The exception is if the administrator wants custom actions to run on user computers before users have logged on. For security reasons, custom actions are disabled by default during logon; they will not run if users select the **Log on using dial-up networking** check box at the logon screen. For a custom action to run during the logon process, values must be specified for the **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Connection Manager***ProfileName***\WinLogon Actions** registry key. The following table describes the fields for the registry key.

**Logon Registry Key Fields**

| Field | Description |
|---|---|
| Name | The name of the executable file that will run. |
| Type | REG_DWORD |
| Data | A value indicating the location of the executable. Supported values for the Data field are:<br><br>**Value**: 0x00000000(0)<br><br>**Location of executable:** %windir%\system32<br><br>**Value**: 0x00000001(1)<br><br>**Location of executable:** Profile directory |

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use

extreme caution.

For more information about remote access APIs, see the Microsoft Platform SDK on MSDN.

**Connection Manager Physical Structure**
Each component of the Connection Manager suite requires physical structures to be stored on the computer on which the component is installed. The following figure illustrates components in the Connection Manager suite and where they exist in relation to each other.

**Physical Placement of Connection Manager Suite Components in a Network Architecture**

At a minimum, Connection Manager requires at least 2 MB to install. The amount of disk space actually required to install a service profile varies depending on how the service profile has been configured. Depending on the service-profile configuration, Connection Manager has the following requirements:

- One of the following operating systems:
    - Microsoft Windows 98
    - Microsoft Windows 2000
    - Microsoft Windows Millennium Edition
    - Microsoft Windows XP
    - Microsoft Windows Server 2003
- A supported version of Internet Explorer. Supported versions of Internet Explorer include Internet Explorer 4.01, Internet Explorer 5, Internet Explorer 5.5, or Internet Explorer 6. Users do not have to set Internet Explorer as their default browser or use the software.
- For dial-up connections, a 28.8 Kbps modem or faster connection. Connection Manager can automatically configure the modem.

After installation, Connection Manager creates directories on the system drive and stores information needed to connect in these directories as follows:

- **\Documents and Settings\ *User* \Application Data\Microsoft\Network\Connections\Cm** This directory contains the .cmp file for each service profile. Connection Manager also creates a subdirectory for each service profile, using the eight-character name for the service profile. This subdirectory contains the rest of the service-profile files, including the .cms file, the .pbk file, all custom icons and graphics, and any custom action files.
- **\Documents and Settings\ *User* \Local Settings\Temp** This directory is the default location for the Connection Manager log files. Administrators can specify where the log files are stored through advanced customization.

- **\Software\Microsoft\Connection Manager** Depending on the service profile and how it is installed, Connection Manager creates the necessary registry keys for the service profile in **HKEY_CURRENT_USER**, **HKEY_LOCAL_MACHINE**, or both.

CMAK requires Windows Server 2003 and 5 MB of free space in order to be installed. After installation, CMAK creates directories on the system drive and stores information needed to create and build service profiles as follows:

- **\Program Files\CMAK\Profiles\Support** This directory contains all the template service-profile files, DLL files for pre-configured custom actions such as automatic proxy configuration, DLL files for installation on specific Windows operating systems, and information files. It also contains a subdirectory, \CMHelp, which contains the template Help files for administrators to customize.

- **\Program Files\CMAK\Profiles\ *ServiceProfileName*** When a service profile is created, CMAK creates a subdirectory in the Profiles directory using the eight-character service profile name and stores the service-profile files in that subdirectory.

PBA requires Windows Server 2003 or Windows XP Professional and 1 MB of free space in order to be installed. After installation, PBA creates directories on the system drive and stores information needed to create and post phone books as follows:

- **\Program Files\PBA** This directory contains the program file, as well as the template database files, the country.txt file, and the context-sensitive Help file for PBA.

- **\Program Files\PBA\ *PhoneBookName*** When a phone book is created, PBA creates a subdirectory in its program directory using the eight-character phone book name and stores all the phone book files in that subdirectory.

- **\Program Files\PBA\ *PhoneBookName* \ *PostNumber*** When a phone book is posted, PBA creates an enumerated folder in the phone book subdirectory and stores the cabinet file and the phone book database file in it.

PBS requires Windows Server 2003 and less than 1 MB to install. However, it also requires IIS to run, so the total installation requires at least 11 MB. After installation, PBS creates directories on the system drive and stores information needed to distribute phone book updates as follows:

- **\Program Files\Phone Book Service\Bin** This directory contains the DLL files for PBS. A virtual directory, named PBServer, for the \Bin directory is created in IIS under the default Web site.

- **\Program Files\Phone Book Service\Data** The Data directory contains subdirectories for each phone book published to the PBS server. These subdirectories contain the cabinet files and a database subdirectory. The Data directory and its subdirectories have virtual directories created for them in IIS. The virtual directory for the Data directory is called PBSData.

**Performance Limitations for Connection Manager**

Phone Book Administrator and Phone Book Server have some performance limitations and requirements.

**Phone Book Administrator**

- A phone book name must contain no more than eight characters, cannot consist of all digits, and must not contain a space or any symbols. Symbols include but are not limited to: **! , ; * = / \ : ? < > | . & % { } [ ] @ ( ) ` ~**

- Phone books can be updated no more than 32,676 times.

- Phone books can contain no more than 65,000 POPs.

- When administrators import POPs to a phone book that has not yet been posted, the import file must contain no more than 32,000 POPs.

- When administrators import POPs to a phone book that has already been posted, the import file must contain no more

than 6,000 POPs (combined adds, edits, and deletes) for each subsequent post.

- Phone Book Administrator is available only in English, French, German, Japanese, and Spanish. Administrators can create phone books in another language by running PBA on an operating system that has been optimized for that language.

- The same phone book cannot be published to more than one phone book server. Publishing the same phone book to more than one phone book server causes version conflicts that will prevent users from obtaining the most recent version of the phone book. However, administrators can use the Distributed File System (DFS) console to automate replication of phone books to multiple servers from the server to which the phone book was published. Administrators can also replicate phone books manually by copying the folder to the other servers.

- Deleting a phone book removes the indexed references. However, released .cab files remain in the file system of the computer on which PBA is running. To remove the .cab files, administrators must manually delete the phone book directory and all of its contents.

**Phone Book Servers**

When a user logs on using a service profile that automatically requests phone book updates, the Phone Book Service (PBS) server receives an HTTP query, initiating the phone-book update process. The maximum number of hits per second depends on the size of the update (.cab) file. Larger update files can slow performance by as much as 25 percent.

The following table details how many hits the listed processors are capable of handling on a dedicated server with 128 megabytes (MB) of RAM. These estimates are based on small update files of about 5 kilobytes (KB).

**Performance Estimates for PBS Servers**

| Processor | Hits/sec | Hits/hour | Hits/day |
|---|---|---|---|
| Intel Pentium III 600 MHz | 275 | 990,000 | 23,760,000 |
| Intel Pentium III 500 MHz (dual processors) | 250 | 900,000 | 21,600,000 |
| Intel Celeron 400 MHz | 125 | 450,000 | 10,800,000 |
| Intel Pentium II 300 MHz | 125 | 450,000 | 10,800,000 |

Deleting a phone book removes the indexed references. However, released .cab files remain on the file system of the PBS server. To remove the .cab files, administrators must manually delete the phone book directory and all of its contents.

**Connection Manager Processes and Interactions**

Connection Manager service profiles are customizable, so the exact processes and interactions between a Connection Manager service profile and other components vary. The following is a brief description of what happens during the creation, distribution, and usage of a double-dial Connection Manager service profile that includes a phone book and automatically checks for phone book updates as its first post-connect custom action.

1. An administrator creates a phone book using PBA.

    a. PBA creates a subdirectory for the phone book files.

    b. PBA creates the version file, the phone book files, and the cabinet files in the phone book subdirectory.

2. The administrator posts the phone book to the PBS server.

    a. PBA creates a post subdirectory in the phone book file subdirectory.

    b. PBA creates a database file in the post subdirectory and copies the cabinet files from the phone book file directory into that subdirectory.

    c. An FTP control session is opened between the computer on which PBA is running and the PBS server on TCP port 21. PBA sends the user name and password of the posting account to the PBS server. The PBS server authenticates the account credentials and sends a response. PBA opens an FTP data session on TCP port 20 and uploads the

contents of the post subdirectory.

d. PBS creates a subdirectory for the phone book under its Data subdirectory. The cabinet file is copied into this subdirectory, and the phone book database is copied into the Database directory.

e. Both FTP sessions are closed.

3. The administrator creates a service profile using CMAK.

   a. CMAK creates a subdirectory for the service profile.

   b. CMAK creates the service-profile files and copies all custom files (including but not limited to graphics, online Help files, and programs for custom actions) and additional files into the service profile subdirectory.

   c. CMAK creates the self-installing executable and saves it to the service profile subdirectory.

4. The administrator distributes the Connection Manager service profile by copying the service profile onto floppy disks and distributing the disks to users.

5. The user installs the service profile on a home computer that is running Windows XP.

   a. Connection Manager creates a subdirectory for the service-profile files in the appropriate user context and unpacks the service-profile files.

   b. Connection Manager creates registry keys in the appropriate user context as the service profile configuration requires (for example, for custom actions).

   c. An icon for the service profile is created in the Network Connections folder.

6. The user opens the Network Connections folder and opens the Connection Manager service profile.

   a. Any pre-init custom actions are run.

   b. The Connection Manager logon screen appears.

7. The user provides the information that this connection requires, as the administrator determined when creating the service profile, and clicks **Connect**.

   a. Any pre-connect custom actions are run.

   b. Any pre-dial custom actions are run.

   c. Connection Manager dials the connection.

      — The ISP answers the call and negotiates a connection speed.

      — The ISP authenticates the user name and password and establishes the connection to the Internet.

   d. Any pre-tunnel custom actions are run.

   e. Connection Manager makes the VPN connection to the corporate network.

      — The remote access server on the corporate network answers the connection request.

      — The user name and password are authenticated, and any Group Policy settings are applied.

— The connection to the corporate intranet is authorized.

f. The Automatically download phone-book updates post-connect action is run.

— Connection Manager sends an HTTP GET request on port 80 to the PBS server using the following format: http://*PhoneBookServerName*/pbserver/pbserver.dll?osarch=0&ostype=0&osver=1&cmver=1&lcid=1033&pbver=*Version*&pb=*PhoneBookName*

— PBS checks the version number of the phone book that is enumerated in pbver= against the version number of the phone book that PBS has. If the version number in the request is the same or higher than the version that PBS has, PBS provides no phone book update. If the number is lower but less than five versions lower, PBS sends a delta phone book. If the number is more than five versions lower, PBS sends a full phone book. For example, assume that the version number of the phone book that PBS has is 10. If the version number in the request is also 10, PBS does nothing. If the version number in the request is 7, PBS sends a delta phone book. If the version number in the request is 3, PBS sends a full phone book.

— If PBS has sent a phone book update, Connection Manager installs the phone book.

g. Any other post-connect custom actions are run.

h. Any monitored action custom actions are run.

8. The user disconnects from the corporate network.

   a. Before the connection is closed, any disconnect custom actions are run.

   b. Connection Manager closes the connection.

**Network Ports Used by Connection Manager**

The following table describes the network ports that Connection Manager service profiles commonly use. Connection Manager service profiles can include custom actions that run scripts or tools that might use additional protocols, so the exact network ports that service profiles use will vary.

**Port Assignments for Connection Manager**

| Service Name | UDP | TCP |
|---|---|---|
| HTTP | | 80 |
| FTP | | 20/21 |

# Connection Manager Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connection Manager Tools and Settings**

**In this section**

- Connection Manager Tools
- Connection Manager Predefined Custom Actions
- Connection Manager Keys and Values
- Connection Manager Registry Entries
- Network Ports Used by Connection Manager
- Related Information

This section contains information about the tools, predefined custom actions, keys and values, registry entries, and ports that are associated with Connection Manager. One of the tools for Connection Manager, the Connection Manager Administration Kit, includes several predefined custom actions. Predefined custom actions are executables that require minimal configuration from the administrator to perform common connection tasks, such as automatically downloading phone book updates. In addition to configuring predefined custom actions, administrators can configure hundreds of individual settings, called keys, to precisely control individual aspects of a Connection Manager service profile.

**Connection Manager Tools**

The following tools are associated with Connection Manager.

**Cmak.exe: Connection Manager Administration Kit**

**Category**

Operating system (optional component)

**Version compatibility**

Connection Manager Administration Kit 1.3 is available as part of the Management and Monitoring Tools in Microsoft Windows Server 2003. It is compatible with Windows Server 2003 and with Microsoft Windows XP Professional if the Windows Server 2003 Administration Tools Pack is installed.

The Connection Manager Administration Kit wizard guides administrators through building service profiles that meet their networking needs. Administrators can configure predefined custom actions, define and include their own, or both. Administrators can customize most elements of a service profile, from graphics to authentication protocols. At the end of the wizard, the service profile is created and compressed into a self-installing, self-extracting executable that administrators can easily distribute.

For more information about the Connection Manager Administration Kit, see Connection Manager Administration Kit.

**Pbserver.dll: Phone Book Service**

**Category**

Operating system (optional component)

**Version compatibility**

Phone Book Service is available as part of the Management and Monitoring Tools in Windows Server 2003. It is compatible with Windows Server 2003.

Phone Book Service (PBS) is an Internet Information Services (IIS) extension. When a service profile that is configured to check for phone book updates establishes a connection, the service profile queries the PBS server for a phone book update. PBS compares the version of the phone book that the service profile is using with the most recent files in the phone book database and then sends any updates to the service profile.

**Pbadmin.exe: Phone Book Administrator**

**Category**
Valueadd tool

**Version compatibility**
Phone Book Administrator 1.2 is a Valueadd tool for Windows Server 2003 and Windows XP Professional. It is compatible with Windows Server 2003 and with Windows XP Professional.

Phone Book Administrator is a tool to create and maintain phone book files for use with Connection Manager service profiles. Each phone book is a collection of points of presence (POPs). Each POP provides a local access number, including connection settings, for a specific region within a country or dependency. PBA compresses phone books into .cab files and posts the files to the PBS server using File Transfer Protocol (FTP).

**Connection Manager Predefined Custom Actions**
The following predefined custom actions are included with Connection Manager Administration Kit.

**Cmdl32.exe: Automatic Phone Book Download**
**Custom Action Type**
Post-connect

**Purpose**
Automatically check for phone book updates; download and install updates as necessary.

**Configuration**
In the CMAK wizard, on the **Phone Book** page, select the **Automatically download phone book updates** check box, specify the URL for the PBS server in **Connection Point Services server**, and specify the name of phone book in **Phone Book Name**.

Associated keys:

- PBFile
- RegionFile
- PBURL

For more information about automatic phone book downloads, see Providing phone book support. For more information about Connection Manager keys, see "Connection Manager Keys and Values" later in this section.

**Cmproxy.dll: Automatic Proxy Configuration**
**Custom Action Type**
Post-connect (configure user proxy settings); Disconnect (restore user proxy settings)

**Purpose**
Ensure that the user has appropriate access to internal and external resources by reconfiguring user proxy settings while the remote computer is connected to the organizational network.

**Configuration**
In the CMAK wizard, click **Automatically configure proxy settings**, specify the proxy file in **Proxy settings file**, and optionally select the **Restore the users' previous proxy settings after disconnecting** check box.

Associated keys: none

To use automatic proxy configuration, administrators must include proxy settings files in plain text with the service profiles. The following table describes the syntax elements of a proxy setting file:

| Key | Value |
|---|---|
| [Automatic Proxy] | No value. Section header for automatic proxy settings. |
| [Manual Proxy] | No value. Section header for manual proxy settings. |

| | |
|---|---|
| AutoProxyEnable | 0 = Automatic proxy detection is disabled.<br><br>1 = Automatic proxy detection is enabled.<br><br>**Note**: This feature is not supported for Internet Explorer 4 and earlier. |
| AutoConfigScriptEnable | 0 = Automatic proxy script will not be executed.<br><br>1 = Automatic proxy script will be executed. |
| AutoConfigScript | The URL that points to the automatic proxy script. |
| ProxyEnable | 0 = Manual proxy detection is disabled.<br><br>1 = Manual proxy detection is enabled. |
| ProxyServer | The name and the port of the proxy server. |
| ProxyOverride | The Domain Name System (DNS) addresses, separated by semi-colons, that should not be passed on to the proxy server. Use the <local> value to bypass the proxy server for local addresses. If the <local> value is included, it must be the final value in the string. |

For more information about automatic proxy configuration, see Using automatic proxy configuration.

**Cmroute.dll: Routing Table Updates**
**Custom Action Type**
Post-connect

**Purpose**
To manage network traffic and security by reconfiguring user routing tables while the remote computer is connected to the organization network.

**Configuration**
In the CMAK wizard, on the **Routing Table Update** page, click **Define a routing table update**, specify the route file in **Route file to include**, optionally specify the URL for an updated route file in **URL to route file**, and optionally select the **If this URL is unavailable, disconnect the client** check box.

Associated keys: none

To use routing table updates, administrators must include routing table update files in plain text with the service profiles. Each line in those files adds or deletes a route. The syntax of each line is as follows:

```
Command Destination
MASK
Netmask Gateway
METRIC
Metric
IF
Interface
```

Certain parameters can contain the value of **default**. In those cases, the appropriate information from the client computer is used. The following table provides more information on each parameter.

| Parameter | Description |
|---|---|
| *Command* | Specifies whether to add or delete a route.<br><br>**ADD** adds a route.<br><br>**DELETE** deletes a route. |
| *Destination* | Specifies the destination IP address on the target network. |
| **MASK** | Specifies that the next parameter is the netmask value. |

| | |
|---|---|
| *Netmask* | Specifies the netmask. |
| *Gateway* | Specifies the gateway. Should contain the value of **default**. |
| **METRIC** | Specifies that the next parameter is the cost for the destination. The **METRIC** parameter is optional. If **METRIC** is not included, do not include *Metric*. |
| *Metric* | Specifies the cost for the destination. Should contain the value of **default**; its default value is 1. |
| **IF** | Specifies that the next parameter is the interface number. |
| *Interface* | Specifies the interface number. Should contain almost always contain the value of **default**. |

To remove the default gateway, you can add the following line to the update file:

```
REMOVE_GATEWAY
```

Unlike the **ADD** and **DELETE** commands, the **REMOVE_GATEWAY** command requires no further syntax.

**Routing table precedence**
During the connection process, update files are applied in a specific sequence.

1. All update files are retrieved.

2. If a service profile contains an update file (static file), routing information from that file is applied to the client computer first.

3. If a service profile contains an update URL, routing information from that file (dynamic file) is applied to the client computer after the static file. The downloaded dynamic file is then immediately deleted.

4. If either the static file or the dynamic file contains the REMOVE_GATEWAY command, this command is run after all other routes have been applied.

Because of this order of precedence, a dynamic file could add routes, replace routes specified in the static file, or both.

If you use the default interface value, the routing changes that you specify are reversed when the user disconnects.

For more information about routing table updates, see Including routing table updates.

**Cmdl32.exe /VPN: Download Update for VPN File**
**Custom Action Type**
Post-connect

**Purpose**
Allows the automatic downloading of an updated VPN file from a specified server. For service profiles that support VPN files, this file is used to update the list of servers available on the **VPN** tab in the properties dialog box for the service profile. Users can choose a VPN server from the list to use for the connection. This tab also contains a customizable text message.

**Configuration**
In the CMAK wizard, on the **VPN Support** page, select the **Phone book from this profile** check box, click **Allow the user to choose a VPN server before connecting**, and specify a VPN file.

Associated keys:

- TunnelFile

- TunnelDUN

To enable users to choose a VPN server from a list when they connect to the network, administrators must include a VPN file in plain text with the service profile. The following table identifies sections, keys, and values that compose a VPN file.

| [Section] or key name | Value |
|---|---|
| [Settings] | Section header for the keys that contain VPN settings. |
| Default | The friendly name of the default VPN server for this service profile. If you create this key but do not give it a value or if you do not create this key, the user must select a VPN server the first time the user connects using the service profile. |
| UpdateURL | The URL of the Web server that contains updates for this VPN file. If this key is added, a post-connect action is added automatically to the service profile. This post-connect action updates the VPN file. |
| Message | The text that appears on the **VPN** tab in the properties dialog box for the service profile. This message cannot exceed 256 characters, and it must be a single paragraph. If this key is created but left blank, default text is used. |
| [VPN Servers] | Section header for the keys that identify VPN servers. |
| *FriendlyName* | The name of this key is the friendly name of one of the VPN servers available to your users. The value of this key is the DNS or IP address of the VPN server for which you named the key. If you want this VPN server to use a specific set of network and security settings, you must follow the DNS address with a comma and the name of a VPN entry that you will edit in the **VPN Entries** page of the CMAK wizard. If you do not specify a VPN entry, the VPN server will use the settings for the default VPN entry. |

For more information about user choice of VPN servers, see Implementing VPN support.

**Connection Manager Keys and Values**

The following keys and values are associated with Connection Manager. The online Help for the Connection Manager Administration Kit includes tables of all keys, settings, and values for Connection Manager, sorted by section header types as they are found in .cms files. The tables below are sorted by usage type. For more information about keys and values, see Advanced Customization.

**Connection Manager Section Headings**

**These section headers define the keys that are contained within the sections.**

| [Section] | Value | Set in |
|---|---|---|
| [Animated Actions] | Specifies the keys that control when to play segments of the animation. | CMAK<br>.cms |
| [Animated Logo] | Specifies the animation for the Connection Manager logon dialog box.<br>The [Animated Logo] section specifies the location of the animation (.spl or .swf) file. This function is provided for compatibility with Connection Manager 1.0, which supports Macromedia Flash animation files.<br>The AnimatedLogo key in the [Connection Manager] section determines whether an animation is used. | .cms |
| [Auto Applications] | Specifies monitored actions that run during a connection. Monitored actions are similar to custom actions, but they cause the disconnect sequence to start as soon as the last monitored application closes. This section uses the following keys: #, #&Flags, and #&Description. Unlike other custom actions, monitored actions do not support DLLs. | CMAK<br>.cms |
| [Connect Actions] | Specifies the post-connect actions that run after a connection is established and, for VPN connections, after the tunnel is established. This section uses the following keys: #, #&Flags, and #&Description. | CMAK<br>.cms |
| [Connection Manager] | Specifies miscellaneous service profile keys and values. | CMAK<br>.cms<br>.cmp |

| | | |
|---|---|---|
| [CustomButton Actions] | Specifies the keys that control what programs start when the custom button is clicked. The format of the value is # = *Program*, where # is an ID number from 0 to *n* and *Program* is the complete name of the program, including the extension and the path to the program. Programs start in sequence: 0 first, 1 next, and so on. Custom button programs cannot be DLLs. | CMAK .cms |
| [Disconnect Actions] | Specifies the disconnect actions that run immediately before disconnecting. If a connection is prematurely dropped, these actions are run immediately after the disconnect. This section uses the following keys: #, #&Flags, and #&Description. | CMAK .cms |
| [Logging] | Specifies the logging keys. | .cms |
| [Menu Options] | Specifies the keys that control the shortcut menu that appears when a user right-clicks the notification area shortcut for your service profile. | CMAK .cms |
| [Networking&*TunnelDUN*] | Specifies the configuration to be used for all VPN connections. In this section title, *TunnelDUN* is the value of the TunnelDUN key in the [Connection Manager] section. | CMAK |
| [On-Cancel Actions] | Specifies the on-cancel actions that run when the user cancels a session after starting the connection attempt (any time that the user clicks **Connect** and then clicks **Cancel**). This section uses the following keys: #, #&Flags, and #&Description. | CMAK .cms |
| [On-Error Actions] | Specifies the on-error actions that run when an error occurs. This section uses the following keys: #, #&Flags, and #&Description. | CMAK .cms |
| [Pre-Connect Actions] | Specifies the pre-connect actions that run before a connection is established. This section uses the following keys: #, #&Flags, and #&Description. | CMAK .cms |
| [Pre-Dial Actions] | Specifies the pre-dial actions that run immediately before dialing. This section uses the following keys: #, #&Flags, and #&Description. | CMAK .cms |
| [Pre-Init Actions] | Specifies the pre-init actions that run as soon as the user accesses the profile. This section uses the following keys: #, #&Flags, and #&Description. | CMAK .cms |
| [Pre-Tunnel Actions] | Specifies the pre-tunnel actions that run after a connection is established but before a VPN connection is established. This section uses the following keys: #, #&Flags, and #&Description. | CMAK .cms |
| [Profile Format] | Specifies the service profile version. | CMAK .cms .cmp |
| [Scripting&*EntryName*] | Specifies the location (path and file name) of the script (.scp) file, where *EntryName* is the name of the dial-up entry. | CMAK |
| [Server&*EntryName*] | Specifies the configuration where *EntryName* is the name of the dial-up entry. | CMAK |
| [Server&*TunnelDUN*] | Specifies the configuration to be used for all VPN connections. In this section title, *TunnelDUN* is the value of the TunnelDUN key in the [Connection Manager] section. This section uses the same format as the [Server&*EntryName*] section, including all keys valid under that section. | CMAK .cms |
| [TCP/IP&*EntryName*] | Specifies the configuration where *EntryName* is the name of the dial-up entry. | CMAK .cms |

| | | |
|---|---|---|
| [TCP/IP&*TunnelDUN*] | Specifies the TCP/IP configuration to be used for all VPN connections. In this section title, *TunnelDUN* is the value of the TunnelDUN key in the [Connection Manager] section. This section uses the same format as the [TCP/IP&*EntryName*] section, including all keys valid under that section. This section is created by the CMAK wizard, but the keys can be edited in the .cms file. | CMAK .cms |

**Keys that Control the Connection Manager User Interface**

**These keys control the appearance of the Connection Manager service profile.**

| Key | Description and values | Set in | Section |
|---|---|---|---|
| # | Controls what programs start when the custom button is clicked. The format of the value is # = *Program*, where # is an ID number from 0 to *n* and *Program* is the complete name of the program, including the extension and the path to the program. Programs start in sequence: 0 first, 1 next, and so on. Custom button programs cannot be DLLs. | CMAK .cms | [CustomButton Actions] |
| AnimatedLogo | Specifies whether an animation is used instead of a static bitmap in the Connection Manager logon dialog box.<br><br>0 (default) = Do not use animated graphic.<br><br>1 = Use animated graphic.<br><br>The [Animated Logo] section specifies the location of the animation (.spl or .swf) file. This function is provided for compatibility with Connection Manager 1.0, which supports Macromedia Flash animation files. | CMAK .cms | [Connection Manager] |
| Authenticating | Specifies the starting frame number of the animation that plays during user authentication. | .cms | [Animated Actions] |
| Connected | Specifies the starting frame number of the animation that plays when a connection is established. | .cms | [Animated Actions] |
| CustomButtonText | Specifies the text that appears on a custom button on the Connection Manager logon dialog box. Custom buttons do not appear or function when a user uses a service profile to log on to Windows. | .cms | [Connection Manager] |
| CustomButtonToolTip | Specifies the text that appears on a ToolTip for a custom button on the Connection Manager logon dialog box. Custom buttons do not appear or function when a user uses a service profile to log on to Windows. | .cms | [Connection Manager] |
| DialAutoMessage | Specifies the text that appears when the **Dial Automatically** check box has been selected. | .cms | [Connection Manager] |
| Dialing0 | Specifies the starting frame number of the animation that plays while the primary phone number is dialed. | .cms | [Animated Actions] |
| Dialing1 | Specifies the starting frame number of the animation that plays while the backup phone number is dialed. | .cms | [Animated Actions] |
| DisableICS | Specifies whether to prevent the user from sharing the connection with Internet Connection Sharing (ICS).<br><br>0 (default) = Do not suppress ICS settings.<br><br>1 = Disable ICS for this connection. The check box for enabling ICS will be unavailable.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Connection Manager] |

| | | | |
|---|---|---|---|
| Error | Specifies the starting frame number of the animation that plays at any connection error. | .cms | [Animated Actions] |
| HelpFile | Specifies the location (including name) of the custom Help file.<br><br>Default Help file = The default value for this key is blank.<br><br>When no value is specified, the standard Help file for service profiles is used. | CMAK | [Connection Manager] |
| HideAdvancedTab | Specifies whether to suppress the display of the **Advanced** tab in the properties dialog box for the service profile.<br><br>0 (default) = Do not suppress display of the **Advanced** tab.<br><br>1 = Suppress display of the **Advanced** tab.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Connection Manager] |
| HideBalloonTips | Specifies whether to suppress display of balloon-tip help for this connection.<br><br>0 (default) = Do not suppress balloon-tip help.<br><br>1 = Suppress balloon-tip help. | .cms | [Connection Manager] |
| HideDelay | Specifies the time (in seconds) to delay before displaying the **Phone Book Updates** dialog box (with progress indicators and message).<br><br>Default = Do not display the dialog box. | .cms | [Connection Manager] |
| HideDialAutomatically | Specifies whether the **Connect automatically** check box appears in the Connection Manager logon dialog box.<br><br>0 (default) = Display the check box.<br><br>1 = Do not display the check box.<br><br>If HideRememberPassword is set to 1, that key value overrides the HideDialAutomatically setting. | .cms | [Connection Manager] |
| HideDomain | Specifies whether the **Logon domain** box appears in the Connection Manager logon dialog box.<br><br>0 = Display the box.<br><br>1 = Do not display the box.<br><br>The default is 1. If the profile supports VPN connections and you have not previously set a value, CMAK sets this value to 0. | .cms | [Connection Manager] |
| HideInternetPassword | Specifies whether the **Password** box appears on the properties dialog box, on the **Internet Logon** tab.<br><br>0 (default) = Display the box.<br><br>1 = Do not display the box.<br><br>If HideInternetPassword and HideInternetUsername are both set to 1, the **Internet Logon** tab does not appear. | .cms | [Connection Manager] |

| | | | |
|---|---|---|---|
| HideInternetUsername | Specifies whether the **User name** box appears on the **Internet Logon** tab.<br><br>0 (default) = Display the box.<br><br>1 = Do not display the box.<br><br>If HideInternetPassword and HideInternetUsername are both set to 1, the **Internet Logon** tab does not appear. | .cms | [Connection Manager] |
| HidePassword | Specifies whether the **Password** box appears in the Connection Manager logon dialog box when dial-up connections are used.<br><br>0 (default) = Display the box.<br><br>1 = Do not display the box. | .cms | [Connection Manager] |
| HideRememberInternetPassword | Specifies whether the **Save Password** check box appears on the **Internet Logon** tab. If this key is not specified, the value of HideRememberPassword is used.<br><br>0 = Display check box.<br><br>1 = Do not display check box. | .cms | [Connection Manager] |
| HideRememberPassword | Specifies whether the **Save Password** check box appears on the Connection Manager logon dialog box and on the **Internet Logon** tab.<br><br>0 (default) = Display the check box.<br><br>1 = Do not display the check box.<br><br>If HideRememberPassword is set to 1, it overrides the HideDialAutomatically setting. | .cms | [Connection Manager] |
| HideTrayIcon | Specifies whether to display notification area shortcuts.<br><br>NULL = If TrayIcon is set, display the notification area shortcut specified. Otherwise, display the connection-status notification area shortcut (“blinking lights”). The NULL value is available for Microsoft Windows 2000, Windows XP, and Windows Server 2003 only.<br><br>0 = If TrayIcon is set, display the notification area shortcut specified and the connection-status notification area shortcut (“blinking lights”). Otherwise, display the Connection Manager notification area shortcut and the connection-status notification area shortcut (“blinking lights”).<br><br>1 = Do not display any notification area shortcuts.<br><br>If you choose not to display any notification area shortcuts, edit the Help file to remove references to them. | .cms | [Connection Manager] |
| HideUserName | Specifies whether the **User name** box appears in the Connection Manager logon dialog box.<br><br>0 (default) = Display the box.<br><br>1 = Do not display the box. | .cms | [Connection Manager] |

| | | | |
|---|---|---|---|
| Icon | Specifies the location and name of the icon (.ico) file for the 32 32 pixel icon, which is used, by default, for the service profile.<br><br>Default = The default value for this key is blank. When no value is specified, the standard program icon for Connection Manager is used. | CMAK | [Connection Manager] |
| Initial | Specifies the starting frame number of the animation that plays when Connection Manager starts. | .cms | [Animated Actions] |
| Logo | Specifies the location and name of the .bmp file that appears in the Connection Manager logon dialog box.<br><br>Default = The default value for this key is blank. When no value is specified, the standard logon bitmap for Connection Manager is used. | CMAK | [Connection Manager] |
| MaxDomain | Specifies the maximum length of the domain name that the user can type.<br><br>Default = 15 characters. | .cms | [Connection Manager] |
| MaxPassword | Specifies the maximum length of the password that the user can type.<br><br>Default = 127 bytes. | .cms | [Connection Manager] |
| MaxPhoneNumber | Specifies the maximum length of the phone number fields. The default for Microsoft Windows 95, Windows 98, and Windows Millennium Edition is 36; the default for Microsoft Windows NT 4.0, Windows 2000, Windows XP, and Windows Server 2003 is 80. | .cms | [Connection Manager] |
| MaxUserName | Specifies the maximum length of the user name that the user can type.<br><br>Default = 256 bytes. | .cms | [Connection Manager] |
| *MenuItemName* | Specifies the command to be run from the shortcut menu. Shortcut menu commands use the format *MenuItemName = Program*, where *MenuItemName* is the descriptive name that appears on the shortcut menu and *Program* is the name of the executable file (.exe or other shell executable), including any parameters that the program requires. For example, if you wanted to add Notepad to the menu with the command name "Editor," the line would be Editor = Notepad.exe.<br><br>Default commands = Status and Disconnect.<br><br>These programs are available in a shortcut menu that appears when a user right-clicks the notification area shortcut. Applications are listed in the menu in the same sequence as they are listed in the .cms file. | CMAK | [Menu Options] |
| Movie | Specifies the location of the animation file that appears in place of the static bitmap in the Connection Manager logon dialog box. Settings in the [Animated Actions] section control how the animation plays based on the connection state. | .cms | [Animated Logo] |

| | | | |
|---|---|---|---|
| NoDialingRules | Specifies whether the user can use dialing rules on access numbers chosen from a phone book. Dialing rules check boxes are unavailable when the value of this key is set to 1.<br><br>0 (default) = Allow dialing rules.<br><br>1 = Do not allow dialing rules. | .cms | [Connection Manager] |
| NoPromptReconnect | Specifies whether the user is prompted for reconnection when the connection is inadvertently dropped.<br><br>0 (default) = Prompt the user.<br><br>1 = Do not prompt the user. | .cms | [Connection Manager] |
| *Parameter* | Specifies other animation parameters passed from software used to create the animation. An example of such a parameter is Quality = 3. | .cms | [Animated Logo] |
| Pausing | Specifies the starting frame number of the animation that plays during pauses between dials. | .cms | [Animated Actions] |
| PBLogo | Specifies the location and name of the .bmp file for the **Phone Book** dialog box.<br><br>Default = The default value for this key is blank. When nothing is specified, the standard phone book bitmap is used. | CMAK | [Connection Manager] |
| PBMessage | Specifies the text that appears in the **Phone Book** dialog box next to the **More access numbers** box when alternate access numbers are available for the selected geographic region.<br><br>Maximum = Approximately 100 characters. | CMAK | [Connection Manager] |
| PBUpdateMessage | Specifies the text that appears in the **Phone Book** dialog box during a phone book update.<br><br>Default = "Downloading new phone book." | .cms | [Connection Manager] |
| ResetPassword | Specifies whether the **New** button appears in the Connection Manager logon dialog box to enable a user to change the password. You can use this button to set up a custom password option. Type the location (including the name) of the executable (.exe) program that you use to support this process. You must provide an executable program for this option and include it as an additional file when you run the CMAK wizard. | .cms | [Connection Manager] |
| ServiceMessage | Specifies the service message that appears in the Connection Manager logon dialog box. This text is usually a customer-support number for the service.<br><br>Maximum = Approximately 50 characters. | CMAK | [Connection Manager] |
| ServiceName | Specifies the primary identifier for the profile. This text appears in the Connection Manager logon dialog box as the service name and as the name of the connection.<br><br>Maximum = Approximately 35 characters. Do not use any of the following in this name:<br><br>* \ / : ? < > \| [ ] | CMAK | [Connection Manager] |

| | | | |
|---|---|---|---|
| SmallIcon | Specifies the location and name of the icon (.ico) file for the 16 16 pixel icon, which is used, by default, for the title bar.<br><br>Default = The default value for this key is blank. When nothing is specified, the standard icon for the Connection Manager title bar is used. | CMAK | [Connection Manager] |
| TrayIcon | Specifies the location and name of the icon (.ico) file for the notification area shortcut.<br><br>Default = The default value for this key is blank. When nothing is specified, the notification area shortcut for Connection Manager is used. | CMAK | [Connection Manager] |
| Tunneling | Specifies the starting frame number of the animation that plays while a VPN connection is being established. | .cms | [Animated Actions] |
| UserNameOptional | Specifies whether the user must type a user name in the Connection Manager logon and **Internet logon** dialog boxes.<br><br>0 (default) = User name required.<br><br>1 = User name not required. | .cms | [Connection Manager] |

**Keys that Control Dial-up Settings**

**These keys control how the Connection Manager service profile makes a dial-up connection.**

| Key | Description and values | Set in | Section |
|---|---|---|---|
| CMSFile&*MergedProfile* | Specifies the location of a .cms file for a component service profile. The format is CMSFile&*MergedProfile*=*Location*, where *MergedProfile* is the name of the top-level service profile, and *Location* is the location of the .cms file for the component service profile. | CMAK | [ISP] |
| ConnectionType | Specifies the connection method to be used.<br><br>0 (default) = Connect by using a dial-up connection.<br><br>1 = Connect by using a direct connection (for example, DSL).<br><br>This key is valid only if both the Dialup key and the Direct key are set to 1. The user can change this option on the **General** tab in the properties dialog box of the service profile. | .cmp | [Connection Manager] |
| Custom_Security | Applies specific security settings on computers that are running Windows 2000, Windows XP, or Windows Server 2003.<br><br>0 = Use standard configuration.<br><br>1 (default) = Use custom configuration.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |

| | | | |
|---|---|---|---|
| CustomAuthData# | Specifies the configuration data for the Extensible Authentication Protocol (EAP) type. The format is CustomAuthData#=EAPConfigurationData, where # is the number of the specific line of data, for example:<br><br>CustomAuthData0=1AFGKLMOFGH23K<br><br>Each line can contain a maximum of 128 characters. If the configuration data has more than 128 characters, it must be specified as multiple lines, incrementing the number for each line of data. For example:<br><br>CustomAuthData0=First128Characters<br><br>CustomAuthData1=Next128Characters<br><br>CustomAuthData2=FinalCharacters<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |
| CustomAuthKey | Specifies the ID of the EAP type to be used with this connection. The format is CustAuthKey=*ID*, where *ID* is the Internet Assigned Numbers Authority (IANA) ID for the EAP type. If no ID is specified, no attempt will be made to read the CustomAuthData value.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |
| DataEncrypt | Specifies whether to force data encryption. This key is ignored for service profiles in which the EncryptionType key is set and that are installed on Windows 2000, Windows XP, or Windows Server 2003.<br><br>0 (default for dial-up entries) = Do not encrypt data.<br><br>1 (default for VPN entries) = Encrypt data. | CMAK | [Server&*EntryName*] |
| Dialup | Specifies whether dial-up connections are supported. If this key is set to 0, the **General** tab in the properties dialog box of the service profile will not appear.<br><br>0 = No.<br><br>1 (default) = Yes. | .cms | [Connection Manager] |
| Disable_LCP | Specifies whether to enable Link Control Protocol (LCP) extensions.<br><br>0 (default) = Enable.<br><br>1 = Disable. | .cms | [Server&*EntryName*] |
| DisableNbtOverIP | Specifies whether to disable the NetBIOS over TCP/IP (NetBT) routing protocol for this connection.<br><br>0 (default) = Disable NetBT.<br><br>1 = Leave NetBT enabled. | .cms | [Server&*EntryName*] |
| DNS_Address | Specifies the DNS address to use for the dial-up entry. | CMAK | [TCP/IP&*EntryName*] |
| DNS_Alt_Address | Specifies the alternate DNS address to use for the dial-up entry. | CMAK | [TCP/IP&*EntryName*] |
| DNSSuffix | Specifies the DNS suffix to use for the dial-up entry. Valid only for Windows XP and Windows Server 2003. | .cms | [TCP/IP&*EntryName*] |

| | | | |
|---|---|---|---|
| DontNegotiateMultilink | Specifies whether to allow multilinking.<br><br>0 (default) = Allow multilink.<br><br>1 = Do not allow multilink.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Server&*EntryName*] |
| DontUseRasCredentials | Specifies whether to cache the credentials of the user in Stored User Names and Passwords for access to resources after the user has logged on to the network.<br><br>0 (default) = Cache and use credentials.<br><br>1 = Do not cache and use credentials.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Server&*EntryName*] |
| DownloadDelay | Specifies the time (in seconds) to delay before downloading phone book updates. The delay time starts when the connection is established.<br><br>Default = 15 seconds.<br><br>This entry is valid only when, in the CMAK wizard, in the **Phone Book** dialog box, the **Automatically download phone book updates** check box is selected. | .cms | [Connection Manager] |
| DUN | Specifies the default network entry used when the **Dial-up Networking Entry** box for a POP is blank.<br><br>Default = *ServiceProfileServiceName*. | .cms | [Connection Manager] |
| EncryptionType | Specifies which encryption level to use.<br><br>0 = None.<br><br>1 (default for VPN) = Require.<br><br>3 (default for dial-up) = Optional.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |
| EnforceCustomSecurity | Specifies whether to require the user to choose a phone book entry that supports advanced security settings.<br><br>0 (default) = Do not enforce phone book entry selection (Valid only for Windows 95, Windows 98, Windows NT 4.0, and Windows Millennium Edition).<br><br>1 = Enforce selection of phone book entries that support advanced security settings. | CMAK | [Server&*EntryName*] |
| FilterA&*MergedProfile* | Specifies the name of the filter to apply to the phone book of the component profile. The format is FilterA&*MergedProfile* = *FilterName*. *MergedProfile* is the name of the component service profile, as specified in the References key in the .cms file, and *FilterName* is the name of the filter to apply.<br><br>The phone numbers that meet the filter criteria appear in the **Phone Book** dialog box, in the **Access numbers** list. | CMAK | [ISP] |

| | | | |
|---|---|---|---|
| FilterA&*ServiceProfile* | Specifies the name of the filter to apply to the access numbers of the top-level profile.<br><br>The selected phone numbers appear in Connection Manager, in the **Phone Book** dialog box, in the **Access numbers** list.<br><br>Default = NoSurchargeSignon | .cms | [ISP] |
| FilterB&*MergedProfile* | Specifies the name of the filter to apply to the phone book of the component profile. The format is FilterB&*MergedProfile* = *FilterName*. *MergedProfile* is the name of the component service profile, as specified in the References key in the .cms file, and *FilterName* is the name of the filter to apply.<br><br>The phone numbers that match the filter criteria appear in Connection Manager, in the **Phone Book** dialog box, in the **More access numbers** list. | CMAK | [ISP] |
| FilterB&*ServiceProfile* | Specifies the name of the filter to apply to the phone book of the top-level profile, for example:<br><br>FilterB& = SurchargeSignon<br><br>Phone numbers that match the filter criteria appear in Connection Manager, in the **Phone Book** dialog box, in the **More access numbers** list.<br><br>Default = SurchargeSignon. | .cms | [ISP] |
| Gateway_On_Remote | Specifies whether to use the default gateway on the remote private network.<br><br>0 = Do not use.<br><br>1 (default) = Use. | CMAK | [TCP/IP&*EntryName*] |
| IdleTimeout | Specifies how long (in minutes) that the connection must be idle before it is disconnected the first time that the service profile is used to connect.<br><br>Default = 10 minutes.<br><br>If this key is set to 0, idle connections are not disconnected. | .cmp | [Connection Manager] |
| IP_Address | Specifies the static IP addresses for the dial-up entry. | .cms | [TCP/IP&*EntryName*] |
| IP_Header_Compress | Specifies whether to enable IP header compression.<br><br>0 = Not enabled.<br><br>1 (default) = Enabled. | CMAK | [TCP/IP&*EntryName*] |

| | | | |
|---|---|---|---|
| IsdnDialMode | Specifies whether Connection Manager binds two channels on the same ISDN device.<br><br>0 (default) = Do not bind (use single channel only).<br><br>1 = Always bind the two channels (connect both channels automatically). If a dual channel connection cannot be made, the connection attempt will fail. This value is valid only for Windows NT 4.0, Windows 2000, Windows Millennium Edition, Windows XP, and Windows Server 2003.<br><br>2 = Attempt to bind the two channels (connect with both channels). If the two channels cannot be bound, use a single channel. This value is valid only for Windows 2000, Windows XP, and Windows Server 2003. | .cms | [Connection Manager] |
| Mask&*FilterName* | Specifies the mask value for *FilterName*. | .cms | [ISP] |
| Match&*FilterName* | Specifies the match value for *FilterName*. | .cms | [ISP] |
| Name | Specifies the location (including path and file name) of the script (.scp) file for the dial-up entry. | CMAK | [Scripting&*EntryName*] |
| Negotiate_IPX | Specifies whether to negotiate the Internetwork Packet Exchange (IPX) protocol.<br><br>0 (default) = Do not negotiate.<br><br>1 = Negotiate.<br><br>The IPX/SPX protocol is not available on Windows XP 64-Bit Edition and the 64-bit versions of Windows Server 2003. | .cms | [Server&*EntryName*] |
| Negotiate_NetBEUI | Specifies whether to negotiate the NetBIOS extended user interface (NetBEUI) protocol.<br><br>0 (default) = Do not negotiate.<br><br>1 = Negotiate | .cms | [Server&*EntryName*] |
| Negotiate_TCP/IP | Specifies whether to negotiate TCP/IP.<br><br>0 = Do not negotiate.<br><br>1 (default) = Negotiate. | .cms | [Server&*EntryName*] |
| NetworkLogon | Specifies whether to log on to the network.<br><br>0 = Do not log on. This is the default for dial-up connections.<br><br>1 = Log on. This is the default for VPN connections. | CMAK | [Server&*EntryName*] |
| PBFile | Specifies the location of the phone book (.pbk) file that the service profile uses. | CMAK | [ISP] |
| PBURL | Specifies the Uniform Resource Locator (URL) for the Phone Book Service (PBS) server. | CMAK | [ISP] |
| PW_Encrypt | Specifies whether to encrypt a password for authentication.<br><br>0 (default) = Do not encrypt.<br><br>1 = Encrypt. | CMAK | [Server&*EntryName*] |

| | | | |
|---|---|---|---|
| PW_EncryptMS | Specifies whether to require MS-CHAP version 1 for this connection.<br><br>0 = Do not require MS-CHAP v1.<br><br>1 = Require MS-CHAP v1. | CMAK | [Server&*EntryName*] |
| RedialCount | Specifies the number of redials to attempt the first time that the service profile is used to try to connect.<br><br>Default = 3. | .cmp | [Connection Manager] |
| RedialDelay | Specifies the delay (in seconds) between dial attempts. The delay is the elapsed time between the point of failure of the first call and the dialing of the first digit of the next phone number.<br><br>Default = 5 seconds. | .cms | [Connection Manager] |
| References | Specifies the service profiles merged through the CMAK wizard. Profile names are separated by commas, tabs, or spaces. Each name is used as a reference to that profile. | CMAK | [ISP] |
| RegionFile | Specifies the location of the region (.pbr) file that the service profile uses. | CMAK | [ISP] |
| Require_CHAP | Specifies whether Challenge Handshake Authentication Protocol (CHAP) is allowed.<br><br>0 = Not allowed.<br><br>1 (default) = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |
| Require_EAP | Specifies whether Extensible Authentication Protocol (EAP) is allowed.<br><br>0 (default) = Not allowed.<br><br>1 = allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |
| Require_MSCHAP | Specifies whether MSCHAP is allowed.<br><br>0 = Not allowed.<br><br>1 (default) = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |
| Require_MSCHAP2 | Specifies whether MSCHAP2 is allowed.<br><br>0 = Not allowed.<br><br>1 (default) = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |

| | | | |
|---|---|---|---|
| Require_PAP | Specifies whether Password Authentication Protocol (PAP) is allowed.<br><br>0 (default) = Not allowed.<br><br>1 = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |
| Require_SPAP | Specifies whether SPAP is allowed.<br><br>0 (default) = Not allowed.<br><br>1 = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*EntryName*] |
| Require_W95MSCHAP | Specifies whether W95MSCHAP is allowed. If the value for this key is set to 1, the value for Require_MS-CHAP must also be set to 1.<br><br>0 (default) = Not allowed.<br><br>1 = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | .cms | [Server&*EntryName*] |
| SecureClientForMSNet | Specifies whether to allow the use of NetBT. If this key is set, the value of the SecureLocalFiles key is ignored on Windows XP and Windows Server 2003.<br><br>0 (default) = Allow the use of NetBT.<br><br>1 = Do not allow the use of NetBT.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [TCP/IP&*EntryName*] |
| SecureFileAndPrint | Specifies whether to enable file and print sharing. If this key is set, the value of the SecureLocalFiles key is ignored on Windows XP and Windows Server 2003.<br><br>0 (default) = Enable.<br><br>1 = Disable. Files and print resources will not be shared.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Server&*EntryName*] |
| SecureLocalFiles | Specifies whether to share local files and allow printer sharing. If the value of the key is set to 1, it will disable NetBT on Windows 2000, Windows XP, and Windows Server 2003. This key is ignored on Windows XP and Windows Server 2003 if a value is assigned to the SecureClientForMSNet key, the SecureFileAndPrint key, or both.<br><br>0 (default) = Share local files.<br><br>1 = Do not share local files.<br><br>Valid only for Windows NT, Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [TCP/IP&*EntryName*] |

| | | | |
|---|---|---|---|
| *ServiceType* | Specifies a service type as a filter name to be applied to the phone book of the component profile. The format of the entry is *ServiceType=FilterName*, where *ServiceType* is the name as it appears in the **Phone Book** dialog box in the **Service type** list, and *FilterName* is the name of the filter to be associated with the entry. For example:<br><br>ISDN Multicast = MulticastISDN<br><br>A service type name should include no more than 25 characters. You can concatenate service type names by inserting a space between each name. At least two service types must be defined in order for phone numbers to appear in the properties dialog box for the service profile. | .cms | [Service Type] |
| Specify_IP_Address | Specifies whether to specify a static IP address for the dial-up entry.<br><br>0 (default) = Do not specify.<br><br>1 = Specify. | .cms | [TCP/IP&*EntryName*] |
| Specify_Server_Address | Specifies whether to specify static DNS or Windows Internet Name Service (WINS) addresses for the dial-up entry.<br><br>0 (default) = Do not specify.<br><br>1 = Specify. | CMAK | [TCP/IP&*EntryName*] |
| SW_Compress | Specifies whether to negotiate PPP software compression of data.<br><br>0 = Do not negotiate.<br><br>1 (default) = Negotiate. | .cms | [Server&*EntryName*] |
| TcpWindowSize | Specifies the size (in bytes) of the window offered by the connection. The window is the number of bytes of information to send before expecting a return packet. Minimum value is 4,096; maximum value is 65,500. If this key is not set, the default window size for the operating system and the connection type is used.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | .cms | [TCP/IP&*EntryName*] |
| UseTerminalWindow | Specifies whether to use a terminal window when connecting to a service.<br><br>0 (default) = Do not use a terminal window.<br><br>1 = Use a terminal window.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | .cms | [Scripting&*EntryName*] |
| Version | Specifies the version of the phone book. If you provide phone books, the PBS server uses this value to determine whether and how to update phone books. If the version listed in this key is more than five versions out of date, the PBS server downloads the complete phone book. Otherwise, the PBS server downloads a delta file. | .cms | [Connection Manager] |
| WINS_Address | Specifies the WINS address for the dial-up entry. | CMAK | [TCP/IP&*EntryName*] |
| WINS_Alt_Address | Specifies the alternate WINS address for the dial-up entry. | CMAK | [TCP/IP&*EntryName*] |

**Keys that control VPN settings**

**These keys control how the Connection Manager service profile makes a VPN connection.**

| | | | |
|---|---|---|---|
| ConnectionType | Specifies the connection method to be used.<br><br>0 (default) = Connect by using a dial-up connection.<br><br>1 = Connect by using a direct connection (for example, DSL).<br><br>This key is valid only if both the Dialup key and the Direct key values are set to 1. The user can change this option in the properties dialog box for the service profile on the **General** tab. | .cmp | [Connection Manager] |
| Custom_Security | Specifies whether specific security settings should be applied on computers that are running Windows 2000, Windows XP, or Windows Server 2003.<br><br>0 = Use standard configuration.<br><br>1 (default) = Use custom configuration.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| CustomAuthData# | Specifies the configuration data for the EAP type. The format is CustomAuthData#=EAPConfigurationData, where # is the number of the specific line of data, for example:<br><br>CustomAuthData0=1AFGKLMOFGH23K<br><br>Each line can contain a maximum of 128 characters. If the ID has more than 128 characters, it must be specified as multiple lines, incrementing the # value for each line of data. For example:<br><br>CustomAuthData0=First128Characters<br><br>CustomAuthData1=Next128Characters<br><br>CustomAuthData2=FinalCharacters<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| CustomAuthKey | Specifies the ID of the EAP type to use with this connection. The format is CustAuthKey=*ID*, where *ID* is the Internet Assigned Numbers Authority (IANA) ID for the EAP type. If no ID is specified, no attempt will be made to read the CustomAuthData value.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| DataEncrypt | Specifies whether to force data encryption. This key is ignored for service profiles in which the EncryptionType key is set and that are installed on Windows 2000, Windows XP, or Windows Server 2003.<br><br>0 (default for dial-up entries) = Do not encrypt data.<br><br>1 (default for VPN entries) = Encrypt data. | CMAK | [Server&*TunnelDUN*] |
| Direct | Specifies whether direct connections are supported.<br><br>0 = No.<br><br>1 (default) = Yes.<br><br>Valid only for VPN service profiles. | .cms | [Connection Manager] |

| | | | |
|---|---|---|---|
| Disable_LCP | Specifies whether to enable Link Control Protocol (LCP) extensions.<br><br>0 (default) = Enable.<br><br>1 = Disable. | .cms | [Server&*TunnelDUN*] |
| DisableNbtOverIP | Specifies whether to disable the NetBT routing protocol for this connection.<br><br>0 (default) = Disable NetBT.<br><br>1 = Leave NetBT enabled. | .cms | [Server&*TunnelDUN*] |
| DNS_Address | Specifies the DNS address for the VPN entry. | CMAK | [TCP/IP&*TunnelDUN*] |
| DNS_Alt_Address | Specifies the alternate DNS address for the VPN entry. | CMAK | [TCP/IP&*TunnelDUN*] |
| DNSSuffix | Specifies the DNS suffix to use for the connection. Valid only for Windows XP and Windows Server 2003. | .cms | [TCP/IP&*TunnelDUN*] |
| DontNegotiateMultilink | Specifies whether to allow multilinking.<br><br>0 (default) = Allow multilinking.<br><br>1 = Do not allow multilinking.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Server&*TunnelDUN*] |
| DontUseRasCredentials | Specifies whether to cache the user credentials in Stored User Names and Passwords for access to network resources after the user has logged on to the network.<br><br>0 (default) = Cache and use credentials.<br><br>1 = Do not cache and use credentials.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Server&*TunnelDUN*] |
| EncryptionType | Specifies which encryption level to use.<br><br>0 = None.<br><br>1 (default for VPN) = Require.<br><br>3 (default for dial-up) = Optional.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| EnforceCustomSecurity | Specifies whether to require the user to select a phone book entry that supports advanced security settings.<br><br>0 (default) = Do not enforce phone book entry selection. This value is valid for Windows 95, Windows 98, Windows NT 4.0, and Windows Millennium Edition only.<br><br>1 = Enforce selection of phone book entries that support advanced security settings. | CMAK | [Server&*TunnelDUN*] |
| Gateway_On_Remote | Specifies whether to use the default gateway on the remote private network.<br><br>0 = Do not use.<br><br>1 (default) = Use. | CMAK | [TCP/IP&*TunnelDUN*] |
| IP_Address | Specifies the static IP addresses for the VPN entry. | .cms | [TCP/IP&*TunnelDUN*] |

| | | | |
|---|---|---|---|
| IP_Header_Compress | Specifies whether to enable IP header compression.<br><br>0 = Not enabled.<br><br>1 (default) = Enabled. | CMAK | [TCP/IP&*TunnelDUN*] |
| Negotiate_IPX | Specifies whether to negotiate the IPX protocol.<br><br>0 (default) = Do not negotiate.<br><br>1 = Negotiate.<br><br>The IPX/SPX protocol is not available on Windows XP 64-Bit Edition and the 64-bit versions of Windows Server 2003. | .cms | [Server&*TunnelDUN*] |
| Negotiate_NetBEUI | Specifies whether to negotiate the NetBIOS extended user interface (NetBEUI) protocol.<br><br>0 (default) = Do not negotiate.<br><br>1 = Negotiate | .cms | [Server&*TunnelDUN*] |
| Negotiate_TCP/IP | Specifies whether to negotiate TCP/IP.<br><br>0 = Do not negotiate.<br><br>1 (default) = Negotiate. | .cms | [Server&*TunnelDUN*] |
| NetworkLogon | Specifies whether to log on to the network.<br><br>0 = Do not log on. This is the default for dial-up connections.<br><br>1 = Log on. This is the default for VPN connections. | CMAK | [Server&*TunnelDUN*] |
| PW_Encrypt | Specifies whether to encrypt a password when authenticating.<br><br>0 (default) = Do not encrypt.<br><br>1 = Encrypt. | CMAK | [Server&*TunnelDUN*] |
| PW_EncryptMS | Specifies whether to require MS-CHAP version 1 for this connection.<br><br>0 = Do not require MS-CHAP v1.<br><br>1 = Require MS-CHAP v1. | CMAK | [Server&*TunnelDUN*] |
| Require_CHAP | Specifies whether Challenge Handshake Authentication Protocol (CHAP) is allowed.<br><br>0 = Not allowed.<br><br>1 (default) = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| Require_EAP | Specifies whether Extensible Authentication Protocol (EAP) is allowed.<br><br>0 (default) = Not allowed.<br><br>1 = allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |

| | | | |
|---|---|---|---|
| Require_MSCHAP | Specifies whether MSCHAP is allowed.<br><br>0 = Not allowed.<br><br>1 (default) = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| Require_MSCHAP2 | Specifies whether MSCHAP2 is allowed.<br><br>0 = Not allowed.<br><br>1 (default) = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| Require_PAP | Specifies whether Password Authentication Protocol (PAP) is allowed.<br><br>0 (default) = Not allowed.<br><br>1 = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| Require_SPAP | Specifies whether SPAP is allowed.<br><br>0 (default) = Not allowed.<br><br>1 = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| Require_W95MSCHAP | Specifies whether W95MSCHAP is allowed. If this key is set to 1, Require_MS-CHAP must also be set to 1.<br><br>0 (default) = Not allowed.<br><br>1 = Allowed.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | .cms | [Server&*TunnelDUN*] |
| SecureClientForMSNet | Specifies whether to allow the use of NetBT. If this key is set, the value of the SecureLocalFiles key is ignored on Windows XP and Windows Server 2003.<br><br>0 (default) = Allow the use of NetBT.<br><br>1 = Do not allow the use of NetBT.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Server&*TunnelDUN*] |
| SecureFileAndPrint | Specifies whether to enable file and print sharing. If this key is set, the SecureLocalFiles key is ignored on Windows XP and Windows Server 2003.<br><br>0 (default) = Enable.<br><br>1 = Disable. Files and print resources will not be shared.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Server&*TunnelDUN*] |

| | | | |
|---|---|---|---|
| SecureLocalFiles | Specifies whether to share local files and allow printer sharing. If the value of the key is set to 1, it will disable NetBT on Windows 2000, Windows XP, and Windows Server 2003. This key value will be ignored on Windows XP and Windows Server 2003 if a value is assigned to the SecureClientForMSNet key, the SecureFileAndPrint key, or both.<br><br>0 (default) = Share local files.<br><br>1 = Do not share local files.<br><br>Valid only for Windows NT 4.0, Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Server&*TunnelDUN*] |
| Specify_IP_Address | Specifies whether to specify a static IP address.<br><br>0 (default) = Do not specify.<br><br>1 = Specify. | .cms | [TCP/IP&*TunnelDUN*] |
| Specify_Server_Address | Specifies whether to specify static DNS or WINS addresses.<br><br>0 (default) = Do not specify.<br><br>1 = Specify. | CMAK | [TCP/IP&*TunnelDUN*] |
| SW_Compress | Specifies whether to negotiate Point-to-Point Protocol (PPP) software compression of data.<br><br>0 = Do not negotiate.<br><br>1 (default) = Negotiate. | .cms | [Server&*TunnelDUN*] |
| TcpWindowSize | Specifies the size (in bytes) of the window offered by the connection. The window is the number of bytes of information to send before expecting a return packet. Minimum value is 4,096; maximum value is 65,500. If this key is not set, the default window size for the operating system and the connection type is used.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | .cms | [TCP/IP&*TunnelDUN*] |
| Tunnel | Specifies whether VPN connections are enabled for the phone numbers in the top-level phone book.<br><br>0 (default) = Not enabled.<br><br>1 = Enabled. | CMAK | [Connection Manager] |
| TunnelAddress | Specifies the IP address or fully qualified domain name for the VPN server. | CMAK | [Connection Manager] |
| TunnelDUN | Specifies the default networking entry used for VPN connections.<br><br>Default = *ServiceProfileServiceName* tunnel. | .cms | [Connection Manager] |
| TunnelFile | Specifies the relative path and file name to the VPN file. If you use macros in the relative path, make sure that the macros are recognized on all operating systems to which you want to distribute the profile. | CMAK | [Connection Manager] |

| | | | |
|---|---|---|---|
| TunnelReferences | Specifies whether VPN connections are enabled for phone numbers taken from the phone book of a component profile.<br><br>0 (default) = Do not use a VPN connection when using any of these phone numbers.<br><br>1 = Use a VPN connection when using a phone number from a component profile. | CMAK | [Connection Manager] |
| UsePreSharedKey | Specifies whether to use a preshared key for Layer Two Tunneling Protocol over Internet Protocol security (L2TP/IPSec) authentication.<br><br>0 (default) = Do not use a preshared key.<br><br>1 = Use a preshared key.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Networking&*TunnelDUN*] |
| VPNEntry | Specifies whether the entry is a VPN entry or a dial-up entry.<br><br>0 = Dial-up entry.<br><br>1 = VPN entry. | CMAK | [Networking&*TunnelDUN*] |
| VpnStrategy | Specifies which tunneling protocol to use when establishing a VPN connection.<br><br>1 = Use PPTP only.<br><br>2 = Try PPTP first.<br><br>3 = Use L2TP only.<br><br>4 = Try L2TP first.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | CMAK | [Networking&*TunnelDUN*] |
| WINS_Address | Specifies the WINS address for the VPN entry. | CMAK | [TCP/IP&*TunnelDUN*] |
| WINS_Alt_Address | Specifies the alternate WINS address for the VPN entry. | CMAK | [TCP/IP&*TunnelDUN*] |

**Keys that Control Required User Information**

**These keys control what information the service profile requires before the user can click . Connect**

| Key | Description and values | Set in | Section |
|---|---|---|---|
| DomainOptional | Specifies whether the user must specify a domain name when making a connection.<br><br>0 = Require a domain.<br><br>1 (default) = Do not require a domain. | .cms | [Connection Manager] |
| GlobalCredentials | Specifies whether to save the user name and password supplied for first-time use of the connection for all users of the connection.<br><br>0 (default) = Save the user name and password for a single user.<br><br>1 = Save the user name and password for all users of the connection.<br><br>Valid only for Windows XP and Windows Server 2003. | .cmp | [Connection Manager] |

| | | | |
|---|---|---|---|
| PasswordOptional | Specifies whether the user must specify a password in the Connection Manager logon and **Internet Logon** dialog boxes.<br><br>0 (default) = Password required.<br><br>1 = Password not required. | .cms | [Connection Manager] |
| UseSameUserName | Specifies whether to use a separate user name and password when connecting to the Internet service provider (for a VPN connection).<br><br>0 (default) = Use the user name and password in the properties dialog box on the **Internet Logon** tab. Service profiles built to support VPN connections contain this additional tab.<br><br>1 = Use the same user name and password when connecting to the Internet service provider as appears in the Connection Manager logon dialog box for logging on to the private service. | CMAK | [Connection Manager] |
| UseWinLogonCredentials | Specifies whether to use the user name, password, and domain that the user specified when the user logged on most recently to Windows.<br><br>0 = Do not use credentials.<br><br>1 (default) = Use credentials.<br><br>Valid only for Windows 2000, Windows XP, and Windows Server 2003. | .cms | [Connection Manager] |

**Keys that Provide Data the First Time the Service Profile is Used**

**These keys populate information in the Connection Manager user interface the first time that a service profile is used.**

| Key | Description and values | Set in | Section |
|---|---|---|---|
| Description0 | Describes the primary phone number that is provided the first time that the service profile is used. Appears in the **Phone Book** dialog box as a Point of Presence (POP) name. | .cmp | [Connection Manager] |
| Description1 | Describes the backup phone number that is provided the first time that the service profile is used. Appears in the **Phone Book** dialog box as a POP name. | .cmp | [Connection Manager] |
| DialAutomatically | Specifies whether to have the **Connect automatically** check box in the Connection Manager logon dialog box selected by default and to connect automatically the first time that the service profile is used.<br><br>0 (default) = Do not select the check box.<br><br>1 = Select the check box and connect automatically. | .cmp | [Connection Manager] |
| Domain | Specifies the logon domain name that appears automatically the first time that the service profile is used. | .cmp | [Connection Manager] |
| DUN0 | Specifies the dial-up entry used for the primary phone number the first time that the service profile is used. Value must exactly match the entry name specified in Phone Book Administrator. | .cmp | [Connection Manager] |
| DUN1 | Specifies the dial-up entry used for the backup phone number the first time that the service profile is used. Value must exactly match the entry name specified in Phone Book Administrator. | .cmp | [Connection Manager] |

| | | | |
|---|---|---|---|
| EnableLogging | Specifies whether a log file is created for the connection the first time that the service profile is used. The log file is named *ServiceProfileServiceName*.log for an all-user profile, and *ServiceProfileServiceName* (Single User).log for a single-user profile.<br><br>0 = Do not create a log file.<br><br>1 (default) = Create a log file. | .cmp | [Connection Manager] |
| InternetPassword | Specifies the password that appears automatically the first time that the user tries to connect using a VPN connection. | .cmp | [Connection Manager] |
| InternetUserName | Specifies the user name that appears automatically the first time that the user tries to connect using a VPN connection. | .cmp | [Connection Manager] |
| KeepDefaultCredentials | Specifies whether to keep first-time credentials such as user name and password in the .cmp file of the profile for persistent default display and usage for all first-time users of the profile. For single-user profiles, this information will appear only once.<br><br>0 (default) = Do not keep first-time credentials in the .cmp file.<br><br>1 = Keep first-time credentials in the .cmp file. | .cmp | [Connection Manager] |
| Password | Specifies the password that appears automatically the first time that the profile is used. | .cmp | [Connection Manager] |
| PCS | Specifies how the password will be stored for pre-population.<br><br>0 = Password stored in plaintext; pre-population is allowed.<br><br>No other value for this key is valid for pre-population. | .cmp | [Connection Manager] |
| Phone0 | Specifies the primary phone number populated for the user the first time the service profile is used and the default phone number any time another phone number is not selected. | .cmp | [Connection Manager] |
| Phone1 | Specifies the backup phone number populated for the user the first time the service profile is used. | .cmp | [Connection Manager] |
| PhoneCanonical0 | Specifies the canonical format of the primary phone number populated for the user the first time the service profile is used. | .cmp | [Connection Manager] |
| PhoneCanonical1 | Specifies the canonical format of the backup phone number populated for the user the first time the service profile is used. | .cmp | [Connection Manager] |
| PhoneCountry0 | Specifies the Telephony Application Programming Interface (TAPI) country/region code for the primary phone number set as default for the user the first time the service profile is used. | .cmp | [Connection Manager] |
| PhoneCountry1 | Specifies the Telephony Application Programming Interface (TAPI) country/region code for the backup phone number set as default for the user the first time the service profile is used. | .cmp | [Connection Manager] |
| PhoneSource0 | Specifies the service profile for the primary phone number to be used the first time the user connects. | .cmp | [Connection Manager] |
| PhoneSource1 | Specifies the service profile for the backup phone number to be used the first time the user connects. | .cmp | [Connection Manager] |
| Region0 | Specifies the default state or province from the phone book for the primary phone number the first time that the service profile is opened. | .cmp | [Connection Manager] |

| | | | |
|---|---|---|---|
| Region1 | Specifies the default state or province from the phone book for the backup phone number the first time that the service profile is opened. | .cmp | [Connection Manager] |
| RememberInternetPassword | Specifies whether the **Save password** check box on the **Internet Logon** tab is selected by default for a populated Internet password. This key is ignored if the InternetPassword key is not set in the .cmp file.<br><br>0 (default) = The check box is cleared by default.<br><br>1 = The check box is selected by default, and the password is saved. | .cmp | [Connection Manager] |
| RememberPassword | Specifies whether to have the **Save password** check box in the Connection Manager logon dialog box selected by default for a populated password. This key is ignored if the Password key is not set in the .cmp file.<br><br>0 (default) = The check box is cleared by default.<br><br>1 = The check box is selected by default, and the password is saved. | .cmp | [Connection Manager] |
| ServiceType0 | Specifies the default service type from the phone book for the primary phone number the first time that the service profile is opened. | .cmp | [Connection Manager] |
| ServiceType1 | Specifies the default service type from the phone book for the backup phone number the first time that the service profile is opened. | .cmp | [Connection Manager] |
| UseDialingRules0 | Specifies whether dialing rules are applied to the primary phone number the first time that the service profile is used.<br><br>0 = Dial the number exactly as it appears in the phone book or as it is typed.<br><br>1 (default) = Apply dialing rules to the number when displaying and dialing. | .cmp | [Connection Manager] |
| UseDialingRules1 | Specifies whether dialing rules are applied to the backup number the first time the service profile is used.<br><br>0 = Dial the number exactly as it appears in the phone book or as it is typed.<br><br>1 (default) = Apply dialing rules to the number when displaying and dialing. | .cmp | [Connection Manager] |
| UserName | Specifies the name used to authenticate the user the first time that the service profile is used. | .cmp | [Connection Manager] |
| UserNamePrefix | Specifies the prefix added to the user name. Enables access to a service that requires a realm name as a user name prefix. This key is not used in a VPN connection. | CMAK | [Connection Manager] |
| UserNameSuffix | Specifies the suffix appended to the user name. Enables access to a service that requires a realm name as a user name suffix. This key not used in a VPN connection. | CMAK | [Connection Manager] |

**Connection Manager Custom Action Keys**

**These keys control when and how a custom action is performed.**

| Key | Description and values | Set in | Section |
|---|---|---|---|

| | | | |
|---|---|---|---|
| # | Specifies a single custom action. The format of the value is # = *Program*, where # is an ID number from 0 to *n* in sequential order and *Program* is the complete name of the program, including the file name extension and the path to the program. Programs start in sequence: 0 first, 1 next, and so on. Macros, such as %UserName% and %ErrorCode%, are set in Connection Manager, and they can be used as parameters for custom action programs. | CMAK | [Pre-Init Actions]<br><br>[Pre-Connect Actions]<br><br>[Pre-Dial Actions]<br><br>[Pre-Tunnel Actions]<br><br>[Connect Actions]<br><br>[Disconnect Actions]<br><br>[On-Cancel Actions]<br><br>[On-Error Actions]<br><br>[Auto Applications] |
| #&Flags | Specifies whether a custom action runs when a specific type of connection is established. The format of the value is #&Flags = *n*, where # is the ID number of a defined custom action and n indicates how dial-up and direct connections for that custom action are handled:<br><br>If *n* = 0 (default), all connections trigger this custom action. (The default key does not appear in the .cms file.)<br><br>If *n* = 1, all direct tunnel connections trigger this custom action.<br><br>If *n* = 2 , all connections that involve dialing (direct or double) trigger this custom action.<br><br>If *n* = 4, only connections that use dial-up trigger this custom action.<br><br>If *n* = 8, only connections that involve a tunnel trigger this custom action | CMAK | [Pre-Init Actions]<br><br>[Pre-Connect Actions]<br><br>[Pre-Dial Actions]<br><br>[Pre-Tunnel Actions]<br><br>[Connect Actions]<br><br>[Disconnect Actions]<br><br>[On-Cancel Actions]<br><br>[On-Error Actions]<br><br>[Auto Applications] |

| | | | |
|---|---|---|---|
| #&Description | Specifies a short description of a custom action. The format of the value is #&Description = *Text*, where # is the number of a defined custom action and *Text* is the descriptive information for that custom action. This option can provide useful information when a synchronous custom action does not run properly.<br><br>Default = The name of the custom action program. | CMAK | [Pre-Init Actions]<br><br>[Pre-Connect Actions]<br><br>[Pre-Dial Actions]<br><br>[Pre-Tunnel Actions]<br><br>[Connect Actions]<br><br>[Disconnect Actions]<br><br>[On-Cancel Actions]<br><br>[On-Error Actions]<br><br>[Auto Applications] |

**Connection Manager Control Keys**

**Connection Manager uses these keys to locate files and determine behavior during a connection.**

| Key | Description and values | Set in | Section |
|---|---|---|---|
| AutoReconnect | Specifies whether to automatically attempt to reconnect when a connection is terminated unexpectedly.<br><br>0 (default) = Do not automatically attempt to reconnect.<br><br>1 = Attempt to reconnect. | .cms | [Connection Manager] |
| CheckOSComponents | Specifies whether Connection Manager checks the operating system components.<br><br>0 (default) = Check the operating system components only when an error occurs.<br><br>1 = Always check the operating system components on service profile initialization. | .cms | [Connection Manager] |
| CMSFile | Specifies the name of the service profile file: (*Path**ServiceProfileFileName*.cms), as specified in **File name** on the **Service and File Names** page. Do not use any of the following in this name: ! @ ^ & ( ) { } ` ´ ~ , ; <space> * = \ / : ? " < > \| . % + [ ] $ #. Do not alter this value in the .cmp file. If a different name is required, use the CMAK wizard to edit the existing profile, specify new names for both the service name and the file name, and then finish running the wizard. | CMAK | [Connection Manager] |
| DisableICS | Specifies whether to prevent the user from sharing the connection with Internet Connection Sharing (ICS).<br><br>0 (default) = Do not suppress ICS settings.<br><br>1 = Disable ICS for this connection. The check box for enabling ICS will be unavailable.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Connection Manager] |

| | | | |
|---|---|---|---|
| DoNotCheckBindings | Specifies whether to include the TCP/IP bindings when checking operating system components.<br><br>0 (default) = Include the TCP/IP bindings in the TCP/IP check and bind all that are not bound.<br><br>1 = Do not include the TCP/IP bindings when checking operating system components.<br><br>TCP/IP services that sit between the TCP/IP protocol and the adapter are protected from being checked only if this option is set to 1 in all installed service profiles. This option does not prevent other service profiles or programs from checking bindings. | .cms | [Connection Manager] |
| EnableICF | Specifies whether to enable Internet Connection Firewall (ICF) for this connection with default settings.<br><br>0 (default) = Do not adjust ICF settings.<br><br>1 = Enable ICF for the connection with default settings.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Connection Manager] |
| FileDirectory | Specifies the location of the log file. If the value is blank, the log file is created in the temp folder. | .cms | [Logging] |
| IdleThreshold | Specifies the maximum bytes per minute that can be received if an idle state is to be detected for the connection.<br><br>Default = 0.<br><br>This key is not valid on Windows NT 4.0. | .cms | [Connection Manager] |
| InternetConnection | Specifies whether to inform the operating system that this connection is a connection to the Internet.<br><br>0 (default) = Do not inform the operating system that this connection connects to the Internet for the purposes of automatically connecting when no connection is present.<br><br>1 = Inform the operating system that this connection connects to the Internet.<br><br>Valid only for Windows XP and Windows Server 2003. | .cms | [Connection Manager] |
| MaxFileSize | Specifies the maximum file size (in kilobytes) before the log is cleared. The file size is checked at initialization to prevent data loss during a connection. The default is 100. | .cms | [Logging] |
| MonitorCallingProgram | Specifies whether to handle Connection Manager as a monitored custom action when Connection Manager is called programmatically and the calling process terminates.<br><br>0 = Do not monitor.<br><br>1 (default) = Monitor. | .cms | [Connection Manager] |
| PasswordHandling | Specifies the method of handling the password during the logon process.<br><br>0 (default) = Normal (case sensitive).<br><br>1 = Change uppercase letters to lowercase.<br><br>2 = Change lowercase letters to uppercase. | .cms | [Connection Manager] |
| Version | Specifies the version of the service provider or service profile file. Do not modify this value. | .cms<br><br>.cmp | [Profile Format] |

**Connection Manager Registry Entries**
The following registry entries are associated with Connection Manager.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**\PBServerMonitor**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Services

**Version**
Windows Server 2003; Windows 2000 Server

The PBServerMonitor subkey is used to store the Performance subkey.

**\Performance**
**Registry path**
HKLM\SYSTEM\CurrentControlSet\Services\PBServerMonitor

**Version**
Windows Server 2003; Windows 2000 Server

The Performance subkey is used to map the locations of the data, library, and binary files that the PBServer performance counter uses.

**\Phone Book Service**
Registry path

**HKLM\SYSTEM\CurrentControlSet\Services\EventLog\Application**
**Version**
Windows Server 2003; Windows 2000 Server

The Phone Book Service subkey is used to map the location of the event file and to enumerate what types of databases are supported.

**\Connection Manager Administration Kit**
**Registry path**
HKLM\Software\Microsoft

**Version**
Windows Server 2003; Windows 2000 Server; Windows XP Professional

The Connection Manager Administration Kit subkey is used to map the location of the last service profile created with the wizard.

**\Connection Manager**
**Registry path**
\Software\Microsoft

**Version**
Windows Server 2003; Windows XP; Windows Millennium Edition; Windows 2000; Windows 98

This registry subkey is located under HKLM, HKCU, or both, depending on how a service profile is installed, and this subkey is used to store subkeys relating to specific service profiles.

**\Access Points**
**Registry path**
\Software\Microsoft\Connection Manager\UserInfo*ProfileName*

**Version**
Windows Server 2003; Windows XP; Windows Millennium Edition; Windows 2000; Windows 98

The Access Points subkey is used to store the *AccessPointName* subkeys in the HKCU context.

**\AccessPointName**
**Registry path**

\Software\Microsoft\Connection Manager\UserInfo*ProfileName*\AccessPoint

**Version**
Windows Server 2003; Windows XP; Windows Millennium Edition; Windows 2000; Windows 98

The *AccessPointName* subkey is used to store the Favorites connection information. The name of the registry key *AccessPointName* is the friendly name that the user gives it. The default friendly name is Home <default>.

**\ICSData**
**Registry path**
\Software\Microsoft\Connection Manager*ProfileName*

**Version**
Windows Server 2003; Windows XP

The ICSData subkey is used to enable Internet Connection Sharing (ICS) for a Connection Manager service profile. Only All-User connections can have this key. The data contained under this subkey duplicates the **UserInfo** subkey data, and this data is used when ICS is invoked and no user is logged on.

**\Mappings**
**Registry path**
\Software\Microsoft\Connection Manager

**Version**
Windows Server 2003; Windows XP; Windows Millennium Edition; Windows 2000; Windows 98

The Mappings subkey is used to store the full path of the .cmp file for each service profile. The format for the value of the registry key is:

Under HKLM: All-users profiles

Under HKCU: Single-user profiles

| Field | Description |
|---|---|
| Name | The friendly name of the service profile. |
| Type | REG_SZ |
| Data | The full path to the .cmp file of the service profile. |

**\ProfileName**
**Registry path**
\Software\Microsoft\Connection Manager

**Version**
Windows Server 2003; Windows XP; Windows Millennium Edition; Windows 2000; Windows 98

The *ProfileName* subkey is used to store system interaction subkeys, such as the WinLogon subkey for Windows logon custom action executables. The name of the registry key *ProfileName* will be the friendly name of the service profile, not the eight-character file name.

**\UserInfo**
**Registry path**
\Software\Microsoft\Connection Manager

**Version**
Windows Server 2003; Windows XP; Windows Millennium Edition; Windows 2000; Windows 98

The UserInfo subkey is used to store the *ProfileName* subkeys in the HKCU context.

**\WinLogon Actions**
**Registry path**
\Software\Microsoft\Connection Manager*ProfileName*

**Version**
Windows Server 2003; Windows XP; Windows Millennium Edition; Windows 2000; Windows 98

**The WinLogon Actions subkey is used to enable custom actions to run during the logon process. The format for the**

**value of the registry key is:**

| Field | Description |
|---|---|
| Name | The name of the executable file that will run. |
| Type | REG_DWORD |
| Data | A value that indicates the location of the executable. |

**Table Supported values for the Data field are:**

| Value | Location of executable |
|---|---|
| 0x00000000(0) | *%windir%*\system32 |
| 0x00000001(1) | Profile directory |

**Network Ports Used by Connection Manager**

The following table describes the network ports that Connection Manager commonly uses. Because administrators can customize Connection Manager service profiles, the exact network ports that service profiles use vary.

**Port Assignments for Connection Manager**

| Service Name | UDP | TCP |
|---|---|---|
| HTTP | | 80 |
| FTP | | 20/21 |

# IAS Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IAS Technical Reference**
Internet Authentication Service (IAS) is the Microsoft implementation of a Remote Authentication Dial-in User Service (RADIUS) server and proxy. IAS is included in Microsoft Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition. You can configure IAS for two roles: RADIUS server and RADIUS proxy. IAS configured as a RADIUS server performs centralized connection authentication, authorization, and accounting for many types of network access, including wireless, authenticating switch, dial-up, virtual private network (VPN), and Windows Server 2003 or Microsoft Windows 2000 servers running Routing and Remote Access service. With IAS configured as a RADIUS proxy, IAS forwards authentication and accounting messages to other RADIUS servers.

# What Is IAS?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Components of an IAS infrastructure
- IAS Features
- New IAS Features Supported by Microsoft Windows Server 2003

Internet Authentication Service (IAS) is the Microsoft implementation of a Remote Authentication Dial-in User Service (RADIUS) server and proxy. RADIUS is an industry standard for the client-server protocol. For more information about RADIUS, see RFC 2865, "Remote Authentication Dial-In User Service (RADIUS)" and RFC 2866, "RADIUS Accounting." For information about standards that apply to IAS in Windows Server 2003, see RFC 2868, "RADIUS Attributes for Tunnel Protocol Support" and RFC 2869, "RADIUS Extensions."

As a RADIUS server, IAS performs centralized connection authentication, authorization, accounting, and auditing (AAAA) for many types of network access including wireless, authenticating switch, and remote access dial-up and virtual private network (VPN) connections.

As a RADIUS proxy, IAS provides the routing of RADIUS messages between RADIUS clients (access servers), RADIUS proxies, and the RADIUS servers that perform AAAA for the connection attempt. When used as a RADIUS proxy, IAS is a central switching or routing point through which RADIUS access and accounting messages flow. Using IAS, you can centrally manage AAAA for organizations of all sizes, including small businesses, medium organizations, enterprise-level organizations, and Internet Service Providers (ISPs). IAS provides you with the ability to secure and manage network access across a variety of network access scenarios such as the following:

- Employees connecting to your organization network through dial-up, VPN, wireless, and wired connections, using a variety of devices, including organization computers, personal digital assistants, and non-domain member computers, such as employee-owned devices.
- Employees connecting to other networks, including the Internet and business partner networks.
- Business partners connecting to your organization network.

IAS enables the use of a heterogeneous or homogenous set of wireless, switch, remote access, or VPN equipment. IAS also supports the use of both certificate-based and password-based authentication protocols, and provides three forms of logging, including the ability to leverage the advantages of logging to a relational database with Structured Query Language (SQL) Server logging. In addition, you can outsource your remote-access infrastructure to a service provider while retaining control over user authentication, authorization, and accounting, thereby keeping sensitive organization information private and more secure on your network.

When an IAS server is a member of an Active Directory domain, IAS uses the Microsoft Active Directory directory service as its user account database and is part of a single sign-on solution. With single sign-on, users supply account credentials (user name and password or a certificate) only once during the authentication and authorization process; these credentials are then used to log on to an Active Directory domain and for network access control (authenticating and authorizing access to a network).

When IAS remote access policies are configured with Protected Extensible Authentication Protocol (PEAP) and a PEAP type as the authentication method for wireless connections, PEAP fast reconnect allows users to roam with portable devices between wireless access points without re-entering user account credentials each time the portable device associates with a new wireless access point.

You can configure IAS in Windows Server 2003, Standard Edition, with a maximum of 50 RADIUS clients and a maximum of 2 remote RADIUS server groups. You can define a RADIUS client using a fully qualified domain name or an IP address, but you

cannot define groups of RADIUS clients by specifying an IP address range. If the fully qualified domain name of a RADIUS client resolves to multiple IP addresses, the IAS server uses the first IP address returned in the Domain Name System (DNS) query. With IAS in Microsoft Windows Server 2003, Enterprise Edition, and Microsoft Windows Server 2003, Datacenter Edition, you can configure an unlimited number of RADIUS clients and remote RADIUS server groups. In addition, you can configure RADIUS clients by specifying an IP address range. IAS is not included on computers running the Windows Server 2003, Web Edition, operating system.

**Components of an IAS infrastructure**

There are five components to an IAS or RADIUS infrastructure: access clients, access servers (RADIUS clients), IAS servers (RADIUS servers), IAS proxies (RADIUS proxies), and user account databases. A RADIUS infrastructure is used to perform authentication, authorization and accounting of user network access attempts. Authentication is the process of verifying the credentials of the users attempting to connect to a network. The authorization process determines whether users have permission to connect to the network, and the conditions under which permission has been granted. Accounting is an option that provides record keeping of successful or failed connection attempts.

The following figure, "Components of an IAS Infrastructure," illustrates the relationships between the five components of an IAS infrastructure.

**Components of an IAS Infrastructure**

**Access Clients**

An access client is a device that requires some level of access to a larger network. Examples of access clients are dial-up or VPN clients, wireless clients, or LAN clients connected to an authenticating switch.

**Access Servers Used as RADIUS Clients**

An access server is a device that provides some level of access to a larger network. An access server using a RADIUS infrastructure is also a RADIUS client, sending connection requests and accounting messages to a RADIUS server. Examples of access servers follow:

- NASs that provide remote access connectivity to an organization network or the Internet. An example is a computer running Windows Server 2003 or Microsoft Windows 2000 that also runs the Routing and Remote Access service, providing either traditional dial-up or VPN remote access to an organization's intranet.
- Wireless access points that provide physical layer access to an organization's network, using wireless-based transmission and reception technologies.
- Switches that provide physical layer access to an organization's network, using traditional LAN technologies such as Ethernet.

**IAS Servers Used as RADIUS Servers**

An IAS or RADIUS server is a device that receives and processes connection requests or accounting messages sent by RADIUS clients or RADIUS proxies. In the case of connection requests, the RADIUS server processes the list of RADIUS attributes in the connection request. Based on a set of rules and the information in the user account database, the RADIUS server authenticates and authorizes the connection and sends back either an Access-Accept message or an Access-Reject message. The Access-Accept message can contain connection restrictions that the access server implements the duration of the connection.

**IAS Proxies and RADIUS Proxies**

An IAS or RADIUS proxy is a device that forwards or routes RADIUS connection requests and accounting messages between RADIUS clients (and RADIUS proxies) and RADIUS servers (or RADIUS proxies). The RADIUS proxy uses information within the RADIUS message, such as the User-Name or Called-Station-ID RADIUS attributes, to route the RADIUS message to the appropriate RADIUS server.

A RADIUS proxy can be used as a forwarding point for RADIUS messages when the authentication, authorization, and accounting must occur at multiple RADIUS servers in different organizations.

**User Accounts Databases**
The user account database is the list of user accounts and their properties that can be checked by a RADIUS server to verify authentication credentials and user account properties containing authorization and connection parameter information.

The user account databases that IAS can use are the local Security Accounts Manager (SAM), a Microsoft Windows NT Server 4.0 domain, or the Active Directory directory service and user accounts database included with Windows Server 2003 and Windows 2000. For Active Directory, IAS can provide authentication and authorization for user or computer accounts in the domain in which the IAS server is a member, two-way trusted domains, and trusted forests with domain controllers running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

If the user accounts for authentication reside in a different type of database, IAS can be configured as a RADIUS proxy to forward the authentication request to a RADIUS server that does have access to the user account database. Different databases for Active Directory include untrusted forests, untrusted domains, or one-way trusted domains.

**IAS Features**
IAS in Windows Server 2003 has an extensive set of features. The core IAS features were introduced in Windows 2000 Server operating system; and new IAS features have been added to Windows Server 2003.

**Core IAS Features**
Core IAS features offer advantages such as multiple authentication methods and centralized administration for access servers.

**Authentication Methods**
The protection of user account credentials during the authentication of users attempting connections is an important security concern. IAS supports a variety of authentication protocols and allows you to use arbitrary authentication methods to meet your requirements for authentication.

- Password-based Point-to-Point Protocol (PPP) authentication protocols. PPP is a set of industry-standard framing and authentication protocols that enables remote access solutions to be interoperable in a multivendor network. IAS supports the authentication protocols within PPP, such as Password Authentication Protocol, CHAP, Microsoft Challenge Handshake Authentication Protocol (MS-CHAP v1), MS-CHAP version 2 (MS-CHAP v2), and Extensible Authentication Protocol (EAP).

- EAP and PEAP. An Internet standards-based infrastructure that allows the addition of arbitrary authentication methods, such as smart cards, certificates, one-time passwords, and token cards. A specific authentication method that uses the EAP infrastructure is an EAP type. IAS includes support for EAP-Message Digest 5 (MD5) and EAP-Transport Layer Security (EAP-TLS), as well as PEAP-MS-CHAP v2 and PEAP-TLS.

**Various Authorization Methods**
IAS supports a number of authorization methods and allows you to add custom methods that meet your authorization requirements. The supported authorization methods are:

- Dialed Number Identification Service (DNIS). The authorization of a connection attempt that is based on the number called. DNIS supplies the number that was called to the call receiver and is provided by most standard telephone companies.

- Automatic Number Identification/Calling Line Identification (ANI/CLI). The authorization of a connection attempt that is based on the phone number of the caller. ANI/CLI service supplies the number of the caller to the call receiver and is provided by most standard telephone companies.

- Guest authentication. The authorization of a connection when the caller does not send a user name or password during the authentication process. If unauthenticated access is enabled, the Guest account is used by default as the identity of the caller.

**Centralized user Authentication and Authorization**
To authenticate a connection request, IAS validates the connection credentials against user and computer accounts in the local SAM, a Windows NT Server 4.0 domain, or an Active Directory domain. For an Active Directory domain, IAS supports the use of Active Directory user principal names and universal groups.

To authorize a connection request, IAS uses the dial-in properties of the user account that correspond to both the connection credentials and remote access policies. One of the elements of authorization is remote access permission, which can be set both on the user or computer account and the remote access policy. Although it is relatively easy to manage remote access permission for each user account, this approach does not scale well as an organization grows. Remote access policies provide a more powerful and flexible way to manage remote access permission.

With remote access policies, you can authorize network access based on various conditions, including:

- User account membership in a group.
- The time of day or day of the week.
- The type of media by which the user is connecting (for example, wireless, Ethernet switch, modem, or VPN).
- The phone number that the user calls.
- The access server from which the request arrives.

By configuring profile settings on remote access policies, you can control many connection parameters, including:

- The use of specific authentication methods.
- The idle time-out.
- The maximum time of a single session.
- The number of links in a multilink session.
- The use of encryption and its strength.
- The use of packet filters to control what the remote access user can access when connected to the network. For example, you can use filters to control which IP addresses, hosts, and ports the user is allowed to use in sending or receiving packets.
- The creation of a compulsory tunnel that forces all packets from that connection to be securely tunneled through the Internet and then terminated in a private network.
- The virtual local area network identifier for wireless or Ethernet connections.

**Heterogeneous Access Servers**
IAS supports NASs that are compliant with RADIUS RFCs 2865 and 2866. In addition to dial-up access servers, IAS also supports the following:

- Wireless access points. By using remote access policies and the Wireless-IEEE 802.11 port type condition, IAS can be used as a RADIUS server for wireless access points that use RADIUS for authentication and authorization of wireless nodes.
- Authenticating switches. By using remote access policies and the Ethernet port type condition, IAS can be used as a RADIUS server for Ethernet network switches that use RADIUS for authentication and authorization of switch nodes.
- Computers running Windows Server 2003 or Windows 2000 and the Routing and Remote Access service. A computer running the Routing and Remote Access service can be configured as a dial-up server, a VPN server, or a VPN router for dial-up or persistent site-to-site (also known as router-to-router) connections between networks. IAS and the Routing and Remote Access service use the same remote access policies and log files. This integration provides a consistent

implementation for both IAS and the Routing and Remote Access service. It enables you to deploy Routing and Remote Access at small sites without the requirement of a separate, centralized IAS server. It also provides the ability to scale to a centralized remote access management model whenever you have multiple Routing and Remote Access servers in your organization. IAS, in conjunction with Routing and Remote Access servers, implements a single point of administration for remote access to your network for outsourced-dial, demand-dial, and VPN access. The policies within IAS at a central and large site can be exported to the independent Routing and Remote Access server in a small site.

### Note

- A site-to-site VPN connection is typically used to connect remote offices together when both routers are connected to the Internet by permanent wide area network (WAN) links, such as T1 or Frame Relay. In this configuration, the VPN connection is always available. However, when a permanent WAN link is not possible or practical, you can configure a dial-up site-to-site VPN connection.

**Centralized Administration for All Access Servers**
Support for the RADIUS standard allows IAS to control connection parameters for any NAS that implements RADIUS. The RADIUS standard also allows individual access server vendors to create proprietary extensions called vendor-specific attributes (VSAs). IAS has incorporated the extensions from a number of vendors in its dictionary of attributes. In circumstances where an attribute is not included in the IAS dictionary of attributes, additional VSAs can be created and added to the profile of individual remote access policies.

**Outsourced Dial-Up and Wireless Network Access**
Outsourced dialing (also known as wholesale dialing) provides a contract between an organization and an ISP. The ISP allows employees of the organization to connect to its network before the VPN tunnel to the private network of the organization is established. When an employee of the organization connects to the network access server of the ISP, the authentication and records of usage are forwarded to the IAS server at the organization. The IAS server enables the organization to control user authentication, track usage, and determine which employees are allowed to access the network of the ISP.

The advantages of outsourced dialing are the potential financial and administrative savings. By using an ISP's hardware and wide area network (WAN) links instead of purchasing and installing your own, you might save a great deal on infrastructure costs. If traveling or remotely located employees dial in to an ISP that has worldwide connections, making a local rather than a long distance connection, you might significantly decrease your long-distance phone bill. And by moving support requirements to the provider, you might eliminate administrative costs.

You can also outsource wireless access. A vendor can provide wireless access in a remote location and use IAS as a RADIUS proxy to forward your employee connection requests to a RADIUS server on your network for authentication and authorization.

**Centralized, Scalable Auditing and Usage Accounting**
You can use IAS as a RADIUS server to centralize the accounting data from many NASs, and you can use IAS SQL Server logging to further centralize accounting data by configuring multiple IAS servers to log to the same database on a computer running SQL Server 2000. Support for the RADIUS standard allows IAS to collect the usage (accounting) records sent by many access servers configured as RADIUS clients to the IAS server. IAS logs audit information (for example, authentication accepts and rejects) and usage information (for example, logon and logoff records) to log files. IAS supports a text-based log-file format that can be directly imported into a database, as well as SQL Server logging, where IAS passes accounting data to the SQL Server Desktop Engine (MSDE 2000) or SQL Server 2000 in XML format. After the accounting data in the database is collected, it can be queried and analyzed by non-Microsoft data-analysis software.

**IAS Integration with the Routing and Remote Access Service**
The Routing and Remote Access service can be configured to use Windows authentication and accounting, or to use RADIUS authentication and accounting. When RADIUS authentication or accounting is selected, any RFC-compliant RADIUS server can be used. However, using an IAS server is recommended to achieve the optimum level of integration in Windows Server 2003 or Windows 2000 environments and to take advantage of centralized remote access policies.

For example, in a small network environment or branch offices with a small number of remote access servers and no requirements for centralized management of remote access, the Routing and Remote Access service can be configured to use Windows authentication and accounting.

In a global enterprise with large numbers of different types of access servers deployed worldwide, centralized authentication and accounting using IAS can be beneficial. However, if a small remote office is configured with a low bandwidth connection to the global organization with the centralized IAS server, the Routing and Remote Access service servers at the branch office can be configured with Windows authentication and accounting and the remote access policy configuration can be copied from a

central location to the remote access servers of the remote office.

IAS and the Routing and Remote Access service share the same remote access policies and authentication capabilities. When the Routing and Remote Access service is configured for Windows authentication, local remote access policies are used, and logging is recorded in a local file by default. You can also configure the Routing and Remote Access service to log accounting data to a database on a computer running Microsoft SQL Server 2000.

When the Routing and Remote Access service is configured as a RADIUS client to an IAS server, the remote access policies of the IAS server are used and logging is recorded in a local file on the IAS server or, when IAS SQL Server logging is configured on the IAS server, to a SQL Server 2000 database.

Because the policies within IAS at a central large site can be exported to the independent remote access server in a small site, a consistent implementation across IAS and the Routing and Remote Access service is provided. It allows you to deploy the Routing and Remote Access service at small sites without the need for a separate, centralized IAS server; it also provides the capability to scale up to a centralized remote access management model when the need arises to do so. In this case, IAS in conjunction with remote access servers implements a single point of administration for remote access to your network for outsourced-dial, demand-dial, and VPN access.

**Graphical User Interface**
You can configure IAS by using the IAS Microsoft Management Console (MMC) snap-in, which enables you to configure local or remote IAS servers. You can add multiple IAS servers to a single snap-in, providing ease of management for many servers using one interface. If you install the Windows Server 2003 Administrative Tools Pack on a computer running Microsoft Windows XP Professional, you can use the IAS snap-in from the client computer to manage your IAS servers.

**Remote Monitoring**
You can monitor IAS by using Windows Server 2003–based tools, such as Event Viewer, Performance Logs and Alerts, and Simple Network Management Protocol (SNMP). You can also use Network Monitor to capture RADIUS messages for detailed traffic analysis and troubleshooting.

**Scalable Configurations**
You can scale IAS to network configurations of varying size, from stand-alone servers for small networks to large corporate and ISP networks. As your network grows, you can add access servers, IAS proxy servers, and IAS servers to scale up and out, exporting and importing server configurations to minimize administrative overhead. IAS logging to SQL Server databases also provides the ability to scale the logging of network session information.

**Import and Export of Configuration to Manage Multiple IAS Servers**
An IAS server configuration can be exported in part or total by using the Netsh commands for network access authentication, authorization, accounting, and auditing. For example, you can export the full configuration of an IAS server using the **netsh aaaa show config** command at the command prompt, or you can export only the remote access policies of the server using the **netsh aaaa show remote_acces_policies** command.

### Note

- The configuration of IAS servers running operating systems in the Windows 2000 Server family can be imported into products in the Windows Server 2003 family with netsh AAAA commands. The reverse, however, is not possible.

**New IAS Features Supported by Windows Server 2003**
In response to advancements in the RADIUS protocol and network access technologies, new features have been added to IAS in Windows Server 2003. For example, IAS in Windows Server 2003 provides support for: RADIUS proxy, mapping network authentication and authorization for IAS proxy. Support for IEEE 802.1X wireless and authenticating switches and PEAP for 802.11 wireless clients has also been added.

**RADIUS Proxy**
In addition to RADIUS server support, Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition provide RADIUS proxy support. With RADIUS proxy support, you can use IAS as a RADIUS message router or forwarder. Based on attributes in the incoming RADIUS message, the RADIUS proxy forwards the message to a specific RADIUS server or client.

You can configure IAS as a RADIUS proxy by using connection request processing and remote RADIUS server groups. Connection request processing is a set of rules that determine how an incoming connection request is processed: It is either authenticated and authorized by the IAS server (when the IAS server is being used as a RADIUS server), or it is forwarded to another RADIUS server for authentication and authorization (when the IAS server is being used as a RADIUS proxy). When IAS is being used as a proxy, it forwards the connection request to a member of a remote RADIUS server group.

By correctly configuring connection request processing rules and remote RADIUS server groups, an IAS server can be used as a

RADIUS server for some requests and a RADIUS proxy for others. The IAS proxy also provides the ability to balance RADIUS requests across multiple RADIUS servers, to detect both which RADIUS servers are no longer available and when they become available again.

**Mapping Network Authentication and Authorization for IAS Proxy**
When you map a user account in a remote user accounts database to a user account in a local user accounts database, the proxy component of IAS can separate the authentication and authorization of connection requests. IAS sends the authentication request to the remote IAS server and processes the authorization request locally. The IAS proxy can forward password-based user credentials to an external RADIUS server for authentication, and perform authorization against a user account in an Active Directory domain and a locally configured remote access policy.

### Note

- Members of a remote RADIUS server group can be IAS servers that authenticate connection requests by using Active Directory or they can be third-party RADIUS servers that can perform authentication by using other user account databases. Regardless of the user accounts database or RADIUS server used with account mapping, authorization is performed on the local IAS proxy.

To configure IAS to split authentication and authorization between two different IAS servers and user accounts databases, you can map the realm portion of a user name to a remote RADIUS server for authentication, even if that RADIUS server is located on another private network.

For example, IAS can authenticate a visitor from a partner organization by using the partner organization RADIUS server and user accounts database. IAS then authorizes access to your network by using connection request policy settings on your IAS server and a Windows user accounts database in an Active Directory domain that is established for visitor accounts.

You can configure the proxy component with the Remote-RADIUS-to-Windows-User-Mapping attribute in the advanced properties of a connection request policy.

**IEEE 802.1X Wireless Access Points and Authenticating Switches**
IAS provides authentication, authorization, and accounting for connections that use the link-layer standard IEEE 802.1X for wireless and switch access.

**Wireless access points**
Wireless networking technology has become more widely used since the adoption of wireless industry standards such as IEEE 802.11b, 802.11a, and 802.11g. You can use wireless networking to roam within a building or area and connect automatically to a network when you are within range of a wireless access point beacon.

While providing convenience, wireless networking technologies and wireless access points have the following security risks:

- Anyone who has a compatible wireless network adapter can gain access to the network.

- Wireless networking signals use radio waves to send and receive information. Anyone within an appropriate distance to a wireless access point can detect and receive all data sent to and from the wireless access point.

To counter the first security risk, wireless access points must require authentication and authorization of the wireless node before data can be sent to and received from the network to which the wireless access point is attached. To provide their own authentication and authorization, each wireless access point should require a user account database with each user's account credentials and a set of rules by which authorization is granted.

Because maintaining separate user accounts databases for each wireless access point is difficult to manage, it is recommended that you use wireless access points that function as RADIUS clients, and use the industry standard RADIUS protocol to send connection request and accounting messages to a central RADIUS server. The RADIUS server has access to a user account database and a set of rules for granting authorization. The RADIUS server processes the wireless access point's connection request and either accepts or rejects the connection request.

To counter the second security risk, the data sent between the wireless nodes and the wireless access points must be encrypted. Therefore, the authentication method that the wireless node uses must allow for the determination of encryption keys that are used to encrypt data.

IAS supports wireless access authentication by means of the following:

- The use of PEAP with MS-CHAP v2 for secure password-based authentication and fast reconnect when users roam with wireless computers between wireless access points that are configured as RADIUS clients to the same RADIUS server.

- The use of EAP-TLS to provide certificate-based authentication and the management of encryption keys that are used to encrypt data sent between wireless access points and wireless nodes.

- The use of the Wireless-IEEE 802.11 and Wireless-Other port types when configuring the NAS-Port-Type condition of remote access policies. By using these port types, you can create a separate remote access policy that contains connection parameters and encryption settings that are specifically designed for wireless nodes.

- By providing a means to grant guest access for a wireless client that does not have a certificate installed or a set of valid account name/password credentials.

**Authenticating switch support**

A network switch provides selective filtering of the traffic received on each port of the switch and allows better traffic management by segmenting a network. A typical switch, however, sends and receives packets to any node that is connected to the switch, and does not perform any authentication to verify that the user has permission to access the network. This can be a problem, for example, if switch ports are installed in a conference room. A person from another organization can simply connect a network adapter to the switch port and gain instant access to the network.

To prevent physical layer access to the network, newer switches can be configured to require switch node authentication and authorization before data is sent to or received from the network node that is attached to the switch. To provide its own authentication and authorization, each switch is required to have a user account database. This database contains each users authentication credentials and a set of rules by which authorization is granted. Multiple individual databases are difficult to manage; however, newer switches can serve as a RADIUS client, using the industry-standard RADIUS protocol to send connection requests and accounting messages to a central RADIUS server. The RADIUS server has access to a user account database and a set of rules for granting authorization. The RADIUS server processes the connection request from the switch and either accepts or rejects the request.

Typically, as the data sent to and from the switch node travels on the wire between the switch node and the switch, encryption of the sent data is neither required nor implemented.

IAS supports switch access authentication by the following means:

- EAP-TLS provides computer or user certificate-based authentication.

- The NAS-Port-Type condition of remote access policies is configured for the Ethernet port type. By using this port type, you can create a separate remote access policy containing connection parameters that are specifically designed for switch nodes.

Virtual local area network (VLAN) switching is used on the basis of whether or not the switch access client is authenticated.

**PEAP for 802.11 Wireless Clients**

PEAP provides protection for clients and authenticators (IAS or RADIUS servers) that are using EAP. The next generation of EAP and PEAP uses Transport Layer Security (TLS) to create end-to-end communication between client and authenticator after the identity of the authenticator is verified.

PEAP creates a session key that is used to derive keys for the encryption of authentication traffic between the wireless client and the IAS server. It also provides smooth and efficient roaming between wireless access points that are configured as RADIUS clients on the same IAS server.

You can use PEAP with two different authentication types: PEAP-MS-CHAP v2 or PEAP-TLS. PEAP-MS-CHAP v2 provides secure password authentication for 802.1X wireless and authenticating switch clients. PEAP-MS-CHAP v2 can be used to complement the security of MS-CHAP v2, and it does not require deployment of user or computer certificates on the client computer. A server certificate is required on the IAS server. With PEAP-MS-CHAP v2, you can obtain a server certificate from a third party certification authority, such as Verisign, instead of deploying your own public key infrastructure (PKI).

You can also use PEAP-TLS, which provides strong security by means of a PKI with certificates. A computer certificate installed on the IAS server is used to authenticate the IAS server and a locally-installed computer and user certificate or a smart card on the wireless client is used to authenticate the wireless client. When you use PEAP-TLS, client certificate information is encrypted, providing improved security over the use of EAP-TLS without PEAP.

**Note**

- When you deploy both PEAP and EAP unprotected by PEAP on the same network, do not use the same EAP authentication type with and without PEAP for the same network access type. For example, if you deploy PEAP-TLS on your wireless network, do not also deploy EAP-TLS. Deploying authentication methods with the same type (one with and the other without the protection of PEAP) for the same network access type creates a security issue.

**Enhanced EAP Configuration for Remote Access Policies**
In Microsoft Windows 2000 Server, you can select only a single EAP type when configuring the kind of authentication allowed by a remote access policy. All connections matching the conditions of the policy must use this single EAP type, which is selected in the policy profile settings. Additionally, the configuration of an EAP type is global for all of the remote access policies configured on the IAS server. This can cause problems when you want to either individually configure the properties for EAP types for each policy or select multiple EAP types by group or for a specific kind of network connection.

In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, these limitations are removed for IAS.

For example, you can select different computer certificates for VPN connections and EAP-TLS authentication for wireless connections, or you can select multiple EAP types for wireless connections in the circumstance where some of your wireless clients use EAP-TLS authentication, and some of them use PEAP-MS-CHAP v2.

**Network Access Quarantine Control**
Network Access Quarantine Control provides phased network access, which restricts remote clients to quarantine mode until each client is either verified as meeting or configured according to organization network access policy. Quarantine mode is applied by a VPN server running Windows Server 2003 and the Routing and Remote Access service. Quarantine mode is created using a session timer, or an IP filter, or both. The IP filter and session timer are configured in a remote access policy in the IAS snap-in. After the client computer configuration is verified as meeting organization network policy by an administrator-provided script that runs on the client, the quarantine restrictions are removed from the to the connection. To deploy this feature, you must use Connection Manager Administration Kit, the Routing and Remote Access service, and additional components deployed on clients and access servers.

**Logging to a SQL Server Database**
You can use Microsoft SQL Server 2000 to log IAS accounting information, such as user authentication requests, accounting requests, and periodic data, to a database that warehouses data from multiple IAS servers. To diminish cost and increase logging performance, you can install the Microsoft SQL Server Desktop Engine (MSDE 2000) on each IAS server, and then periodically publish records from the MSDE 2000 database on each IAS server to the central database on the SQL Server, providing comprehensive data views for troubleshooting network access authentication and report creation.

**Ignoring the Dial-In Properties of User Accounts**
To ignore the dial-in properties of user accounts, you can configure a RADIUS attribute on the profile properties of a remote access policy. The dial-in properties of the user account contain the following properties:

- Remote access permission
- Caller-ID
- Callback options
- Static IP address
- Static routes

To support multiple types of connections for which IAS provides authentication and authorization, you might need to disable the processing of user account dial-in properties. This can be done to support scenarios in which specific dial-in properties are not required.

For example, the caller-ID, callback, static IP address, and static routes properties are designed for a client that is dialing into a NAS, not for wireless access points. A wireless access point that receives these settings in a RADIUS message might not be able to process them, which could cause the wireless client to be disconnected. When IAS provides authentication and authorization for users who are both dialing in and accessing the organization network by means of wireless technology, the dial-in properties must be configured to support either dial-in connections (by setting dial-in properties) or wireless connections (by not setting dial-in properties).

You can use IAS to enable dial-in properties processing for the user account in some scenarios (such as dial-up connections)

and to disable dial-in properties processing for user account dial-in properties in other scenarios (such as wireless and authenticating switch). This is accomplished by configuring the **Ignore-User-Dialin-Properties** attribute on the **Advanced** tab of the profile settings for a remote access policy.

The **Ignore-User-Dialin-Properties** attribute is set to the following options:

- To enable user account dial-in properties processing, delete the **Ignore-User-Dialin-Properties** attribute or set it to **False**. For example, for a remote access policy that is designed for dial-in connections, no additional configuration is required.

- To disable user account dial-in properties processing, set the **Ignore-User-Dialin-Properties** attribute to the value of **True**. For example, this is set for the remote access policy that is designed for wireless or authenticating switch connections. When the dial-in properties of the user account are ignored, remote access permission is determined by the remote access permission setting in the remote access policy.

You can also use this attribute to manage network access control by means of groups and the remote access permissions on the remote access policy. By setting the **Ignore-User-Dialin-Properties** attribute to the value of **True**, the remote access permission on the user account is ignored. The disadvantage to using the **Ignore-User-Dialin-Properties** attribute in this way is that you cannot use the additional dial-in properties of caller-ID, callback, static IP address, and static routes.

**Note**

- The **Ignore-User-Dialin-Properties** attribute disables the use of all dial-in properties for the user account. Specific dial-in properties cannot be selectively disabled.

#### Configuring RADIUS Clients by IP Address Range

For IAS in Windows 2000, you must specify a RADIUS client by IP address or by DNS name. In addition, you must configure each RADIUS client separately, even if you have a number of RADIUS clients on the same subnet. While this is not an issue for typical dial-in or VPN access server configurations, wireless access points are frequently deployed in large numbers on the same subnet, and configuring each wireless access point as a RADIUS client at the RADIUS server can be time consuming.

In Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, you can use IAS to specify a group of RADIUS clients by using an IP address range. This simplifies the configuration of multiple RADIUS clients that are on the same network segment, or that are configured on a virtual local area network (VLAN). When you configure RADIUS clients by IP address range, all RADIUS clients in the range must be identically configured and use the same shared secret.

When you configure RADIUS clients using this method, the IP address range for RADIUS clients is expressed in the network prefix length notation *w.x.y.z/p*, where *w.x.y.z* is the dotted decimal notation of the address prefix and *p* is the prefix length (the number of high order bits that define the network prefix). This is also known as Classless Inter-Domain Routing notation. An example is 192.168.21.0/24. To convert from subnet mask notation to network prefix length notation, *p* is the number of high-order bits set to one in the subnet mask.

**Note**

- You cannot configure RADIUS clients by using the IP address range in IAS for Windows Server 2003, Standard Edition.

#### Computer Authentication

In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, Active Directory and IAS support the authentication of computer accounts by using standard user authentication methods, such as PPP. This allows a computer and its computer certificate to be authenticated for wireless or authenticating switch access clients.

#### Checking User Certificate Purposes

To enforce the use of specific types of user certificates for specific connection types, you can configure IAS to check the purposes, also called object identifiers (OIDs), of certificates in their Enhanced Key Usage (EKU) extensions when the client computer supplies the certificate as proof of identity.

When PEAP-TLS or EAP-TLS are configured as authentication methods for a remote access policy in IAS, the access client can send a smart card certificate or a user certificate from the client computer certificate store during the authentication process.

Because smart card certificates are more secure than certificates from the client computer certificate store, you might want to ensure that remote access VPN connections use a smart card certificate for user authentication instead of a locally-installed

user certificate. In this case, you can configure a remote access policy to require that the user certificate EKU extensions contain the **Smart Card Logon** purpose object identifier (1.3.6.1.4.1.311.20.2.2). When the VPN client offers the smart card certificate for user authentication, the IAS server checks the EKU extensions according to remote access policy. Because the **Smart Card Logon** object identifier is present in the VPN client certificate, authentication succeeds.

You can configure more than one object identifier that is required to be present in the user certificate, which the access client offers to IAS. To configure more than one object identifier, use the **Allow certificates with these OIDs** attribute on the **Advanced** tab in the properties of a remote access policy profile. No required OIDs are specified by default.

**Improved Support for Attribute Manipulation**
In Windows 2000, you can use IAS to manipulate the contents of the User-Name RADIUS attribute. Using connection request policies in IAS for Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, you can manipulate the User-Name, Called-Station-ID, and Calling-Station-ID RADIUS attributes.

**Authentication Type Remote Access Policy Condition**
You can create remote access policies by using the Authentication Type condition. You can use Authentication Type to specify connection constraints that are based on the authentication protocol or method that is used for authentication by the access client.

**Improved Support for the Class Attribute**
In Windows 2000, IAS generates a value for the Class attribute and appends it to the existing value of the Class attribute received in the RADIUS request message by NASs that send the Class attribute. The result is the Class attribute in the RADIUS response message. In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition:

- You can disable the automatic generation of a value for the Class attribute by using **Generate-Class-Attribute** on the **Advanced** tab in the properties of a remote access policy profile. Automatic generation of a value for the Class attribute is disabled by default.

- Instead of appending the generated value of the Class attribute to the existing Class attribute, IAS creates a separate Class attribute. The RADIUS response message contains both the original Class attribute and the second Class attribute that IAS generates.

### Note

- To provide the best session correlation for applications that query the accounting log, it is recommended that you use NASs that are capable of sending the Class attribute.

# How IAS Technology Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- RADIUS Protocol
- IAS Roles
- IAS as a RADIUS Server
- IAS as a RADIUS Proxy

Internet Authentication Service (IAS) is the Microsoft implementation of a Remote Authentication Dial-In User Service (RADIUS) server and proxy in Microsoft Windows Server 2003; Standard Edition, Windows Server 2003; Enterprise Edition, and Windows Server 2003; Datacenter Edition. As a RADIUS server, IAS performs centralized connection authentication, authorization, accounting, and auditing (AAAA) for many types of network access, including wireless, authenticating switch, dial-up and virtual private network (VPN) remote access, and router-to-router connections. As a RADIUS proxy, IAS forwards authentication and accounting messages to other RADIUS servers. IAS supports the Internet Engineering Task Force (IETF) standards for RADIUS described in RFC 2865 and RFC 2866.

**RADIUS Protocol**

RADIUS is an industry standard protocol described in RFC 2865, "Remote Authentication Dial-in User Service (RADIUS)," and RFC 2866, "RADIUS Accounting." RADIUS is used to provide authentication, authorization, and accounting services. A RADIUS client, — typically a dial-up server, VPN server, or wireless access point (AP) — sends user credentials and connection parameter information in the form of a RADIUS message to a RADIUS server. The RADIUS server authenticates and authorizes the RADIUS client request, and sends back a RADIUS message response. RADIUS clients also send RADIUS accounting messages to RADIUS servers. Additionally, the RADIUS standards support the use of RADIUS proxies. A RADIUS proxy is a computer that forwards RADIUS messages between RADIUS-enabled computers.

RADIUS messages are sent as UDP messages. UDP port 1812 is used for RADIUS authentication messages and UDP port 1813 is used for RADIUS accounting messages. Some network access servers (NASs) might use UDP port 1645 for RADIUS authentication messages and UDP port 1646 for RADIUS accounting messages. By default, IAS supports receiving RADIUS messages sent to both sets of UDP ports.

The RADIUS protocol is implemented solely between NASs (RADIUS clients) and IAS servers and proxies (RADIUS servers and proxies). A user's client computer does not use the RADIUS protocol when connecting to a NAS.

**RADIUS Authentication Process**

The RADIUS authentication process begins when a user attempts to access a network through a NAS that is configured as a RADIUS client to a RADIUS server.

For example, when the remote access user sends credentials using the Challenge Handshake Authentication Protocol (CHAP), the RADIUS client creates a RADIUS Access-Request message containing such attributes as the Port ID the user is accessing and the results of the CHAP authentication process (the user name, the challenge string, and the response of the remote access client).

The RADIUS Access-Request message is sent from the RADIUS client to the RADIUS server. If a response is not received within a length of time, the request is re-sent. The RADIUS client can also be configured to forward requests to an alternate server or servers in the event that the primary server is down or unreachable. An alternate server can be used either after a specified number of tries to the primary server are not responded to, or in a round-robin fashion.

In the case of the Routing and Remote Access service, multiple RADIUS servers can be added and prioritized using a scoring mechanism. If a primary RADIUS server does not respond within three seconds, the Routing and Remote Access service automatically switches to the RADIUS server with the next highest score.

After the RADIUS server receives the request, it validates the sending RADIUS client. Validation occurs by verifying that the RADIUS Access-Request message is sent from a configured RADIUS client. If the Access-Request message is sent by a valid

RADIUS client, and if the Message-Authenticator attribute is required for the RADIUS client, the value of the Message-Authenticator attribute is verified using the RADIUS shared secret. If the Message-Authenticator attribute is either missing or contains an incorrect value, the RADIUS message is silently discarded — that is, the message is discarded without logging an event in the Event Log or making an entry in the IAS accounting log.

If the RADIUS client is valid, the RADIUS server consults a database of users to find the user whose name matches the User-Name attribute in the request. The user account contains a list of requirements that must be met to allow access for the user. This list of requirements can include verification of the password, and it can also specify whether the user is allowed access.

If any condition where the authentication or authorization is not met, the RADIUS server sends a RADIUS Access-Reject message in response, indicating that this user request is not valid.

If all conditions are met, the list of configuration values for the user is placed into a RADIUS Access-Accept message that is sent back to the RADIUS client. These values include a list of RADIUS attributes and all necessary values to deliver the desired service. For Serial Line Internet Protocol (SLIP) and Point-to-Point Protocol (PPP) service types, this can include values such as encryption types, the Class attribute, Maximum Transmission Unit (MTU), as well as the desired compression and packet filter identifiers.

**RADIUS Message Format**

The following section provides information that might be useful for the following:

- Understanding a Network Monitor capture.
- Understanding the different message formats for analyzing the accounting log.
- Entering vendor-specific attribute (VSA) numbers.

RADIUS messages sent to the RADIUS server are sent as UDP messages. RADIUS authentication messages are sent using UDP port 1812, and RADIUS accounting messages are sent on UDP port 1813. Some older NASs use UDP port 1645 for RADIUS authentication messages and UDP port 1646 for RADIUS accounting messages.

IAS supports the receiving of RADIUS messages on any configurable set of ports; however by default it is configured to receive messages on both sets of UDP ports. Exactly one RADIUS message is encapsulated in the UDP payload.

**General Packet Structure**

The figure, "General Structure of RADIUS Packet," provides a summary of the data structure of a RADIUS packet. The RADIUS client or server sends the fields from top to bottom, or from the Code field in vertical order to the Attributes.

### General Structure of RADIUS Packet

**Code field**

The Code field is 1 byte long and indicates the type of RADIUS message. A message with an invalid Code field is silently discarded. The defined values for the RADIUS Code field are listed in the following table "Values for the RADIUS Code Field."

### Values for the RADIUS Code Field

| Codes (Decimal) | Packets |
|---|---|
| 1 | Access-Request |
| 2 | Access-Accept |
| 3 | Access-Reject |
| 4 | Accounting-Request |
| 5 | Accounting-Response |
| 11 | Access-Challenge |

| | |
|---|---|
| 12 | Status-Server (experimental) |
| 13 | Status-Client (experimental) |
| 255 | Reserved |

**Identifier field**

The Identifier field is 1 byte long and is used to match a request with its corresponding response.

**Length field**

The Length field is two octets long and indicates the entire length of the RADIUS message, including the Code, Identifier, Length, and Authenticator fields, and the RADIUS attributes. The Length field can vary from 20 to 4,096 bytes.

**Authenticator field**

The Authenticator field is sixteen octets long and contains the information that the RADIUS client and server use to verify that the message came from a computer that is configured with a common shared secret

**Attributes section**

The Attributes section of the RADIUS message contains one or more RADIUS attributes, which carry the specific authentication, authorization, information, and configuration details for RADIUS messages.

**RADIUS Attributes**

The figure, "RADIUS Attribute Structure," shows the structure of each RADIUS attribute. RADIUS attributes use the common Type-Length-Value format used by other protocols.

**RADIUS Attribute Structure**

**Type field**

The Type field is 1 byte long and indicates the specific type of RADIUS attribute. The RADIUS Standard attributes are listed in the following table, "RADIUS Standard Attribute Types." For information about other RADIUS attributes and their use, see RFCs 2865 and 2866.

### RADIUS Standard Attribute Types

| Type Values | Description | Type Values | Description |
|---|---|---|---|
| 1 | User-Name | 45 | Acct-Authentic |
| 2 | User-Password | 46 | Acct-Session-Time |
| 3 | CHAP-Password | 47 | Acct-Input-Packets |
| 4 | NAS-IP-Address | 48 | Acct-Output-Messages |
| 5 | NAS-Port | 49 | Acct-Terminate-Cause |
| 6 | Service-Type | 50 | Acct-Multi-Session-Id |
| 7 | Framed-Protocol | 51 | Acct-Link-Count |
| 8 | Framed-IP-Address | 52 | Acct-Input-Gigawords |
| 9 | Framed-IP-Netmask | 53 | Acct-Output-Gigawords |
| 10 | Framed-Routing | 55 | Event-Timestamp |
| 11 | Filter-ID | 60 | CHAP-Challenge |
| 12 | Framed-MTU | 61 | NAS-Port-Type |
| 13 | Framed-Compression | 62 | Port-Limit |

| | | | |
|---|---|---|---|
| 14 | Login-IP-Host | 63 | Login-LAT-Port |
| 15 | Login-Service | 64 | Tunnel-Type |
| 16 | Login-TCP-Port | 65 | Tunnel-Medium-Type |
| 18 | Reply-Message | 66 | Tunnel-Client-Endpt |
| 19 | Callback-Number | 67 | Tunnel-Server-Endpt |
| 20 | Callback-Id | 68 | Acct-Tunnel-Connection |
| 22 | Framed-Route | 69 | Tunnel-Password |
| 23 | Framed-IPX-Network | 70 | ARAP-Password |
| 24 | State | 71 | ARAP-Features |
| 25 | Class | 72 | ARAP-Zone-Access |
| 26 | Vendor-Specific | 73 | ARAP-Security |
| 27 | Session-Time-out | 74 | ARAP-Security-Data |
| 28 | Idle-Time-out | 75 | Password-Retry |
| 29 | Termination-Action | 76 | PROMPT |
| 30 | Called-Station-Id | 77 | Connect-Info |
| 31 | Calling-Station-Id | 78 | Configuration-Token |
| 32 | NAS-Identifier | 79 | EAP-Message |
| 33 | Proxy-State | 80 | Message-Authenticator |
| 34 | Login-LAT-Service | 81 | Tunnel-Pvt-Group-ID |
| 35 | Login-LAT-Node | 82 | Tunnel-Assignment-ID |
| 36 | Login-LAT-Group | 83 | Tunnel-Preference |
| 37 | Framed-AppleTalk-Link | 84 | ARAP-Challenge-Response |
| 38 | Framed-AppleTalk-Network | 85 | Acct-Interim-Interval |
| 39 | Framed-AppleTalk-Zone | 86 | Acct-Tunnel-Packets-Lost |
| 40 | Acct-Status-Type | 87 | NAS-Port-Id |
| 41 | Acct-Delay-Time | 88 | Framed-Pool |
| 42 | Acct-Input-Octets | 90 | Tunnel-Client-Auth-ID |
| 43 | Acct-Output-Octets | 91 | Tunnel-Server-Auth-ID |
| 1 | User-Name | 45 | Acct-Authentic |
| 2 | User-Password | 46 | Acct-Session-Time |
| 44 | Acct-Session-Id | | |

**Length field**

The Length field indicates the length of the attribute, including the Type, Length, and Value fields.

**Value field**

The Value field is zero or more octets and contains information specific to the Attribute. The format and length of the Value field is based on the type of RADIUS attribute. Note that value 26 is reserved for VSAs.

**Vendor-Specific Attributes**
VSAs are available to allow vendors to support their own proprietary attributes that are not covered in RFC 2865. IAS includes VSAs from a number of vendors in its multivendor dictionary. However, this list evolves over time and new attributes, and vendors are always being added.

You can add attributes that are not in the IAS multivendor dictionary as Vendor-Specific (RADIUS standard attribute type 26) on the **Advanced** tab of a remote access policy profile. Therefore, unlike many RADIUS implementations that allow you to add attributes to their multivendor dictionary, IAS allows you to add attributes to each remote access policy profile. To use attribute type 26, an administrator must know the VSA format and the exact information to enter. The VSA formats are documented in the following section. For information about what values to enter, see your NAS documentation. The following figure, "Vendor-Specific Attribute Structure," shows the structure of the VSA structure.

### Vendor-Specific Attribute Structure

**Type value**
The Type value is set to 26 (0x1A) to indicate a VSA.

**Length value**
The Length value is set to the number of bytes in the VSA.

**Vendor-ID**
Vendor-ID is 4 octets long. The high-order octet is 0, and the low-order is 3 octets. Together, they make up the Structure and Identification of Management Information (SMI) Network Management Private Enterprise Code of the vendor.

**String field**
The String field is the VSA consisting of one or more octets. To conform to the recommendation of RFC 2865, the String field should consist of the fields as shown in the figure "Structure of the String Field."

### Structure of the String Field

**Vendor type**
The Type value is used to indicate a specific VSA for the vendor.

**Vendor length**
The Type value is set to the number of bytes in the string.

**Attribute-Specific field**
The Attribute-Specific field contains the data for the specific vendor attribute.

Vendors who do not conform to RFC 2865 use the attribute type 26 to identify a VSA but do not use the Vendor Type, Vendor Length, and Attribute-Specific fields within the String field. In this case, the VSA format appears as shown in the figure, "Structure of the String Field," earlier in this section.

When adding a VSA for a particular NAS as type 26, you need to know whether the attribute conforms to RFC 2865. For information about whether your NAS uses the VSA format documented in the figure, "Structure of the String Field," earlier in this section, see your NAS documentation.

VSAs are configured from the **Vendor-Specific Attribute Information** dialog box when adding a Vendor-Specific Attribute from the **Advanced** tab of a remote access policy profile. If the VSA format conforms to RFC 2865, use the **Yes. It conforms.** option and configure the attribute with the vendor-assigned attribute number, attribute format, and attribute value as defined in NAS documentation. If the VSA format does not conform to RFC 2865, choose **No. It does not conform,** and configure the attribute with the hexadecimal attribute value, which includes the string of the VSA format (everything after Vendor-ID) as defined in NAS documentation.

**RADIUS Message Example**
A Windows Server 2003 Point-to-Point Tunneling Protocol (PPTP) client attempts a remote access connection to a Windows

Server 2003 VPN server. The VPN server is at the IP address 10.10.210.13, and the IAS server is at the IP address 10.10.210.12.

**Access-Request Message**

The following Network Monitor capture display shows the Access-Request message sent by the VPN server to the IAS server.

```
+ IP: ID = 0x850; Proto = UDP; Len: 248
+ UDP: Src Port: Unknown, (1327); Dst Port: Unknown (1812); Length = 228 (0xE4)
  RADIUS: Message Type: Access Request(1)
  RADIUS: Message Type = Access Request
  RADIUS: Identifier = 2 (0x2)
  RADIUS: Length = 220 (0xDC)
  RADIUS: Authenticator = 8A 6F DC 03 23 5F 4B 62 CA 40 92 38 DC 75
          CB 74
  RADIUS: Attribute Type: NAS IP Address(4)
    RADIUS: Attribute type = NAS IP Address
    RADIUS: Attribute length = 6 (0x6)
    RADIUS: NAS IP address = 10.10.210.13
  RADIUS: Attribute Type: Service Type(6)
    RADIUS: Attribute type = Service Type
    RADIUS: Attribute length = 6 (0x6)
    RADIUS: Service type = Framed
  RADIUS: Attribute Type: Framed Protocol(7)
    RADIUS: Attribute type = Framed Protocol
    RADIUS: Attribute length = 6 (0x6)
    RADIUS: Framed protocol = PPP
  RADIUS: Attribute Type: NAS Port(5)
    RADIUS: Attribute type = NAS Port
    RADIUS: Attribute length = 6 (0x6)
    RADIUS: NAS port = 32 (0x20)
  RADIUS: Attribute Type: Vendor Specific(26)
    RADIUS: Attribute type = Vendor Specific
    RADIUS: Attribute length = 12 (0xC)
    RADIUS: Vendor ID = 311 (0x137)
    RADIUS: Vendor string =    _
  RADIUS: Attribute Type: Vendor Specific(26)
    RADIUS: Attribute type = Vendor Specific
    RADIUS: Attribute length = 18 (0x12)
    RADIUS: Vendor ID = 311 (0x137)
    RADIUS: Vendor string = MSRASV5.00
  RADIUS: Attribute Type: NAS Port Type(61)
    RADIUS: Attribute type = NAS Port Type
    RADIUS: Attribute length = 6 (0x6)
    RADIUS: NAS port type = Virtual
  RADIUS: Attribute Type: Tunnel Type(64)
    RADIUS: Attribute type = Tunnel Type
    RADIUS: Attribute length = 6 (0x6)
    RADIUS: Tag = 0 (0x0)
    RADIUS: Tunnel type = Point-to-Point Tunneling Protocol(PPTP)
  RADIUS: Attribute Type: Tunnel Media Type(65)
    RADIUS: Attribute type = Tunnel Media Type
    RADIUS: Attribute length = 6 (0x6)
    RADIUS: Tag = 0 (0x0)
    RADIUS: Tunnel media type = IP (IP version 4)
  RADIUS: Attribute Type: Calling Station ID(31)
    RADIUS: Attribute type = Calling Station ID
    RADIUS: Attribute length = 14 (0xE)
    RADIUS: Calling station ID = 10.10.14.226
  RADIUS: Attribute Type: Tunnel Client Endpoint(66)
    RADIUS: Attribute type = Tunnel Client Endpoint
    RADIUS: Attribute length = 14 (0xE)
    RADIUS: Tunnel client endpoint = 10.10.14.226
  RADIUS: Attribute Type: User Name(1)
    RADIUS: Attribute type = User Name

    RADIUS: User name = NTRESKIT\johndoe
  RADIUS: Attribute Type: Vendor Specific(26)
    RADIUS: Attribute type = Vendor Specific
    RADIUS: Attribute length = 24 (0x18)
    RADIUS: Vendor ID = 311 (0x137)
    RADIUS: Vendor string = _+-_e_$+fN<N
  RADIUS: Attribute Type: Vendor Specific(26)
    RADIUS: Attribute type = Vendor Specific
```

```
    RADIUS: Attribute length = 58 (0x3A)
    RADIUS: Vendor ID = 311 (0x137)
    RADIUS: Vendor string = _4
```

The RADIUS attributes sent by the VPN server include the framed protocol, the service type, the class, various tunnel attributes for the PPTP connection, and a series of VSAs for Microsoft CHAP (MS-CHAP v1) authentication. For more information about Microsoft vendor-specific RADIUS attributes, see RFC 2548.

**Access-Accept Message**

The following Network Monitor capture display shows the Access-Accept message sent by the IAS server to the VPN server.

```
+ IP: ID = 0xB18; Proto = UDP; Len: 248
+ UDP: Src Port: Unknown, (1812); Dst Port: Unknown (1327); Length = 228 (0xE4)
  RADIUS: Message Type: Access Accept(2)
  RADIUS: Message Type = Access Accept
  RADIUS: Identifier = 2 (0x2)
  RADIUS: Length = 220 (0xDC)
  RADIUS: Authenticator = 52 E19 98 2E F8 E2 D3 B7 3B E1 24 5B 72          55 9E
  RADIUS: Attribute Type: Framed Protocol(7)
    RADIUS: Attribute type = Framed Protocol
    RADIUS: Attribute length = 6 (0x6)
    RADIUS: Framed protocol = PPP
  RADIUS: Attribute Type: Service Type(6)
    RADIUS: Attribute type = Service Type
    RADIUS: Attribute length = 6 (0x6)
    RADIUS: Service type = Framed

```

The RADIUS attributes sent by the IAS server include the user name, the service type, the framed protocol, the service class, and a series of VSAs for MS-CHAP authentication.

**Validating an Incoming RADIUS Message**

For RADIUS packets for which IAS is acting as RADIUS server, IAS performs the following validation checks:

1. IAS first verifies that the RADIUS message was sent from a configured RADIUS client by checking the source IP address of the RADIUS message.

2. If the message is not from a configured RADIUS client, it is silently discarded and an event is logged in the system event log.

3. IAS checks to ensure that the packet type is valid for the port on which it was received and then checks the structure of the RADIUS message. Items checked include valid values of the Code field, the size of the RADIUS message, and the size of the RADIUS attributes in the RADIUS message. IAS also checks whether or not the attributes themselves are the expected data type. If the attribute is not the expected data type, or if the RADIUS message is malformed, the message is

discarded and an event is logged in the system event log.

4. The User-Name attribute is checked for the value of the **Ping User-Name** registry setting. If there is a match between the value of the User-Name attribute and the value of the **Ping User-Name** registry setting, IAS sends an Access-Reject for authentication requests and an accounting response for accounting requests.

5. If the Message-Authenticator attribute is present, its value is validated using the shared secret. A shared secret is a text string that serves as a password between a RADIUS server and a RADIUS client.

For RADIUS request packets for which IAS is acting as RADIUS proxy, IAS performs the following validation checks:

1. IAS first verifies that the RADIUS message was sent from a configured RADIUS client by checking the source IP address of the RADIUS message.

   If the message is not from a configured RADIUS client, it is silently discarded, and an event is logged in the system event log.

2. IAS checks to ensure that the packet type is valid for the port on which it was received and then checks the structure of the RADIUS message. Items checked include valid values of the Code field, the size of the RADIUS message, and the size of the RADIUS attributes in the RADIUS message.

   If the RADIUS message is malformed, it is silently discarded and an event is logged in the system event log.

3. IAS checks for the presence of the Proxy-State attribute and whether the value of the Proxy-State attribute corresponds to an active proxy session in the proxy session table. If the RADIUS message does not contain a valid Proxy-State attribute, it is silently discarded and an event is logged in the system event log.

4. If the Message-Authenticator attribute is present, its value is validated using the shared secret. A shared secret is a text string that serves as a password between a RADIUS server and a RADIUS client. If the Message-Authenticator attribute is required but missing, or verification of its value fails, the message is silently discarded, and an event is logged in the system event log.

For RADIUS response packets for which IAS is acting as RADIUS proxy, IAS performs the following validation checks:

1. IAS first verifies that the RADIUS message was sent from a configured remote RADIUS server by checking the source IP address of the RADIUS message.

2. If the message is not from a configured remote RADIUS server, it is silently discarded and an event is logged in the system event log.

3. IAS checks to ensure that the packet type is valid for the port on which it was received and then checks the structure of the RADIUS message. Items checked include valid values of the Code field, the size of the RADIUS message, and the size of the RADIUS attributes in the RADIUS message.

4. If the RADIUS message is malformed, it is silently discarded, and an event is logged in the system event log.

5. IAS checks for the presence of the Proxy-State attribute and whether the value of the Proxy-State attribute corresponds to an active proxy session in the proxy session table. If the RADIUS message does not contain a valid Proxy-State attribute, it is silently discarded and an event is logged in the system event log.

6. IAS checks the IP source address and UDP source port of the message against the matching entry in the proxy session table to verify that the message was sent from the remote RADIUS server to which the initial request was sent.

7. The value of the Authenticator field is checked.

   If the RADIUS message contains an invalid Authenticator field, it is silently discarded and an event is logged in the system event log. This is typically caused by mismatched shared secrets between the IAS server and the remote RADIUS server

sending the RADIUS message.

8. If the Message-Authenticator attribute is present, its value is validated using the shared secret. If the Message-Authenticator attribute is required but missing, or verification of its value fails, the message is silently discarded, and an event is logged in the system event log.

**IAS Roles**

In Microsoft Windows 2000, you can use IAS only as a RADIUS server. In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, you can use IAS as either a RADIUS server or a RADIUS proxy. In addition, you can use IAS simultaneously as both proxy and server to perform AAAA on some Access-Request messages while forwarding others to remote RADIUS server groups. For multiple domain environments, an IAS server can authenticate credentials for user accounts in the domain of which it is a member and all domains that trust this domain. To read the dial-in properties for user, you must add the computer account of the IAS server to the **RAS and IAS Servers** group for each domain.

When configuring your IAS server to function as a RADIUS server, proxy server, or both, it is important to understand how IAS processes each Access-Request message received from a RADIUS client.

**Using IAS as a RADIUS Server**

When you use IAS as a RADIUS server, Access-Request messages are authenticated with Active Directory, a Microsoft Windows NT Server 4.0 domain, or by the Security Account Manager (SAM) in Microsoft Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition. Access-Request messages are authorized with the user or computer account dial-in properties and remote access policies that are configured on the IAS server. Additionally, IAS can return an Access-Accept message without authenticating and authorizing the Access-Request message.

The contents of user authentication and accounting requests are logged in a local log file or are sent to a Structured Query Language (SQL) Server database, depending on how remote access logging settings are configured in the IAS console.

You can use IAS as a RADIUS server to do the following:

- Centralize authentication, authorization, and accounting for a heterogeneous set of access servers.
- Deploy secure password authentication with Protected Extensible Authentication Protocol (PEAP) for 802.1X authenticating switches and wireless clients
- Use a Windows NT Server 4.0 domain, an Active Directory domain, or the local SAM as your user account database.
- Centralize both the configuration of remote access policies and connection logging for accounting when you are using the Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; or Windows 2000 Routing and Remote Access service on multiple dial-up servers, VPN servers, or demand-dial routers.
- Outsource your dial-in, VPN, or wireless access to a service provider. The access servers use RADIUS to authenticate and authorize connections that are made by members of your organization.

**Note**

- The configuration of IAS servers running on products in the Windows 2000 Server family can be imported into products in the Windows Server 2003 family by using netsh AAAA commands. The reverse, however, is not possible. To centrally manage IAS on both Windows 2000 and Windows Server 2003, you can first make configuration changes on IAS servers running Windows 2000, and then import the new server configuration into IAS servers running Windows Server 2003.

When you configure IAS as a RADIUS server, Access-Request messages are processed locally. In this process, IAS does the following:

1. **Validates the RADIUS packet**. The incoming Access-Request message is validated for source IP address, the digital signature, valid attributes, and so on. If the RADIUS message is not valid, an event is logged in the system event log and the RADIUS Access-Request message is discarded. An Access-Reject message is not sent.

**Checks for auto-reject**. Auto Reject, also called **Ping User-Name**, is used to send an immediate Access-Reject message when the User-Name attribute in the Access-Request message matches a specific value.

Some RADIUS proxy servers and network access servers periodically send authentication and accounting requests, or ping requests, to verify that the IAS server is present on the network. These ping requests include fictional user names. When IAS processes these requests, the event and accounting logs become filled with access reject records, making it difficult to keep track of valid records. When you configure a registry entry for **Ping User-Name**, IAS matches the registry entry value against the value of the **User-Name** attribute in ping requests that other servers make. If the registry entry and the user name value match, IAS automatically rejects the request but does not create an event or accounting log entry.

2. **Performs connection request policy evaluation**. If no connection request policies are matched, an event is logged in the system event log and the RADIUS Access-Request message is discarded.

3. **Applies realm stripping rules**. IAS determines or defines the domain name and the user identity for the Access-Request message. If the User-Name attribute in the Access-Request message is not the Auto Reject name, then the user identity is determined. User identity is how IAS identifies the user for the purposes of authentication and authorization. Typically, the user identity is the string value of the User-Name RADIUS attribute. If the User-Name attribute is not present, the user identity is set to the Guest account or the account specified by the Default User Identity registry value.

   IAS can use any RADIUS attribute to identify the user. The RADIUS attribute that IAS uses to identify the user is configurable by setting the User Identity Attribute registry setting.

4. **Determines authentication server**. IAS determines whether to authenticate locally or forward to a remote RADIUS server group (In this example, the message is authenticated locally and is not forwarded.)

5. **Performs name cracking**. Name cracking is the resolution of the user identity to a user account using user principal names (UPNs), Lightweight Directory Access Protocol (LDAP), distinguished names (DNA), Canonical Names, and so on. If a user principal name is encountered by IAS, IAS performs a query to the Active Directory Global Catalog in an attempt to resolve the name. To speed up this process, a copy of the Global Catalog must be located on a domain controller within the same site as the IAS server.

   When the user identity does not contain a domain name, IAS supplies a domain name. By default, the IAS-supplied domain name is the domain for which the IAS server is a member. You can specify the IAS-supplied domain by means of the DefaultDomain registry setting.

6. **Checks for authentication plug-ins**. The existence of authentication plug-ins is checked. Authentication plug-ins are optional components created using the IAS software development kit (SDK); each plug-in can return Accept, Reject, or Continue. If an authentication plug-in returns an Accept, the user is considered to be authenticated and the account is then validated. If the authentication plug-in returns a Reject, an Access-Reject message is sent, and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings. If the authentication plug-in returns a Continue, the next plug-in is checked. If there are no more plug-ins, the user still needs to be authenticated.The authentication plug-in can also return RADIUS attributes to be included in the Access-Accept message.

7. **Checks for remote access account lockout.** After the authentication plug-ins are checked, the registry on the IAS server is read for remote access account lockout entry for the user account. If the account is locked out by way of the remote access account lockout, IAS sends an Access-Reject message back to the NAS and logs an authentication event. For more information, see "IAS Tools and Settings."

8. **Checks for PAP, CHAP, MS-CHAP** . If Password Authentication Protocol (PAP), CHAP, Microsoft Challenge Handshake Authentication Protocol (MS-CHAP v1), or MS-CHAP v2 are used to authenticate the remote access client, IAS consults an authentication sub-module based on the authentication protocol to perform the authentication. The user's credentials (user name and password) are authenticated against the user name and password of the accounts database (either a domain or the local accounts database), and the group membership of the user account is determined. The exact method of authentication varies depending on the authentication protocol.

If the authentication of the credentials is not successful, an Access-Reject message is sent and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings.

If either EAP or unauthenticated access is being used, then the user authentication process is bypassed. EAP authentication takes place later in this process. For unauthenticated access, no user authentication is performed.

9. **Validates user account**. Based on the user or computer account determined through name cracking, the user account is validated to discover whether the account is locked out (which is not the same as remote access account lockout), whether the account is disabled, and whether the user account's password has expired. If the user account is not valid, an Access-Reject message is sent and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings.

10. **Performs remote access policy evaluation**. Remote access policies configured on the IAS server are evaluated to find a policy that matches the parameters of the connection. If a matching policy is not found, an Access-Reject message is sent and an event is logged.

11. **Checks user properties and profile properties**. If the Ignore-User-Dialin-Properties attribute is set to 0, the dial-in properties of the user account and the profile properties of the matching remote access policy are evaluated against the parameters of the connection attempt to ensure that the connection attempt is allowed. If the Ignore-User-Dialin-Properties attribute is set to 1, the profile properties from the matching policy become the set of properties for the connection.

    If the connection attempt is not allowed, an Access-Reject message is sent, and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings.

12. **Checks for EAP authentication**. If Extensible Authentication Protocol (EAP) is the authentication protocol used for the connection attempt, EAP authentication takes place. The initial negotiation for EAP consists of selecting EAP as the authentication protocol and negotiating an EAP type. Based on the EAP type, the profile settings for the matching policy are checked to ensure that the EAP type is allowed. If the EAP type is not allowed with the profile settings, an Access-Reject message is sent and the authentication failure event is logged in the system event log or the IAS accounting log, depending on the configured logging settings.

    If the EAP type is allowed with the profile settings, EAP authentication for the EAP type occurs. IAS sends an EAP challenge to the NAS requesting it to start EAP negotiation. Communications between EAP modules on a RADIUS client and server are tunneled using the RADIUS protocol. After negotiation is complete, an EAP provider can return attributes that are sent back to the NAS in the Access-Accept message. If EAP authentication fails, an Access-Reject message is sent, and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings.

13. **Checks for authorization plug-ins**. The existence of authorization plug-ins is checked. Authorization plug-ins are optional components you can create using the IAS SDK. Each plug-in can return either Reject or Continue. If the authorization plug-in returns a Reject, an Access-Reject message is sent and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings. If the authorization plug-in returns Continue, the next plug-in is checked. If there are no more plug-ins, the user is considered to be authorized.

    The authorization plug-in can also return RADIUS attributes to be included in the Access-Accept message.

14. **Sends an Access-Accept**. If the dial-in properties of the user account, the profile properties of the matching remote access policy, and the conditions imposed by authorization plug-ins allow the connection attempt, an Access-Accept message is sent back to the NAS. Included with the Access-Accept message is the set of RADIUS attributes for the restrictions on the connection. In addition, an authentication success event is logged in either the system event log or the IAS authentication log, depending on the configured logging settings.

The authentication and authorization process for the Routing and Remote Access service, when configured for Windows authentication, requires steps 6 through 15 of this process. The authentication and authorization success and failure are the return values of functions called by the Routing and Remote Access service. Local event or authentication logging depends on the configured logging settings of the Routing and Remote Access service.

**Using IAS as a RADIUS Proxy**
When you use IAS as a RADIUS proxy, Access-Request messages are forwarded to a remote RADIUS server for authentication and authorization.

If you configure the IAS proxy to map user accounts between a remote RADIUS server and the local user accounts database, Access-Request messages are authenticated by the remote server and are authorized with the user or computer account dial-in properties and remote access policies that are configured on the IAS proxy.

IAS can also return an Access-Accept message without authenticating and authorizing the Access-Request message.

Accounting-Request messages are logged in a local log file (based on remote access logging settings) and forwarded to another RADIUS server for accounting.

You can use IAS as a RADIUS proxy when the following conditions exist:

- You want to provide authentication and authorization for user accounts that are not members of either the domain in which the IAS server is a member or another domain that has a two-way trust with the domain in which the IAS server is a member. This includes accounts in untrusted domains, one-way trusted domains, and other untrusted forests. Instead of configuring your access servers to send their connection requests to an IAS RADIUS server, you can configure them to send their connection requests to an IAS RADIUS proxy. The IAS RADIUS proxy uses the realm name portion of the user name and forwards the request to an IAS server in the correct domain or forest. Connection attempts for user accounts in one domain or forest can be authenticated for NASs in another domain or forest.

- IAS supports authentication across forests without a RADIUS proxy when the two forests contain only domains that consist of domain controllers running Microsoft Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition. The forest functional level must be Windows Server 2003, and there must be a two-way trust relationship between forests. If you use Extensible Authentication Protocol-Transport Layer Security (EAP-TLS) with certificates as your authentication method, however, you must use a RADIUS proxy for authentication across forests that consist of Windows Server 2003 domains.

- Your user accounts database is not a Windows user accounts database, and it is not compliant with LDAP. Additionally, you are using a non-Microsoft RADIUS server. In this case, the IAS proxy server forwards connection requests that match a specified realm name to a non-Microsoft RADIUS server in a remote RADIUS server group. The remote RADIUS server performs authentication and authorization against the non-Microsoft user accounts database. Examples of non-Microsoft user accounts databases include Novell Directory Services (NDS) and SQL databases.

- You want to process a large number of connection requests. In this case, instead of configuring your RADIUS clients to attempt to balance their connection and accounting requests across multiple RADIUS servers, you can configure them to send their connection and accounting requests to an IAS RADIUS proxy. The IAS RADIUS proxy dynamically balances the load of connection and accounting requests across multiple RADIUS servers and increases the processing of large numbers of RADIUS clients and authentications per second.

- You want to provide RADIUS authentication and authorization for outsourced service providers and minimize intranet firewall configuration. An intranet firewall is between your perimeter network (the network between your intranet and the Internet) and intranet. By placing an IAS server on your perimeter network, the firewall between your perimeter network and intranet must allow traffic to flow between the IAS server and multiple domain controllers. When replacing the IAS server with an IAS proxy, the firewall must allow only RADIUS traffic to flow between the IAS proxy and one or multiple IAS servers within your intranet.

- You are a service provider that offers outsourced dial, VPN, or wireless network access services to multiple customers. Your NASs send connection requests to the IAS RADIUS proxy. Based on the realm portion of the user name in the connection request, the IAS RADIUS proxy forwards the connection request to a RADIUS server that is maintained by the customer and can authenticate and authorize the connection attempt. .

When you configure IAS as a RADIUS proxy, Access-Request messages are forwarded to a remote RADIUS server and are processed remotely.

When you map external user accounts to a local Windows user account, authentication is performed remotely and authorization is performed locally. In this process, IAS does the following tasks:

1. **Validates the RADIUS packet**. The incoming Access-Request message is validated for source IP address, the digital

signature, valid attributes, and so on. If the RADIUS message is not valid, an event is logged in the system event log and the RADIUS Access-Request message is discarded. An Access-Reject message is not sent.

2. **Checks for auto-reject**. Auto Reject, also called **Ping User-Name,** is used to send an immediate Access-Reject message when the User-Name attribute in the Access-Request message matches a specific value.

   Some RADIUS proxy servers and NASs periodically send authentication and accounting requests, also called ping requests, to verify that the IAS server is present on the network. These ping requests include fictional user names. When IAS processes these requests, the event and accounting logs become filled with access reject records, making it more difficult to keep track of valid records. When you configure a registry entry for **Ping User-Name**, IAS matches the registry entry value against the value of the User-Name attribute in ping requests made by other servers. If the registry entry and the user name value match, IAS rejects the request but does not create an event or accounting log entry.

3. **Performs connection request policy evaluation**. Connection request policies configured on the IAS server are evaluated to find a policy that matches the parameters of the connection. If a policy is found that matches the connection request, the name of the remote RADIUS server group to which the Access-Request should be forwarded is injected into the message.

   If a matching policy is not found, an Access-Reject message is sent and an event is logged. For more information about connection request policies and policy evaluation logic, see "Connection Request Policies" later in this section.

4. **Applies realm stripping rules**. IAS determines or defines the domain name and the user identity for the Access-Request message. If the User-Name attribute in the Access-Request message is not the Auto Reject name, then the user identity is determined. User identity is the value that IAS uses to identify the user for the purposes of authentication and authorization. Typically, the user identity is the string value of the User-Name RADIUS attribute. If the User-Name attribute is not present, the user identity is set to the Guest account or the account specified by the **Default User Identity r**egistry value.

   IAS can use any RADIUS attribute to identify the user. The RADIUS attribute that IAS uses to identify the user is configurable by setting the User Identity Attribute registry setting.

5. **Determines whether to authenticate locally or forward to a remote RADIUS server group**. Based on the realm portion of the user name, the IAS proxy determines whether to forward the message or continue to process it locally.

6. **Check for authentication plug-ins**. The existence of authentication plug-ins is checked. Authentication plug-ins are optional components you can create with the IAS SDK; each plug-in can return Accept, Reject, or Continue. If an authentication plug-in returns an Accept, the user is considered to be authenticated and the account is then validated. If the authentication plug-in returns a Reject, an Access-Reject message is sent and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings. If the authentication plug-in returns a Continue, the next plug-in is checked. If there are no more plug-ins, the user still needs to be authenticated.

   The authentication plug-in can also return RADIUS attributes to be included in the Access-Accept message.

7. **Forward the Access-Request to a remote RADIUS server group**. IAS creates a RADIUS message, which includes the attributes received from the RADIUS client, with the exception of the proxy state attribute. IAS forwards the message to the remote RADIUS server group specified in the request. When a valid reply is received from the remote server, attributes from the RADIUS packet are merged with the attributes in the request. Attributes returned by the remote RADIUS server are not added if the same attribute has already been added by the connection request policy. In other words, local settings override remote settings.

8. **Maps a remote user account to a local Windows account**. If the IAS proxy server is configured to map an external user account to a local Windows account, and if the remote RADIUS server has performed authentication and returned an Access-Accept, mapping of the accounts is performed.

   If mapping is not configured, IAS proceeds to number 12 in this process, "Check for authorization plug-ins." For more information about account mapping, see "Mapping Network Authentication and Authorization" later in this section.

9. **Validates user account**. Based on the user or computer account that is determined by means of name cracking, the user account is validated to check whether the account is locked out (which is not the same as remote access account lockout), whether the account is disabled, and whether the user account's password has expired. If the user account is not valid, an Access-Reject message is sent and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings.

10. **Performs remote access policy evaluation**. Remote access policies configured on the IAS server are evaluated to find a policy that matches the parameters of the connection. If a matching policy is not found, an Access-Reject message is sent and an event is logged.

11. **Checks user properties and profile properties**. If the Ignore-User-Dialin-Properties attribute is set to 0, the dial-in properties of the user account and the profile properties of the matching remote access policy are evaluated against the parameters of the connection attempt. This is done to ensure that the connection attempt is allowed. If the Ignore-User-Dialin-Properties attribute is set to 1, the profile properties from the matching policy become the set of properties for the connection.

    If the connection attempt is not allowed, an Access-Reject message is sent, and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings.

12. **Checks for authorization plug-ins**. Authorization plug-ins are optional components created using the IAS SDK. Each plug-in can return either Reject or Continue. If an authorization plug-in is installed and it returns a Reject, an Access-Reject message is sent and the authentication failure event is logged in the system event log or the IAS authentication log, depending on the configured logging settings. If the authorization plug-in returns Continue, the next plug-in is checked. If there are no more plug-ins, the user is authorized.

    An authorization plug-in can also return RADIUS attributes to be included in the Access-Accept message.

13. **Sends an Access-Accept**. If the dial-in properties of the user account, the profile properties of the matching remote access policy, and the conditions imposed by authorization plug-ins allow the connection attempt, an Access-Accept message is sent back to the NAS. Included with the Access-Accept message is the set of RADIUS attributes for the restrictions on the connection. In addition, an authentication success event is logged in the system event log or the IAS authentication log, depending on the configured logging settings.

**IAS as a RADIUS Server**

IAS can be used as a RADIUS server to perform AAAA for connection requests at RADIUS clients. A RADIUS client can be either a NAS or a RADIUS proxy. When IAS is used as a RADIUS server, it provides the following:

- A central authentication and authorization service for all access requests that are sent by RADIUS clients.

  IAS uses a Microsoft Windows NT Server 4.0 domain, an Active Directory domain, or the local SAM to authenticate user credentials for a connection attempt. IAS uses the dial-in properties of the user account and remote access policies to authorize a connection.

- A central accounting recording service for all accounting requests that RADIUS clients send.

- Accounting requests are stored in a local log file or a SQL server database for analysis.

When IAS is used as a RADIUS server, RADIUS messages provide authentication, authorization, and accounting for network access connections in the following order:

1. Access servers, such as dial-up NASs, VPN servers, and wireless APs, receive connection requests from access clients.

2. The access server that is configured to use RADIUS as the authentication, authorization, and accounting protocol creates an Access-Request message and sends it to the IAS server.

3. The IAS server evaluates the Access-Request message.

4. If required, the IAS server sends an Access-Challenge message to the access server. The access server processes the challenge and sends an updated Access-Request to the IAS server.

5. IAS checks the user name for a domain name. If a domain name is specified and IAS is configured to access the user accounts database in the specified domain, IAS proceeds with processing the connection request. When the user name does not contain a domain name, IAS supplies one. By default, the IAS-supplied domain name is the domain of which the IAS server is a member. IAS resolves a user name without a specified domain name by using the following sequence:

    a. IAS checks the default domain registry key. If a default domain is specified, IAS authenticates the user against the domain specified in the registry key.

    b. If the IAS server is a member of a domain, IAS authenticates the user against the domain to which it is joined.

    c. If the IAS server is not a member of a domain, IAS authenticates the user against the local SAM database.

6. IAS checks the user identity in the User-Name attribute. User identity is what IAS uses to identify the user for the purposes of authentication and authorization. Typically, the user identity is the string value of the User-Name RADIUS attribute. If the User-Name attribute is not present, the user identity is set to the Guest account or the account specified by the **Default User Identity** registry value.

7. The dial-in properties of the user account are obtained by using a secure connection to a domain controller.

8. The connection attempt is authorized with both the dial-in properties of the user account and remote access policies. If the connection attempt is both authenticated and authorized, the IAS server sends an Access-Accept message to the access server.

9. If the connection attempt is either not authenticated or not authorized, or the connection request parameters do not match a connection request policy and a remote access policy, the IAS server sends an Access-Reject message to the access server.

10. The access server completes the connection process with the access client and sends an Accounting-Request message to the IAS server where the message is logged in IAS format, database-compatible format, or to a SQL Server.

11. The IAS server sends an Accounting-Response to the access server.

The access server also sends Accounting-Request messages when the connection is being established, when the access client connection is closed, and when the access server is started and stopped.

**IAS Authentication**

The authentication of access clients is an important security concern. Authentication methods typically use an authentication protocol that is negotiated during the connection establishment process. IAS also supports unauthenticated connections.

Each authentication method has advantages and disadvantages in terms of security, usability, and breadth of support. The authentication method used is determined by the configuration of the access client, the access server, and the RADIUS server. Consult your access server documentation to determine which authentication methods are supported.

You can configure IAS to accept multiple authentication methods. You can also configure your access servers to attempt to negotiate a connection by using the most secure protocol first, and then the next most secure, and so on down to the least secure. For example, the Routing and Remote Access service tries to negotiate a connection using EAP first, then MS-CHAP v2, then MS-CHAP v1 , then CHAP, and then PAP. When EAP is chosen as the authentication method, the negotiation of the EAP type occurs between the access client and the IAS server.

In addition, you can use remote access policies for various authentication methods, depending on the type of client being authenticated. For example, you can create two remote access policies, one for VPN clients and one for wireless clients—each of which uses a different authentication method. The remote access policy for VPN clients can be configured to use EAP-TLS with smart cards or certificates as the authentication method and authentication type, while the remote access policy for wireless clients can be configured to use PEAP-MS-CHAP v2, which provides secure password authentication.

**Authentication process**

A NAS functions as a RADIUS client of an IAS server. The NAS can be a dial-up server, VPN server, wireless AP, or an

authenticating switch. When a user or computer attempts to log on to a network through a NAS, the access client sends identity information, such as account credentials, to the access server. The access server sends the credentials to the RADIUS server.

When the NAS passes the account credentials to IAS, IAS authenticates the user or computer by sending the supplied credentials to a domain controller that compares the credentials with the credentials of an account in the accounts database. IAS also verifies that the account is authorized to access all or part of the network by examining properties of the account in Active Directory and by using remote access policies configured on the IAS server.

If the user is authenticated and authorized, IAS returns necessary configuration information to the RADIUS client so that it can deliver service to the user.

When a user or computer attempts to connect to a network, the authentication request is processed as follows:

1. The NAS tries to negotiate a connection with the remote access client by using the most secure protocol first, then the next least secure protocol, and so on, down to the least secure protocol (for example, the NAS tries to negotiate a connection by using EAP, MS-CHAP v2, then MS-CHAP , then CHAP, and finally PAP).

2. The NAS forwards the authentication request to an IAS server in the form of a RADIUS Access-Request message.

3. The IAS server validates the RADIUS Access-Request message.

4. If digital signatures are enabled and the verification of the digital signature fails, the IAS server silently discards the message. When the NAS does not get a response within its time-out period, it retries and then disconnects the user. If the IAS server cannot connect to the domain controller or cannot find the domain controller the user belongs to, it silently discards the message. This allows a RADIUS proxy to retransmit the request to the backup IAS server, which would then attempt to authenticate the user against the database of the domain.

5. If digital signatures are enabled and the verification of the digital signature is successful, the IAS server queries the domain controller, which validates the user credentials.

6. If the user credentials are authentic, the IAS server evaluates the connection attempt against the configured remote access policies and the dial-in properties of the user's account to decide whether to authorize the request. If the connection attempt matches the conditions of at least one policy and the user account dial-in properties, remote access policy properties, and the remote access policy profile properties authorize the connection, IAS sends a RADIUS Access-Accept message to the NAS that sent the Access-Request message. The Access-Accept message authorizes the connection but also contains connection parameters based on the remote access policy profile settings and the dial-in properties of the user account. The NAS interprets this authorization data to determine the connection parameters that the server has authorized.

If the user is not authentic or the user's attempt to connect does not match conditions in at least one policy, or matches conditions in a policy that denies access, IAS sends a RADIUS Access-Reject message to the NAS, and the NAS disconnects the user.

**Ping User-Name value**

The **Ping User-Name** registry entry specifies the fictional user name (or a user name pattern, with variables, that matches the fictional user name) sent by RADIUS proxy servers and NASs to IAS servers to test whether the IAS server is available. When IAS receives ping requests that match the **Ping User-Name** registry entry value, IAS rejects the authentication requests without processing the request. IAS does not record transactions involving the fictional user name in any log files, which makes the event log easier to interpret.

**Adding Ping User-Name to the registry**

When you add **Ping User-Name** to the registry, you must supply values for **Name**, **Type**, and **Data**, as shown in the following table, "**Ping User-Name** Values."

**Ping User-Name Values**

| Name | Type | |
|---|---|---|
| ping user-name | REG_SZ | *User name* |

To indicate more than one user name for a **Ping User-Name** value, enter a name pattern, such as a Domain Name System

(DNS) name including wildcard characters, in **Data**.

**IAS and Tunneling**
The entire process of packet encapsulation, transmission, and de-encapsulation is called tunneling. Tunneling is a method of using an internetwork infrastructure of one protocol to transfer a payload. Sometimes, the payload consists of the frames (or packets) of another protocol. Instead of being sent as the originating host produces it, the frame is encapsulated with an additional header. The additional header provides routing information so that the encapsulated payload can traverse an intermediate internetwork (also known as a transit internetwork). The encapsulated packets are then routed between tunnel endpoints over the transit internetwork. After the encapsulated payload packets reach their destination on the transit internetwork, the frame is de-encapsulated and forwarded to its final destination.

The logical path in the transit internetwork through which the encapsulated packets travel is called a tunnel.

With remote access VPN connections, there are two types of tunneling: voluntary and compulsory

**Voluntary tunneling**
When a client computer is configured with the appropriate tunneling protocol, the user or client computer can issue a VPN request to create and configure a voluntary tunnel from the client computer to the VPN server. In this case, the user's computer is a tunnel endpoint that acts as the tunnel client, and the VPN server is the tunnel server.

A simple example of voluntary tunneling occurs when a user with a dial-up connection to the Internet through an Internet service provider (ISP) connects to an organization VPN server that is also connected to the Internet. In this scenario, the user has two separate accounts, each account having its own set of credentials:

- A set of credentials for an account with an ISP
- A set of credentials for an account with the organization

To connect to the organization VPN server, the client computer uses a dial-up modem to attempt to connect to the ISP dial-up server. The user supplies his ISP account credentials, is authenticated by the ISP RADIUS server against the ISP user accounts database, and is authorized by the ISP RADIUS server to connect to the ISP and the Internet.

After the dial-up connection is established and the client computer is on the Internet, the user initiates a VPN connection to his organization VPN server. The VPN server is configured as a RADIUS client to an IAS server at the organization. The user supplies organization account credentials for the connection attempt, and the organization IAS server uses the credentials to authenticate and authorize the user against an Active Directory user accounts database. After the user is authenticated and authorized, the VPN tunnel is established and the user can access organization resources.

In another example, IAS is used in an outsourced bulk dial scenario for voluntary tunneling. In the outsourced bulk dial scenario, an ISP is providing both dial-up and non-dedicated broadband digital subscriber line (DSL) Internet access for all the employees of an organization. Rather than providing the ISP with a copy of its user accounts database, the organization and the ISP use IAS as a RADIUS proxy so that users, when connecting to the ISP, can be authenticated and authorized using the organization RADIUS servers and Active Directory user accounts database on the organization network. This provides strong security and prevents exposure of sensitive information contained in the user accounts database to the ISP and its employees.

When the organization employee attempts to connect to the organization VPN server, the following process occurs:

1. The client computer establishes the dial-up or DSL connection to the ISP NAS.
2. Based on the connection parameters, the NAS sends an Access-Request message to an IAS server that is configured as a RADIUS proxy.
3. The RADIUS proxy processes the Access-Request message and determines where to send it based on the realm portion of the User-Name attribute. The RADIUS proxy forwards the Access-Request message to the organization IAS server, which is accessible on the Internet through a firewall configured to allow traffic on the default RADIUS UDP ports of 1812 (authentication) and 1813 (accounting).
4. The organization IAS server authenticates and authorizes the connection attempt of the client computer and sends an Access-Accept message back to the RADIUS proxy.
5. The RADIUS proxy forwards the Access-Accept message to the ISP NAS and the ISP NAS connects the client computer to the Internet.

6. After it is on the Internet, the client computer initiates a VPN tunnel connection with the organization VPN tunnel server on the Internet.

7. Based on the tunnel connection parameters, the tunnel server sends an Access-Request message to the organization IAS server.

8. The organization IAS server authenticates and authorizes the connection attempt of the tunnel client and sends an Access-Accept message back to the tunnel server.

9. The tunnel server completes the tunnel creation and the tunnel client can now send packets to the organization intranet through the tunnel across the Internet.

The figure, "Voluntary Tunnel Created by a Dial-Up User," illustrates the establishment of a voluntary VPN tunnel by a dial-up user.

**Voluntary Tunnel Created by a Dial-Up User**

Voluntary tunneling is not different from other types of network access, and IAS can be used for authentication, authorization, and accounting when the tunnel server is configured as a RADIUS client to the IAS server.

**Compulsory tunneling**

Compulsory tunneling is the creation of a secure tunnel by another computer or network device on behalf of the client computer. Compulsory tunnels are configured and created automatically for the user without their knowledge or intervention. With a compulsory tunnel, the user's computer is not a tunnel endpoint. Another device between the user's computer and the tunnel server is the tunnel endpoint, acting as the tunnel client. The dial-up access server dialed by the client computer is the tunnel endpoint, acting as the tunnel client.

A number of vendors that sell dial-up access servers have implemented the ability to create a tunnel on behalf of a dial-up client. The computer or network device providing the tunnel for the client computer is known as a Front End Processor (FEP) in PPTP, a Layer Two Tunneling Protocol (L2TP), an Access Concentrator in L2TP, or an IP Security Gateway in Internet Protocol Security (IPSec).

In this section, "How IAS Works," the acronym FEP describes this functionality, regardless of the tunneling protocol. To carry out its function, the FEP must have the appropriate tunneling protocol installed and must be capable of establishing the tunnel when the client computer attempts a connection.

A corporation can contract with an ISP to deploy a nationwide set of FEPs. These FEPs can establish tunnels across the Internet to a tunnel server connected to the private network of the corporation, thereby consolidating calls from geographically diverse locations into a single Internet connection at the corporate network.

The following figure, "Compulsory Tunnel Created by a Tunneling-Enabled NAS," shows the client computer placing a dial-up call to a tunneling-enabled NAS at the ISP to authenticate against an IAS server on the other side of the tunnel.

**Compulsory Tunnel Created by a Tunneling-Enabled NAS**

The preceding figure, "Compulsory Tunnel Created by a Tunneling-Enabled NAS," illustrates how IAS is used in an outsourced bulk dial scenario for compulsory tunneling.

In the outsourced bulk-dial scenario, a dial-up client establishes a dial-up connection to an ISP that is providing tunneled access across the Internet for all the employees of an organization. Based on the dial-up connection parameters, the ISP NAS sends an Access-Request message to an IAS server. The ISP IAS server authorizes, but does not authenticate, the tunnel connection. The ISP IAS server sends an Access-Accept message to the ISP NAS with a series of VPN tunnel attributes. The ISP NAS then acts as a tunnel client and creates a VPN tunnel to the VPN tunnel server of the organization that faces the Internet.

**Note**

- Typically, IAS provides both authentication and authorization. However, it is common for the ISP IAS server to provide only authorization when the dial-in user is authenticated by the organization IAS server.

The ISP NAS then sends a PPP message to the dial-up client to restart the authentication process so that the dial-up user can be authenticated by the organization IAS server through the tunnel. The dial-up client sends the authentication information to the ISP NAS, which encapsulates the user account credentials and sends them through the tunnel to the organization tunnel server.

After the user account credentials are received by the tunnel server, the tunnel server sends an Access-Request message to the organization IAS server. The organization IAS server authenticates and authorizes the connection of the dial-up client to the tunnel server and sends an Access-Accept message to the tunnel server. The tunnel server then completes the connection to the dial-up client.

All data that is sent by the dial-up client is automatically sent through the tunnel to the tunnel server by the ISP NAS.

This configuration is known as compulsory tunneling because the client is compelled to use the tunnel created by the FEP. After the initial connection is made, all network traffic to and from the client is automatically sent through the tunnel.

In addition, you can configure IAS to instruct an FEP to tunnel different remote access clients to different tunnel servers.

Unlike the separate tunnels created for each voluntary client, a compulsory tunnel between the FEP and organization VPN server can be shared by multiple dial-up clients. When a second client dials into the same access server (the FEP) to reach a destination for which a tunnel already exists, the data traffic for the new client is carried over the existing VPN tunnel.

The following RADIUS Attributes are used to carry the tunneling information from the IAS server to the NAS.

Used in authorization only:

- Tunnel-Pvt-Group-ID
- Tunnel-Assignment-ID
- Tunnel-Preference
- Tunnel-Password
- Tunnel-Client-Auth-ID
- Tunnel-Server-Auth-ID

Used in authorization and accounting:

- Tunnel-Type (such as PPTP and L2TP)
- Tunnel-Medium-Type (X.25, ATM, Frame Relay, IP, and so on)
- Tunnel-Client-Endpt
- Tunnel-Server-Endpt

Used for accounting only:

- Acct-Tunnel-Connection

The Windows Server 2003 or Windows 2000 Routing and Remote Access service cannot be used as a FEP for compulsory tunneling.

**Authentication Methods**
The RADIUS protocol supports several PPP authentication protocols, each with its advantages and disadvantages in terms of security, usability, and breadth of support. The protocol used is determined by the configuration of the NAS device. For information about support for the various authentication protocols, see your NAS documentation, or consult your ISP or other vendor support.

The following sections focus on the advantages and disadvantages of the authentication protocols that are currently supported by IAS, and discuss how to deploy certificate-based authentication methods. The information is also useful in configuring a particular authentication method for network access authentication.

**PAP**
Password Authentication Protocol (PAP) sends a password as a plaintext string from the user's computer to the NAS device. When the NAS forwards the password as the User-Password attribute in the Access-Request message, it is encrypted using the RADIUS shared secret as an encryption key. PAP is the most flexible protocol because passing a plaintext password to the authentication server enables that server to compare the password with nearly any storage format. For example, UNIX passwords are stored as one-way encrypted strings that cannot be decrypted. PAP passwords can be compared to these strings by reproducing the one-way encryption method.

**Note**

- The use of this authentication method is not recommended for security reasons.

When PAP is enabled as an authentication protocol, user passwords are sent from a client to a NAS in plaintext form. The NAS encrypts the password, using the shared secret, and then sends it in an Access-Request message. Because a RADIUS proxy must encrypt the PAP password by using the shared secret of its forwarding RADIUS server, a RADIUS proxy must decrypt the PAP password, using the shared secret between the RADIUS proxy and the NAS. Because it uses a plaintext version of the password, PAP has a number of security vulnerabilities. Although the RADIUS protocol encrypts the password, it is transmitted as plaintext across the dial-up connection.

PAP-based authentication is enabled:

- On the appropriate remote access policy. PAP is disabled by default.
- On a remote access client.
- As an authentication protocol on the remote access server. For the Routing and Remote Access service, PAP is disabled by default.

For information about a default setting on a particular NAS, see your NAS documentation.

If you set the **User passwords to be changed at the next attempt to log on** option, users must first log on using a local area network (LAN) connection and change the password before attempting to log on with a remote access connection using PAP. PAP and CHAP do not support changing passwords during the authentication process. If the password is not first changed using a LAN connection, logon fails. An alternative method for changing passwords is to temporarily log on using MS-CHAP to change the password.

**Note**

- A malicious user or process on a RADIUS proxy can record user names and passwords for PAP connections while the password is in its plaintext form. For this reason, the use of PAP is highly discouraged, especially for virtual private network connections.

**CHAP**

Challenge Handshake Authentication Protocol (CHAP) is designed to address the concern of passing passwords in plaintext. By using CHAP, the NAS sends a random number challenge to the user's computer. The challenge and the user's password is then hashed by using Message Digest 5 (MD5). The client computer then sends the hash as a response to the NAS challenge and the NAS forwards both the challenge and response in the RADIUS Access-Request message.

When the authenticating server receives the RADIUS message, it uses the challenge and the user's password to create its own version of the response. If the version of the server matches the response supplied by the user's computer, the access request is accepted.

CHAP responses cannot be reused because NAS devices send a unique challenge each time a client computer connects to them. Because the algorithm for calculating CHAP responses is well known, it is very important that passwords be carefully chosen and sufficiently long. CHAP passwords that are common words or names are vulnerable to dictionary attacks if they can be discovered by comparing responses to the CHAP challenge with every entry in a dictionary. Passwords that are not sufficiently long can be discovered by brute force by comparing the CHAP response to sequential trials until a match to the user's response is found.

Historically, CHAP is the most common dial-up authentication protocol used. When the server does not store the same password that was used to calculate the CHAP response, it cannot calculate an equivalent response. Because standard CHAP clients use the plaintext version of the password to create the CHAP challenge response, passwords must be stored in a reversibly encrypted form on the server to validate the CHAP response of the client.

Although the IAS server supports CHAP, a Windows NT 4.0–based domain controller cannot validate CHAP requests without support for storing reversibly encrypted passwords. This support is available in Windows Server 2003 and Windows 2000; in Windows NT 4.0, this support is available after installing Service Pack 3 or later.

CHAP-based authentication is enabled when you have done the following:

- Enabled CHAP on the appropriate remote access policy. CHAP is disabled by default.

- Enabled storage of a reversibly encrypted form of the user's password. For a stand-alone server, use computer Group Policy to enable storage of reversibly encrypted passwords for all users of the computer. For Active Directory domains, Group Policy at the domain or Organizational Unit (OU) level can be used.

- Forced a reset of users' passwords so that the new password is in a reversibly encrypted form. When you enable passwords to be stored in a reversibly encrypted form, the current passwords are in a non-reversibly encrypted form and are not automatically changed. You must either reset user passwords or set user passwords to be changed the next time you log on. After the password is changed, it is stored in a reversibly encrypted form.

- Enabled CHAP on the remote access client.

- Enabled CHAP as an authentication protocol on the remote access server. For the Routing and Remote Access service, CHAP is disabled by default.

For information about a default setting on a particular NAS, see your NAS documentation.

If you set the **User passwords to be changed at the next attempt to log on** option, the user must first log on using a LAN connection and change the password before attempting to log on with a remote access connection using CHAP. CHAP and PAP do not support changing passwords during the authentication process. If the password is not first changed by using a LAN connection, logon fails. As an alternative to this method for changing passwords, you can temporarily log on by using MS-CHAP to change the password.

**MS-CHAP v1**

MS-CHAP v1, is a variant of CHAP that does not require a plaintext version of the password on the authenticating server. In MS-CHAP v1, the challenge response is calculated with a hashed version of the password and the NAS challenge. This enables authentication over the Internet to a Windows Server 2003 or Windows 2000 domain controller.

**Note**

- The use of this authentication method is not recommended for security reasons.

MS-CHAP v1 passwords are stored more securely at the server but have the same vulnerabilities to dictionary and brute force attacks as CHAP. If you deploy MS-CHAP v1, use strong passwords for all user accounts. A strong password includes the following:

- Has at least seven characters.
- Does not contain your user name, real name, or company name.
- Does not contain a complete dictionary word.
- Is significantly different from previous passwords. Incremental passwords (Password1, Password2, Password3) are not strong.
- Contains characters from each of the following four groups: uppercase letters, lowercase letters, numerals, and symbols.

With MS-CHAP v1 in Windows Server 2003, users are prompted to change their password before it expires. In addition, you can configure MS-CHAP v1 on the profile of a remote access policy by using the **Allow user to change password after it has expired** check box to allow or prevent users from changing a password *after* it has expired.

**Note**

- If the **Allow user to change password after it has expired** check box is disabled, and a user's password expires, the user is denied access and cannot change the password to regain network access.

MS-CHAP v1 is enabled as follows :

- As an authentication protocol on the remote access server. MS-CHAP v 1 is not enabled by default on the Routing and Remote Access service. For information about default settings on other NASs, see your NAS documentation.
- On the appropriate remote access policy. MS-CHAP v 1 is not enabled by default.
- On a remote access client.

By default, MS-CHAP v1 for Windows Server 2003 does not support LAN Manager authentication. This is a change from Windows 2000.

If you want to enable the use of LAN Manager authentication with MS-CHAP v1 for older operating systems, such as Microsoft Windows NT 3.5*x* and Microsoft Windows 95, you must change the value of **Allow LM Authentication** in the Windows registry.

**MS-CHAP v2**

Microsoft CHAP v2 (MS-CHAP v2) provides mutual authentication, stronger initial data encryption keys, and different encryption keys for sending and receiving. For VPN connections, Windows Server 2003 offers MS-CHAP v 2 before offering MS-CHAP v1. Windows clients that have been updated with the most recent service pack accept MS-CHAP v2 when it is offered.

MS-CHAP v2 is a one-way encrypted password, mutual authentication process that works as follows:

1. The remote access server sends a challenge to the remote access client that consists of a session identifier and an arbitrary challenge string.
2. The remote access client sends a response that contains the following:
    - The user name.

- An arbitrary peer challenge string.
- A one-way encryption of the received challenge string, the peer challenge string, the session identifier, and the user's password.

3. The remote access server checks the response from the client and sends back a response containing:
   - An indication of the success or failure of the connection attempt.
   - An authenticated response based on the sent challenge string, the peer challenge string, the encrypted response of the client, and the encrypted version of the user's password.
4. The remote access client verifies the authentication response and, if correct, uses the connection. If the authentication response is not correct, the remote access client terminates the connection.
5. If a user authenticates by using MS-CHAP v2 and attempts to use an expired password, MS-CHAP prompts the user to change the password while connecting to the server. Other authentication protocols do not support this feature effectively locking out the user who used the expired password. New to Windows Server 2003 is the ability to prevent a user from changing their expired password using MS-CHAP v2 by clearing the **Allow user to change password after it has expired** check box, under the **Microsoft Encrypted Authentication version 2 (MS-CHAP v2)** check box on the **Authentication** tab on the profile of a remote access policy.

MS-CHAP v2 is enabled as follows:

- As an authentication protocol on the remote access server. MS-CHAP v2 is enabled by default on the Routing and Remote Access service. For information about default settings on other NASs, see your NAS documentation.
- On the appropriate remote access policy. MS-CHAP v2 is enabled by default.
- On the remote access client.

For information about default settings on other NASs, see your NAS documentation.

**Note**

- Note Windows 95 and Microsoft Windows 98 support MS-CHAP v2 only for VPN connections. Windows 95 and Windows 98 do not support MS-CHAP v2 for dial-up connections.

**EAP**

Extensible Authentication Protocol (EAP) is an extension to PPP that works with dial-up, PPTP, L2TP, and 802.1X authentication clients. EAP allows the addition of new authentication methods known as EAP types. Both the access client and the remote access server must support the same EAP type for successful authentication to occur.

Windows Server 2003 includes an EAP infrastructure and two EAP types, EAP-MD5 and EAP-TLS. The IAS proxy implementation in Windows Server 2003 can forward EAP messages to a RADIUS server.

When you configure EAP as an authentication method in a remote access policy on an IAS server, NASs configured with RADIUS authentication can pass EAP messages from access clients to the IAS server or proxy using the RADIUS protocol. The EAP messages sent between the access client and access server are encapsulated and formatted as RADIUS messages between the remote access server and the RADIUS server.

One advantage of EAP is that EAP types do not need to be installed at each NAS, only at the RADIUS server. In a typical use of EAP, a NAS is configured to use EAP and to use RADIUS as its authentication provider. When a connection is made, the network access client negotiates the use of EAP with the NAS. When the client sends an EAP message to the NAS, the NAS encapsulates the EAP message as a RADIUS message and sends it to its configured RADIUS server. The RADIUS server processes the message and sends a RADIUS-encapsulated EAP message back to the NAS. The NAS then forwards the EAP message to the

network access client. In this configuration, the NAS is only a pass-through device. All processing of EAP messages occurs at the network access client and the RADIUS server.

**EAP-MD5**
MD5 with CHAP (EAP-MD5) is a required EAP type that uses the same challenge-handshake protocol as PPP-based CHAP, but the challenges and responses are sent as EAP messages. A typical use for EAP-MD5 is to authenticate the credentials of remote access clients by using user name and password security systems. You can use EAP-MD5 to test EAP interoperability.

**EAP-TLS**
Extensible Authentication Protocol-Transport Layer Security (EAP-TLS) is an EAP type that is used in certificate-based security environments. To use smart cards for remote access authentication, you can deploy a PKI with Certificate Services in Windows Server 2003 or with a non-Microsoft certification authority, and then configure the EAP-TLS authentication method in remote access policies on your IAS servers. The EAP-TLS exchange of messages provides mutual authentication, negotiation of the encryption method, and secured private key exchange between the network access client and the IAS server. EAP-TLS provides the strongest authentication and key exchange method.

Use of the TLS authentication type with EAP (EAP-TLS) reduces latency for authentication requests because, during the first authentication attempt, TLS caches certificate properties on the access client and on the IAS server. For subsequent authentication attempts, TLS uses the cached certificate properties instead of reading the certificate from the certificate store on the IAS server or client computer. In addition, the load on the IAS server that is typically caused by processing certificates is greatly reduced, improving server performance. Improved performance and response time are especially useful for wireless networks because the wireless client frequently authenticates to the network when moved from one AP to another.

EAP-TLS also supports computer authentication by using the computer account and computer certificate (also called machine certificate). For computer authentication with EAP-TLS, you must install a computer certificate on the client computer. This certificate is used to authenticate the client computer so that the computer can obtain network connectivity and Group Policy updates prior to user login. For user authentication with EAP-TLS, after a network connection is made and the user logs in, a user certificate on the client computer is necessary.

The computer certificate is installed on the IAS server computer so that during EAP-TLS authentication, the IAS server has a certificate to send to the client computer for mutual authentication, regardless of whether the client computer authenticates with a computer certificate or a user certificate. The computer and user-certificates that are submitted by the access client and the IAS server during EAP-TLS authentication, must conform to specified requirements. For more information about these requirements, see “Using Certificate-Based Authentication Methods” later in this section.

**Deploying EAP**
When you configure a remote access policy with EAP, if the EAP types displayed in the **Select EAP Providers** dialog box are selected as **(Server-Configured)**, then the configuration of the EAP type is common to the server and applies to all remote access policies that are configured on the server. Otherwise, the EAP type configuration is specific to the current remote access policy, in which case the EAP method must be configured for each policy to which you want it to apply.

EAP-TLS is not supported if the IAS server is not a member of the domain.

### Note

- When deploying EAP-TLS, if you have issued a certificate to your IAS server that has a blank **Subject**, the certificate is not available to authenticate your IAS server. To change this, you can use Certificate Templates to create a new certificate for enrollment on your IAS server. In the **Certificate Properties** dialog box, on the **Subject Name** tab, in **Subject name format**, select a value other than **None**.

EAP-based authentication is enabled when:

- EAP is enabled as an authentication protocol on the NAS.
- EAP is enabled on the IAS server and configure the EAP type on the appropriate remote access policy.
- EAP is enabled and configure EAP on a network access client.

In addition to the EAP types defined and supported in Windows Server 2003, you can include new EAP authentication methods by using the EAP Software Development Kit.

### Note

- When using EAP-TLS on computers running Microsoft Windows XP (prior to Service Pack 1), you must have user certificates stored on the computer for user authentication (instead of using smart cards). For computers running Windows Server 2003, Windows XP (Service Pack 1 or later), or Windows 2000, you can use either user certificates stored on the computer or a smart card for user authentication.

**Protected Extensible Authentication Protocol**

Protected Extensible Authentication Protocol (PEAP) is a new member of the family of EAP authentication methods. PEAP uses TLS to create an encrypted channel between an authenticating PEAP client, such as a wireless client computer, and a PEAP authenticator, such as an IAS server. PEAP does not specify an authentication type. Instead, it provides additional security for other EAP authentication protocols, such as MS-CHAP v2, which can operate within the TLS encrypted channel provided by PEAP. PEAP is used as an authentication method for 802.1X connections, such as 802.11 wireless connections and authenticating switches. PEAP is not supported for VPN or other remote access clients.

To use PEAP in your environment with Windows Server 2003, IAS requires little infrastructure change. If your wireless APs support 802.1X and EAP, then you can use PEAP without any additional changes to your wireless APs. In addition, PEAP is available for Microsoft Windows XP, Service Pack 1 and later; Windows 2000, Service Pack 4; and Pocket PC 2002.

To enhance both the EAP protocols and network security, PEAP provides the following:

- Protection for the EAP method negotiation that occurs between client and server through a TLS channel. This helps prevent an attacker from injecting packets between the client and the NAS to cause the negotiation of a less secure EAP method. The encrypted TLS channel also helps prevent denial of service attacks against the IAS server.

- Support for the fragmentation and reassembly of messages, allowing the use of EAP types that do not provide this.

- Wireless clients that can authenticate the IAS or RADIUS server. Because the server also authenticates the client, mutual authentication occurs.

- Support for computer authentication using the client computer account and computer certificate.

- Protection against the deployment of an unauthorized wireless access point (AP) or authenticating switch when the EAP client authenticates the certificate provided by the IAS server. In addition, the TLS master secret created by the PEAP authenticator and client is not shared with the access server. Because of this, the access server cannot decrypt the messages protected by PEAP.

- PEAP fast reconnect reduces the latency for authentication requests and responses between an access client and the IAS server when the access client moves from one AP to another. The IAS server caches a portion of the access client credentials and uses these cached credentials to quickly authorize the connection after the client is associated with a new AP.

**PEAP authentication process**

There are two stages in the PEAP authentication process. The first stage establishes a secure channel between the EAP client and the IAS server. The second stage provides EAP authentication between the EAP client and the IAS server. The following example describes the two stage PEAP authentication process for wireless clients:

**TLS encrypted channel**

The wireless client associates with a wireless access point. An IEEE 802.11-based association provides an Open System or Shared Key Authentication before a secure association is created between the client and AP. If Shared Key Authentication is configured for use at the AP, then 802.1X is not used. If the AP is configured for Open System Authentication, 802.1X is used. After the IEEE 802.11-based association is successfully established between the client and AP, the TLS session is negotiated with the RADIUS server. The key that is derived during this negotiation is used to encrypt all subsequent communication, and the TLS encrypted channel is established.

**EAP-authenticated communication**

An EAP negotiation in which the wireless client authenticates to the IAS server occurs through the TLS channel. The IAS server authenticates the user or client computer with the method that is determined by the EAP type and selected for use within PEAP (either TLS or MS-CHAP v2). The AP only forwards messages between wireless client and RADIUS server. The AP (or person monitoring the AP) cannot decrypt these messages because the AP is not the TLS endpoint.MS-CHAP v2

**802.11 wireless deployments using PEAP**

You can choose either of these two EAP types to use with PEAP: MS-CHAP v2 or TLS.

MS-CHAP v2 uses credentials (user name and password) for user authentication, and a certificate in the server computer certificate store for server authentication.

TLS uses either certificates installed in the client computer certificate store or a smart card to authenticate a user or client computer, and a certificate in the server computer certificate store for server authentication.

**PEAP with EAP-MS-CHAP v2**
PEAP with EAP-MS-CHAP v2 (PEAP-MS-CHAP v2) is easier to deploy than EAP-TLS because user authentication is accomplished with password-based credentials (user name and password) instead of certificates or smart cards. Only the IAS server is required to have a certificate. Additionally, the server certificate can be issued by a public CA that is trusted by the client computer, meaning that the public CA certificate already exists in the Trusted Root Certification Authority folder in the client computer certificate store. In this case, the server certificate is not downloaded and added to the client trusted root certificate store, and the user is not prompted to make a decision about whether to trust the server.

PEAP-MS-CHAP v2 provides improved security over MS-CHAP v2 by using mutual authentication, by preventing an unauthorized server from negotiating the least secure authentication method, and by providing key generation with TLS. PEAP-MS-CHAP v2 requires that the client trust the certificates provided by the server.

**PEAP with EAP-TLS**
Public Key certificates provide a much stronger authentication method than those that use password-based credentials. PEAP with EAP-TLS (PEAP-TLS) uses certificates for server authentication and either certificates or smart cards for user and client computer authentication. To use PEAP-TLS, you must deploy a PKI.

PEAP-TLS also supports computer authentication by using the computer account and computer certificate. For computer authentication with PEAP-TLS, you must install a computer certificate, on the client computer. A computer certificate installed on the client computer is used to authenticate the client computer so that the computer can obtain network connectivity and Group Policy updates prior to user login. For user authentication with PEAP-TLS after a network connection is made and the user logs in, a user certificate on the client computer is necessary.

The computer certificate is installed on the IAS server computer so that during PEAP-TLS authentication, the IAS server has a certificate to send to the client computer for mutual authentication, regardless of whether the client computer authenticates with a computer certificate or a user certificate. The computer and user certificates submitted by the access client and the IAS server during PEAP-TLS authentication must conform to the requirements specified in the section "Using Certificate-Based Authentication Methods."

**TLS caching of certificate properties**
When using the PEAP-TLS and EAP-TLS authentication methods with certificates, TLS uses cached certificate properties instead of reading the certificate from the certificate store on the IAS server.

If a certificate is deleted, its TLS credential cache entry is removed. If a certificate is renewed, its TLS credential cache entry is removed and TLS caches properties for the renewed certificate. If a certificate expires, TLS continues using outdated cached certificate information until the cache expires or is refreshed.

If you change or replace a certificate, you can refresh the TLS cache by restarting the server computer.

**Deploying PEAP**
PEAP is used as an authentication method for 802.1X-based connections and is not supported for VPN or other remote access clients. When you deploy both PEAP and EAP unprotected by PEAP on the same network, do not use the same authentication type (MS-CHAP v2 or TLS) with and without PEAP.

For example, if you deploy PEAP with EAP-TLS (PEAP-TLS), do not also deploy EAP-TLS without PEAP. Deploying authentication methods with the same type — one with and the other without external protection of PEAP or IPSec — creates a security issue.

If you need to deploy both PEAP and EAP on the same network, use different authentication types for each deployment.

An example of a deployment of both authentication methods that does not introduce a security issue is to use PEAP-MS-CHAP v2 for secure password authentication for wireless clients while using EAP-TLS as the authentication method for remote access clients using VPN connections. For this configuration, two remote access policies are configured at the IAS server, one for wireless clients and one for VPN clients, with the appropriate authentication method and type configured for each policy.

**PEAP fast reconnect**
PEAP fast reconnect enables wireless clients to move between wireless APs on the same network without being reauthenticated each time they associate with a new AP.

Wireless APs are configured as RADIUS clients to RADIUS servers. If a wireless client roams between APs that are configured as clients of the same RADIUS server, the client is not required to be authenticated with each new association.

PEAP fast reconnect reduces the response time for authentication between client and authenticator because the authentication request is forwarded from the new server to the original server. Because both the PEAP client and authenticator use previously cached TLS connection properties (the collection of which is named the TLS handle), the authenticator can quickly determine that the client connection is a reconnect.

If the original PEAP authenticator is unavailable, full authentication must occur between the client and the new authenticator. The TLS handle of the new PEAP authenticator is cached by the client. The client can cache TLS handles for multiple PEAP authenticators. For smart cards or PEAP-MS-CHAP v2 authentication, the user is asked to supply the personal identification number (PIN) or credentials, respectively.

The following tables, PEAP-MS-CHAP v2 and "PEAP-TLS" describe authentication behavior with PEAP-MS-CHAP v2 and PEAP-TLS when wireless clients roam from one wireless AP to a new AP. PEAP authentication behavior differs when wireless APs are configured either as clients to the same RADIUS server or as clients to different RADIUS servers.

**PEAP-MS-CHAP v2**

| **New AP Is RADIUS Client to Same RADIUS Server** | **New AP Is RADIUS Client to a Different RADIUS Server** |
|---|---|
| The user is not prompted for credentials each time the client computer associates with a new AP. | The user is prompted for credentials on this initial association. By default, the domain credentials of the currently logged in user are sent automatically. The next time the client computer associates with an AP that is a client to this server, user credentials are not required. |
| The RADIUS server is not required to provide a certificate. | The RADIUS server provides a certificate on this initial association so that the wireless client can authenticate to the RADIUS server. The next time the client computer associates with an AP that is a client to this server, the server is not required to be reauthenticated. |

**PEAP-TLS**

| **New AP is RADIUS Client to Same RADIUS Server** | **New AP Is RADIUS Client to a Different RADIUS Server** |
|---|---|
| The wireless client and RADIUS server are not required to exchange certificates. | The wireless client and RADIUS server exchange certificates on this initial association. The next time the client computer associates with an AP that is a RADIUS client to this RADIUS server, certificates are not exchanged. |
| The user is not prompted for a smart card PIN each time the wireless client computer associates with a new AP. | The user is prompted for a smart card PIN on this initial association. The next time the client computer associates with an AP that is a RADIUS client to this RADIUS server, the user is not prompted for the PIN. When the TLS cache expires, the user is prompted to reenter the PIN. |

PEAP fast reconnect requires the following:

- Both the PEAP client (802.11 wireless client) and PEAP authenticator (RADIUS server) must have fast reconnect enabled.
- All APs to which the PEAP client roams must be configured as RADIUS clients to a RADIUS server (the PEAP authenticator) for which PEAP is configured as the authentication method for wireless connections.
- All APs to which the PEAP client associates must be configured to prefer the same RADIUS server (PEAP authenticator) in order to avoid being prompted for credentials from every RADIUS server. If the AP cannot be configured to prefer a RADIUS server, you can configure an IAS RADIUS proxy with a preferred RADIUS server.

PEAP-based authentication is enabled when:

- You install a certificate on the IAS server that meets the minimum server certificate requirements.
- You configure PEAP as the authentication method for a remote access policy on your IAS server.
- You enable and configure PEAP on a remote access client.

**Using Certificate-Based Authentication Methods**
Certificates are used for network access authentication because they provide strong security for authenticating users and computers and eliminate the need for less secure password-based authentication methods.

Two authentication methods use certificates: EAP-TLS and PEAP. Both methods always use certificates for server authentication, and both the remote access client and the IAS server are TLS endpoints during the authentication process, providing strong security.

Depending on the authentication type configured with the authentication method, certificates might also be used for user authentication and client computer authentication. Certificates are stored in one of two places: either in the computer or user certificate store, or embedded in a computer chip on a smart card. If you deploy EAP-TLS, user authentication can be performed by using either a smart card or a certificate in the Current User certificate store on the client computer. If you deploy PEAP-TLS, the same is true. If you deploy PEAP-MS-CHAP v2, certificates are not used on the client computer; the user supplies password-based credentials when logging on to the network.

You can configure remote access policies in IAS to use EAP-TLS to perform certificate-based authentication for many types of network access, including VPN and wireless connections. In addition, you can use PEAP as the authentication method for wireless or wired 802.1X connections.

To deploy certificates to users and computers, you must first do the following:

- Design a PKI.
- Deploy a CA by using Certificate Services or by using a third party certification authority.
- Design and publish one or more certificates using Certificate Templates, which are installed with Certificate Services.
- Select one or more distribution methods (also called certificate enrollment methods) to install the certificates on computers and distribute them to users.

If you deploy PEAP-MS-CHAP v2 for wireless clients, you can use a non-Microsoft CA to obtain a server certificate.

Because user authentication is accomplished with password-based credentials with PEAP-MS-CHAP v2, you do not need to deploy a PKI or a CA on your network, however the server certificate you obtain from a third party CA must conform to server certificate requirements.

All certificates that are used for network access authentication must meet the requirements for X.509 certificates and work for connections that use Secure Sockets Layer-Transport Layer Security (SSL/TLS). After this minimum requirement is met, both server and client certificates must meet the additional requirements listed in the "Server certificate requirements" section.

**Server certificate requirements**
You can configure clients to validate server certificates by using the **Validate server certificate** option. Using PEAP-MS-CHAP v2, PEAP-TLS, or EAP-TLS as the authentication method, the client accepts the authentication attempt of the server when the certificate meets the following requirements:

- The Subject name contains a value. If you issue a certificate to your IAS server that has a blank Subject, the certificate is not available to authenticate your IAS server.
- The computer certificate on the server chains to a trusted root CA and does not fail any of the checks that are performed by CryptoAPI.
- The IAS or VPN server computer certificate is configured with the Server Authentication purpose in Enhanced Key Usage (EKU) extensions (the object identifier for Server Authentication is 1.3.6.1.5.5.7.3.1).
- The server certificate is configured with a required cryptographic service provider (CSP) value of Microsoft RSA SChannel Cryptographic Provider.
- The Subject Alternative Name (SubjectAltName) extension, if used, must contain the DNS name of the server. With PEAP and EAP-TLS, servers display a list of all installed certificates in the computer's certificate store, with the following exceptions:

- Certificates that do not contain the Server Authentication purpose in EKU extensions are not displayed.
- Certificates that do not contain a Subject name are not displayed.
- Servers do not display registry-based and smart card-logon certificates.

**Note**

- You can designate which certificate is used by the IAS or VPN server in the remote access policy profile. When you configure EAP and PEAP authentication methods that require a certificate for server authentication and you do not select a specific certificate in the **Smart Card or other Certificate Properties** dialog box, the IAS or VPN server automatically selects a certificate from the computer certificate store. If the server obtains a newer certificate, it uses the new certificate. This might cause the IAS or VPN server to use a certificate that is not correctly configured for authentication, causing authentication to fail as the result. To prevent this, always manually select a server certificate when configuring PEAP and EAP authentication methods that require one.

**Client certificate requirements**

With EAP-TLS or PEAP-TLS, the server accepts the client authentication attempt when the certificate meets the following requirements:

- The client certificate is issued by an enterprise CA or mapped to a user or computer account in Active Directory.
- The user or computer certificate on the client chains to a trusted root CA, includes the Client Authentication purpose in EKU extensions (the object identifier for Client Authentication is 1.3.6.1.5.5.7.3.2), and fails neither the checks that are performed by CryptoAPI and specified in the remote access policy nor the Certificate object identifier checks that are specified in IAS remote access policy.
- The 802.1X client does not use registry-based certificates that are either smart card-logon or password-protected certificates.
- For user certificates, the Subject Alternative Name (SubjectAltName) extension in the certificate contains the user principal name (UPN).
- For computer certificates, the Subject Alternative Name (SubjectAltName) extension in the certificate must contain the fully qualified domain name (FQDN) of the client, which is also called the DNS name. With PEAP-TLS and EAP-TLS, clients display a list of all installed certificates in the Certificates snap-in with the following exceptions:
    - Wireless clients do not display registry-based and smart card-logon certificates.
    - Wireless clients and VPN clients do not display password-protected certificates.
    - Certificates that do not contain the Client Authentication purpose in EKU extensions are not displayed.

**Certificate enrollment methods and domain membership**

The domain membership of computers for which you want to enroll certificates affects the certificate enrollment method that you can choose. Certificates for domain member computers can be enrolled automatically (also known as auto-enrollment), while an administrator must enroll certificates for non-domain member computers using the CA Web enrollment pages or a floppy disk. The certificate enrollment method for non-domain member computers is known as a trust bootstrap process, through which certificates are created and then manually requested or distributed securely by administrators, providing administrators the ability to build common trust between non-domain member computers and the domain.

**Domain member certificate enrollment**

If your VPN server, IAS server, or client running Windows 2000 or Windows XP Professional is a member of a domain running Windows Server 2003 and Active Directory, you can configure the auto-enrollment of computer and user certificates through Group Policy. After auto-enrollment is configured and enabled, all domain member computers receive computer certificates the next time Group Policy is refreshed whether the refresh is triggered manually by using the **gpupdate** command or automatically when logging on to the domain.

If your computer is a member of a domain where Active Directory is not installed, you can install computer certificates manually by requesting them through the Certificates snap-in.

**Note**

- Computers running Windows 2000 can auto-enroll computer certificates only.

**Non-domain member certificate enrollment**

Certificate enrollment for computers that are not domain members cannot be done with auto-enrollment. When a computer is joined to a domain, a trust is established that allows auto-enrollment to occur without administrator intervention. When a computer is not joined to a domain, trust is not established and a certificate is not issued. Trust must be established using one of the following methods:

- An administrator (who is, by definition, trusted) must request a computer or user certificate by using the CA Web enrollment tool.

- An administrator must save a computer or user certificate to a floppy disk and install it on the non-domain member computer. Or, when the computer is not accessible to the administrator (for example, a home computer connecting to an organization network by means of an L2TP/IPSec VPN connection), a domain user whom the administrator trusts can install the certificate.

- An administrator can distribute a user certificate on a smart card issued to a user (computer certificates are not distributed on smart cards).

Many network infrastructures contain VPN and IAS servers that are not domain members. For example, a VPN server in a perimeter network might not be a domain member for security purposes. In this case, a computer certificate with the Server Authentication purpose contained in the EKU extensions must be installed on the non-domain member VPN server before it can successfully negotiate L2TP/IPSec-based VPN connections with clients. Note that if the non-domain member VPN server is used as an endpoint for a VPN connection with another VPN server, EKU extensions must contain both the Server Authentication and Client Authentication purposes.

**Choosing certificate templates and certificate enrollment methods**

Windows Server 2003, Standard Edition, provides different certificate templates from Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

If you run an enterprise CA on a computer that runs Windows Server 2003, Standard Edition, you can use the following table, “Certificate Use for Windows Server 2003, Standard Edition,” to determine the following: the best certificate templates; the certificate purposes configured in the EKU extensions of the certificate; and the certificate enrollment method for your requirements.

**Certificate Use for Windows Server 2003, Standard Edition**

| Object and Domain Membership | Certificate Template | Certificate Purposes | Preferred Certificate Enrollment Method | Alternate Certificate Enrollment Method |
|---|---|---|---|---|
| VPN or IAS server, domain member | Computer | Server Authentication | Auto-enrollment | Request a certificate with the Certificates snap-in |
| VPN server with site-to-site connection, domain member | Computer | Server Authentication and Client Authentication | Auto-enrollment | Request a certificate with the Certificates snap-in |
| Windows XP Professional client, domain member | Computer | Client Authentication | Auto-enrollment | Request a certificate with the Certificates snap-in |
| VPN or IAS server, non-domain member | Computer | Server Authentication | CA Web enrollment tool | Install from a floppy disk |
| VPN server with site-to-site connection, non-domain member | Computer | Server Authentication and Client Authentication | CA Web enrollment tool | Install from a floppy disk |

| | | | | |
|---|---|---|---|---|
| Windows XP Professional client, non-domain member | Computer | Client Authentication | CA Web enrollment tool | Install from a floppy disk |
| User, domain user | User | Client Authentication | Auto-enrollment | Use a smart card or the CA Web enrollment tool |

If you are running an enterprise CA on a computer running Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; the 64-bit of Windows Server 2003, Enterprise Edition; or the 64-bit version of Windows Server 2003, Datacenter Edition, you can use the following table, "Certificate Use for Other Versions of Windows Server 2003," to determine the best certificate templates and certificate enrollment method for your requirements.

**Certificate Use for Other Versions of Windows Server 2003**

| Object and Domain Membership | Certificate Template | Certificate Purpose | Preferred Certificate Enrollment Method | Alternate Certificate Enrollment Method |
|---|---|---|---|---|
| VPN or IAS server, domain member | RAS and IAS Server | Server Authentication | Auto-enrollment | Request a certificate with the Certificates snap-in |
| Windows XP Professional client, domain member | Workstation Authentication | Client Authentication | Auto-enrollment | Request a certificate with the Certificates snap-in |
| VPN or IAS server, non-domain member | RAS and IAS Server | Server Authentication | CA Web enrollment tool | Install from a floppy disk |
| Windows XP Professional client, non-domain member | Workstation Authentication | Client Authentication | CA Web enrollment tool | Install from a floppy disk |

**Note**

- If your server running IAS is not a domain controller but is a member of a domain with a Windows 2000 mixed functional level, you must add the server to the access control list (ACL) of the **RAS and IAS Server** certificate template. You must also configure the correct permissions for auto-enrollment. There are different procedures for adding single servers and groups of servers to the ACL.

You can add an individual server to the ACL for the **RAS and IAS Server** certificate template by doing the following: In Certificate Templates, select the template **RAS and IAS Server**, and then add the IAS server to the template **Security** properties. For more information, see "To allow subjects to request a certificate that is based on the template" in Help and Support Center for Windows Server 2003. After you add your IAS server to the ACL, grant **Read**, **Enroll**, and **Auto-enroll** permissions.

You can manage a group of servers by adding the servers to a new global or universal group, and then adding the group to the ACL of the certificate template:

1. In Active Directory Users and Computers, create a new global or universal group for IAS servers. Next, add to the group all computers that are IAS servers, are not domain controllers, and are members of a domain with a Windows 2000 mixed functional level.

2. In Certificate Templates, select the **RAS and IAS Server** template, and then add the group you created to the template Security properties by completing the steps.

After you add your new group, grant **Read**, **Enroll**, and **Auto-enroll** permissions.

**Unauthenticated Access**

The unauthenticated access method allows remote access users to log on without having their identity verified by IAS. For example, IAS does not verify the user's name and password against an account in Active Directory when unauthenticated access is enabled. The only user validation performed with the unauthenticated access method is authorization to verify that the user has permission to access the network.

Enabling unauthenticated access presents security risks that you must carefully consider to determine whether to enable this authentication method. Three scenarios that illustrate typical security considerations for unauthenticated access include the following: Guest Access; Dialed Number Identification Service (DNIS) authorization; and Automatic Number

Identification/Calling Line Identification (ANI/CLI) authorization.

**Guest access for PPP users**

Guest access is the ability to log on to a domain without a user name or a password. Both Routing and Remote Access service and IAS must be configured to support unauthenticated access.

When a remote access server receives a connection attempt, it negotiates with the user different authentication types enabled at the server. If the client accepts one of them, it sends the appropriate credentials for the accepted authentication type. It the user refuses authentication, Routing and Remote Access service checks its properties to verify if unauthenticated access is enabled and, if enabled, forwards the Access-Request message to IAS. This Access-Request message does not contain a User-Name attribute or any other credentials.

When IAS receives the message without a User-Name attribute, it processes the message as an attempt by the user to connect as guest. In this case, IAS uses the name of the guest account in a domain as the user identity. IAS then evaluates policies to determine the right profile. If a match is found, and unauthenticated access is enabled in the profile, other authorizations are validated, and an Access-Accept message is returned. The accounting log file logs the user identity and authentication type, which can be used to determine whether the user is logged on with guest access.

You can enable Guest access by doing the following:

1. Enable unauthenticated access on the remote access server.

2. Enable unauthenticated access on the appropriate remote access policy.

3. Enable the Guest account.

4. Set the remote access permission on the Guest account to either Allow access or Control access through Remote Access Policy depending on your remote access policy administrative model.

If you do not want to enable the Guest account, do the following:

1. Create a user account and set the remote access permission to either **Allow access** or **Control access through Remote Access Policy**.

2. Set the **Default User Identity** registry value on the authenticating server (either the remote access server or the IAS server) to the name of the account.

Following is an example of guest access.

1. During PPP negotiation, the dial-in client rejects all of the PPP authentication protocols of the NAS.

2. If the NAS is configured to allowed unauthenticated access, the NAS sends an Access-Request message without the User-Name attribute and without a password. For the Windows Server 2003 or Windows 2000 Routing and Remote Access service, unauthenticated access is enabled from the **Authentication** tab on the properties of a server in the Routing and Remote Access snap-in.

3. Because the User-Name attribute is not included in the Access-Request message and by default the IAS user identity is using the User-Name attribute, the user identity is set to Guest (or the value of **Default User Identity**).

4. With the user identity of Guest and an unauthenticated connection attempt, The authentication and authorization process as discussed earlier in the chapter is performed. If the connection attempt matches a policy whose profile settings have unauthenticated access enabled and the Guest account is enabled and has the appropriate remote access permission, IAS sends an Access-Accept message to the NAS.

**DNIS authorization**

Dialed Number Identification Service (DNIS) authorization is the authorization of a connection attempt based on the number called. This attribute is referred to as Called-Station-ID. DNIS is used by standard telecommunication companies. This service returns the number called to the called party. Based on the Called-Station-ID attribute, IAS can deliver different services to dial-up/remote access users.

You can enable DNIS authorization by doing the following tasks:

1. Enable unauthenticated access on the remote access server.

2. Create a remote access policy on the authenticating server (remote access server or IAS server) for DNIS-based authorization with the Called-Station-ID condition set to the phone number.

3. Enable unauthenticated access on the remote access policy for DNIS-based authorization.

**ANI authorization**

ANI authorization is based on the number the user calls from. This attribute is referred to as Calling Station ID, or Caller ID. Based on the Calling-Station-ID attribute, IAS can deliver different services to dial-up/remote access users.

Using ANI authorization is different from using the Caller ID dial-in property of a user account. ANI authorization is performed when the user does not type any user name or password, and refuses to use any valid authentication method. In this case, IAS receives Calling-Station-ID, and no user name and password. To support ANI authorization, the Active Directory must have user accounts with Caller IDs as user names. This kind of authentication is used with the cellular phone authentication and by ISPs in Germany and Japan.

When using the Caller ID property on a user account, the user types in credentials, such as a user name and password, and uses a valid authentication method to log on. IAS authenticates the user with the credentials, and then compares the Calling-Station-ID attribute in the Access-Request to the Caller ID property of the user account to authorize the connection attempt.

You can enable ANI authorization by doing the following:

1. Enable unauthenticated access on the remote access server.

2. Enable unauthenticated access on the appropriate remote access policy for ANI/CLI-based authentication.

3. Create a user account for each number calling, for which you want to provide ANI/CLI authorization. The name of the user account must match the number that the user is dialing from. For example, If a user is dialing in from 555-0100, create a "5550100" user account.

4. Set the **User Identity Attribute** registry value to 31 on the authenticating server.

   To always use the calling number as the user identity, set the **Override User-Name** registry value to 1 on the authenticating server.

### Note

- If the Override User-Name is set to 1 and the User Identity Attribute is set to 31, then the authenticating server can perform only ANI/CLI-based authentication. The result is that normal authentication using authentication protocols such as MS CHAP v1, CHAP, and EAP is disabled.

**ANI example**

The following example explains how ANI/CLI authorization works for a dial-up client with an existing user account called 5550100. The client is dialing in from the phone number 555-0100.

1. During PPP negotiation, the dial-in client rejects all of the PPP authentication protocols of the NAS.

2. If the NAS is configured to allow unauthenticated access, the NAS sends an Access-Request message without the User-Name attribute and without a password. (For the Routing and Remote Access service, you can enable unauthenticated access on the Authentication tab in the properties of a server in the Routing and Remote Access snap-in.)

3. Because the User-Name attribute is not included in the Access-Request message, and the IAS user identity is set to use the Calling-Station-ID attribute, the user identity is set to 5550100.

4. With the user identity of 5550100 and an unauthenticated connection attempt, the authentication and authorization process is performed. IAS sends an Access-Accept message to the NAS if the following two conditions are met:

- The connection attempt matches a policy with a profile setting of unauthenticated access enabled.
- The 550100 account has the appropriate remote access permissions.

**MAC address authorization**

Media Access Control (MAC) address authorization functions in the same way as ANI authorization, but it is used for wireless clients and clients connecting to your network by using an 802.1X authenticating switch.

MAC address authorization is based on the MAC address of the network adapter installed in the user's client computer. Like ANI authorization, MAC address authorization uses the Calling-Station-ID attribute instead of user name and password or certificate-based credentials to identify the user during the connection attempt.

MAC address authorization is performed when the user does not type in any user name or password, and refuses to use any valid authentication method. In this case, IAS receives Calling-Station-ID, and no user name and password. To support MAC address authorization, the Active Directory must have user accounts with MAC addresses as user names.

MAC address authorization is enabled when you do the following:

1. Enable MAC address authorization on access servers (such as wireless APs).
2. Enable unauthenticated access on the appropriate remote access policy for MAC address-based authentication, and enable PAP.
3. Create a user account for each MAC address for which you want to provide MAC address authorization. The name of the user account must match the MAC address of the network adapter installed in the computer from which the user is connecting. The format of the password assigned to the account is determined by the network access server vendor. Review the network access server documentation to determine the appropriate password.
4. Set the **User Identity Attribute** registry value to 31 on the authenticating server. This registry value location is: **HKLM\SYSTEM\CurrentControlSet\Services\RemoteAccess\Policy**
   - The **User Identity Attribute** registry DWORD decimal value: **31**
5. To always use the MAC address as the user identity, set the **Override User-Name** registry value to 1 on the IAS server. This registry value location is: **HKLM\SYSTEM\CurrentControlSet\Services\RemoteAccess\Policy**
   - The **Override User-Name** registry DWORD decimal value: **1**

| ⚠**Caution** |
| --- |
| Incorrectly editing the registry can severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. |

**IAS Authorization**

You can use the authorization feature of IAS to allow or deny connection attempts that are based on the connection parameters. The following sections include in-depth information about configuring remote access policies and VSAs.

**Remote Access Policies**

In Windows NT, versions 3.5, 3.51, and 4.0, authorization is based on **Grant dial-in permission to user** option in either User Manager or the Remote Access Admin utility. An individual user configured callback options. For the Routing and Remote Access service and IAS in Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and Windows 2000, network access authorization is granted on the basis of user account dial-in properties and remote access policies.

Remote access policies are an ordered set of rules that define how connections are either authorized or rejected. For each rule, there are one or more conditions, a set of profile settings, and a remote access permission setting.

If a connection is authorized, the remote access policy profile specifies a set of connection restrictions. The dial-in properties of the user account also provide a set of restrictions. Where applicable, user account connection restrictions override the remote access policy profile connection restrictions.

Remote access policies validate several connection settings before authorizing the connection, including the following:

- Remote access permission
- Group membership
- Type of connection
- Time of day
- Authentication methods
- Advanced conditions:
    - Access server identity
    - Access client phone number or MAC address
    - Whether user account dial-in properties are ignored
    - Whether unauthenticated access is allowed

After the connection is authorized, remote access policies can also be used to specify connection restrictions, including the following:

- Idle time-out time
- Maximum session time
- Encryption strength
- IP packet filters
- Advanced restrictions:
    - IP address for PPP connections
    - Static routes

The following settings can also affect connection restrictions:

- Group membership
- Type of connection
- Time of day
- Authentication methods
- Identity of the access server
- Access client phone number or media access control (MAC) address

- Whether unauthenticated access is allowed

It is important to remember that a network connection is accepted only if the settings of the connection attempt match at least one of the configured remote access policies (subject to the conditions of the dial-in properties of the user object and the profile properties of the remote access policy). If the settings of the connection attempt do not match at least one of the remote access policies, the connection attempt is rejected regardless of the dial-in properties of the user account.

For Windows Server 2003 and Windows 2000 IAS servers, remote access policies are administered from the Routing and Remote Access snap-in (when configured for Windows authentication) or the IAS snap-in.

**Authorizing access**
You can use remote access policies to manage authorization by user or by group.

**Authorization by user**
If you are managing authorization by user, set the remote access permission on the user or computer account to either Grant access or to Deny access. Optionally, create different remote access policies based on different types of connections. For example, you might want to have one remote access policy for dial-up connections and a different remote access policy for wireless connections. Managing authorization by user is recommended only when you have a small number of user or computer accounts to manage.

If you are managing authorization by user, the basic process for authorizing a connection attempt occurs as follows:

- If the connection attempt matches all policy conditions, check the remote access permission setting of the account.
    - If the remote access permission is set to **Grant access**, apply the connection settings of the policy profile and user account.
    - If the remote access permission is set to **Deny access**, reject the connection attempt.
- If the connection attempt does not match all policy conditions, process the next remote access policy.

If the connection attempt does not match all conditions of any remote access policy, reject the connection attempt.

**Authorization by group**
If you are managing authorization by group, set the remote access permission on the user account to **Control access through Remote Access Policy** and create remote access policies that are based on different types of connections and group membership. You can use existing Active Directory groups when you configure remote access policies in IAS, or you can use the Active Directory Users and Computers snap-in to create new Windows groups upon which to base your remote access policies. For example, you might want to have one remote access policy for dial-up connections for employees (members of the Employees group) and a different remote access policy for dial-up connections for contractors (members of the Contractors group).

If you have a large number of user accounts, you can configure IAS to ignore the dial-in properties of user accounts instead of individually configuring each account to **Control access through Remote Access Policy**. You can set **Ignore-User-Dialin-Properties** on the **Advanced** tab of a remote access policy profile in the IAS console.

If you are managing authorization by group, the basic process for authorizing a connection attempt occurs as follows:

- If the connection attempt matches all policy conditions, check the remote access permission of the remote access policy.
    - If the remote access permission is set to **Grant remote access permission**, apply the connection settings of the policy profile and user account.
    - If the remote access permission is set to **Deny remote access permission**, reject the connection attempt.
- If the connection attempt does not match all policy conditions, process the next remote access policy.

If the connection attempt does not match all conditions of any remote access policy, reject the connection attempt.

**Note**

- It is not recommended that you manage network access authorization by user while also setting user account dial-in properties to **Control access through Remote Access Policy**. When you set user account dial-in properties to **Control access through Remote Access Policy**, manage network access authorization by group instead of by user.

**Local vs. Centralized Policy Management**
Because remote access policies are stored locally on either a remote access server or an IAS server, you must take the following steps in order to use centralized management of a single set of remote access policies for multiple remote access or VPN servers:

1. Install IAS as a Remote Authentication Dial-In User Service (RADIUS) server on a computer.

2. Configure IAS with RADIUS clients that correspond to each of the NASs.

3. On the IAS server, create the central set of policies that all NASs are using.

4. Configure each of the NASs as a RADIUS client to the IAS server.

After you configure a Windows Server 2003 or Windows 2000 remote access server as a RADIUS client to an IAS server, the local remote access policies stored on the remote access server are no longer used.

Centralized management of remote access policies are also used when you have remote access servers that are running Windows NT 4.0 with the Routing and Remote Access Service (RRAS). You can configure the server that is running Windows NT 4.0, using RRAS as a RADIUS client to an IAS server. You cannot configure a remote access server that is running Windows NT 4.0 without using RRAS to take advantage of centralized remote access policies.

**Dial-in properties of a user object**
In Windows Server 2003, the user object for a stand-alone server or Active Directory–based server contains a set of dial-in properties that are used when allowing or denying a connection attempt made by a user. For a stand-alone server, the dial-in properties are available on the **Dial-in** tab of the user object in the local User Manager. For an Active Directory–based server, the dial-in properties are available on the **Dial-in** tab of the user object in the Active Directory Users and Computers snap-in. The Windows NT 4.0 User Manager for Domains administrative tool cannot be used for Active Directory–based servers.

The dial-in properties for a user object are the following:

**Remote Access Permission (Dial-in or VPN)**
Use this property to set whether remote access is explicitly allowed, denied, or determined through remote access policies. If access is explicitly allowed, remote access policy conditions or user object or profile properties can override the setting. The **Control access through Remote Access Policy** option is available only on user objects for stand-alone Routing and Remote Access service servers or members of a domain that has a Windows 2000 native or Windows Server 2003 domain functional level.

### Note

- When the domain functional level in Active Directory is set to Windows 2000 mixed, the **Control access through Remote Access Policy** radio button is disabled on the **Dial-in** tab in user account **Properties**. To enable the use of **Control access through Remote Access Policy**, you must raise the domain functional level in Active Directory to either Windows 2000 native or Windows Server 2003.

By default, the Administrator and Guest accounts are set to **Control access through Remote Access Policy** on a stand-alone remote access server or in a Windows 2000 native domain. For a Windows 2000 mixed domain, the Administrator and Guest accounts are set to **Deny access** by default. New accounts created on a stand-alone remote access server or in a Windows 2000 native domain are set to **Control access through Remote Access Policy**. New accounts created in a domain with a Windows 2000 mixed domain functional level are set to **Deny access**.

**Verify Caller ID**
When Caller ID is enabled, the server verifies the caller's phone number. If the caller's phone number does not match the configured phone number, the connection attempt is denied.

Caller ID must be supported by the caller, the phone system between the caller and the remote access server, and the remote access server. On a computer running the Routing and Remote Access service, caller ID support consists of call answering equipment that provides caller ID information and the appropriate Windows driver to pass the information to the Routing and

Remote Access service.

If you configure a caller ID phone number for a user and you do not have support for the passing of caller ID information from the caller to the Routing and Remote Access service, the connection attempt is denied.

**Callback Options**
If this property is enabled, the server calls the caller back during the connection establishment at a phone number set by the caller or a specific phone number set by the administrator.

**Assign a Static IP Address**
If this property is enabled, the administrator assigns a specific IP address to the user when the connection is made.

**Apply Static Routes**
If this property is enabled, the administrator defines a series of static IP routes that are added to the routing table of the remote access server when a connection is made. This setting is designed for user accounts that Windows Server 2003 or Windows 2000 routers use for demand-dial routing.

For a user account that is a member of a Windows NT 4.0 domain or a Windows 2000 mixed domain, only the **Allow access** and **Deny access** Remote Access Permission options and **Callback Options** dial-in properties are available. In addition, the User Manager for Domains administrative tool can be used to grant or deny dial-in access and set callback options.

For a user account that is on a stand-alone server or in a Windows 2000 native domain, the callback number can be of unlimited size. For a user account that is in a Windows NT 4.0 domain or a Windows 2000 mixed domain, the callback number can only be 128 characters long. Callback numbers that are long than 128 characters are truncated during a callback connection attempt, which results in a failed callback connection.

When a Windows NT 4.0 RAS server uses a Windows 2000 native domain to obtain the dial-in properties of a user account, the **Control access through Remote Access Policy** option is retrieved as **Deny access**. Callback settings are retrieved correctly.

User accounts upgraded to Windows Server 2003 or Windows 2000 that were configured with dial-in permission enabled are set to **Allow access**. User accounts upgraded to Windows Server 2003 or Windows 2000 that were configured with dial-in permission disabled are set to **Control access through Remote Access Policy**.

A Windows NT 4.0 Remote Access Service (RAS) server does not use remote access policies. It is recommended that you upgrade Windows NT 4.0 RAS servers to take advantage of remote access policies.

**Elements of a Remote Access Policy**
A remote access policy is a named rule that consists of the following elements:

- Conditions
- Remote access permission
- Profile

**Remote access policy conditions**
Remote access policy conditions are one or more attributes that are compared to the settings of the connection attempt. If there are multiple conditions, all of the conditions must match the settings of the connection attempt in order for the connection attempt to match the policy. Not all NASs send all of the IAS server-specific attributes.

The table "Condition Attributes for a Remote Access Policy" shows the condition attributes that you can set for a remote access policy.

**Condition Attributes for a Remote Access Policy**

| Attribute Name | Description |
|---|---|
| Authentication Type | The type of authentication that is being used by the access client. Authentication types include CHAP, EAP, MS-CHAP , and MS-CHAP v2 |

| | |
|---|---|
| Called Station ID | The phone number of the NAS. This attribute is a character string. You can use pattern matching syntax to specify area codes. In order to receive called station ID information during a call, the phone line, the hardware, and the Windows Server 2003 driver for the hardware must support the passing of the called ID. Otherwise, the called station ID is manually set for each port. |
| Calling Station ID | The phone number used by the caller. This attribute is a character string. You can use pattern matching syntax to specify area codes. |
| Client Friendly Name | The name of the RADIUS client that is requesting authentication. This name is configured in **Friendly name** on the **Settings** tab in the properties of a RADIUS client in IAS. This attribute is a character string. You can use pattern matching syntax to specify client names. |
| Client IP Address | The IP address of the RADIUS client. This can be the IP address of either the originating RADIUS client or an intermediate RADIUS proxy. This attribute is a character string. You can use pattern matching syntax to specify IP networks. |
| Client Vendor | The vendor of the NAS that requests authentication. Ensure that you configure the NAS vendor when registering the RADIUS client on the IAS server. For example, the Routing and Remote Access service is the Microsoft NAS manufacturer. You can use this attribute to configure separate policies for RADIUS clients from different NAS manufacturers. This attribute is used by the IAS server. |
| Day and Time Restrictions | The day of the week and the time of day of the connection attempt. The day and time is relative to the day and time of the server providing the authorization. |
| Framed Protocol | The type of framing for incoming packets. Examples are PPP, SLIP, Frame Relay, and X.25. This attribute is used by the IAS server. |
| NAS Identifier | The name of the NAS. This attribute is a character string. You can use pattern matching syntax to specify multiple NASs. |
| NAS IP Address | The IP address of the NAS (the RADIUS client) that sent the message. This attribute is a character string. You can use pattern matching syntax to specify IP networks. |
| NAS Port Type | The type of media that is used by the access client. Examples include analog phone lines (known as async), ISDN, tunnels or virtual private networks (known as virtual), IEEE 802.11 wireless, and Ethernet switches. |
| Service Type | The type of service that is being requested. Examples include framed (such as PPP connections) and login (such as Telnet connections). For more information about RADIUS service types, see RFC 2865, "Remote Authentication Dial In User Service (RADIUS)." This attribute is used by the IAS server. |
| Tunnel Type | The type of tunnel that is being created by the requesting client. Tunnel types include the Point-to-Point Tunneling Protocol (PPTP) and the Layer Two Tunneling Protocol (L2TP), which are used by Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; Windows XP; and Windows 2000 remote access clients and demand-dial routers. You can use this condition to specify profile settings, such as authentication methods or encryption strengths for a specific type of tunneling technology. |
| Windows Groups | The names of the groups to which the user or computer account that is attempting the connection belongs. There is no condition attribute for a specific user or computer name. It is not necessary to have a separate remote access policy for each group. Instead, you can use multiple groups or nested groups to consolidate and delegate the administration of group membership. For a remote access or IAS server in a Windows 2000 native domain, you can use universal groups. You cannot use the built-in local or domain groups for the Windows Groups attribute. |

If conditions that use an IAS server attribute are evaluated against a Routing and Remote Access service server that is configured for Windows authentication, they do not match and the policy is not applied.

**Remote access permission**

IAS evaluates all remote access policies in the ordered list of remote access policies in an effort to match policy conditions with the connection attempt. If IAS can match all of the conditions of one of the remote access policies with the settings of the connection attempt, the matching remote access policy is used for the request. IAS then determines remote access permission by evaluating the setting for **If a connection request matches the specified conditions**. **If a connection request matches the specified conditions** is a setting found in the properties of a remote access policy, and can have one of the following values:

- **Deny remote access permission** . If **Deny remote access permission** is set on the policy, then remote access permission is denied.

- **Grant remote access permission**. If **Grant remote access permission** is set on the policy, then remote access permission is granted.

Remote access permission is also granted or denied for each user account. The user account remote access permission overrides the policy remote access permission. When remote access permission on a user account is set to the **Control access through Remote Access Policy** option, the policy remote access permission determines whether the user is granted access.

Granting access with either the user account permissions setting or the policy permission setting is the first step in accepting a connection. The connection attempt is then subjected to the settings of the user account properties and the policy profile properties and restrictions. If the connection attempt does not match the settings of the user account properties or the profile properties, or if specific restrictions defined in the profile prevent the connection, the connection attempt is rejected. For example, if the remote access policy profile restricts connections to use only EAP as an authentication method but the connection attempt is made using MS-CHAP v2 by a client that is not configured to use EAP, the connection attempt is rejected even when the value of **If a connection request matches the specified conditions** is **Grant remote access permission**.

By default, the **Deny remote access permission policy** permission is selected.

**Profile**
A remote access policy profile is a set of properties that are applied to a connection when the connection is granted remote access permission, either through the user account permission setting or the policy permission setting. A profile consists of the following groups of properties:

- Dial-in constraints

- IP

- Multilink

- Authentication

- Encryption

- Advanced

**Dial-in constraints**
You can set the following dial-in constraints:

- **Minutes server can remain idle before it is disconnected (Idle-Timeout)** The time after which a connection is disconnected when there is no activity. By default, this property is not set. Additionally, the Routing and Remote Access service does not disconnect an idle connection.

- **Minutes client can be connected (Session-Timeout)** The maximum time that a connection is connected. The connection is disconnected by the access server after the maximum session length. By default, this property is not set and there is no maximum session limit.

- **Allow access only on these days and at these times** The days of the week and hours of each day that a connection is allowed. If the day and time of the connection attempt do not match the configured day and time limits, the connection attempt is rejected. By default, this property is not set and there are no day or time limits. The Routing and Remote Access service does not disconnect active connections that were previously connected at a time when connection attempts were allowed.

- **Allow access to this number only (Called-Station-ID)** The specific phone number that a caller must call in order for a connection to be allowed. If the dial-in number of the connection attempt does not match the configured dial-in number, the connection attempt is rejected. By default, this property is not set, and all dial-in numbers are allowed.

- **Allow access only through these media (NAS-Port-Type)** The specific media type, such as modem (also known as

*asy*nc), ISDN (also known as virtual), or 802.11 wireless that a caller must use so that a connection is allowed. If the media of the connection attempt does not match the configured dial-in media, the connection attempt is rejected. By default, this property is not set and all media types are allowed.

**IP**

You can set IP properties that specify IP address assignment behavior. You have the following options:

- The access server must supply an IP address.
- The access client can request an IP address.
- IP address assignment is determined by the access server (this is the default setting).
- A static IP address is assigned. A static IP address assigned to the user account overrides this setting. The IP address assigned is typically used to accommodate VSAs for IP addresses.

You can also use the IP tab to define IP packet filters that apply to remote access connection traffic. This is intended for use with the Routing and Remote Access service. You can configure IP traffic that is allowed to remote access clients (output filters) or from remote access clients (input filters) on an exception basis. Either all traffic is allowed, except traffic specified by filters; or all traffic is blocked, except traffic specified by filters. Remote access policy profile filtering applies to all remote access connections that match the remote access policy.

Filters configured on the IP tab are applied to client connections on a computer running Windows Server 2003 and the Routing and Remote Access service, but are not applied to dial-on-demand connections.

**Multilink**

You can set Multilink properties that both enable Multilink and determine the maximum number of ports that a Multilink connection can use. Additionally, you can set Bandwidth Allocation Protocol (BAP) policies that both determine BAP usage and specify when extra BAP lines are dropped. The Multilink and BAP properties are specific to the Routing and Remote Access service. By default, Multilink and BAP are disabled.

The Routing and Remote Access service must have Multilink and BAP enabled in order for the Multilink properties of the profile to be enforced.

**Authentication**

You can set authentication properties to both enable the authentication types that are allowed for a connection and specify the EAP type that must be used. Additionally, you can configure the EAP type. With Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, you can specify whether users can change their expired passwords using MS-CHAP and MS-CHAP v2.

The Routing and Remote Access service must have the corresponding authentication types enabled in order for the authentication properties of the profile to be enforced.

**Encryption**

You can set encryption properties for the following encryption strengths:

- No Encryption

  When selected, this option allows an unencrypted connection. To require encryption, clear the **No Encryption** option. For L2TP over IPSec-based VPN connections, the Authentication Header (AH) is used.

- Basic

  For dial-up and PPTP-based VPN connections, Microsoft Point-to-Point Encryption (MPPE) with a 40-bit key is used. For L2TP over IPSec-based VPN connections, 40-bit DES encryption is used.

- Strong

  For dial-up and PPTP-based VPN connections, MPPE with a 56-bit key is used. For L2TP over IPSec-based VPN connections, 56-bit DES encryption is used.

- Strongest

  For dial-up and PPTP-based VPN connections, MPPE with a 128-bit key is used. For L2TP over IPSec-based VPN connections, triple DES (3DES) encryption is used.

**Advanced**

You can set **Advanced** properties to specify the series of RADIUS attributes that are sent back to the RADIUS client by the IAS server. RADIUS attributes are specific to performing RADIUS authentication and are ignored by the remote access server. By default, Framed-Protocol is set to PPP and Service-Type is set to Framed.

The only attributes that the Routing and Remote Access service uses are **Account-Interim-Interval, Framed-Protocol, Framed-MTU, Reply-Message**, and **Service-Type**.

**Configuration issues**

Following are several issues that might impact your configuration of IAS, depending on your network and needs:

- Some elements of a remote access policy correspond to RADIUS attributes that are used during RADIUS-based authentication. For remote access policies on an IAS server, verify that the NASs used are sending RADIUS attributes that correspond to the configured remote access policy conditions and profile settings. If a NAS does not send a RADIUS attribute that corresponds to a remote access policy condition or profile setting, then all RADIUS authentication requests from that NAS are denied.

- You can only use the **Generate-Session-Time-out** attribute if your user account database is a Security Accounts Manager (SAM) database or is the user account database for an Active Directory domain. When the value of **Generate-Session-Time-out** is set to **True**, the **ForceLogoff** value for a SAM database should be set to **0**. In the Local Security Settings console, **ForceLogoff** is changed to zero when **Network security: Force logoff when logon hours expire** is enabled.

- You can configure wireless connection policy so that wireless clients periodically reauthenticate. This ensures that the client Wired Equivalent Privacy (WEP) encryption keys are changed often enough to provide adequate security for the wireless connection. To configure reauthentication, set the session time-out in your remote access policy or connection request policy for wireless connections (using the Session-Time-out attribute) to the required interval (for example, 10 minutes). Additionally, configure the Termination-Action attribute with the **Attribute value** set to **RADIUS-Request**. If the Termination-Action attribute is not set to **RADIUS-Request**, wireless APs might end the connection during reauthentication. For more information, see your hardware documentation.

**Default remote access policies**

Two default remote access policies are installed with IAS in Windows Server 2003, with the following names and configurations:

1. The **Connections to Microsoft Routing and Remote Access server** policy has the following configuration:

   - Policy conditions are set to process Access-Request messages sent by RADIUS clients that are computers running the Microsoft Routing and Remote Access service. This policy condition is set by using the MS-RAS Vendor attribute with a wildcard value of **^311$**.

   - Permission is set to **Deny remote access permission**.

   - Two connection attributes are configured in profile properties: Framed-Protocol is configured with a value of **PPP**, and Service-Type is configured with a value of **Framed**.

   - Connections that use no encryption are not allowed. Only connections using basic, strong, or strongest encryption are allowed.

   - IP packet filters are configured to allow traffic only between the IAS server and network access servers configured as RADIUS clients.

   - All other profile properties are set to default values.

2. The **Connections to other access servers** policy has the following configuration:

    - The **Day-and-Time-Restrictions** condition is set to all times and all days.
    - Permission is set to **Deny remote access permission**.
    - Two connection attributes are configured in profile properties: Framed-Protocol is configured with a value of **PPP**, and Service-Type is configured with a value of **Framed**.
    - All profile properties are set to default values.

**Vendor Profiles**
Some vendors use VSAs to provide functionality that is not supported in standard attributes. IAS enables you to create or modify VSAs to take advantage of the proprietary functionality that is supported by some NAS vendors.

If you need to configure more than one VSA for a specific profile, you must arrange them in the appropriate order. If you are using filters and the order of the filters is important, use the arrow buttons to rearrange the attributes.

**Example 1**
The following example demonstrates the procedure of adding a Cisco VSA to a profile. The example illustrates only the mechanism of adding a standard-conforming VSA to a profile. Cisco VSAs are readily available through the IAS multi-vendor dictionary.

Cisco VSAs conform to the RADIUS RFC 2548 for Vendor-Specific Attributes (type 26). The following information is for a Cisco attribute to specify a primary DNS server:

- Vendor ID: 9. This is the unique ID for Cisco. When you specify that vendor, this is automatically supplied.
- Vendor Type: 1. This is the vendor-type number for VSAs that take the attribute-value pair form, referred to in Cisco documentation as "cisco-avpair."
- Data Type: String.
- Format: If the attribute is mandatory, the format is: <protocol>: attribute=value

If the attribute is optional, the attribute-value pair is separated by an asterisk (*) instead of an equal sign (=). In this example, <protocol> is a value of the Cisco "protocol" attribute for a particular type of authorization. "Attribute" and "value" represent an appropriate attribute/value (AV) pair defined in the Cisco TACACS+ specification. This allows the full set of features available for TACACS+ authorization to also be used for RADIUS.

The Cisco attribute used to specify a primary DNS server appears as follows:

```
ip:dns-servers=10.10.10.10
```

**Example 2**
The following example demonstrates how to add a 3Com/U.S. Robotics VSA to a profile.

### Note

- Example 2 is included only to illustrate the mechanism for adding a standard nonconforming VSA to a profile. 3Com/U.S. Robotics VSAs are readily available from the IAS multivendor dictionary.

U.S. Robotics VSAs do not conform to the recommended format for Vendor-Specific Attributes (type 26) in RFC 2865. Therefore, all U.S. Robotics VSAs must be entered in hexadecimal format.

The following information is for a U.S. Robotics attribute to specify a primary DNS/NBNS server:

- Vendor ID: 429. This is the unique ID for U.S. Robotics. When you specify that vendor, this ID is automatically supplied.

- Indicator: 0x900F
- Data Type: String
- Format: The VSA must be entered in hexadecimal format.

For more information about the proprietary attributes of U.S. Robotics, see your U.S. Robotics documentation.

**Accepting a Connection Attempt**

When a user attempts a connection, the connection attempt is accepted or rejected based on the following:

1. The first policy in the ordered list of remote access policies is checked. If there are no policies, the connection attempt is rejected.
2. If all the conditions of the policy do not match the connection attempt, go to next policy. If there are no more policies, reject the connection attempt.
3. If all the conditions of the policy match the connection attempt, check the value of the **Ignore-User-Dialin-Properties** attribute.
4. If the **Ignore-User-Dialin-Properties** attribute is set to **False**, check the remote access permission setting for the user attempting the connection:
   - If **Deny access** is selected, reject the connection attempt.
   - If **Allow access** is selected, apply the user account properties and profile properties:

     If the connection attempt does not match the settings of the user account properties and profile properties, reject the connection attempt.

     If the connection attempt matches the settings of the user account properties and profile properties, accept the connection attempt.
5. If the remote access permission is not set to **Allow access** or **Deny access**, the remote access permission must be set to **Control access through Remote Access Policy**. In that case, check the remote access permission setting of the policy:
   - If **Deny remote access permission** is selected, reject the connection attempt.
   - If **Grant remote access permission** is selected, apply the user account properties and profile properties:

     If the connection attempt does not match the settings of the user account properties and profile properties, reject the connection attempt.

     If the connection attempt matches the settings of the user account properties and profile properties, accept the connection attempt.
6. If the **Ignore-User-Dialin-Properties** attribute is set to **True**, check the remote access permission setting of the policy:
   - If **Deny remote access permission** is selected, reject the connection attempt.
   - If **Grant remote access permission** is selected, apply the profile properties:

     If the connection attempt does not match the settings of the profile properties, reject the connection attempt.

If the connection attempt matches the settings of the profile properties, accept the connection attempt.

**IAS Accounting**
Support for the RADIUS standard allows IAS to log the accounting data produced by NASs and IAS. User authentication and accounting requests and periodic data recorded in log files is used primarily for IAS troubleshooting, connection analysis, and billing purposes. In addition, accounting records can provide you with a useful tool when analyzing possible security problems, such as an attempt by a malicious user to access network resources. You can log accounting data in three formats, including IAS format, database-compatible format, and SQL Server Logging format.

**RADIUS Accounting**
IAS supports RADIUS accounting, with which an administrator can track network usage for auditing and billing purposes. Accounting data can also be queried by Help desk and other applications to assist with network access troubleshooting. RADIUS accounting provides the following benefits:

- Real-time data collection.
- Accounting data can be collected from a central location.
- Non-Microsoft products can be used to analyze RADIUS accounting data to provide charge-back, troubleshooting, performance, and exception reports.

When configured for accounting, IAS can log accounting data to a log file or to a SQL Server database.

When a RADIUS client is configured to use RADIUS accounting, at the start of service delivery it generates an Accounting-Start message describing the type of service being delivered and the user it is being delivered to. The message is then sent to the RADIUS Accounting server, which sends back an acknowledgment to the RADIUS client. At the end of service delivery, the client generates an Accounting-Stop message describing the type of service that was delivered and statistics (optional), such as elapsed time, input and output octets, or input and output packets. It then sends that data to the RADIUS accounting server, which sends back an acknowledgment to the RADIUS client.

The Accounting-Request message (whether for the Start or Stop message) is submitted to the RADIUS accounting server through the network. If no response is returned within a length of time, the request is re-sent a number of times. The client can also forward requests to an alternate server or servers in the event that the primary server is down or unreachable. An alternate server can be used either after a number of tries to the primary server fail, or in a round-robin fashion. If the RADIUS accounting server can not successfully record the accounting message, it does not send an Accounting-Response acknowledgment to the RADIUS client. For example, when the log file gets filled up, IAS starts discarding accounting messages. This prompts the RADIUS client to switch to the backup IAS server.

**SQL Server Logging**
You can use SQL Server logging to record user authentication and accounting requests received from one or more NASs to a data source on a computer running the Microsoft SQL Server Desktop Engine (MSDE 2000) or Microsoft SQL Server 2000. Accounting data is passed from IAS in eXtensible Markup Language (XML) format to a stored procedure in an MSDE 2000 or SQL Server 2000 database, which support both SQL and XML (SQLXML).

Logging to a SQL Server 2000 relational database instead of a standard text file (that is, either IAS format or database-compatible format) has many advantages, including the following:

- Relationships between data tables enable the flexible creation of dynamic data views by using queries and reports.
- SQL Server 2000 has high-speed optimizations that can effectively support very large, terabyte-sized databases.
- Multiple bulk copy operations can be performed concurrently against a single table in SQL Server to speed data entry.
- The Transact-SQL BACKUP and RESTORE statements are optimized to read through a database serially and write in parallel to multiple backup devices. In addition, SQL Server 2000 supports differential backups, which replicate only the data changed after the last backup.
- You can configure SQL Server logging to provide failover and redundancy, and multiple IAS servers can log to the same database, providing ease of administration.
- Data from multiple IAS servers can be stored in the same database, providing a centralized data source for many IAS

servers and the ability to achieve a more comprehensive data view for applications that query the database, such as Help desk applications.

In addition, you can improve logging performance and, in some circumstances, reduce the cost of deploying SQL Server logging by using MSDE 2000 databases installed on each IAS server.

The recommended deployment model for SQL Server logging is to configure IAS to log to a stored procedure in a MSDE 2000 database installed on the local server. You can then write a program, service, or component that periodically publishes the accounting data from the MSDE 2000 database to a central SQL Server.

**Components of IAS SQL Server logging**
IAS SQL Server logging includes several components, some of which are installed on the IAS server, and some of which are configured on the computer running SQL Server 2000.

The figure, "IAS SQL Server Logging," illustrates the components of SQL Server logging with IAS in Windows Server 2003 and a computer running SQL Server 2000.

**IAS SQL Server Logging**

**IAS server**
A computer running Windows Server 2003 and IAS configured to use SQL Server logging.

**MSDE 2000 database**
A data engine and database built and based on core SQL Server technology that is installed on the computer running Windows Server 2003 and IAS.

**Stored procedure**
A group of Transact-SQL statements compiled into a single execution plan, or program, that runs inside the MSDE 2000 database on the computer running Windows Server 2003 and IAS. The stored procedure must be named report_event. Report_event accepts and processes data from the IAS server and stores it in MSDE 2000 tables.

**Custom accounting-forwarder component**
A low-level program installed on the computer running Windows Server 2003 and IAS that automatically manages and administers the MSDE 2000 database. The custom component, service, or application should periodically publish records from the MSDE 2000 database on the IAS server to the IAS database on the computer running SQL Server. The custom component should also flag records as published, and delete previously published records from the MSDE 2000 database during off-peak hours. If there are multiple IAS servers configured for SQL Server logging, each server must have the custom component installed to process records in the local MSDE 2000 database and forward records to the SQL Server database.

**SQL server**
A computer or computer cluster running SQL Server 2000. If you have a small IAS deployment, you might need only one computer running SQL Server; if you have a large IAS deployment in an enterprise network environment, you might need more than one computer running SQL Server or a cluster of computers running SQL Server.

**IAS database**
A database on the computer running SQL Server dedicated to storing the records from all IAS servers configured for SQL Server logging.

**Configuring accounting to provide the best session correlation**
When you use an application to query your SQL Server 2000 database, it is important that sufficient data is logged to provide the application the ability to correlate related fields and information into a cohesive view of any particular user session. This is called *session correlation*. To provide the best session correlation, take the following actions:

- Use NASs that send the Class attribute in all accounting-requests. The Class attribute is sent to the RADIUS client in an Access-Accept message, and is useful for correlating Accounting-Request messages with authentication sessions.

- If the Class attribute is sent by the NAS in the accounting request messages, it can be used to match the accounting and authentication records. The combination of the attributes Unique-Serial-Number, Service-Reboot-Time, and Server-Address must be a unique identification for each authentication that the server accepts.

- Use NASs that support interim accounting.

- Use NASs that send on/off accounting messages.

- Use NASs that support the storing and forwarding of accounting data. NASs that support this feature can store accounting data in circumstances when it cannot communicate with the IAS server. When the IAS server is available, the NAS forwards the stored records to the IAS server, providing increased reliability in accounting over NASs that do not provide this feature.

- Always configure the Acct-Interim-Interval attribute in remote access policies. The Acct-Interim-Interval attribute sets the interval (in seconds) between each interim update that the NAS sends. You can add the Acct-Interim-Interval RADIUS attribute on the Advanced tab on the profile settings of the remote access policy. According to RFC 2869, the value of the Acct-Interim-Interval attribute must not be smaller than 60 seconds, or one minute, and should not be smaller than 600 seconds, or 10 minutes. For more information, see RFC 2869, "RADIUS Extensions."

- Ensure that logging of periodic status is enabled on your IAS servers.

**IAS log file**

IAS can create a log file based on the data returned by the NASs. This information is useful for keeping track of usage and correlating authentication information with accounting records (for example, to discover missing records or instances of over-billing).

IAS supports two formats of the log file: IAS format and database. Database format allows you to keep track of a predetermined set of attributes, and IAS format is more detailed and can contain information about all attributes. Use database format if you want to import the data directly into a database. The IAS format can be used if you need to record more detailed information than the database log format allows.

### Note

- The IAS log file contains all the IAS user-related events. IAS service and system-related events are recorded in the Event log files.

**IAS Authentication and Domain Functionality**

IAS authentication features and behavior vary with the functional levels of the domains in which IAS is running. Knowing the differences is useful when making decisions about a particular domain in which IAS is deployed.

Domain and forest functionality, introduced in Windows Server 2003 Active Directory, provides a way to enable domain- or forest-wide Active Directory features within your network environment. Different levels of domain functionality and forest functionality are available depending on your environment.

If all domain controllers in your domain or forest are running Windows Server 2003 and the functional level is set to Windows Server 2003, all domain- and forest-wide features are available. When Windows NT 4.0 or Windows 2000 domain controllers are included in your domain or forest with domain controllers running Windows Server 2003, Active Directory features are limited.

The concept of enabling additional functionality in Active Directory exists in Windows 2000 with mixed and native modes. Mixed-mode domains can contain Windows NT 4.0 backup domain controllers and cannot use Universal security groups, group nesting, and security ID (SID) history capabilities. When the domain is set to native mode, Universal security groups, group nesting, and SID history capabilities are available. Domain controllers running Windows 2000 Server are not aware of domain and forest functionality.

**Domain Functionality**

Domain functionality enables features that will affect the entire domain and that domain only. Four domain functional levels are available: Windows 2000 mixed (default), Windows 2000 native, Windows Server 2003 interim, and Windows Server 2003. By default, domains operate at the Windows 2000 mixed functional level.

The following table, “Domain Controller Support by Domain Functional Level,” lists the domain functional levels and their corresponding supported domain controllers.

**Domain Controller Support by Domain Functional Level**

| Domain Functional Level | Domain Controllers Supported |
|---|---|
| Windows 2000 mixed (default) | Windows NT 4.0<br>Windows 2000<br>Windows Server 2003 family |
| Windows 2000 native | Windows 2000<br>Windows Server 2003 family |
| Windows Server 2003 interim | Windows NT 4.0<br>Windows Server 2003 family |
| Windows Server 2003 | Windows Server 2003 family |

IAS is capable of authenticating access requests received through the RADIUS protocol against domains with Windows 2000 native, Windows 2000 mixed, Windows Server 2003 interim, and Windows Server 2003 domain functional levels. When you have a stand-alone IAS server, IAS can also authenticate access requests when configured with a Windows Server 2003 local accounts database.

The IAS authentication features and capabilities available to administrators are dependant upon the domain functional level of a particular domain against which the users authenticate.

**The Windows Server 2003 Domain Functional Level**
Domains configured with the Windows Server 2003 domain functional level provide the most flexibility in managing remote access through groups, including full support for all features.

**The Windows Server 2003 Interim Domain Functional Level**
Domains with a Windows Server 2003 interim functional level are mainly used for migration from Windows NT 4.0 to Windows Server 2003. For IAS, a Windows Server 2003 interim domain acts exactly like a Windows NT 4.0 domain.

For an IAS server that is a member of a Windows Server 2003 interim domain, the following authentication and remote access management features are available:

- User account dial-in properties
- Remote access permissions include only **Allow access** and **Deny access**

  Without the **Control access through Remote Access Policy** option, policy-based management using groups becomes more difficult because the user’s remote access permission overrides remote access policy permissions.
- Callback options

In order for the IAS server to access user account dial-in properties stored in Active Directory, the Internet Authentication service must run in the security context of a computer account that is a member of the **RAS and IAS Servers** security group. This assignment can be implemented through the Active Directory Users and Computers snap-in or by registering the IAS server in the IAS snap-in. You can also use the **netsh ras add registeredserver** command.

If IAS is a member of Windows NT 4.0 domain but has to authenticate users against a trusted Active Directory domain, it is not able to gain access to Active Directory because its computer account cannot become a member of the RAS and IAS Servers security group. In this case, verify that the **Everyone** group is added to the Pre-Windows 2000 Compatible Access group with the **net localgroup "Pre-Windows 2000 Compatible Access"** command. If not, issue the **net localgroup "Pre-Windows 2000 Compatible Access" everyone /add** command on a domain controller computer and then restart the domain controller computer.

**The Windows 2000 Native Domain Functional Level**
From the network access management perspective, the following benefits are available in the Windows 2000 native domain

functional level:

- Full ability to manage remote access permissions through groups. An administrator can use the universal group feature to create a single policy for users in different domains. Nested groups can be used to organize extremely large numbers of users into smaller groups for better management.

- An ability to connect remote network to office network. You can specify routes for the remote network through Static Routes.

- Support for User Principal Names (UPNs).

Users can have the same UPN regardless of what domain the user belongs to. This indirection provides scalability that might be required in organizations that have large number of domains.

The following is a detailed list of authentication and remote management features available for an IAS server that is a member of a domain with a Windows 2000 domain functional level.

- User or computer account dial-in properties, which include:

    - All remote access permissions options are available, including **Allow access**, **Deny access**, and **Control access through Remote Access Policy**.

    - Caller-ID

    - Callback options

    - Static IP address

    - Static routes

- Support for UPNs and Universal Groups

- Support for EAP-TLS and PEAP.

In order for the IAS server to access user account dial-in properties stored in Active Directory, IAS must run in the security context of a computer account that is a member of the **RAS and IAS Servers** security group. This assignment can be implemented through the Active Directory Users and Computers snap-in or by registering the IAS server in the IAS snap-in. You can also use the **netsh ras add registeredserver** command.

**The Windows 2000 Mixed Domain Functional Level**

Domains with a Windows 2000 mixed functional level are mainly used for migration from Windows NT 4.0 to Windows Server 2003 or Windows 2000. For IAS, a Windows 2000 mixed domain acts exactly like a Windows NT 4.0 domain.

For an IAS server that is a member of a Windows 2000 mixed domain, the following authentication and remote access management features are available:

- User account dial-in properties

- Remote access permissions include only **Allow access** and **Deny access**

  **Note**

    - Without the **Control access through Remote Access Policy** option, policy-based management, using groups becomes more difficult because the user's remote access permission overrides remote access policy permissions.

- Callback options

Just as in Windows 2000 native domains, in order for the IAS server to access user account dial-in properties stored in Active

Directory, the Internet Authentication service must run in the security context of a computer account that is a member of the **RAS and IAS Servers** security group. This assignment can be implemented through the Active Directory Users and Computers snap-in or by registering the IAS server in the IAS snap-in. You can also use the **netsh ras add registeredserver** command.

If IAS is a member of Windows NT 4.0 domain but has to authenticate users against a trusted Active Directory domain, it is not able to gain access to Active Directory because its computer account cannot become a member of the RAS and IAS Servers security group. In this case, verify that the Everyone group is added to the Pre-Windows 2000 Compatible Access group with the **net localgroup "Pre-Windows 2000 Compatible Access"** command. If not, issue the **net localgroup "Pre-Windows 2000 Compatible Access" everyone /add** command on a domain controller computer and then restart the domain controller computer.

**Stand-Alone IAS Servers**
Stand-alone IAS servers can be used in very small networks with no domains. All the users need to be defined in the local accounts database of a stand-alone server.

The following authentication features are available on a stand-alone IAS server:

- Dial-in User Account Properties
    - All remote access permission options, including **Allow access**, **Deny access**, and **Control access through Remote Access Policy**
- Caller-ID
- Callback options
- Static IP address
- Static routes

Support for UPNs, Universal Groups, and EAP-TLS is not available on a stand-alone IAS server computer.

User account dial-in properties can be administered through the properties of the Incoming Connections connection in the Network Connections folder or through the Local Users and Groups snap-in.

**Differences in IAS Implementations**
A previous version of IAS was released with the Windows NT 4.0 Option Pack. The following section describes the differences in behavior between the two versions.

**Windows NT 4.0 IAS**

- If no domain name is specified during authentication, the IAS server authenticates the user against only the local SAM database.
- IAS does not use the callback permissions for all user objects. IAS
- IAS log files are written in ASCII.

**Windows 2000 and Windows Server 2003 IAS**
IAS resolves a user name with no domain specified by using the following sequence:

- IAS determines a default domain from the registry, if one is specified there.
    - If the IAS server is a member of a domain, IAS authenticates the user against that domain.
    - If the IAS server is not a member of a domain, IAS authenticates the user against the local SAM database.
- IAS uses the callback permissions for all user objects.
- IAS log files are multi-language and are written in UTF-8.

**IAS as a RADIUS Proxy**

IAS can be used as a RADIUS proxy to provide the routing of RADIUS messages between RADIUS clients (NASs) and RADIUS servers that perform user authentication, authorization, and accounting for the connection attempt. When used as a RADIUS proxy, IAS is a central routing point through which RADIUS access and accounting messages flow. IAS records information in an accounting log about the messages that are forwarded.

The figure, "IAS as a RADIUS Proxy," illustrates how the feature can be used to relays messages between RADIUS clients (access servers) and either RADIUS servers or another RADIUS proxy.

**IAS as a RADIUS Proxy**

IAS acts as a RADIUS proxy for incoming RADIUS messages when the message matches a connection request policy that is configured to forward the request to a remote RADIUS server group.

When IAS is a RADIUS proxy between a RADIUS client and a RADIUS server, the messages that RADIUS sends for network access are forwarded as follows:

1. Access servers, such as dial-up network access servers, VPN servers, and wireless access points, receive connection requests from access clients.

2. The access server, configured to use RADIUS as the authentication, authorization, and accounting protocol, creates an Access-Request message and sends it to the IAS server that is being used as the IAS RADIUS proxy.

3. The IAS RADIUS proxy receives the Access-Request message and, based on the locally configured connection request policies, determines where to forward the Access-Request message.

4. The IAS RADIUS proxy forwards the Access-Request message to the appropriate RADIUS server.

5. The RADIUS server evaluates the Access-Request message.

6. If required, the RADIUS server sends an Access-Challenge message to the IAS RADIUS proxy, where it is forwarded to the access server. The access server processes the challenge with the access client and sends an updated Access-Request to the IAS RADIUS proxy, where it is forwarded to the RADIUS server.

7. The RADIUS server authenticates and authorizes the connection attempt.

8. If the connection attempt is both authenticated and authorized, the RADIUS server sends an Access-Accept message to the IAS RADIUS proxy, where it is forwarded to the access server.

9. If the connection attempt is either not authenticated or not authorized, the RADIUS server sends an Access-Reject message to the IAS RADIUS proxy, where it is forwarded to the access server.

10. The access server completes the connection process with the access client and sends an Accounting-Request message to the IAS RADIUS proxy. The IAS RADIUS proxy logs the accounting data and forwards the message to the RADIUS server.

11. The RADIUS server sends an Accounting-Response to the IAS RADIUS proxy, where it is forwarded to the access server.

**Access-Request Messages**
Forwarding a RADIUS Access-Request message from a RADIUS client to a RADIUS server results in the following changes to the RADIUS Access-Request message:

- Attribute manipulation rules are applied and the RADIUS attribute is modified according to the configured find and replace rules.

- All RADIUS message fields for which the RADIUS shared secret is used are recalculated. The recalculation is performed by using the shared secret of the IAS server and the remote RADIUS server to which the message is being forwarded. These RADIUS attributes include the Message Authenticator (also known as the Signature attribute), User-Name, Tunnel-Password, and MS-CHAP -MPPE-Keys. Additionally, the Authenticator field in the RADIUS header is recalculated.

- If the Access-Request message contains a Proxy-State attribute indicating that the message has been forwarded by another RADIUS proxy, the contents of the Proxy-State attribute are saved in a proxy session table and the Proxy-State attribute is rewritten with a value determined by the IAS server. The new value of the Proxy-State attribute is stored in a proxy session table.

When forwarding the Access-Request message, the set of additional RADIUS attributes as configured on the **Advanced** tab from the profile settings of the matching connection request policy is stored in the proxy session table. These attributes are not actually added to the Access-Request message but are saved for the response to the Access-Request message.

**Access-Accept Messages**
The proxy-state attribute in the Access-Accept message is used to find the corresponding entry in the proxy session table. The entry in the proxy session table indicates the IP address of the client to which the message is forwarded, the Proxy-State attribute of the original Access-Request message, and any additional RADIUS attributes to add. If an entry is not found, the Access-Accept message is discarded.

Forwarding a RADIUS Access-Accept message from a RADIUS server to a RADIUS client results in the following changes to the RADIUS Access-Accept message:

- All RADIUS message fields for which the RADIUS shared secret is used are recalculated by using the shared secret of the IAS server and the RADIUS client to which the message is being forwarded. These RADIUS attributes include the Message Authenticator (also known as the Signature attribute), Tunnel-Password, and MS-CHAP -MPPE-Keys. Additionally, the Authenticator field in the RADIUS header is recalculated.

- If the proxy session table entry contains an original Proxy-State attribute, the Proxy-State attribute in the Access-Accept message is replaced with the original Proxy-State attribute of the Access-Request message.

- If the proxy session table entry contains an additional RADIUS attributes, these RADIUS attributes are added to the Access-Accept message. If any of these RADIUS attributes are already present, their values are overwritten with new values.

**Access-Reject Messages**
The proxy-state attribute in the Access-Reject message is used to lookup the corresponding entry in the proxy session table. The entry in the proxy session table indicates the IP address of the client to which the message is to be forwarded, the Proxy-State attribute of the original Access-Request message, and any additional RADIUS attributes to add. If an entry is not found, the Access-Reject message is discarded.

Forwarding a RADIUS Access-Reject message from a RADIUS server to a RADIUS client results in the following changes to the RADIUS Access-Reject message:

- All RADIUS message fields for which the RADIUS shared secret are used are recalculated by using the shared secret of the IAS server and the RADIUS client to which the message is being forwarded. These RADIUS attributes include the Message Authenticator (also known as the Signature attribute), Tunnel-Password, and MS-CHAP -MPPE-Keys. Additionally, the Authenticator field in the RADIUS header is recalculated.

- If the proxy session table entry contains an original Proxy-State attribute, the Proxy-State attribute in the Access-Reject message is replaced with the Proxy-State attribute of the original Access-Request message.

- If the proxy session table entry contains an additional RADIUS attributes, these RADIUS attributes are added to the Access-Reject message. If any of these RADIUS attributes are already present, their values are overwritten with new values.

**Accounting-Request Messages**
When a RADIUS proxy forwards a RADIUS Accounting-Request message from a RADIUS client to a RADIUS server, it results in the following changes:

- Attribute manipulation rules are applied and the RADIUS attribute is modified according to the configured find and replace rules.

- All RADIUS message fields for which the RADIUS shared secret are used are recalculated using the shared secret of the IAS server and the remote RADIUS server to which the message is being forwarded. These RADIUS attributes include the Message Authenticator (also known as the Signature attribute) and User-Name. Additionally, the Authenticator field in the RADIUS header is recalculated.

- If the Accounting-Request message contains a Proxy-State attribute indicating that the message has been forwarded by another RADIUS proxy, the contents of the Proxy-State attribute are saved in a proxy session table and the Proxy-State attribute is rewritten with a value determined by the IAS server. The new value of the Proxy-State attribute is stored in a proxy session table.

When forwarding the Accounting-Request message, the set of additional RADIUS attributes as configured on the **Advanced** tab from the profile settings of the matching connection request policy is stored in the proxy session table. These attributes are not actually added to the Accounting-Request message but are saved for the response to the Accounting-Request message.

**Accounting-Response Messages**
The Proxy-State attribute in the Accounting-Response message is used to lookup the corresponding entry in the proxy session table. The entry in the proxy session table indicates the IP address of the client to which the message is to be forwarded, the Proxy-State attribute of the original Accounting-Request message, and any additional RADIUS attributes to add. If an entry is not found, the Accounting-Response message is discarded.

When a RADIUS proxy forwards a RADIUS Accounting-Response message from a RADIUS server to a RADIUS client, it results in the following changes to the RADIUS Accounting-Response message:

- All RADIUS message fields for which the RADIUS shared secret are used are recalculated using the shared secret of the IAS server and the RADIUS client to which the message is being forwarded, such as the Message Authenticator (also known as the Signature attribute). Additionally, the Authenticator field in the RADIUS header is recalculated.

- If the proxy session table entry contains an original Proxy-State attribute, the Proxy-State attribute in the Accounting-Response message is replaced with the original Proxy-State attribute of the Accounting-Request message.

- If the proxy session table entry contains additional RADIUS attributes, these RADIUS attributes are added to the Accounting-Response message. If any of these RADIUS attributes are already present, their values are overwritten with new values.

**Connection Request Processing**
To determine whether a specific connection attempt request or an accounting message received from a RADIUS client should be processed locally or forwarded to another RADIUS server, the IAS server uses connection request processing. Connection-request processing is a combination of the following:

- Connection request policies that determine, for any incoming RADIUS request message, whether the message is processed locally or forwarded to another RADIUS server.

- Remote RADIUS server groups that specify multiple RADIUS servers when an incoming RADIUS request message is forwarded.

**Connection Request Policies**

Connection request policies are sets of conditions and profile settings that give network administrators flexibility in configuring how incoming authentication and accounting request messages are handled by the IAS server. Using connection request policies, you can create a series of policies so that some RADIUS request messages sent from RADIUS clients are processed locally (IAS is being used as a RADIUS server) and other types of messages are forwarded to another RADIUS server (IAS is being used as a RADIUS proxy). This capability allows IAS to be implemented in many new RADIUS deployments.

With connection request policies, you can use IAS as a RADIUS server or as a RADIUS proxy, based on the time of day and day of the week, by the realm name in the request, by the type of connection being requested, by the IP address of the RADIUS client, and so on.

It is important to remember that with connection request policies, a RADIUS request message is processed only if the settings of the incoming RADIUS request message match at least one of the connection request policies. For example, if the settings of an incoming RADIUS Access-Request message do not match at least one of the connection request policies, an Access-Reject message is sent.

**Elements of a Connection Request Policy**

A connection request policy is a named rule that consists of the following elements:

- Conditions
- Profile

Connection request policies, like remote access policies, operate on the following principle:

- If the RADIUS request message matching all of the conditions of a connection request policy, the profile settings of the policy are applied to determine how the message is processed.

**Policy Conditions**

Connection request policy conditions are one or more RADIUS attributes that are compared to the attributes of the incoming RADIUS request message. If there are multiple conditions, then all conditions must match the attributes of the incoming RADIUS message so that the RADIUS request message matches the policy.

The following table, "Connection Request Policy Condition Attributes," shows the condition attributes that you can set for a connection request policy.

**Connection Request Policy Condition Attributes**

| Attribute name | Description |
|---|---|
| Called Station ID | The phone number of the NAS. This attribute is a character string. You can use pattern matching syntax to specify area codes. |
| Calling Station ID | The phone number used by the caller (the access client). This attribute is a character string. You can use pattern matching syntax to specify area codes. |
| Client Friendly Name | The name of the RADIUS client computer that is requesting authentication. This attribute is a character string. You can use pattern matching syntax to specify client names. |
| Client IP Address | The IP address of the NAS (the RADIUS client). This attribute is a character string. You can use pattern matching syntax to specify IP networks. |
| Client Vendor | The vendor of the NAS that is requesting authentication. You can use this attribute to configure separate policies for different NAS manufacturers that are configured as RADIUS clients to an IAS server. |
| Day and Time Restrictions | The day of the week and the time of day of the connection attempt. The day and time is relative to the date and time of the IAS server. |
| Framed Protocol | The type of framing for incoming packets. Examples are PPP, SLIP, Frame Relay, and X.25. |

| | |
|---|---|
| NAS Identifier | The name of the NAS. This attribute is a character string. You can use pattern matching syntax to specify NAS identifiers. |
| NAS IP Address | The IP address of the NAS (the RADIUS client). This attribute is a character string. You can use pattern matching syntax to specify IP networks. |
| NAS Port Type | The type of media used by the caller. Examples are analog phone lines (known as async), ISDN, and tunnels or virtual private networks (known as virtual). |
| Remote RADIUS to Windows User Mapping | Specifies that authorization is performed locally with remote access policies and user account properties, and authentication is performed against a remote RADIUS server. For example, visitors to your network are authenticated by their organization's RADIUS server, while a Windows user account created for the visitor at your organization is used for authorization. This configuration allows you to provide visitors with limited access to your network resources, while authenticating them against the user account database at their own organization. |
| Service Type | The type of service being requested. Examples include framed (such as PPP connections) and login (such as Telnet connections). For more information about RADIUS service types, see RFC 2865. |
| Tunnel Type | The type of tunnel being created by the requesting client. Tunnel types include the Point-to-Point Tunneling Protocol (PPTP) and the Layer Two Tunneling Protocol (L2TP) used by Windows Server 2003 and Windows 2000 remote access clients and demand-dial routers. |
| User Name | The user name used by the access client in the RADIUS message. This attribute is a character string. You can use pattern matching syntax to specify client names. |

**Policy Profile**

A connection request policy profile is a set of properties that are applied to an incoming RADIUS message. A connection request policy profile consists of the following groups of properties:

- Authentication
- Accounting
- Attribute Manipulation
- Advanced

**Authentication**

You can set the following authentication options used for RADIUS Access-Request messages:

- Authenticate requests on this server

  Use a Windows NT 4.0 domain or the Active Directory directory service, or the local SAM on Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, for both authentication and the matching remote access policy and user account dial-in properties for authorization. In this case, the IAS server is being used as a RADIUS server.

- Forward requests to another RADIUS server in a remote RADIUS server group

  Forward the Access-Request message to another RADIUS server in a specified remote RADIUS server group. If the IAS server receives a valid Access-Accept message that corresponds to the Access-Request message, the connection attempt is considered authenticated and authorized. In this case, the IAS server is being used as a RADIUS proxy.

- Accept the connection attempt without performing authentication or authorization

  Do not verify the user credentials and do not check user account properties or remote access policies to verify that the user is authorized to access network resources. An Access-Accept message is immediately sent to the RADIUS client by IAS without performing authentication or authorization. This setting is used for some types of compulsory tunneling where the access client is tunneled before the users credentials are authenticated.

This authentication option cannot be used when the authentication protocol of the access client is PEAP, MS-CHAP v2, or EAP-TLS, which provide mutual authentication. In mutual authentication, the access client proves that it is a valid access client to the authenticating server (the IAS server), and the authenticating server proves that it is a valid authenticating server to the access client. When this authentication option is used, the Access-Accept message is returned. However, the authenticating server does not provide validation to the access client and mutual authentication fails.

**Accounting options**

You can set the following accounting options that are used for RADIUS Accounting-Request messages:

- Forward accounting information in a specific remote RADIUS server group

  Pass the accounting request to another RADIUS server in a specified remote RADIUS server group. In this case, the IAS server is acting as a RADIUS proxy.

  **Note**

  - IAS always records the accounting information for Accounting-Request messages in local log files on the basis of remote access logging settings.

**Attribute manipulation rules**

You can configure a set of find and replace rules that manipulate the text strings of one of the following attributes:

- User Name
- Called Station ID
- Calling Station ID

Attribute manipulation rule processing occurs for one of the preceding attributes before the RADIUS message is subject to authentication and accounting settings.

You can configure attribute manipulation rules in the profile of a connection request policy. When you configure attribute manipulation rules, you specify text that you want IAS to find in the attribute and you specify replacement text. While processing attribute manipulation rules, IAS seeks the text you specify in the rule. If the text is found in the attribute, IAS deletes the text and replaces it with the replacement text that you specify in the rule.

Configuring an attribute manipulation rule for the User Name attribute in IAS for Windows Server 2003 is equivalent to configuring realm replacement rules for IAS in Windows 2000.

If you are using the MS-CHAP v2 authentication protocol, you cannot manipulate the User Name attribute if the connection request policy is used to forward the RADIUS message. The only exception occurs when a backslash (\) character is used and the manipulation only affects the information to the left of this character. A backslash character is typically used to indicate a domain name (the information to the left of the backslash character) and a user account name within the domain (the information to the right of the backslash character). In this case, only attribute manipulation rules that modify or replace the domain name are allowed.

**Note**

- Find and replace rules apply only to a single attribute. You cannot configure find and replace rules for each attribute or add to the list of attributes available for manipulation.

**Advanced properties**

You can set advanced properties to specify the series of RADIUS attributes that are:

- Added to the RADIUS response message when the IAS server is being used as a RADIUS authentication or accounting server.

When there are attributes specified on both a remote access policy and the connection request policy, the attributes that are sent in the RADIUS response message are the combination of the two sets of attributes.

- Added to the RADIUS message when the IAS server is being used as a RADIUS authentication or accounting proxy. If the attribute already exists in the message that is forwarded, it is replaced with the value of the attribute specified in the connection request policy.

**Default Connection Request Policy**

A default connection request policy named **Use Windows authentication for all users** is created when you install IAS. This policy has the following configuration:

- The Day-and-Time-Restrictions condition is set to all times and all days.
- Authentication is set to authenticate requests on this server.
- Accounting is not set to forward accounting information to a remote RADIUS server group.
- Attribute manipulation rules are not configured.
- Advanced attributes are not configured.

The default connection request policy uses IAS as a RADIUS server. To configure an IAS server to act as a RADIUS proxy, you must also configure a remote RADIUS server group. You can create a new remote RADIUS server group while you are creating a new connection request policy with the New Connection Request Policy Wizard. You can either delete the default connection request policy or verify that the default connection request policy is the last policy processed.

**Realm Names**

When an access client sends password-based user account credentials during connection attempts with a NAS, a user name and password are included. The user name consists of two elements:

- Identification of the user account name.
- Identification of the user account location on the network.

For example, for the user name user1@microsoft.com, user1 is the user account name and microsoft.com is the location of the user account. The identification of the location of the user account is known as a realm. There are two forms of realm names:

- The realm name can be a prefix.

  For example, Microsoft\user1, where Microsoft is the name of a Windows NT domain.

- The realm name can be a suffix.

  For example, user1@microsoft.com, where microsoft.com is either a DNS domain name or the name of an Active Directory domain.

When initiating a network connection, users can be required to provide the realm name as either a prefix or a suffix when typing account credentials in the **Connect** dialog box. For example, when the owner of the account user1 connects to microsoft.com with a VPN connection, they can be required to type either MICROSOFT\user1 or user1@microsoft.com.

If you use Connection Manager Administration Kit (CMAK) to create Connection Manager profiles for distribution to users, the profile can be configured to automatically append the realm name to the user account name during connection attempts by users.

For example, you can specify a realm name and syntax when you create a custom dialing package with CMAK so that the user must specify only the user account name.

In this circumstance, if the realm name is Microsoft, the correct syntax is to specify the realm name as a prefix. When a user logs on with the account name **user1**, the user enters the string “user1,” but does not enter a realm name. The Connection Manager profile automatically appends the realm name to **user1** and sends the following user name to the NAS: **MICROSOFT\user1**.

For more information, see “Pattern Matching Syntax” later in this section.

**RADIUS User-Name Attribute**
During the authentication phase of the connection attempt, the user name is passed from the access client to the access server. The access server creates an Access-Request message, using the user name as the value for the RADIUS attribute User-Name. The access server, which is configured as a RADIUS client to an IAS server or IAS proxy, sends the Access-Request message containing the User-Name attribute to the IAS server or proxy.

The IAS server evaluates the Access-Request message against the set of configured connection request policies. Connection request policies are a set of conditions and profile settings that determine, for any incoming RADIUS request message, whether the message is processed locally or forwarded to another RADIUS server. The realm name, contained in the RADIUS User-Name attribute, can be specified in the connection request policy and assist IAS in determining how to route connection requests.

**Using Realm Names to Route Connection Requests**
You can configure a set of connection request policies that are specific to the realm name within the User-Name attribute of incoming messages. This allows to you create routing rules that forward RADIUS messages with a specific realm name to a specific set of RADIUS servers (a remote RADIUS server group) when IAS is used as a RADIUS proxy.

Before the RADIUS message is either processed locally (when IAS is being used as a RADIUS server) or forwarded to another RADIUS server (when IAS is being used as a RADIUS proxy), the User-Name attribute in the message might be modified by attribute manipulation rules that are configured in the profile of the first matching connection request policy. Attribute manipulation rules for the User-Name attribute might change the following:

- Remove the realm name from the user name (also known as realm stripping).

  For example, the user name user1@microsoft.com is changed to user1.

- Change the realm name but not its syntax.

  For example, the user name user1@microsoft.com is changed to user1@wcoast.microsoft.com.

- Change the syntax of the realm name.

  For example, the user name microsoft\user1 is changed to user1@microsoft.com.

Attribute manipulation rules are configured in the Attribute tab on the profile of a connection request policy.

IAS attribute manipulation rules use regular expression syntax.

After the User-Name attribute is modified according to attribute manipulation rules, additional settings on the profile of the first matching connection request policy are used by IAS to determine whether to process the message locally or to forward the message to a remote RADIUS server group:

- When IAS is configured as a RADIUS server, the Access-Request message is processed locally

- When IAS is configured as a RADIUS proxy, the Access-Request message is forwarded to another RADIUS server that is configured as a member of a remote RADIUS server group.

**Pattern Matching Syntax**
IAS supports regular expressions for pattern matching, which is widely used in UNIX environments. You can use this syntax to specify the conditions of remote access policy attributes and RADIUS realms, as specified in the following table, “Pattern Matching Syntax Characters.”

### Pattern Matching Syntax Characters

| Character | Description | Example |
|---|---|---|
| \ | Marks the next character as a character to match. | /”n”/ matches the character “n”. The seque”n”ce /\”n”/ matches a line feed or newline character. |

| | | |
|---|---|---|
| ^ | Matches the beginning of the input or line. | |
| $ | Matches the end of the input or line. | |
| * | Matches the preceding character zero or more times. | /zo*/ matches either “z” or “zoo.” |
| + | Matches the preceding character one or more times. | /zo+/ matches “zoo” but not “z.” |
| ? | Matches the preceding character zero or one times. | /a?ve?/ matches the “ve” in “never.” |
| . | Matches any single character except a newline character. | |
| **(** *pattern* **)** | Matches *pattern* and remembers the match. To match ( ) (parentheses), use "\(" or "\)." | |
| *x* **\|** *y* | Matches either *x* or *y*. | /z\|food?/ matches “zoo” or “food.” |
| **{** *n* **}** | Matches exactly *n* times (*n* is a nonnegative integer). | /o{2}/ does not match the “o” in “Bob,” but matches the first two instances of the letter “o” in “foooood.” |
| **{** *n* **,}** | Matches at least *n* times (*n* is a nonnegative integer). | /o{2,}/ does not match the “o” in “Bob” but matches all of the instances of the letter “o” in “foooood.” /o{1,}/ is equivalent to /o+/. |
| **{** *n* **,}** | Matches at least *n* times (*n* is a nonnegative integer). | /o{2,}/ does not match the “o” in “Bob” but matches all of the instances of the letter “o” in “foooood.” /o{1,}/ is equivalent to /o+/. |
| **{** *n* **,** *m* **}** | Matches at least *n* and at most *m* times (*m* and *n* are nonnegative integers). | /o{1,3}/ matches the first three instances of the letter “o” in “foooood.” |
| **[** *xyz* **]** | Matches any one of the enclosed characters (a character set). | /[abc]/ matches the “a” in “plain.” |
| **[^** *xyz* **]** | Matches any characters that are not enclosed (a negative character set). | /[^abc]/ matches the “p” in “p”lain. |
| **\b** | Matches a word boundary (for example, a space). | /ea*r\b/ matches the “er” in “never early.” |
| **\B** | Matches a nonword boundary. | /ea*r\B/ matches the “ear” in “never early.” |
| **\d** | Matches a digit character (equivalent to [0-9]). | |
| **\D** | Matches a nondigit character (equivalent to [^0-9]). | |
| **\f** | Matches a form feed character. | |
| **\n** | Matches a line feed character. | |
| **\r** | Matches a carriage return character. | |
| **\s** | Matches any white space character including space, tab, and form feed (equivalent to [ \f\n\r\t\v]). | |
| **\S** | Matches any non-white space character (equivalent to [^ \f\n\r\t\v]). | |
| **\t** | Matches a tab character. | |
| **\v** | Matches a vertical tab character. | |

| | | |
|---|---|---|
| **\w** | Matches any word character, including underscore (equivalent to [A-Za-z0-9_]). | |
| **\W** | Matches any nonword character, excluding underscore (equivalent to [^A-Za-z0-9_]). | |
| **** *num* | Refers to remembered matches (?*num*, where *num* is a positive integer). For example, \1 replaces what is stored in the first remembered match. This option can be used only in the **Replace** text box when configuring attribute manipulation. | |
| **/** *n* **/** | Allows the insertion of ASCII codes into regular expressions (?*n*, where *n* is an octal, hexadecimal, or decimal escape value). | |

**Examples for Remote Access Policy Attributes**
The following examples illustrate the use of the pattern matching syntax to specify remote access policy attributes:

- To specify all phone numbers within the 899 area code, the syntax is: 899.*
- To specify a range of all IP addresses that begin with 192.168.1, the syntax is: 192\.168\.1\..+

**Examples for Manipulation of the Realm Name in the User-Name Attribute**
The following examples illustrate the use of the pattern matching syntax to manipulate realm names for the User-Name attribute. In the first example, the realm name is removed before the message is forwarded by an IAS proxy to an IAS server. In the other examples, additional variations of realm name manipulation are demonstrated.

**To remove the realm portion of the User-Name attribute**
Find: @microsoft\.com

Replace:

**To replace user@example.microsoft.com with example.microsoft.com\user**
Find: (.*)@(.*)

Replace: $2\$1

**To replace domain\user with specific_domain\user**
Find: (.*)\\(.*)

Replace: specific_domain\$2

**To replace user with user@specific_domain**
Find: $

Replace: @specific_domain

**Example for RADIUS Message Forwarding by a Proxy Server**
You can create routing rules that forward RADIUS messages with a specific realm name to a specific set of RADIUS servers when IAS is used as a RADIUS proxy. A recommended syntax for routing requests based on realm name follows:

- NetBIOS name: WCOAST
- Pattern: ^wcoast\\

In the following example, wcoast.microsoft.com is a unique user principal name (UPN) suffix for the DNS or Active Directory domain wcoast.microsoft.com. Using the supplied pattern, the IAS proxy can route messages based on domain NetBIOS name or UPN suffix as follows:

- NetBIOS name: WCOAST
- UPN suffix: wcoast.microsoft.com
- Pattern: ^wcoast\\|@wcoast\.microsoft\.com$

**Remote RADIUS Server Groups**
A remote RADIUS server group is a named group that contains one or more RADIUS servers to which messages are forwarded by the RADIUS proxy. When IAS is being used as a RADIUS proxy for RADIUS request messages, a remote RADIUS server group must be specified. You can specify various settings to determine the order in which the servers are used by the proxy server. You can also specify how the proxy distributes the RADIUS messages across the servers in the group.

Each server in the group has the following settings:

- Name or address

  Each group member must have a unique name within the group. The name can be an IP address or a name that can be resolved to its IP address.

- Authentication and accounting

  When IAS is used as a RADIUS proxy, it is acting as a RADIUS client to another RADIUS server. Therefore, each group member must be configured to send RADIUS messages to the correct UDP port that is used by the RADIUS server for RADIUS traffic. Additionally, each group member must be configured for the correct shared secret. The default authentication port is 1812. The default accounting port is 1813.

- Load balancing

  A priority setting is used to indicate which member of the group is the primary server (the priority is set to 1). For group members that have the same priority, a weight setting is used to calculate how often RADIUS messages are sent to each of them. You can use additional settings to configure the way in which the IAS server detects when a group member first becomes unavailable and when it becomes available after it has been determined to be unavailable.

After a remote RADIUS server group is configured, it can be specified in the authentication and accounting settings of a connection request policy. Because of this, it is recommended that you configure a remote RADIUS server group first. Next, you can configure the connection request policy to use the newly configured remote RADIUS server group. Alternately, you can use the New Connection Request Policy Wizard to create a new remote RADIUS server group while you are creating the connection request policy.

**Authentication Across Forests**
With IAS as a RADIUS proxy configured to forward messages to remote RADIUS server groups in different forests, you can authenticate users across forests. For example, if you have NASs in a perimeter network that serves users from two forests, you can configure the NASs as RADIUS clients to a RADIUS proxy server. At the proxy server you can configure two remote RADIUS server groups, each group containing the RADIUS servers in one forest. When a user connects to a NAS, the RADIUS proxy examines the realm portion of the user name and forwards the message to the remote RADIUS server group for authentication in the Active Directory user accounts database for that forest.

**Using Remote RADIUS Server Groups to Focus Accounting**
In some circumstances, you might want to assign the task of logging RADIUS accounting data to one or more remote RADIUS server groups, while assigning the task of processing authentication requests to other remote RADIUS server groups. This configuration is especially useful in organizations that regularly query RADIUS accounting data for network access troubleshooting and report creation. If you use IAS as a RADIUS proxy to route accounting data to one or more remote RADIUS server groups, you can configure the RADIUS servers in the remote RADIUS server groups to log to a central SQL Server database. Help desk and other applications can then query this database for comprehensive data views of network access sessions. Fore more information about IAS SQL Server logging, see “IAS Accounting” earlier in this section.

**Processing a Connection Request**
When an IAS server receives a valid RADIUS message from a RADIUS client, the RADIUS message is processed based on the following:

1. The first policy in the ordered list of connection request policies is checked. If there are no policies and the RADIUS message is an Access-Request message, an Access-Reject message is immediately sent.

2. If all the conditions of the policy do not match the RADIUS message, then go to next policy. If there are no more policies and the RADIUS message is an Access-Request message, an Access-Reject message is immediately sent.

3. If all the conditions of the policy match the RADIUS message, then apply the attribute manipulation rules configured in the policy.

4. If the RADIUS message is an Access-Request message, check the authentication settings on the matching connection request policy profile:

    - If the authentication setting is to authenticate using this server, use either the local SAM in Windows Server 2003 or Active Directory for authentication and the local remote access policies and user account dial-in properties for authorization.

    - If the authentication setting is to forward the request to a specific remote RADIUS server group, forward the Access-Request message containing the attribute(s) changed by the attribute manipulation rules to the appropriate RADIUS server in the group based on the priority and weight settings.

    - If the authentication setting is to accept the connection attempt without performing authentication or authorization, send back an Access-Accept message immediately.

5. If the RADIUS message is an accounting message, check the accounting settings on the profile of the matching policy:

    - If the accounting settings specify that accounting information is to be sent to a member of a remote RADIUS server group, forward the accounting message containing the attribute(s) changed by the attribute manipulation rules to the appropriate RADIUS server in the group on the basis of priority and weight settings.

    - Based on the settings for remote access logging, log the accounting message in the IAS accounting log.

**Using IAS as a RADIUS Proxy for Load Balancing**

IAS proxies, placed between access servers and IAS servers, can be used to balance the load of a large volume of authentication traffic. The following figure, "RADIUS Proxy Load Balancing," illustrates how IAS proxies are used for load balancing authentication requests to multiple IAS servers.

**RADIUS Proxy Load Balancing**

By using IAS as a RADIUS proxy, you can evenly distribute authentication, authorization, and accounting traffic across all the IAS servers in the organization. This load balancing solution is easily scaled up and out as your organization grows, and as you add more NASs and IAS servers.

Additionally, when you use IAS as a RADIUS proxy for load balancing, there is a consistent scheme for failure detection and RADIUS server failover.

Primary characteristics of load balancing include:

1. Active Directory is configured for user accounts and groups. Ensure that all users that are making network access connections have a corresponding user account. Also organize remote access by group to take advantage of group-based remote access policies.

2. Configure IAS as a RADIUS server on each domain controller. Configure IAS to read the user account properties in Active Directory, and configure the IAS proxies as RADIUS clients to the IAS servers.

3. Configure one or more IAS proxy servers. Configure NASs as RADIUS clients to the proxy servers. Use the New Remote RADIUS Server Group Wizard to create a custom remote RADIUS server group, and create a connection request policy that forwards RADIUS request messages to the IAS servers where the realm name matches the accounts in the domain. Also delete the default connection request policy.

4. Configure each access server to use the IAS proxies for the authentication, authorization, and accounting of network connections.

**Mapping Network Authentication and Authorization**

You can use IAS proxy to split network access authorization and authentication between two user account databases. For example, you can configure IAS to authenticate visitors (such as employees of a partner organization) by using their password-based credentials stored in the external partner organization user database, while performing authorization, using an account created for the visitor, in your local Active Directory user account database.

To split authentication and authorization between two user account databases, you must create a local user account for each visitor. The visitor account user name must map to an account with the same user namein the partner organization user database. When the visitor logs on to your network, the external user database provides authentication while the local user database and remote access policies are used to process authorization.

The forwarding of authentication requests to the partner organization RADIUS server is necessary only when visitor authentication is performed with password-based credentials. Visitors can also be authenticated by mapping certificates to local user accounts. If a partner organization uses certificate-based authentication, you can authenticate visitors by trusting the partner organization certification authority (CA) and mapping visitor certificates to local user accounts. Because the visitor is authenticated locally with a certificate, it is not necessary to forward authentication requests to the remote RADIUS server at the partner organization.

**Configuring Visitor User Accounts**

If you use password-based authentication, you must create a user account for each visitor. The visitor user account must be created so that the user name in the local database and the user name in the partner organization user database match exactly. To allow visitors access to your organization network while authenticating them at their partner organization, perform the following actions to configure visitor accounts:

1. Add the user principal name suffix to the domain.

2. Create an organizational unit that contains the user accounts for visitors.

3. Create user accounts in the organizational unit for visitors. When you create the user account, the user logon name must exactly match the visitor's user logon name as configured in the user account database at the partner organization. For example, if the visitor's user logon name at Microsoft Corporation is "user"@microsoft.com, designate "user" as the User logon namein the Active Directory Users and Computers snap-in.

4. Select the correct UPN suffix from the drop-down list of suffixes. For example, if in step one you added the UPN suffix "microsoft.com," select "@microsoft.com" from the list.

5. Configure other user account properties as needed. Make sure that the user account is configured in a way that allows the visitor to have network access, but also contains necessary security restrictions. For example, in user account properties, on the Dial-in tab, you can set Remote Access Permission (Dial-in or VPN) to Allow access.

**Configuring the IAS Proxy Server**

To allow visitors access to your organization network, you need to perform the following actions on your IAS proxy server:

- Configure the partner organization RADIUS server as a member of a Remote RADIUS server group.

  Run the New Remote RADIUS Server Group Wizard, create and name a custom group, and then add the partner organization RADIUS server (or servers) to the group. While adding each server, configure the shared secret (obtained from the partner organization) on the **Authentication/Accounting** tab of the **Add RADIUS server** dialog box.

- Configure a connection request policy for visitor access.

  To determine whether a specific connection attempt request or an accounting message received from a RADIUS client should be processed locally or forwarded to another RADIUS server, the IAS server uses connection request processing. When you allow visitor access with external authentication, you must configure a minimum of two connection request policies on your IAS proxy server. One policy allows your organization employees access, while denying access to other network access attempts. Another policy allows visitor access. When you configure your policy evaluation order, place the policy or policies for your organization users last, with the visitor policy processed first.

  To configure a connection request policy, run the New Connection Request Policy Wizard, create and name a custom policy, and then add **Policy Conditions**. You can configure as many conditions as you want, but you must include the User-Name attribute. Use wildcard and other characters to configure a value that must be matched by the user principal name (UPN) suffix your visitors will use when logging on. For example, if you want to authenticate all visitors from Microsoft Corporation with this connection request policy, you can type "^.@microsoft\.com$" in **User-Name**. In **Request Processing Method**, click **Edit Profile**, and then click the **Advanced** tab. Click **Add**, and then add the attribute **Remote-RADIUS-to-Windows-User-Mapping**, with the attribute value set to **True**. This attribute tells the IAS proxy server to authenticate users (whose properties match other policy conditions) against the RADIUS servers configured in the remote RADIUS server group. On the **Attribute** tab, you can configure replacement text for the User-Name attribute, as well as configure any other attributes that you require. On the **Authentication** tab, click **Forward requests to the following remote RADIUS server group for authentication**, and then choose the Remote RADIUS server group that can authenticate your visitors.

- Configure a remote access policy for visitor access.

  Because you can create remote access policies that are based on different types of connections and group membership, you can create a remote access policy used specifically to process network access attempts by visitors. At minimum, you need two remote access policies: one for your employees and a different one for visitors.

- Ensure that NASs are configured as RADIUS clients to this IAS proxy.

  When visitors log on to your network, they do so through NASs, such as wireless APs. These APs must be configured as RADIUS clients to your IAS proxy server.

After the IAS proxy is configured to forward authentication requests and user accounts for visitors are created in Active Directory, the password-based authentication request is forwarded to the partner organization RADIUS server when the visitor logs onto your organization network. If the user is authenticated, authorization is performed against your organization Active Directory user database. Active Directory returns user attributes (values configured for the user account, such as Allow access on the **Dial-in** tab of user properties), and IAS performs policy evaluation against these local user account attributes.

**Note**

- By configuring a local user account with the UPN of an account in the remote partner organization user account database, you map one account to the other. If the partner organization changes the user name of an account you have mapped, you must also change the user name in your user account database.

**Mapping with Certificate-Based Authentication**

Certificate-based authentication is more secure than password-based authentication. In addition, when you map certificates to user accounts instead of using password-based authentication methods, an authentication request is not forwarded to the partner organization RADIUS server and user account database. For these reasons, certificate mapping enhances security and can significantly reduce logon time for users.

A certificate is mapped to a user account in one of two ways: a single certificate is mapped to a single user account (one-to-one mapping) or multiple certificates are mapped to one user account (many-to-one mapping).

**One-to-One Mapping**

For one-to-one mapping of certificates to visitor user accounts, you must perform the following tasks:

- Create a user account for each visitor.

  Because the user account itself is not mapped to the user account at the partner organization, the user account names do

not have to exactly match the user account names in the partner organization user accounts database. Configuring the local account with the same user name, however, can make it easier to configure realm manipulation rules.

- Map the certificate to a user account.

- Perform cross-certification or authorize the partner organization CA as a qualified subordinate certification authority using a computer running Windows Server 2003, Enterprise Edition and Certificate Services.

  Performing cross-certification or authorizing the partner organization CA as a qualified subordinate CA is recommended for domains with a Windows Server 2003 domain functional level and clients running Windows XP. If your domains are Windows 2000 native, it is recommended that you use a certificate trust list (CTL) instead.

- Configure your IAS server or IAS proxy server

  Because authentication requests are not forwarded to external RADIUS servers when authentication is performed with certificates, you are not required to use IAS as a proxy server.

- Configure a connection request policy for visitor access with the New Connection Request Policy Wizard.

- Create a realm manipulation rule to map the partner organization realm name, which is contained in the user's certificate, to the user's local user account.

  For example, if user@tailspintoys.com is mapped to user@microsoft.com, the realm manipulation rule must replace "@tailspintoys.com" with "@microsoft.com" using pattern-matching syntax.

- Configure a remote access policy for visitor access.

- Ensure that NASs are configured as RADIUS clients to this IAS server.

When visitors log on to your network, they do so through NASs, such as wireless APs. These APs must be configured as RADIUS clients to your IAS proxy server or IAS server.

**Many-to-One Mapping**

Many-to-one certificate mapping allows you to map many certificates to one user account. After you have trusted the enterprise root CA of a partner organization, you can map all certificates issued by the partner organization CA to one account that you create in your local domain. This solution provides ease of management for many users, and eliminates the need to create an individual user account for every visitor to your organization.

For many-to-one mapping of certificates, you must perform the following steps:

- Perform cross-certification or authorize the partner organization CA as a qualified subordinate certification authority using a computer running Windows Server 2003, Enterprise Edition and Certificate Services.

Performing cross-certification or authorizing the partner organization CA as a qualified subordinate CA is recommended for domains with a Windows Server 2003 domain functional level and clients running Windows XP. If your domains are Windows 2000 native, it is recommended that you use a certificate trust list (CTL) instead.

- Create one user account and map the partner organization certificate to the account.

- Configure your IAS server or IAS proxy server

Because authentication requests are not forwarded to external RADIUS servers when authentication is performed with certificates, you are not required to use IAS as a proxy server.

- Configure a connection request policy for visitor access with the New Connection Request Policy Wizard.

- Create a realm manipulation rule to map the partner organization realm name, which is contained in the user's certificate, to the user's local user account.

For example, if user@tailspintoys.com is mapped to user@microsoft.com, the realm manipulation rule must replace @tailspintoys.com with "@microsoft.com," using pattern-matching syntax.

- Ensure that NASs are configured as RADIUS clients to this IAS server.

- Configure a remote access policy for visitor access.

When visitors log on to your network, they do so through NASs, such as wireless APs. These APs must be configured as RADIUS clients to your IAS proxy server or IAS server.

**Note**

- For strong security between your IAS proxy server and your partner organization RADIUS servers, you can use Internet Protocol security (IPSec).

# IAS Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- IAS Tools
- IAS Settings
- IAS Registry Entries
- Related Information

You can use Internet Authentication Service (IAS) tools, such as the IAS console and the Netsh commands for IAS, to configure your IAS servers. IAS settings include the use of the Message Authenticator attribute, shared secrets, domain name, and certificate templates. Because the correct configuration of your certificate templates for use with certificate-based authentication methods is critical to the success of your IAS deployment, this document provides step-by-step information about how to configure the Computer template and the IAS and RAS Servers template in Certificate Templates for Windows Server 2003.

**IAS Tools**
You can use the following tools to configure and manage your IAS servers.

**IAS Console**
After you install IAS, you can use the IAS console to configure Internet Authentication Service on the local computer. The console is launched through **Administrative Tools**, and can be used to configure Remote Authentication Dial-In User Service (RADIUS) clients, Remote Access Logging, Remote Access Policies, Connection Request Processing, and other server properties.

The IAS console can also be loaded as a snap-in from the Microsoft Management Console (MMC), allowing you to administer IAS on the local computer and on remote computers that are running IAS.

**Netsh Command Reference for AAAA**
You can use commands in the Netsh AAAA context to show and set the configuration of the authentication, authorization, accounting, and auditing (AAAA) database used by IAS and the Routing and Remote Access service. The AAAA database is also known as the IAS database (Ias.mdb). The primary use of commands in the Netsh AAAA context is to:

- Export the configuration of one IAS server, including registry keys and the IAS database, as a Netsh script using either the **dump** command or one of the **show** commands.
- Import the configuration to another IAS server using the **netsh exec** command, and a Netsh script that contains the **set config** command.

You can run the Netsh commands for AAAA from the Windows Server 2003 command prompt or from the command prompt for the Netsh AAAA context. For these commands to work at the Windows Server 2003 command prompt, you must type **netsh aaaa** before typing commands and parameters as they appear in the following syntax. There might be functional differences between Netsh context commands on Windows 2000 and Windows Server 2003.

The following table provides the command reference formatting legend, which describes how to interpret the syntax statement for each command.

**Command Reference Formatting**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply. |
| **Bold** | Elements that the user must type exactly as shown. |
| Between brackets [()] | Optional items. |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one. |

The following is the full command reference for the Netsh commands for AAAA.

**dump**
Displays the configuration of the IAS database file (Ias.mdb) as a Netsh command script.

**Syntax**

```
dump
```

**Remarks**
The **dump** command displays the Netsh command script that you can use to duplicate the configuration of the server running IAS or the Routing and Remote Access service on which the command is executed. The Netsh command script contains the configuration of the IAS server, including the registry keys and database file, in a compressed text format as a large data block. This large data block is used by the **set config** command within the script to import the configuration of a saved data block into an existing IAS database on the same or another computer using the **netsh exec** command. To save the Netsh command script to a file, type the following at a command prompt: **netsh aaaa show config >** *Path**File.txt*.

The **dump** command is not supported on computers running Windows 2000 Server.

**set config**
Configures the IAS server and IAS database with the registry keys and database imported from the specified data block.

**Syntax**

```
set config [type= {server_settings | clients | connection_request_policies |
logging | remote_access_policies ]blob= DataBlock}
```

**Parameters**
**blob**=*DataBlock*

Required. Specifies the file that contains the configuration of the IAS server, including registry keys and IAS database, in a compressed text format as output by the **dump** or **show** commands.

**type**=

Specifies the kind of data that you want to import from the *DataBlock* to the local server configuration.

**server_settings**

Specifies that the server configuration settings are imported from the *DataBlock* to the local server. The imported settings include Server Description, system event log settings, registry keys, and ports that are used specifically for the IAS service.

**clients**

Specifies that the settings for **RADIUS Clients**, as viewed in the IAS console, are imported to the local server from *DataBlock*.

**connection_request_policies**

Specifies that the IAS settings for **Connection Request Processing**, including **Connection Request Policies** and **Remote RADIUS Server Groups**, as viewed in the IAS console, are imported to the local server from *DataBlock*.

**logging**

Specifies that the IAS settings for **Remote Access Logging**, as viewed in the IAS console, are imported to the local server from *DataBlock*.

**remote_access_policies**

Specifies that the IAS settings for **Remote Access Policies**, as viewed in the IAS console, are imported to the local server from *DataBlock*.

**Remarks**
Running the **set config** command manually is not supported. This command is used only within a Netsh command script that is created by using the **dump** or **show** commands.

To view the version of the IAS database on which the Netsh script is being run, use the **show version** command. Scripts older than those created with Windows Server 2003 are supported.

The configuration of IAS servers running on products in the Windows 2000 Server family can be imported into products in the Windows Server 2003 family that support IAS with the **set config** command. The reverse, however, is not possible.

**show clients**
Displays the RADIUS client list for the local IAS server.

**Syntax**

```
show clients
```

**Remarks**
This command dumps the RADIUS client list of the IAS server on which the command is run. In the IAS console, this client list is displayed in **RADIUS Clients**.

The Netsh command script contains the local server settings, including registry keys and the IAS database (Ias.mdb), as a large data block in a compressed text format. To import the configuration into an existing IAS server on either the same or another computer, you can use the **netsh**

**exec** command. To save the Netsh command script to a file, type **netsh aaaa show clients >***Path**File.txt* at a command prompt.

This command is not available on computers running Windows 2000 Server.

**show config**
Displays the configuration of the IAS database file as a Netsh command script.

**Syntax**

```
show config
```

**Remarks**
The **show config** command is equivalent to the **dump** command.

The **show config** command displays the Netsh command script that you can use to duplicate the configuration of the server running IAS or the Routing and Remote Access service on which the command is run. The Netsh command script contains the configuration of the IAS server, including registry keys and the IAS database, as a large data block in a compressed text format. To import the configuration into an existing IAS server on either the same or another computer, you can use the **netsh exec** command. To save the Netsh command script to a file, type **netsh aaaa show config >***Path**File.txt* at a command prompt.

This command is not available on computers running Windows 2000 Server.

**show connection_request_policies**
Displays the Connection Request Processing policies configuration of the IAS server in script format.

**Syntax**

```
show connection_request_policies
```

**Remarks**
This command displays Connection Request Policies for the IAS server on which the command is run. In the IAS console, these policies are displayed in **Connection Request Processing** and include **Connection Request Policies** and **Remote RADIUS Server Groups**.

The Netsh command script contains the local server settings as a large data block in a compressed text format. To import the configuration into an existing IAS server on either the same or another computer, you can use the **netsh exec** command. To save the Netsh command script to a file, type **netsh aaaa show connection_request_policies>***Path**File.txt* at a command prompt.

This command is not available on computers running Windows 2000 Server.

**show logging**
Displays the logging configuration for the local IAS server.

**Syntax**

```
show logging
```

**Remarks**
This command displays the Remote Access Logging configuration for the IAS server on which the command is run. In the IAS console, this information is displayed in **Remote Access Logging**.

The Netsh command script contains the local server settings as a large data block in a compressed text format. To import the configuration into an existing IAS server on either the same or another computer, you can use the **netsh exec** command. To save the Netsh command script to a file, type **netsh aaaa show logging >***Path**File.txt* at a command prompt.

This command is not available on computers running Windows 2000 Server.

**show remote_access_policies**
Displays all objects within the remote access policy.

**Syntax**

```
show remote_access_policies
```

**Remarks**
This command displays the Remote Access Policies for the IAS server on which the command is run. In the IAS console, this information is displayed in Remote Access Policies.

The Netsh command script contains the local server settings as a large data block in a compressed text format. To import the configuration into an existing IAS server on either the same or another computer, you can use the **netsh exec** command. To save the Netsh command script to a file, type **netsh aaaa show remote_access_policies >** *Path**File.txt* at a command prompt.

This command is not available on computers running Windows 2000 Server.

The output of this command is an encoded data block that is either displayed in the command prompt window or saved to a text file at the folder location you specify. The following registry keys and values are contained in the data block:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RasMan\PPP\ControlProtocols\BuiltIn\DefaultDomain\REG_SZ**

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Policy\Allow LM Authentication\REG_DWORD**

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Policy\Default User Identity\REG_SZ**

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Policy\User Identity Attribute\REG_DWORD**

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Policy\Override User-Name\REG_DWORD**

**show server_settings**
Displays the configuration of the local IAS server as a Netsh command script.

**Syntax**

```
show server_settings
```

**Remarks**
This command displays the configuration of server settings for the IAS server on which the command is run. These settings include: server description; settings for accounting and authorization events in the system event log; ports used by the service; and registry keys and their values. To display server settings in the IAS console, right-click the server and click **Properties**.

The Netsh command script contains the local server settings as a large data block in a compressed text format. This large data block is used within the script by the **netsh exec** command to import the configuration of a saved data block into an existing IAS server on the same or another computer. To save the Netsh command script to a file, type **netsh aaaa show server_settings >** *Path\File.txt* at a command prompt.

This command is not available on computers running Windows 2000 Server.

The output of this command is an encoded data block that is either displayed in the command prompt window or saved to a text file at the folder location you specify. The following registry keys and values are contained in the data block:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\IAS\Parameters\Allow SNMP Set\REG_DWORD**

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Parameters\AccountLockout\MaxDenials\REG_DWORD**

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Parameters\AccountLockout\ResetTime\REG_DWORD**

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\IAS\Parameters\Ping User-Name\REG_SZ**

**show version**
Displays the version of the IAS database.

**Syntax**

```
show version
```

**Importing or Exporting Configurations**
You can export IAS server configuration in part or total by using the Netsh commands for AAAA. For example, you can export the full configuration of an IAS server using the **netsh aaaa show config** command at the command prompt, or you can export only the remote access policies of the server using the **netsh aaaa show remote_acces_policies** command. IAS configuration can then be imported by using the **netsh exec** command.

When importing or exporting configurations, keep the following in mind:

- You do not need to stop IAS on the destination computer to run the **netsh exec** command. When the command is run, IAS is automatically refreshed with the updated configuration settings.

- Do not use this procedure if the source IAS database is a higher version number than the version number of the destination IAS database. You can view the version number of the IAS database from the display of the **netsh aaaa show config** command.

### Note

- The configuration of IAS servers running on products in the Windows 2000 Server family can be imported into products in the Windows Server 2003 family with netsh AAAA commands. The reverse, however, is not possible. To centrally manage IAS on both Windows 2000 and Windows Server 2003, you can first make configuration changes on IAS servers running Windows 2000, and then import the new server configuration into IAS servers running Windows Server 2003.

- IAS configurations are encoded and compressed; however, they are not encrypted in the text file. Because IAS configurations are not encrypted in the text file, sending the text file over a network poses a security risk and is not recommended.

- You can copy a remote access configuration from a server running Windows 2000 or Windows Server 2003 and the Routing and Remote Access service to an IAS server. Use the **netsh aaaa dump** command at the remote access server to create a file that contains the configuration, copy the file to the IAS server, and then use the **netsh exec** command to import the configuration to the IAS server. Next, configure RADIUS clients on the IAS server.

**Software Development Kits**
The Microsoft Platform Software Development Kit (SDK) contains the IAS and EAP SDKs, which you can use to extend the functionality of IAS.

**IAS Software Development Kit**
The IAS SDK can be used to:

- Return custom attributes to the access server in addition to those returned by IAS. For example, you can create a customized module to assign IP addresses.
- Control the number of user network sessions.
- Import usage and audit data directly into an Open Database Connectivity (ODBC)-compliant database.
- Create customized authorization modules.
- Create customized authentication modules (non-EAP).

**EAP Software Development Kit**
The Extensible Authentication Protocol (EAP) SDK allows you to create EAP types and implement arbitrary authentication methods using EAP.

**Network Monitor**
The optional management and monitoring component Network Monitor tool can be used to capture the RADIUS messages being sent and received for detailed analysis.

For more information about setting up and using Network Monitor, see “Monitoring Network Performance” in the *Microsoft Windows Server 2003 Resource Kit Server Operations Guide*.

To view RADIUS messages, configure Network Monitor with a display filter to display only RADIUS messages by disabling all protocols except the RADIUS protocol.

**IAS Settings**
The following section provides step-by-step information about how to configure the domain name and certificate templates, as well as how to use shared secrets and other IAS features and settings.

**Configuring the Default Domain Name**
While processing connection requests, IAS examines the user name portion of the Access-Request message to determine whether a domain name has been specified. If a domain name is specified and IAS is configured to access the user accounts database in the designated domain, IAS proceeds with processing the connection request.

### Note

- Some network access servers delete or modify the domain name as specified by the user. As a result, the network access request is authenticated against the default domain, which might not be the domain for the user’s account. To resolve this problem, configure your RADIUS servers to change the user name into the correct format with the accurate domain name.

When the user name does not contain a domain name, IAS supplies one. By default, the IAS-supplied domain name is the domain of which the IAS server is a member.

IAS resolves a user name without a specified domain name in the following sequence:

1. IAS checks the default domain registry key. If one is specified, IAS authenticates the user against the domain specified in the registry key.
2. If the IAS server is a member of a domain, IAS authenticates the user against the domain to which it is joined.
3. If the IAS server is not a member of a domain, IAS authenticates the user against the local Security Accounts Manager (SAM) database.

For information about how to specify the IAS-supplied domain name, see "IAS Registry Entries."

**Configuring Certificate Templates**
The configuration of certificate templates is not a function performed within the IAS console; however, the correct configuration of your certificate templates is critical to the success of your IAS deployment. The following two sections provide server certificate requirements and client certificate requirements, as well as how to configure your certificate template in the Certificate Templates snap-in.

**Note**

- You can view the IAS console and the Certificate Templates snap-in within the same Microsoft Management Console (MMC) window. Just create a custom snap-in configuration by adding the snap-ins you want to view to the console window. To reuse your custom view, save the console configuration.

These instructions are based on the following assumptions:

- You have designed a public key infrastructure (PKI).
- Based on both Certificate Services best practices and your own network and PKI requirements, you have installed Certificate Services in Windows Server 2003.

**Note**

- If you are running an enterprise certification authority (CA) on a computer running Windows Server 2003, Enterprise Edition, Windows Server 2003, Datacenter Edition, the 64-bit version of Windows Server 2003, Enterprise Edition, or the 64-bit version of Windows Server 2003, Datacenter Edition, it is recommended that you use the **RAS and IAS Server** certificate template for server certificates and the **Workstation Authentication** template for client certificates. If you are running an enterprise CA on a computer running Windows Server 2003, Standard Edition, you can use the **Computer** certificate template for both server and client certificates. However, you must configure the certificate purposes to match the certificate function.

**Server certificate requirements**

Client computers can be configured to validate server certificates by using the **Validate server certificate** option.

With Protected EAP Microsoft Challenge Handshake Authentication Protocol version 2 (PEAP-MS-CHAP v2), Protected EAP Transport Level Security (PEAP-TLS), or EAP-TLS as the authentication method, the client accepts the server's authentication attempt when the certificate meets the following requirements:

- The Subject name contains a value. If you issue a certificate to your IAS server that has a blank Subject, the certificate is not available to authenticate your IAS server.

  **To configure the certificate template with a Subject name**

  1. Open Certificate Templates.
  2. In the details pane, right-click the certificate template that you want to change, and then click **Properties**.
  3. Click the **Subject Name** tab, and then click **Build from this Active Directory information**.
  4. In **Subject name format**, select a value other than **None**.

- The computer certificate on the server chains to a trusted root CA and does not fail any of the checks that are performed by CryptoAPI and specified in the remote access policy. When you use the **RAS and IAS Servers** certificate template, the certificate based on the template passes CryptoAPI checks.
- The IAS or VPN server computer certificate is configured with the Server Authentication purpose in Enhanced Key Usage (EKU) extensions. The object identifier for Server Authentication is 1.3.6.1.5.5.7.3.1.
- For user certificates, the Subject Alternative Name (SubjectAltName) extension in the certificate contains the user principal name (UPN).

  **To configure the UPN name in a certificate template**

  1. Open Certificate Templates.
  2. In the details pane, right-click the certificate template that you want to change, and then click **Properties**.
  3. Click the **Subject Name** tab, and then click **Build from this Active Directory information**.
  4. In **Include this information in alternate subject name**, select **User principal name (UPN)**.

- For computer certificates, the Subject Alternative Name (SubjectAltName) extension in the certificate must contain the client's fully qualified domain name (FQDN), which is also called the DNS name.

**To configure this name in the certificate template**

1. Open Certificate Templates.
2. In the details pane, right-click the certificate template that you want to change, and then click **Properties**.
3. Click the **Subject Name** tab, and then click **Build from this Active Directory information**.
4. In **Include this information in alternate subject name**, select **DNS name**.

With PEAP-TLS and EAP-TLS, clients display a list of all installed certificates in the Certificates snap-in, with the following exceptions:

- Wireless clients do not display registry-based and smart card-logon certificates.
- Wireless clients and virtual private network (VPN) clients do not display password-protected certificates.
- Certificates that do not contain the Client Authentication purpose in EKU extensions are not displayed.

**Note**

- You can designate which certificate is used by the IAS or VPN server in the remote access policy profile. When you configure EAP and PEAP authentication methods that require a certificate for server authentication and you do not select a specific certificate in the **Smart Card or other Certificate Properties** dialog box, the IAS or VPN server automatically selects a certificate from the computer certificate store. If the server obtains a newer certificate, it uses the new certificate. This might cause the IAS or VPN server to use a certificate that is not correctly configured for authentication, causing authentication to fail as a result. To prevent this, always manually select a server certificate when configuring PEAP and EAP authentication methods that require one.

**Client certificate requirements**

With EAP-TLS or PEAP-TLS, the server accepts the client authentication attempt when the certificate meets the following requirements:

- The client certificate is issued by an enterprise CA and maps to a user or computer account in Active Directory.
- The user or computer certificate on the client chains to a trusted root CA, includes the Client Authentication purpose in EKU extensions (the object identifier for Client Authentication is 1.3.6.1.5.5.7.3.2), and fails neither the checks that are performed by CryptoAPI and specified in the remote access policy nor the Certificate object identifier checks that are specified in IAS remote access policy. When you use the **Workstation Authentication** certificate template, the certificate based on the template passes CryptoAPI checks by default.
- The 802.1X client does not use registry-based certificates that are either smart card-logon or password-protected certificates.
- For user certificates, the Subject Alternative Name (SubjectAltName) extension in the certificate contains the user principal name (UPN).

  **To configure the UPN in a certificate template**

  1. Open Certificate Templates.
  2. In the details pane, right-click the certificate template that you want to change, and then click **Properties**.
  3. Click the **Subject Name** tab, and then click **Build from this Active Directory information**.
  4. In **Include this information in alternate subject name**, select **User principal name (UPN)**.

- For computer certificates, the Subject Alternative Name (SubjectAltName) extension in the certificate must contain the client's fully qualified domain name (FQDN), which is also called the DNS name.

  **To configure the DNS name in the certificate template**

  1. Open Certificate Templates.
  2. In the details pane, right-click the certificate template that you want to change, and then click **Properties**.

3. Click the **Subject Name** tab, and then click **Build from this Active Directory information**.

4. In **Include this information in alternate subject name**, select **DNS name**.

With PEAP-TLS and EAP-TLS, clients display a list of all installed certificates in the Certificates snap-in, with the following exceptions:

- Wireless clients do not display registry-based and smart card-logon certificates.
- Wireless clients and VPN clients do not display password-protected certificates.
- Certificates that do not contain the Client Authentication purpose in EKU extensions are not displayed.

**Using the Message Authenticator Attribute**

When you add one or more RADIUS clients in the IAS snap-in, you configure the IP address of one RADIUS client or you configure multiple RADIUS clients using an IP address range. If an incoming RADIUS Access-Request message does not originate from an IP address of a configured RADIUS client, IAS automatically discards the message, providing protection for an IAS server. However, source IP addresses can be spoofed (substituted with other IP addresses) by malicious users.

To provide protection from spoofed Access-Request messages and RADIUS message tampering, each RADIUS message can be additionally protected with the RADIUS Message Authenticator attribute, which is described in RFC 2869, "RADIUS Extensions."

The RADIUS Message Authenticator attribute is a Message Digest 5 (MD5) hash of the entire RADIUS message. The shared secret configured on the IAS server and the RADIUS client is used as the key. If the RADIUS Message Authenticator attribute is present, it is verified. If the Access-Request message fails verification, the message is discarded by the IAS server. If the RADIUS client settings require the Message Authenticator attribute and it is not present, the RADIUS message is discarded.

With IAS in Windows Server 2003, all EAP and PEAP authentication methods use the Message Authenticator attribute by default.

**Enabling Remote Access Account Lockout**

You can use remote access account lockout to specify how many times a remote access authentication fails against a valid user account before the user is denied access. Remote access account lockout is especially important for remote access VPN connections over the Internet. An attacker on the Internet can attempt to access an organization intranet by sending credentials (valid user name, guessed password) during the VPN connection authentication process. During a dictionary attack, the attacker sends hundreds or thousands of credentials by using a list of passwords based on common words or phrases.

When remote access account lockout is enabled, a dictionary attack is thwarted after a specified number of failed attempts. As the network administrator, you must decide on two remote access account lockout variables:

- The number of failed attempts before future attempts are denied.

  After each failed attempt, a failed attempts counter for the user account is incremented. If the user account's failed attempts counter reaches the configured maximum, future attempts to connect are denied.

  A successful authentication resets the failed attempts counter when its value is less than the configured maximum. In other words, the failed attempts counter does not accumulate beyond a successful authentication.

- The frequency with which the failed attempts counter is reset.

  The failed attempts counter is periodically reset to 0. If an account is locked out after the maximum number of failed attempts, the failed attempts counter is automatically reset to 0 after the reset time.

You enable the remote access account lockout feature by changing settings in the registry on the computer that provides the authentication. If the remote access server is configured for Windows Authentication, modify the registry on the remote access server computer. If the remote access server is configured for RADIUS authentication and IAS is being used, modify the registry on the IAS server.

For more information about how to enable remote access account lockout, see "IAS Registry Entries."

**Using Shared Secrets**

A shared secret is a text string that serves as a password between:

- A RADIUS client and RADIUS server.
- A RADIUS client and a RADIUS proxy.
- A RADIUS proxy and a RADIUS server.

For a configuration that uses a RADIUS client, a RADIUS proxy, and a RADIUS server, the shared secret that is used between the RADIUS client and the RADIUS proxy can be different from the shared secret used between the RADIUS proxy and the RADIUS server.

Shared secrets are used to verify that RADIUS messages, with the exception of the Access-Request message, are sent by a RADIUS-enabled device that is configured with the same shared secret. Shared secrets also verify that the RADIUS message has not been modified in transit. The shared secret is also used to encrypt some RADIUS attributes, such as User-Password and Tunnel-Password. To provide verification for Access-Request messages, you can enable use of the RADIUS Message Authenticator attribute for both the RADIUS client configured on the IAS server and the access server.

If you specify RADIUS clients by using an IP address range, all RADIUS clients within the address range must use the same shared secret.

When creating and using a shared secret:

- Use the same case-sensitive shared secret on both RADIUS devices.
- Use a different shared secret for each RADIUS server-RADIUS client pair.
- Generate a random sequence at least 22 characters long.
- Use any standard alphanumeric and special characters.
- Use a shared secret of up to 128 characters in length. To protect your IAS server and your RADIUS clients from brute force attacks, use long shared secrets (more than 22 characters).
- Make the shared secret a random sequence of letters, numbers, and punctuation, as shown in the following table.

  **Alphanumeric and special characters**

| Group | Examples |
|---|---|
| Letters (uppercase and lowercase) | A, B, C and a, b, c |
| Numerals | 0, 1, 2, 3 |
| Symbols (all characters not defined as letters or numerals) | Exclamation point (!), asterisk (*), colon (:) |

- Change your shared secret often to protect your IAS server and your RADIUS clients from dictionary attacks.
- Be certain that the RADIUS client's shared secret and the shared secret you type when running the New RADIUS Client Wizard are identical.

The stronger your shared secret, the more secure are the attributes (for example, those used for passwords and encryption keys) that are encrypted with the shared secret. An example of a strong shared secret is 5d#>3fq4bV)J7%a3-zR13sM. Before creating your shared secret, verify that your network access servers support the use of the letters, numerals, and symbols that you have chosen.

**Note**

- When the Password Authentication Protocol (PAP) is used between an access client and an access server (a RADIUS client), the access server encrypts the PAP password by using the shared secret and sends it in an Access-Request packet. If the access server sends the Access-Request message to a RADIUS proxy, the RADIUS proxy must first decrypt the PAP password with the shared secret that was used between the RADIUS proxy and the access server. Next, it encrypts the PAP password with the shared secret that was used between the RADIUS proxy and the RADIUS server before forwarding the Access-Request message. Because a malicious user or process at a RADIUS proxy can record user names and passwords for PAP connections after they are decrypted but before they are encrypted, the use of PAP is strongly discouraged. In addition, if you are using a password-based authentication method, it is strongly recommended that you use MS-CHAP v2, MS-CHAP, or CHAP with strong passwords to provide password protection from dictionary attacks.

**IAS Registry Entries**

In Windows Server 2003, IAS supports registry values that provide the following functionality:

**Note**

- Incorrectly editing the registry can severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**HKEY_LOCAL_MACHINE\SYSTEM**
**Eventlogging**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL

Secure channel (Schannel) is a security support provider (SSP) that supports a set of Internet security protocols, such as Secure Sockets Layer (SSL) and TLS. These protocols provide identity authentication and secure, private communication through encryption. Logging of client

certificate validation failures is a secure channel event, and is not enabled on the IAS server by default.

Logging of client certificate validation failures is a secure channel event, and is not enabled on the IAS server by default.

**To enable secure channel events**
You can enable additional secure channel events by changing the registry key value from **1** (**REG_DWORD** type, data **0x00000001**) to **3** (**REG_DWORD** type, data **0x00000003**).

**Note**

- The logging of rejected or discarded authentication events is enabled by default.

**Ping User-Name**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\IAS\Parameters

**Ping User-Name** can be added to the registry on your IAS servers by a member of the local Administrators group. When you add **Ping User-Name** to the registry, you must supply values for **Name**, **Type**, and **Data**.

**Note**

- **Ping User-Name** is not installed by default. You must add **Ping User-Name** to the registry. You can add an entry to the registry using Registry Editor.

**Values for Ping User-Name**

| Name | Type | Data |
|---|---|---|
| ping user-name | REG_SZ | *User name* |

To indicate more than one user name for a **Ping User-Name** value, enter a name pattern, such as a DNS name including wildcard characters, in **Data**.

**Ping User-Name** can be added to the registry key as a string value:

**HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\IAS\Parameters**

**Note**

- When you configure **Ping User-Name** in the IAS server registry, you must configure NASs and RADIUS proxies to use the same User name, or a User name that matches the name and wildcard characters, that you configured in **Data**. If the User name value configured for the NASs and RADIUS proxies do not match the value in **Data**, and IAS is configured for logging, IAS will log the RADIUS traffic, and log files will become cluttered with accounting data from ping requests.

**MaxConcurrentApi**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Netlogon\Parameters

If the IAS server is on a computer other than a domain controller and it is receiving a very large number of authentication requests per second, you can improve performance by increasing the number of concurrent authentications between the IAS server and the domain controller.

**To increase concurrent authentication**
Add a new value named **MaxConcurrentApi** to this registry key and assign to it a value from **2** through **5**.

**DefaultDomain**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RasMan\PPP\ControlProtocols\BuiltIn

**To specify the IAS-supplied domain**
By default, the IAS-supplied domain name is the domain for which the IAS server is a member. You can specify the IAS-supplied domain through the **DefaultDomain** registry setting.

**AccountLockout**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Parameters

**To enable remote access account lockout**
Set the **MaxDenials** entry in the registry to **1** or greater. **MaxDenials** is the maximum number of failed attempts before the account is locked out.

By default, **MaxDenials** is set to **0**, which means that remote access account lockout is disabled.

**To modify the amount of time before the failed attempts counter is reset**
Set the **ResetTime (mins)** entry in the registry to the required number of minutes.

By default, **ResetTime (mins)** is set to **0xb40**, or 2,880 minutes (48 hours).

**To manually reset a user account that has been locked out before the failed attempts counter is automatically reset**
Delete the following registry subkey that corresponds to the user's account name:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Parameters\AccountLockout\domain name:user name**

When the lockout count for a user account is reset to **0** due to either a successful authentication or an automatic reset, the registry subkey for the user account is deleted.

**Default User Identity**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Policy

User identity is the means by which IAS identifies the user for the purposes of authentication and authorization. Normally, the user identity is the string value of the User-Name RADIUS attribute. If the User-Name attribute is not present, or is present but equals null, the user identity is set to the Guest account or the account specified by the **Default User Identity** registry value:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Policy**

**Enable or Disable LAN Manager Authentication**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Policy

By default, MS-CHAP for Windows Server 2003 does not support LAN Manager authentication. This is a change from Windows 2000.

Although the use of MS-CHAP or LAN Manager authentication is not recommended for security reasons, you might need to deploy one or both of these authentication methods to support legacy clients. If you deploy MS-CHAP with change password capability enabled in IAS, you must also deploy LAN Manager authentication.

**To enable LAN Manager authentication**
If you want to enable the use of LAN Manager authentication with MS-CHAP for older Microsoft operating systems such as Windows NT 3.5 and Windows 95, you must set **Allow LM Authentication** to **1** on the authenticating server.

**To disable LAN Manager authentication**
LAN Manager authentication is disabled by default. However, if you have previously enabled it and want to disable it again, set **Allow LM Authentication** to **0**.

**Override User-Name**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Policy

To always use the calling number as the user identity, set the **Override User-Name** registry value to **1** on the authenticating server.

**Note**

- If you set Override User-Name to **1** and the User Identity Attribute to **31**, the authenticating server can perform only Automatic Number Identification/Calling Line Identification (ANI/CLI)-based authentication. Normal authentication by using authentication protocols (such as MS CHAP and EAP) is disabled.

**User Identity Attribute**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\RemoteAccess\Policy

The RADIUS attribute that IAS uses to identify the user is configurable by setting the **User Identity Attribute** registry setting.

You can change this key's value to the number of the RADIUS attribute that is used for the user identity. By default, **User Identity Attribute** is set to **1**, the RADIUS type value for the User-Name RADIUS attribute.

This registry setting tells the authenticating server to use the calling number (RADIUS attribute 31, Calling-Station-ID) as the identity of the calling user. The user identity is set to the calling number only when there is no user name being supplied in the connection attempt.

# VPN Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**VPN Technical Reference**
Virtual private network (VPN) is a network access technology that is available as part of the Routing and Remote Access service that is included in Microsoft Windows Server 2003. VPN enables administrators to provide access to private networks at a lower cost than using leased-line connections.

VPN technology is the extension of a private network that encompasses point-to-point links across shared or public networks, such as the Internet. VPN allows remote clients to connect to an organization's network resources. VPN also allows remote offices to connect to each other to share resources and information. A VPN connection uses authentication and data encryption to help preserve the privacy and integrity of data as it traverses a public network.

**In this subject**

# What Is VPN?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is VPN?**

### In this section

- VPN Scenarios
- VPN Connection Properties
- Tunneling Overview
- Routing for VPN
- VPN and Firewalls Overview
- Technologies Related to VPN
- Related Information

The virtual private network (VPN) technology included in Windows Server 2003 helps enable cost-effective, secure remote access to private networks. VPN allows administrators to take advantage of the Internet to help provide the functionality and security of private WAN connections at a lower cost. In Windows Server 2003, VPN is enabled using the Routing and Remote Access service. VPN is part of a comprehensive network access solution that includes support for authentication and authorization services, and advanced network security technologies.

There are two main strategies that help provide secure connectivity between private networks and enabling network access for remote users.

**Dial-up or leased line connections**
A dial-up or leased line connection creates a physical connection to a port on a remote access server on a private network. However, using dial-up or leased lines to provide network access is expensive when compared to the cost of providing network access using a VPN connection.

**VPN connections**
VPN connections use either Point-to-Point Tunneling Protocol (PPTP) or Layer Two Tunneling Protocol/Internet Protocol security (L2TP/IPSec) over an intermediate network, such as the Internet. By using the Internet as a connection medium, VPN saves the cost of long-distance phone service and hardware costs associated with using dial-up or leased line connections. A VPN solution includes advanced security technologies such as data encryption, authentication, authorization, and Network Access Quarantine Control.

### Note

- Network Access Quarantine Control is used to delay remote access to a private network until the configuration of the remote access computer has been examined and validated.

Using VPN, administrators can connect remote or mobile workers (VPN clients) to private networks. Remote users can work as if their computers are physically connected to the network. To accomplish this, VPN clients can use a Connection Manager profile to initiate a connection to a VPN server. The VPN server can communicate with an Internet Authentication Service (IAS) server to authenticate and authorize a user session and maintain the connection until it is terminated by the VPN client or by the VPN server. All services typically available to a LAN-connected client (including file and print sharing, Web server access, and messaging) are enabled by VPN.

VPN clients can use standard tools to access resources. For example, clients can use Windows Explorer to make drive connections and to connect to printers. Connections are persistent: Users do not need to reconnect to network resources during their VPN sessions. Because drive letters and universal naming convention (UNC) names are fully supported by VPN, most commercial and custom applications work without modification.

**VPN Scenarios**
Virtual private networks are point-to-point connections across a private or public network such as the Internet. A VPN client uses special TCP/IP-based protocols, called tunneling protocols, to make a virtual call to a virtual port on a VPN server. In a typical VPN deployment, a client initiates a virtual point-to-point connection to a remote access server over the Internet. The remote access server answers the call, authenticates the caller, and transfers data between the VPN client and the organization's private network.

To emulate a point-to-point link, data is encapsulated, or wrapped, with a header. The header provides routing information that enables the data to traverse the shared or public network to reach its endpoint. To emulate a private link, the data being sent is encrypted for confidentiality. Packets that are intercepted on the shared or public network are indecipherable without the encryption keys. The link in which the private data is encapsulated and encrypted is known as a VPN connection.

### A VPN Connection

There are two types of VPN connections:

- Remote access VPN
- Site-to-site VPN

**Remote Access VPN**
Remote access VPN connections enable users working at home or on the road to access a server on a private network using the infrastructure provided by a public network, such as the Internet. From the user's perspective, the VPN is a point-to-point connection between the computer (the VPN client) and an organization's server. The exact infrastructure of the shared or public network is irrelevant because it appears logically as if the data is sent over a dedicated private link.

**Site-to-Site VPN**
Site-to-site VPN connections (also known as router-to-router VPN connections) enable organizations to have routed connections between separate offices or with other organizations over a public network while helping to maintain secure communications. A routed VPN connection across the Internet logically operates as a dedicated WAN link. When networks are connected over the Internet, as shown in the following figure, a router forwards packets to another router across a VPN connection. To the routers, the VPN connection operates as a data-link layer link.

A site-to-site VPN connection connects two portions of a private network. The VPN server provides a routed connection to the network to which the VPN server is attached. The calling router (the VPN client) authenticates itself to the answering router (the VPN server), and, for mutual authentication, the answering router authenticates itself to the calling router. In a site-to site VPN connection, the packets sent from either router across the VPN connection typically do not originate at the routers.

### VPN Connecting Two Remote Sites Across the Internet

**VPN Connection Properties**
PPTP-based VPN and L2TP/IPSec-based VPN connection properties are described in the following sections.

**Encapsulation**
VPN technology provides a way of encapsulating private data with a header that allows the data to traverse the network.

**Authentication**
There are three types of authentication for VPN connections:

**User authentication**
For the VPN connection to be established, the VPN server authenticates the VPN client attempting the connection and verifies that the VPN client has the appropriate permissions. If mutual authentication is being used, the VPN client also authenticates the VPN server, providing protection against masquerading VPN servers.

The user attempting the PPTP or L2TP/IPSec connection is authenticated using Point-to-Point (PPP)-based user authentication protocols such as Extensible Authentication Protocol-Transport Layer Security (EAP-TLS), Microsoft Challenge-Handshake Authentication Protocol (MS-CHAP), Microsoft Challenge-Handshake Authentication Protocol version 2 (MS-CHAP v2), Shiva Password Authentication Protocol (SPAP), and Password Authentication Protocol (PAP). For PPTP connections, you must use EAP-TLS, MS-CHAP, or MS-CHAP v2. EAP-TLS using smart cards or MS-CHAP v2 is highly recommended, as they provide mutual authentication and are the most secure methods of exchanging credentials.

**Computer authentication with L2TP/IPSec**
By performing computer-level authentication with IPSec, L2TP/IPSec connections also verify that the remote access client computer is trusted.

**Data authentication and integrity**
To verify that the data being sent on an L2TP/IPSec VPN connection originated at the other end of the connection and was not modified in transit, L2TP/IPSec packets include a cryptographic checksum based on an encryption key known only to the sender and the receiver.

**Data Encryption**
Data can be encrypted for protection between the endpoints of the VPN connection. Data encryption should always be used for VPN connections where private data is sent across a public network such as the Internet. Data that is not encrypted is vulnerable to unauthorized interception. For VPN connections, Routing and Remote Access uses Microsoft Point-to-Point Encryption (MPPE) with PPTP and IPSec encryption with L2TP.

**Address and Name Server Allocation**
When a VPN server is configured, it creates a virtual interface that represents the interface on which all VPN connections are made. When a VPN client establishes a VPN connection, a virtual interface is created on the VPN client that represents the interface connected to the VPN server. The virtual interface on the VPN client is connected to the virtual interface on the VPN server, creating the point-to-point VPN connection.

The virtual interfaces of the VPN client and the VPN server must be assigned IP addresses. The assignment of these addresses is done by the VPN server. By default, the VPN server obtains IP addresses for itself and VPN clients using the Dynamic Host Configuration Protocol (DHCP). Otherwise, a static pool of IP addresses can be configured to define one or more address ranges, with each range defined by an IP network ID and a subnet mask or start and end IP addresses.

Name server assignment, the assignment of Domain Name System (DNS) and Windows Internet Name Service (WINS) servers to the VPN connection, also occurs during the process of establishing the VPN connection.

**Tunneling Overview**
Tunneling is a method of using a network infrastructure to transfer data for one network over another network. The data (or payload) to be transferred can be the frames (or packets) of another protocol. Instead of sending a frame as it is produced by the originating node, the tunneling protocol encapsulates the frame in an additional header. The additional header provides routing information so that the encapsulated payload can traverse the intermediate network.

The encapsulated packets are then routed between tunnel endpoints over the network. The logical path through which the

encapsulated packets travel through the network is called a tunnel. After the encapsulated frames reach their destination on the network, the frame is de-encapsulated (the header is removed) and the payload is forwarded to its final destination. Tunneling includes this entire process (encapsulation, transmission, and de-encapsulation of packets).

**Tunneling**

**Tunneling Protocols**

Tunneling enables the encapsulation of a packet from one type of protocol within the datagram of a different protocol. For example, VPN uses PPTP to encapsulate IP packets over a public network such as the Internet. A VPN solution based on either PPTP or L2TP can be configured.

PPTP and L2TP depend heavily on the features originally specified for PPP. PPP was designed to send data across dial-up or dedicated point-to-point connections. For IP, PPP encapsulates IP packets within PPP frames and then transmits the encapsulated PPP-packets across a point-to-point link. PPP was originally defined as the protocol to use between a dial-up client and a network access server (NAS).

**PPTP**

PPTP allows multiprotocol traffic to be encrypted and then encapsulated in an IP header to be sent across an organization's IP network or a public IP network such as the Internet. PPTP encapsulates Point-to-Point Protocol (PPP) frames in IP datagrams for transmission over the network. PPTP can be used for remote access and site-to-site VPN connections. PPTP is documented in RFC 2637 in the IETF RFC Database.

PPTP uses a TCP connection for tunnel management and a modified version of Generic Routing Encapsulation (GRE) to encapsulate PPP frames for tunneled data. The payloads of the encapsulated PPP frames can be encrypted, compressed, or both. The following figure shows the structure of a PPTP packet containing an IP datagram.

**Structure of a PPTP Packet Containing an IP Datagram**

When using the Internet as the public network for VPN, the PPTP server is a PPTP-enabled VPN server with one interface on the Internet and a second interface on the intranet.

**L2TP**

L2TP allows multiprotocol traffic to be encrypted and then sent over any medium that supports point-to-point datagram delivery, such as IP, X.25, frame relay, or asynchronous transfer mode (ATM). L2TP is a combination of PPTP and Layer 2 Forwarding (L2F), a technology developed by Cisco Systems, Inc. L2TP represents the best features of PPTP and L2F. L2TP encapsulates PPP frames to be sent over IP, X.25, frame relay, or ATM networks. When configured to use IP as its datagram transport, L2TP can be used as a tunneling protocol over the Internet. L2TP is documented in RFC 2661 in the IETF RFC Database.

L2TP over IP networks uses User Datagram Protocol (UDP) and a series of L2TP messages for tunnel management. L2TP also uses UDP to send L2TP-encapsulated PPP frames as tunneled data. The payloads of encapsulated PPP frames can be encrypted, compressed, or both, although the Microsoft implementation of L2TP does not use MPPE to encrypt the PPP payload. The following figure shows the structure of an L2TP packet containing an IP datagram.

**Structure of an L2TP Packet Containing an IP Datagram**

**L2TP with IPSec (L2TP/IPSec)**
In the Microsoft implementation of L2TP, IPSec Encapsulating Security Payload (ESP) in transport mode is used to encrypt L2TP traffic. The combination of L2TP (the tunneling protocol) and IPSec (the method of encryption) is known as L2TP/IPSec. L2TP/IPSec is described in RFC 3193 in the IETF RFC Database.

The result after applying ESP to an IP packet containing an L2TP message is shown in the following figure.

**Encryption of L2TP Traffic with IPSec ESP**

**Routing for VPN**
Routing for remote access and site-to-site VPN connections is described in the following sections.

**Routing for Remote Access VPN Connections**
Conventional routing occurs between routers over either LAN-based shared access technologies, such as Ethernet or Token Ring, or WAN-based point-to-point technologies, such as T1 or frame relay.

**Default Routing**
The preferred method for directing packets to a remote network is to create a default route on the remote access client that directs packets to the remote network (the default configuration for VPN remote access clients). Any packet that is not intended for the neighboring LAN segment is sent to the remote network. When a connection is made, the remote access client, by default, adds a default route to its routing table and increases the metric of the existing default route to ensure that the newest default route is used. The newest default route points to the new connection, which ensures that any packets that are not addressed to the local LAN segment are sent to the remote network.

Under this configuration, when a VPN client connects and creates a new default route, Internet sites that have been accessible are no longer accessible (unless Internet access is available through the organization's intranet). This poses no problem for remote VPN clients that require access only to the organization's network. However, it is not acceptable for remote clients that need access to the Internet while they are connected to the organization's network.

**Split Tunneling**
Split tunneling enables remote access VPN clients to route corporate-based traffic over the VPN connection while sending Internet-based traffic using the user's local Internet connection. This prevents the use of corporate bandwidth for access to Internet sites.

However, a split tunneling implementation can introduce a security issue. If a remote access client has reachability to both the Internet and a private organization network simultaneously, the possibility exists that the Internet connection could be exploited to gain access to the private organization network through the remote access client. Security-sensitive companies can choose to use the default routing model to help ensure that all VPN client communications are protected by the corporate firewall.

**Routing for Site-to-Site VPN Connections**
With conventional WAN technologies, IP packets are forwarded between two routers over a physical or logical point-to-point connection. This connection is dedicated to the customer across a private data network that is provided by the WAN service provider.

With the advent of the Internet, packets can now be routed between routers that are connected to the Internet across a virtual connection that emulates the properties of a dedicated, private, point-to-point connection. This type of connection is known as a site-to-site VPN connection. Site-to-site VPN connections can be used to replace expensive long-haul WAN links with short-haul WAN links to a local Internet service provider (ISP).

A site-to-site VPN connection connects two portions of a private network. The VPN server provides a routed connection to the network to which the VPN server is attached. On a site-to-site VPN connection, the packets sent from either router across the VPN connection typically do not originate at the routers.

To facilitate routing between the sites, each VPN server and the routing infrastructure of its connected site must have a set of routes that represent the address space of the other site. These routes can be added manually, or routing protocols can be used to automatically add and maintain a set of routes.

**Site-to-Site Routing Protocols**
There are two routing protocols that can be used in a site-to-site VPN deployment:

- Routing Information Protocol (RIP)
- Open Shortest Path First (OSPF)

**RIP**
RIP is designed for exchanging routing information within a small to medium-size network. RIP routers dynamically exchange routing table entries.

The Windows Server 2003 implementation of RIP has the following features:

- The ability to select which RIP version to run on each interface for incoming and outgoing packets.
- Split-horizon, poison-reverse, and triggered-update algorithms that are used to avoid routing loops and speed recovery of the network when topology changes occur.
- Route filters for choosing which networks to announce or accept.
- Peer filters for choosing which router's announcements are accepted.
- Configurable announcement and route-aging timers.
- Simple password authentication support.
- The ability to disable subnet summarization.

**OSPF**
OSPF is designed for exchanging routing information within a large or very large network. Instead of exchanging routing table entries like RIP routers, OSPF routers maintain a map of the network that is updated after any change to the network topology. This map, called the link state database, is synchronized between all the OSPF routers and is used to compute the routes in the routing table. Neighboring OSPF routers form an adjacency, which is a logical relationship between routers to synchronize the link state database.

**VPN and Firewalls Overview**
The routing service supports a variety of inbound and outbound packet-filtering features that block certain types of traffic. The filtering options include the following: TCP port, UDP port, IP protocol ID, Internet Control Message Protocol (ICMP) type, ICMP code, source address, and destination address. A VPN server can be placed behind a firewall or in front of a firewall. These two approaches are described in the following sections.

**VPN Server Behind a Firewall**
In the most common configuration, the firewall is connected to the Internet, and the VPN server is an intranet resource that is attached to the perimeter network. The VPN server has an interface on both the perimeter network and the intranet. In this scenario, the firewall must be configured with input and output filters on its Internet interface that allow tunnel maintenance traffic and tunneled data to pass to the VPN server. Additional filters can allow traffic to pass to Web, FTP, and other types of servers on the perimeter network. For an additional layer of security, the VPN server should also be configured with PPTP or L2TP/IPSec packet filters on its perimeter network interface.

**VPN Server in Front of a Firewall**
When the VPN server is in front of the firewall and connected to the Internet, packet filters must be added to the VPN server's Internet interface to allow only VPN traffic to and from the IP address of that interface.

For inbound traffic, when the tunneled data is decrypted by the VPN server, it is forwarded to the firewall. Through the use of its filters, the firewall allows the traffic to be forwarded to intranet resources. Because the only traffic that crosses the VPN server is generated by authenticated VPN clients, in this scenario, firewall filtering can be used to prevent VPN users from accessing specific intranet resources. Because Internet traffic allowed on the intranet must pass through the VPN server, this approach also prevents the sharing of FTP or Web intranet resources with non-VPN Internet users.

**Technologies Related to VPN**

Integrating VPN with the other network infrastructure components is an important part of VPN design and implementation. VPN has to be integrated with directory, authentication, and security services, as well as with IP address assignment and name server assignment services. Without proper design, VPN clients are unable to obtain proper IP addresses and resolve intranet names, and packets cannot be forwarded between VPN clients and intranet resources.

VPN-related technologies are described in the following sections:

- Connection Manager
- DHCP
- EAP-RADIUS
- IAS
- Name Server Assignment (DNS and WINS)
- NAT

**Connection Manager**

Connection Manager is a service profile that can be used to provide customized remote access to a network through a VPN connection. The advanced features of Connection Manager are a superset of basic dial-up networking. Connection Manager provides support for local and remote connections by using a network of points of presence (POPs), such as those available worldwide through ISPs. Windows Server 2003 includes a set of tools that enable a network manager to deliver pre-configured connections to network users. These tools are:

- The Connection Manager Administration Kit (CMAK)
- Connection Point Services (CPS)

**CMAK**

A network administrator can tailor the appearance and behavior of a connection made with Connection Manager by using CMAK. With CMAK, an administrator can develop client dialer and connection software that allows users to connect to the network by using only the connection features that the administrator defines for them. Connection Manager supports a variety of features that both simplify and enhance implementation of connection support, most of which can be incorporated using the Connection Manager Administration Kit Wizard.

CMAK enables administrators to build profiles that customize the Connection Manager installation package so that it reflects an organization's identity. CMAK allows administrators to determine which functions and features to include and how Connection Manager appears to end-users. Administrators can do this by using the CMAK wizard to build custom service profiles.

**CPS**

Connection Point Services (CPS) automatically distributes and updates custom phone books. These phone books contain one or more Point of Presence (POP) entries, with each POP supplying a telephone number that provides dial-up access to an Internet access point for VPN connections. The phone books give users complete POP information, so when they travel they can connect to different Internet POPs rather than being restricted to a single POP.

Without the ability to update phone books (a task CPS handles automatically), users would have to contact their organization's technical support staff to be informed of changes in POP information and to reconfigure their client-dialer software. CPS has two components:

- Phone Book Administrator

- Phone Book Service

**Phone Book Administrator**
Phone Book Administrator is a tool used to create and maintain the phone book database and to publish new phone book information to the Phone Book Service.

**Phone Book Service**
The Phone Book Service runs on an IIS server and responds to requests from Connection Manager clients to verify the current version of subscribers' or corporate employees' current phone books and, if necessary, downloads a phone book update to the Connection Manager client.

**DHCP**
For both PPTP and L2TP connections, the data being tunneled is a PPP frame. A PPP connection must be established before data can be sent. The VPN server must have IP addresses available in order to assign them to a VPN server's virtual interface and to VPN clients during the IP Control Protocol (IPCP) negotiation phase that is part of the process of establishing a PPP connection. The IP address assigned to a VPN client is also assigned to the virtual interface of that VPN client.

For Windows Server 2003-based VPN servers, the IP addresses assigned to VPN clients are obtained through DHCP by default. A static IP address pool can also be configured. DHCP is also used by remote access VPN clients to obtain additional configuration settings after the PPP connection is established.

**EAP-RADIUS**
EAP-RADIUS is the passing of EAP messages of any EAP type by an authenticator to a Remote Authentication Dial-In User Service (RADIUS) server for authentication. For example, for a remote access server that is configured for RADIUS authentication, the EAP messages sent between the remote access client and remote access server are encapsulated and formatted as RADIUS messages between the remote access server (the authenticator) and the RADIUS server (the authenticator).

EAP-RADIUS is used in environments where RADIUS is the authentication provider. An advantage of using EAP-RADIUS is that EAP types only need to be installed at the RADIUS server, not at each remote access server. In the case of an IAS server, only EAP types need to be installed.

In a typical use of EAP-RADIUS, a server running Routing and Remote Access is configured to use EAP and to use an IAS server for authentication. When a connection is made, the remote access client negotiates the use of EAP with the remote access server. When the client sends an EAP message to the remote access server, the remote access server encapsulates the EAP message as a RADIUS message and sends it to its configured IAS server. The IAS server processes the EAP message and sends a RADIUS-encapsulated EAP message back to the remote access server. The remote access server then forwards the EAP message to the remote access client. In this configuration, the remote access server is only a pass-through device. All processing of EAP messages occurs at the remote access client and the IAS server.

Routing and Remote Access can be configured to authenticate locally or to a RADIUS server. If Routing and Remote Access is configured to authenticate locally, all EAP methods will be authenticated locally. If Routing and Remote Access is configured to authenticate to a RADIUS server, then all EAP messages will be forwarded to the RADIUS server with EAP-RADIUS.

**IAS**
The VPN server can be configured to use either Windows or RADIUS as an authentication provider. If Windows is selected as the authentication provider, the user credentials sent by users attempting VPN connections are authenticated using typical Windows authentication mechanisms, and the connection attempt is authorized using local remote access policies.

If RADIUS is selected and configured as the authentication provider on the VPN server, user credentials and parameters of the connection request are sent as RADIUS request messages to a RADIUS server.

The RADIUS server receives a user-connection request from the VPN server and authenticates and authorizes the connection attempt. In addition to a yes or no response to an authentication request, RADIUS can inform the VPN server of other applicable connection parameters for this user such as maximum session time, static IP address assignment, and so on.

RADIUS can respond to authentication requests based on its own user account database, or it can be a front end to another database server, such as a Structured Query Language (SQL) server or a Windows domain controller (DC). The DC can be located on the same computer as the RADIUS server, or elsewhere. In addition, a RADIUS proxy can be used to forward requests to a remote RADIUS server.

IAS is the Windows implementation of a RADIUS server and proxy.

**Name Server Assignment (DNS and WINS)**
Name server assignment, the assignment of Domain Name System (DNS) and Windows Internet Name Service (WINS)

servers, occurs during the process of establishing a VPN connection. The VPN client obtains the IP addresses of the DNS and WINS servers from the VPN server for the intranet to which the VPN server is attached.

The VPN server must be configured with DNS and WINS server addresses to assign to the VPN client during IPCP negotiation. For NetBIOS name resolution, you do not have to use WINS and can enable the NetBIOS over TCP/IP (NetBT) proxy on the VPN server.

**NAT**

A network address translator (NAT) translates the IP addresses and Transmission Control Protocol/User Datagram Protocol (TCP/UDP) port numbers of packets that are forwarded between a private network and the Internet. The NAT on the private network can also provide IP address configuration information to the other computers on the private network.

PPTP-based VPN clients can be located behind a NAT if the NAT includes an editor that can translate PPTP packets. PPTP-based VPN servers can be located behind a NAT if the NAT is configured with static mappings for PPTP traffic. If the L2TP/IPSec-based VPN clients or servers are positioned behind a NAT, both client and server must support IPSec NAT traversal (NAT-T).

- VPN and NAT
- Related Information

Microsoft Windows Server 2003 includes extensive support for virtual private network (VPN) technology, which leverages the IP connectivity of the Internet to connect remote clients and remote sites.

A VPN connection is the extension of a private network that includes links across shared or public networks, such as the Internet. VPN connections (VPNs) enable organizations to send data between two computers across the Internet in a manner that emulates the properties of a point-to-point private link.

**VPN Architecture**
Using VPNs, an organization can help secure private network traffic over an unsecured network, such as the Internet. VPN helps provide a secure mechanism for encrypting and encapsulating private network traffic and moving it through an intermediate network. Data is encrypted for confidentiality, and packets that might be intercepted on the shared or public network are indecipherable without the correct encryption keys. Data is also encapsulated, or wrapped, with an IP header containing routing information.

VPNs help enable users working at home, on the road, or at a branch office to connect in a secure fashion to a remote corporate server using the Internet. From the users perspective, the VPN is a point-to-point connection between the user's computer and a corporate server. The nature of the intermediate network, the Internet, is irrelevant to the user because it appears as if the data is being sent over a dedicated private link.

There are a number of ways to use VPN. The most common scenario is when a remote user accesses a private network across the Internet using a remote access VPN connection. In another scenario, a remote office connects to the corporate network using either a persistent or an on-demand site-to-site VPN connection (also known as a router-to-router VPN connection).

Each of these VPN scenarios can be deployed to provide connectivity over a public network, such as the Internet, or over a private intranet. VPN connections can also be deployed in an extranet scenario to communicate securely with business partners. An extranet functions as an intranet that can be securely shared with a designated business partner.

With both the remote access and site-to-site connections, VPNs enable an organization to replace long distance dial-up or leased lines with local dial-up or leased lines to an Internet service provider (ISP).

**Remote access VPN**
A remote access VPN connection is made by a remote access client. A remote access client is a single computer user who connects to a private network from a remote location. The VPN server provides access to the resources of the network to which the VPN server is connected. The packets sent across the VPN connection originate at the VPN client.

The VPN client authenticates itself to the VPN server and, for mutual authentication, the VPN server authenticates itself to the

VPN client.

**Site-to-site VPN**
A site-to-site VPN connection connects two portions of a private network or two private networks. For example, this allows an organization to have routed connections with separate offices, or with other organizations, over the Internet. A routed VPN connection across the Internet logically operates as a dedicated Wide Area Network (WAN) link.

The VPN server provides a routed connection to the network to which the VPN server is attached. On a site-to-site VPN connection, the packets sent from either router across the VPN connection typically do not originate at the routers. The calling router (the VPN client) authenticates itself to the answering router (the VPN server), and, for mutual authentication, the answering router authenticates itself to the calling router.

**Internet-based VPN Connections**
Using an Internet-based VPN connection, an organization can avoid long-distance charges while taking advantage of the global availability of the Internet.

**Remote Access VPN Connections over the Internet**
A remote access VPN connection over the Internet enables a remote access client to initiate a dial-up connection to a local ISP instead of connecting to a corporate or outsourced network access server (NAS). By using the established physical connection to the local ISP, the remote access client initiates a VPN connection across the Internet to the organization's VPN server. When the VPN connection is created, the remote access client can access the resources of the private intranet. The following figure shows remote access over the Internet.

### VPN Connecting a Remote Client to a Private Intranet

**Site-to-Site VPN Connections Over the Internet**
When networks are connected over the Internet, as shown in the following figure, a router forwards packets to another router across a VPN connection. To the routers, the VPN connection operates as a data-link layer link.

### VPN Connecting Two Remote Sites Across the Internet

**Intranet-based VPN Connections**
The intranet-based VPN connection takes advantage of IP connectivity in an organization's Local Area Network (LAN).

**Remote Access VPN Connections over an Intranet**
In some organization intranets, the data of a department, such as human resources, is so sensitive that the network segment of the department is physically disconnected from the rest of the intranet. While this protects the data of the human resources department, it creates information accessibility problems for authorized users not physically connected to the separate network segment.

VPN connections help provide the required security to enable the network segment of the human resources department to be physically connected to the intranet. In this configuration, a VPN server can be used to separate the network segments. The VPN server does not provide a direct routed connection between the corporate intranet and the separate network segment. Users on the corporate intranet with appropriate permissions can establish a remote access VPN connection with the VPN server and gain access to the protected resources. Additionally, all communication across the VPN connection is encrypted for data confidentiality. For those users who are not authorized to establish a VPN connection, the separate network segment is hidden from view.

The following figure shows remote access over an intranet.

**VPN Connection Allowing Remote Access to a Secured Network over an Intranet**

**Site-to-Site VPN Connections over an Intranet**

Two networks can be connected over an intranet using a site-to-site VPN connection. This type of VPN connection might be necessary, for example, for two departments in separate locations, whose data is highly sensitive, to communicate with each other. For instance, the finance department might need to communicate with the human resources department to exchange payroll information.

The finance department and the human resources department are connected to the common intranet with computers that can act as VPN clients or VPN servers. When the VPN connection is established, users on computers on either network can exchange sensitive data across the corporate intranet.

The following figure shows two networks connected over an intranet.

**VPN Connecting Two Networks over an Intranet**

**VPN Tunneling**

Tunneling is a network technology that enables the encapsulation of one type of protocol packet within the datagram of a different protocol. For example, Windows VPN connections can use Point-to-Point Tunneling Protocol (PPTP) packets to encapsulate and send private network traffic, such as TCP/IP traffic over a public network such as the Internet.

For PPTP and Layer Two Tunneling Protocol (L2TP), a tunnel is similar to a session. Both of the tunnel endpoints must agree to the tunnel and must negotiate configuration variables, such as address assignment, encryption, or compression parameters. In most cases, data transferred across the tunnel is sent using a datagram-based protocol. A tunnel management protocol is used as the mechanism to create, maintain, and terminate the tunnel.

After the tunnel is established, data can be sent. The tunnel client or server uses a tunnel data transfer protocol to prepare the data for transfer. For example, when the tunnel client sends a payload to the tunnel server, the tunnel client first appends a tunnel data transfer protocol header to the payload. The client then sends the resulting encapsulated payload across the network, which routes it to the tunnel server. The tunnel server accepts the packets, removes the tunnel data transfer protocol header, and forwards the payload to the target network. Information sent between the tunnel server and the tunnel client behaves similarly.

There are two types of tunneling:

- Voluntary tunneling
- Compulsory tunneling

**Voluntary Tunneling**

A user or client computer can issue a VPN request to configure and create a voluntary tunnel. In this case, the users computer is a tunnel endpoint and acts as the tunnel client.

Voluntary tunneling occurs when a client computer or routing server creates a virtual connection to the target tunnel server. To accomplish this, tunneling client software and the appropriate tunneling protocol must be installed on the client computer. For the protocols discussed in this technical reference, voluntary tunnels require an IP connection (either LAN or dial-up).

In a dial-up situation, the client must establish a dial-up connection to the network before the client can set up a tunnel. This is the most common case. The best example of this is the dial-up Internet user, who must dial an ISP and obtain an Internet

connection before a tunnel over the Internet can be created.

For a LAN-attached client computer, there is already a connection to the network that can provide routing of encapsulated payloads to the chosen LAN tunnel server. This would be the case for a client that is using an always-on broadband Internet connection.

It is a common misconception that VPN connections require a dial-up connection. They require only IP connectivity between the VPN client and VPN server. Some clients (such as home computers) use dial-up connections to the Internet to establish IP transport. This is a preliminary step in preparation for creating a tunnel and is not part of the tunnel protocol itself.

**Compulsory Tunneling**

In compulsory tunneling, a VPN-capable remote access server configures and creates a compulsory tunnel. With a compulsory tunnel, the user's computer is not a tunnel endpoint. Another device, the dial-up access server, between the user's computer and the tunnel server is the tunnel endpoint and acts as the tunnel client.

A number of vendors that sell dial-up access servers have implemented the ability to create a tunnel on behalf of a dial-up client. The computer or network device providing the tunnel for the client computer is variously known as a Front End Processor (FEP) for PPTP or an L2TP Access Concentrator (LAC) for L2TP. For the purposes of this reference, the term FEP is used to describe this functionality, regardless of the tunneling protocol. To carry out its function, the FEP must have the appropriate tunneling protocol installed and must be capable of establishing the tunnel when the client computer connects.

In compulsory tunneling, the client computer places a dial-up call to a tunneling-enabled NAS at the ISP. For example, a corporation might have contracted with an ISP to deploy a nationwide set of FEPs. These FEPs can establish tunnels across the Internet to a tunnel server connected to the organization’s private network, thus consolidating calls from geographically diverse locations into a single Internet connection at the organization network.

This configuration is known as compulsory tunneling because the client is compelled to use the tunnel created by the FEP. Once the initial connection is made, all network traffic to and from the client is automatically sent through the tunnel. With compulsory tunneling, the client computer makes a single PPP connection. When a client dials into the NAS, a tunnel is created and all traffic is automatically routed through the tunnel. An FEP can be configured to tunnel all dial-up clients to a specific tunnel server. The FEP could also tunnel individual clients, based on the user name or destination.

Unlike the separate tunnels created for each voluntary client, multiple dial-up clients can share a tunnel between the FEP and the tunnel server. When a second client dials into the access server (FEP) to reach a destination for which a tunnel already exists, there is no need to create a new instance of the tunnel between the FEP and tunnel server. Instead, the data traffic for the new client is carried over the existing tunnel. Since there can be multiple clients in a single tunnel, the tunnel is not terminated until the last user of the tunnel disconnects.

**PPTP**

Point-to-Point Tunneling Protocol (PPTP) encapsulates Point-to-Point Protocol (PPP) frames into IP datagrams for transmission over an IP-based network, such as the Internet or over a private intranet. PPTP is described in RFC 2637 in the IETF RFC Database.

PPTP uses a TCP connection, known as the PPTP control connection, to create, maintain, and terminate the tunnel. PPTP uses a modified version of Generic Routing Encapsulation (GRE) to encapsulate PPP frames as tunneled data. The payloads of the encapsulated PPP frames can be encrypted, compressed, or both.

PPTP assumes the availability of an IP network between a PPTP client (a VPN client using the PPTP tunneling protocol) and a PPTP server (a VPN server using the PPTP tunneling protocol). The PPTP client might already be attached to an IP network that can reach the PPTP server, or the PPTP client might have to use a dial-up connection to a NAS to establish IP connectivity as in the case of dial-up Internet users.

Authentication that occurs during the creation of a PPTP-based VPN connection uses the same authentication mechanisms as PPP connections, such as Extensible Authentication Protocol (EAP), Microsoft Challenge-Handshake Authentication Protocol (MS-CHAP), Microsoft Challenge-Handshake Authentication Protocol version 2 (MS-CHAP v2), CHAP, Shiva Password Authentication Protocol (SPAP), and Password Authentication Protocol (PAP). PPTP inherits encryption, compression, or both of PPP payloads from PPP. For PPTP connections, EAP-Transport Layer Security (EAP-TLS), MS-CHAP, or MS-CHAP v2 must be used for the PPP payloads to be encrypted using Microsoft Point-to-Point Encryption (MPPE).

MPPE provides only link encryption between the VPN client and the VPN server. It does not provide end-to-end encryption, which is data encryption between the client application and the server hosting the resource or service that is being accessed by the client application. If end-to-end encryption is required, IPSec can be used to encrypt IP traffic from end-to-end after the PPTP tunnel is established.

**Tunnel Maintenance with the PPTP Control Connection**

There is a PPTP control connection between the IP address of the PPTP client using a dynamically allocated TCP port and the IP

address of the PPTP server using the reserved TCP port 1723. The PPTP control connection carries the PPTP call control and management messages that are used to maintain the PPTP tunnel. This includes the transmission of periodic PPTP Echo-Request and PPTP Echo-Reply messages to detect a connectivity failure between the PPTP client and PPTP server. PPTP control connection packets consist of an IP header, a TCP header, a PPTP control message, and a data-link trailer and header as shown in the following figure:

**PPTP Control Connection Packet**

The following table lists the primary PPTP control messages that are sent over the PPTP control connection. For all of the PPTP control messages, the specific PPTP tunnel is identified by the TCP connection.

**PPTP Call Control and Connection Management Messages**

| Message Type | Purpose |
|---|---|
| Start-Control-Connection-Request | Sent by the PPTP client to establish the control connection. Each PPTP tunnel requires a control connection to be established before any other PPTP messages can be issued. |
| Start-Control-Connection-Reply | Sent by the PPTP server to reply to the Start-Control-Connection-Request message. |
| Outgoing-Call-Request | Sent by the PPTP client to create a PPTP tunnel. Included in the Outgoing-Call-Request message is a Call ID that is used in the GRE header to identify the tunneled traffic of a specific tunnel. |
| Outgoing-Call-Reply | Sent by the PPTP server in response to the Outgoing-Call-Request message. |
| Echo-Request | Sent by either the PPTP client or PPTP server as a keep-alive mechanism. If the Echo-Request is not answered, the PPTP tunnel is eventually terminated. |
| Echo-Reply | The reply to an Echo-Request. The PPTP Echo-and Echo-Reply messages are not related to the ICMP Echo Request and Echo Reply messages. |
| WAN-Error-Notify | Sent by the PPTP server to all VPN clients to indicate error conditions on the PPP interface of the PPTP server. |
| Set-Link-Info | Sent by the PPTP client or PPTP server to set PPP-negotiated options. |
| Call-Clear-Request | Sent by the PPTP client, indicating that a tunnel is to be terminated. |
| Call-Disconnect-Notify | Sent by the PPTP server in response to a Call-Clear-Request or for other reasons to indicate that a tunnel is to be terminated. If the PPTP server terminates the tunnel, a Call-Disconnect-Notify is sent. |
| Stop-Control-Connection-Request | Sent by the PPTP client or the PPTP server to inform the other that the control connection is being terminated. |
| Stop-Control-Connection-Reply | The reply to the Stop-Control-Connection-Request message. |

For information about the exact structure of PPTP control messages, see RFC 2637 in the IETF RFC Database.

**PPTP Data Tunneling**

PPTP data tunneling is performed through multiple levels of encapsulation. The following figure shows the resulting structure of tunneled PPTP data.

**Tunneled PPTP Data**

**PPP and GRE encapsulation**
The initial PPP payload is encrypted and encapsulated with a PPP header to create a PPP frame. The PPP frame is then encapsulated with a modified GRE header. GRE is described in RFC 1701 and RFC 1702 in the IETF RFC Database and was designed to provide a simple, general purpose mechanism for encapsulating data sent over IP networks. GRE is a client protocol of IP using IP protocol 47.

For PPTP, the GRE header is modified in the following ways:

An acknowledgement bit is used to indicate that a 32-bit acknowledgement field is present and significant.

The Key field is replaced with a 16-bit Payload Length field and a 16-bit Call ID field. The Call ID field is set by the PPTP client during the creation of the PPTP tunnel.

A 32-bit Acknowledgement field is added.

Within the GRE header, the Protocol Type is set to 0x880B, the EtherType value for a PPP frame.

### Note

- GRE is sometimes used by ISPs to forward routing information within an ISP's network. To prevent the routing information from being forwarded to Internet backbone routers, ISPs filter out GRE traffic on the interfaces connected to the Internet backbone. As a result of this filtering, PPTP tunnels can be created using PPTP control messages, but tunneled PPTP data is not forwarded.

The resulting encapsulated GRE and PPP payload is then encapsulated with an IP header containing the appropriate source and destination IP addresses for the PPTP client and PPTP server.

**Encapsulation of the data-link layer**
To be sent on a local area network (LAN) or WAN link, the IP datagram is finally encapsulated with a header and trailer for the data-link layer technology of the outgoing physical interface. For example, when IP datagrams are sent on an Ethernet interface, the IP datagram is encapsulated with an Ethernet header and trailer. When IP datagrams are sent over a point-to-point WAN link, such as an analog phone line or ISDN, the IP datagram is encapsulated with a PPP header and trailer.

**Processing of the tunneled PPTP data**
Upon receipt of the tunneled PPTP data, the PPTP client or PPTP server:

- Processes and removes the data-link header and trailer.
- Processes and removes the IP header.
- Processes and removes the GRE and PPP headers.
- Decrypts and, if needed, decompresses the PPP payload.
- Processes the payload for receipt or forwarding.

**PPTP Packet Development**
The following figure shows the path that tunneled PPTP data takes through the Windows Server 2003 networking architecture from a VPN client over a remote access VPN connection using an analog modem. The following steps outline this process:

1. An IP datagram is submitted by its appropriate protocol to the virtual interface that represents the VPN connection using Network Driver Interface Specification (NDIS).
2. NDIS submits the packet to NDISWAN, which encrypts and optionally compresses the data and provides a PPP header consisting of only the PPP Protocol ID field. This assumes that address and control field compression were negotiated during the Link Control Protocol (LCP) phase of the PPP connection process.
3. NDISWAN submits the data to the PPTP protocol driver, which encapsulates the PPP frame with a GRE header. In the GRE header, the Call ID field is set to the appropriate value to identify the tunnel.
4. The PPTP protocol driver then submits the resulting packet to the TCP/IP protocol driver.

5. The TCP/IP protocol driver encapsulates the tunneled PPTP data with an IP header and submits the resulting packet to the interface that represents the dial-up connection to the local ISP using NDIS.

6. NDIS submits the packet to NDISWAN, which provides PPP headers and trailers.

7. NDISWAN submits the resulting PPP frame to the appropriate WAN miniport driver representing the dial-up hardware (for example, the asynchronous port for a modem connection).

**PPTP Packet Development**

**Resulting Packet Structure**

**Note**

- It is possible to negotiate an encrypted PPP connection for the dial-up connection with the ISP. This is unnecessary and not recommended because the private data being sent, the tunneled PPP frame, is already encrypted. The additional level of encryption is not needed and can impact performance.

**L2TP**

Layer Two Tunneling Protocol (L2TP) is a combination of PPTP and Layer 2 Forwarding (L2F), a technology developed by Cisco Systems, Inc. Rather than having two incompatible tunneling protocols competing in the marketplace and causing customer confusion, the Internet Engineering Task Force (IETF) mandated that the two technologies be combined into a single tunneling protocol that represents the best features of PPTP and L2F. L2TP is described in RFC 2661 in the IETF RFC Database.

L2TP encapsulates PPP frames to be sent over IP, X.25, frame relay, or ATM networks. When sent over an IP network, L2TP frames are encapsulated as User Datagram Protocol (UDP) messages. L2TP can be used as a tunneling protocol over the Internet or over private intranets.

L2TP uses UDP messages over IP networks for both tunnel maintenance and tunneled data. The payloads of encapsulated PPP frames can be encrypted or compressed (or both); however, L2TP clients do not negotiate the use of MPPE for L2TP connections. Encryption for L2TP connections is provided by IPSec Encapsulating Security Payload (ESP) in transport mode.

It is possible to create Windows-based L2TP connections that are not encrypted by IPSec. However, this does not apply to a VPN connection because the private data being encapsulated by L2TP is already not encrypted. Non-encrypted L2TP connections can be used temporarily to troubleshoot an L2TP over IPSec connection by eliminating the IPSec authentication and negotiation process.

L2TP for Windows assumes the availability of an IP network between an L2TP client (a VPN client using the L2TP tunneling protocol and IPSec) and an L2TP server (a VPN server using the L2TP tunneling protocol and IPSec). The L2TP client might already be attached to an IP network that can reach the L2TP server, or the L2TP client might have to use a dial-up connection to a NAS to establish IP connectivity as in the case of dial-up Internet users.

Authentication that occurs during the creation of L2TP tunnels must use the same authentication mechanisms as PPP connections.

An Internet-based L2TP server is an L2TP-enabled remote access server with one interface on the Internet and a second interface on a private intranet.

L2TP tunnel maintenance and tunneled data have the same packet structure.

**Tunnel Maintenance with L2TP Control Messages**

In contrast to PPTP, L2TP tunnel maintenance is not performed over a separate TCP connection. L2TP call control and management traffic is sent as UDP messages between the L2TP client and the L2TP server. In Windows, the L2TP client and the

L2TP server both use UDP port 1701.

**Note**

- The L2TP client and L2TP server in Windows always use UDP port 1701. The Windows Server 2003 L2TP server supports L2TP clients that use a UDP port other than 1701.

L2TP control messages over IP connections are sent as UDP datagrams. In the Windows Server 2003 implementation, L2TP control messages sent as UDP datagrams are sent as the encrypted payload of IPSec ESP transport mode as shown in the following figure.

**L2TP Control Message**

Because a TCP connection is not used, L2TP uses message sequencing to ensure delivery of L2TP messages. Within the L2TP control message, the Next-Received field (similar to the TCP Acknowledgment field) and the Next-Sent field (similar to the TCP Sequence Number field) are used to maintain the sequence of control messages. Out-of-sequence packets are dropped. The Next-Sent and Next-Received fields can also be used for sequenced delivery and flow control for tunneled data.

L2TP supports multiple calls for each tunnel. In the L2TP control message and the L2TP header for tunneled data is a Tunnel ID that identifies the tunnel and a Call ID that identifies a call within the tunnel.

The following table lists the primary L2TP control messages.

**L2TP Control Messages**

| Message Type | Purpose |
|---|---|
| Start-Control-Connection-Request | Sent by the L2TP client to establish the control connection. Each L2TP tunnel requires a control connection to be established before any other L2TP messages can be issued. It includes an Assigned Tunnel-ID that is used to identify the tunnel. |
| Start-Control-Connection-Reply | Sent by the L2TP server to reply to the Start-Control-Connection-Request message. |
| Start-Control-Connection-Connected | Sent in reply to a Start-Control-Connection-Reply message to indicate that tunnel establishment was successful. |
| Outgoing-Call-Request | Sent by the L2TP client to create an L2TP tunnel. Included in the Outgoing-Call-Request message is an Assigned Call ID that is used to identify a call within a specific tunnel. |
| Outgoing-Call-Reply | Sent by the L2TP server in response to the Outgoing-Call-Request message. |
| Start-Control-Connection-Connected | Sent in reply to a received Outgoing-Call-Reply message to indicate that the call was successful. |
| Hello | Sent by either the L2TP client or L2TP server as a keep-alive mechanism. If the Hello is not acknowledged, the L2TP tunnel is eventually terminated. |
| WAN-Error-Notify | Sent by the L2TP server to all VPN clients to indicate error conditions on the PPP interface of the L2TP server. |
| Set-Link-Info | Sent by the L2TP client or L2TP server to set PPP-negotiated options. |
| Call-Disconnect-Notify | Sent by either the L2TP server or L2TP client to indicate that a call within a tunnel is to be terminated. |

| | |
|---|---|
| Stop-Control-Connection-Notification | Sent by either the L2TP server or L2TP client to indicate that a tunnel is to be terminated. |

For the exact structure of L2TP control messages, see RFC 2661 in the IETF RFC Database.

**L2TP Data Tunneling**
L2TP data tunneling is performed using multiple levels of encapsulation. The following figure shows the resulting structure of tunneled L2TP over IPSec data.

### L2TP Packet Encapsulation

**L2TP encapsulation**
The initial PPP payload is encapsulated with a PPP header and an L2TP header.

**UDP encapsulation**
The encapsulated L2TP packet is then encapsulated with a UDP header with the source and destination ports set to 1701.

**IP encapsulation**
The UDP message is encrypted and encapsulated with an IPSec ESP header and trailer and an ESP Authentication (Auth) trailer.

**Encapsulation of the data-link layer**
To send on a LAN or WAN link, the IP datagram is finally encapsulated with a header and trailer for the data-link layer technology of the outgoing physical interface. For example, when an IP datagram is sent on an Ethernet interface, the IP datagram is encapsulated with an Ethernet header and trailer. When an IP datagram is sent over a point-to-point WAN link such as an analog phone line or ISDN, the IP datagram is encapsulated with a PPP header and trailer.

**Processing of the tunneled L2TP/IPSec data**
Upon receipt of the tunneled L2TP/IPSec data, the L2TP client or L2TP server:

- Processes and removes the data-link header and trailer.
- Processes and removes the IP header.
- Uses the IPSec ESP Auth trailer to authenticate the IP payload and the IPSec ESP header.
- Uses the IPSec ESP header to decrypt the encrypted portion of the packet.
- Processes the UDP header and sends the L2TP packet to the L2TP driver.
- Uses the Tunnel ID and Call ID in the L2TP header to identify the specific L2TP tunnel.
- Uses the PPP header to identify the PPP payload and forward it to the proper protocol driver for processing.

**L2TP with Internet Protocol security (L2TP/IPSec)**
Tunneling protocols such as PPTP and L2TP are implemented at the data-link layer of the Open Systems Interconnection (OSI) reference model and provide data security by helping to create secure tunnels. In contrast, the IPSec protocol is implemented at the network layer and helps secure data at the packet level. IPSec provides two security protocols: Authentication Header (AH) and ESP.

**IPSec ESP encapsulation protocol**
To provide maximum security for L2TP/IPSec packets, ESP can also be used to encapsulate IPSec packets.

**L2TP Packet Development**
The figure below shows the path that tunneled L2TP data takes through the Windows Server 2003 networking architecture from a VPN client over a remote access VPN connection using an analog modem. The following steps outline the process:

1. An IP datagram is submitted by the appropriate protocol to the virtual interface that represents the VPN connection

using NDIS.

2. NDIS submits a packet to NDISWAN, which optionally compresses and provides a PPP header consisting of only the PPP Protocol ID field. This assumes that address and control field compression were negotiated during the LCP phase of the PPP connection process.

3. NDISWAN submits the PPP frame to the L2TP protocol driver, which encapsulates the PPP frame with an L2TP header. In the L2TP header, the Tunnel ID and the Call ID are set to the appropriate value identifying the specific L2TP connection.

4. The L2TP protocol driver then submits the resulting packet to the TCP/IP protocol driver with information to send the L2TP packet as a UDP message from UDP port 1701 to UDP port 1701 with the IP addresses of the VPN client and the VPN server.

5. The TCP/IP protocol driver constructs an IP packet with the appropriate IP header and UDP header. IPSec then analyzes the IP packet and matches it with a current IPSec policy. Based on the settings in the policy, IPSec encapsulates and encrypts the UDP message portion of the IP packet using the appropriate ESP headers and trailers.

6. The original IP header with the Protocol field set to 50 is added to the front of the ESP payload.

7. Using NDIS, the TCP/IP protocol driver then submits the resulting packet to the interface that represents the dial-up connection to the local ISP using NDIS.

8. NDIS submits the packet to NDISWAN.

9. NSIDWAN provides PPP headers and trailers and submits the resulting PPP frame to the appropriate WAN miniport driver representing the dial-up hardware.

**L2TP Packet Development**

**Resulting Packet Structure**

**Note**

- It is possible to negotiate an encrypted PPP connection for the dial-up connection with an ISP. This is not necessary and not recommended because the private data being sent, the tunneled PPP frame, is already encrypted with IPSec. The additional level of encryption is not needed and can impact performance.

**VPN Authentication**

The VPN server can be configured to use either Windows or Remote Authentication Dial-In User Service (RADIUS) as an authentication provider. If Windows is selected as the authentication provider, the user credentials sent by users attempting VPN connections are authenticated using typical Windows authentication mechanisms, and the connection attempt is authorized using the VPN client's user account properties and local remote access policies.

If RADIUS is selected and configured as the authentication provider on the VPN server, user credentials and parameters of the connection request are sent as RADIUS request messages to a RADIUS server.

The RADIUS server receives a user-connection request from the VPN server and authenticates and authorizes the connection attempt. In addition to a yes or no response to an authentication request, RADIUS can inform the VPN server of other applicable connection parameters for this user such as maximum session time, static IP address assignment, and so on.

RADIUS can respond to authentication requests based on its own user account database, or it can be a front end to another database server, such as a Structured Query Language (SQL) server or a Windows domain controller (DC). The DC can be located on the same computer as the RADIUS server or elsewhere. In addition, a RADIUS server can act as a proxy client to a remote RADIUS server.

The RADIUS protocol is described in RFC 2865 and RFC 2866 in the IETF RFC Database.

The VPN server can be configured to use either Windows or RADIUS as an accounting provider. If Windows is selected as the accounting provider, the accounting information accumulates on the VPN server for later analysis. Logging options can be specified from the properties of the **Local File** or **SQL Server** objects in the **Remote Access Logging** folder in the Routing and Remote Access snap-in. If RADIUS is selected, RADIUS accounting messages are sent to the RADIUS server for accumulation and later analysis.

Most RADIUS servers can be configured to place authentication request records into an audit file. A number of third parties have written billing and audit packages that read RADIUS accounting records and produce various useful reports. For more information about RADIUS accounting, see RFC 2866 in the IETF RFC Database.

The VPN server can be managed using industry-standard network management protocols and infrastructure. The computer acting as the VPN server can participate in a Simple Network Management Protocol (SNMP) environment as an SNMP agent if the Windows Server 2003 SNMP service is installed. The VPN server records management information in various object identifiers of the Internet Management Information Base (MIB) II, which is installed with the Windows Server 2003 SNMP service. Objects in the Internet MIB II are documented in RFC 1213 in the IETF RFC Database.

**Authentication Protocols**

The following authentication protocols are used to identify VPN users and grant or deny user access to network resources based on the user's credentials.

**PAP**

Password Authentication Protocol (PAP) is a clear-text authentication scheme. The NAS requests the user name and password, and PAP returns them in clear text (unencrypted). Obviously, this authentication scheme is not secure because a malicious user could capture the user's name and password and use it to get subsequent access to the NAS and all of the resources provided by the NAS. PAP provides no protection against replay attacks or remote client impersonation once the user's password is compromised.

**SPAP**

The Shiva Password Authentication Protocol (SPAP) is a reversible encryption mechanism employed by Shiva Corporation. A computer running Windows XP Professional uses SPAP when connecting to a Shiva LAN Rover. A Shiva client that connects to a server running Routing and Remote Access also uses SPAP. Currently, this form of authentication is more secure than plaintext but less secure than CHAP or MS-CHAP.

**CHAP**

Challenge Handshake Authentication Protocol (CHAP) is an encrypted authentication mechanism that prevents transmission of the actual password on the connection. The NAS sends a challenge, which consists of a session ID and an arbitrary challenge string, to the remote client. The remote client must use the MD5 one-way hashing algorithm to return the user name and a hash of the challenge, session ID, and the client’s password. The user name is sent as plain text.

CHAP is an improvement over PAP because the clear-text password is not sent over the link. Instead, the password is used to create a hash from the original challenge. The server knows the client’s clear-text password and can, therefore, replicate the operation and compare the result to the password sent in the client’s response. CHAP protects against replay attacks by using an arbitrary challenge string for each authentication attempt. CHAP protects against remote-client impersonation by unpredictably sending repeated challenges to the remote client throughout the duration of the connection.

**MS-CHAP**

Microsoft Challenge Handshake Authentication Protocol (MS-CHAP) is an encrypted authentication mechanism very similar to CHAP. As in CHAP, the NAS sends a challenge, which consists of a session ID and an arbitrary challenge string, to the remote client. The remote client must return the user name and an encrypted form of the challenge string, the session ID, and the MD4-hashed password. This design, which uses the MD4 hash of the password, helps provides an additional level of security because it allows the server to store hashed passwords instead of clear-text passwords or passwords that are stored using reversible encryption. MS-CHAP also provides additional error codes, including a password-expired code, and additional encrypted client-server messages that permit users to change their passwords during the authentication process. In MS-CHAP, both the client and the NAS independently generate a common initial encryption key for subsequent data encryption by MPPE.

**MS-CHAP v2**

MS-CHAP version 2 (MS-CHAP v2) is an updated encrypted authentication mechanism that provides stronger security for the exchange of user name and password credentials and determination of encryption keys. With MS-CHAP v2, the NAS sends a challenge to the client that consists of a session identifier and an arbitrary challenge string. The remote access client sends a

response that contains the user name, an arbitrary peer challenge string, and an encrypted form of the received challenge string, the peer challenge string, the session identifier, and the user's password. The NAS checks the response from the client and sends back a response containing an indication of the success or failure of the connection attempt and an authenticated response based on the sent challenge string, the peer challenge string, the encrypted response of the client, and the user's password. The remote access client verifies the authentication response and, if correct, uses the connection. If the authentication response is not correct, the remote access client terminates the connection.

Using this process, MS-CHAP v2 provides mutual authentication — the NAS verifies that the client has knowledge of the user's password, and the client verifies that the NAS has knowledge of the user's password. MS-CHAP v2 also determines two MPPE encryption keys, one for data sent and one for data received.

**EAP**

Extensible Authentication Protocol (EAP) is a PPP authentication protocol that allows for an arbitrary authentication method. EAP differs from the other authentication protocols in that, during the authentication phase, EAP does not actually perform authentication. Phase 2 for EAP only negotiates the use of a common EAP authentication method (known as an EAP type). The actual authentication for the negotiated EAP type is performed after Phase 2.

During phase 2 of PPP link configuration, the NAS collects the authentication data and then validates the data against its own user database or a central authentication database server, such as one maintained by a Windows domain controller, or the authentication data is sent to a RADIUS server.

As stated previously, most implementations of PPP provide a limited number of authentication methods. EAP is an IETF standard extension to PPP that allows for arbitrary authentication mechanisms for the validation of a PPP connection. EAP was designed to allow the dynamic addition of authentication plug-in modules at both the client and authentication server. This allows vendors to supply a new authentication scheme at any time. EAP provides the highest flexibility in authentication uniqueness and variation.

EAP is documented in RFC 2284 in the IETF RFC Database, and is supported in Windows Server 2003, Windows XP, and Windows 2000.

**EAP-MD5 Challenge**

Extensible Authentication Protocol-Message Digest 5 Challenge (EAP-MD5 Challenge) is a required EAP type that uses the same challenge handshake protocol as PPP-based CHAP, but the challenges and responses are sent as EAP messages. A typical use for EAP-MD5 Challenge is to authenticate the credentials of remote access clients by using user name and password security systems. EAP-MD5 Challenge can be used to test EAP interoperability.

**EAP-TLS**

Extensible Authentication Protocol-Transport Layer Security (EAP-TLS) is an EAP type that is used in certificate-based security environments. If smart cards are used for remote access authentication, EAP-TLS is the required authentication method. The EAP-TLS exchange of messages provides mutual authentication, negotiation of the encryption method, and encrypted key determination between the remote access client and the authenticator. EAP-TLS provides the strongest authentication and key-determination method.

When the Routing and Remote Access service is configured to use Windows authentication, EAP-TLS is supported only when the VPN server is a member of a domain. A VPN server running as a stand-alone server or a member of a workgroup does not support EAP-TLS.

EAP-TLS is an IETF standard (RFC 2716 in the IETF RFC Database for a strong authentication method based on public-key certificates. With EAP-TLS, a client presents a user certificate to the server, and the server presents a server certificate to the client. The first provides strong user authentication to the server; the second provides assurance that the VPN client has reached a trusted VPN server. Both systems rely on a chain of trusted certification authorities (CAs) to verify the validity of the offered certificate.

The user's certificate could be stored on the VPN client computer or in an external smart card. In either case, the certificate cannot be accessed without some form of user identification (PIN number or name/password credentials) between the user and the client computer. This approach meets the something-you-know-plus-something-you-have criteria recommended by most security experts.

EAP-TLS is supported in Windows Server 2003 and Windows XP. Like MS-CHAP and MS-CHAP v2, EAP-TLS returns an encryption key to enable subsequent data encryption by MPPE.

**RADIUS**

The Remote Authentication Dial-In User Service (RADIUS) protocol is used to provide centralized administration of authentication, authorization, and accounting (AAA) and an industry-standard security infrastructure. RADIUS is defined in RFCs 2138 and 2139 in the IETF RFC Database. RADIUS enables administrators to manage a set of authorization policies, accumulate accounting information, and access an account database from a central location.

Because it is impossible to update separate user accounts on separate servers for the same user simultaneously, most administrators set up a master account database at a domain controller or on a RADIUS server. This enables the VPN server to send the authentication credentials to a central authenticating device, and the same user account can be used for both dial-up remote access and VPN-based remote access.

**VPN Encryption**

To help ensure confidentiality of the data as it traverses the shared or public transit network, it is encrypted by the sender and decrypted by the receiver. Because data encryption is performed between the VPN client and VPN server, it is not necessary to use data encryption on the communication link between a dial-up client and its Internet service provider (ISP). For example, a mobile user uses a dial-up networking connection to dial in to a local ISP. Once the Internet connection is made, the user creates a VPN connection with the corporate VPN server. If the VPN connection is encrypted, there is no need to use encryption on the dial-up networking connection between the client and the ISP.

Remote access data encryption does not provide end-to-end data encryption. End-to-end encryption is data encryption between the client application and the server that hosts the resource or service being accessed by the client application. To get end-to-end data encryption, use IPSec to help create a secure connection after the remote access connection has been made.

Data encryption for PPP or PPTP connections is available only if MS-CHAP, MS-CHAP v2, or EAP-TLS is used as the authentication protocol. Data encryption for L2TP connections relies on IPSec, which does not require a specific PPP-based authentication protocol.

The encryption and decryption processes depend on both the sender and the receiver having knowledge of a common encryption key. Intercepted packets sent along the VPN connection in the transit network are unintelligible to any computer that does not have the common encryption key. The length of the encryption key is an important security parameter. Computational techniques can be used to determine the encryption key. Such techniques require more computing power and computational time as the encryption key gets larger. Therefore, it is important to use the largest possible key size.

In addition, the more information that is encrypted with the same key, the easier it is to decipher the encrypted data. With some encryption technologies, administrators are given the option to configure how often the encryption keys are changed during a connection.

PPTP uses user-level PPP authentication methods and Microsoft Point-to-Point Encryption (MPPE) for data encryption.

**Data Encryption with MPPE**

PPTP inherits MPPE encryption, which uses the Rivest-Shamir-Adleman (RSA) RC4 stream cipher. MPPE is available only for PPTP-based VPN connections when the EAP-TLS, MS-CHAP, or MS-CHAP v2 authentication protocols are used.

For the Routing and Remote Access service, MPPE encryption strengths are configured on the Encryption tab on the properties of a remote access policy to use 40-bit (the Basic setting), 56-bit (the Strong setting), or 128-bit (the Strongest setting) encryption keys. Administrators should use 40-bit MPPE encryption keys to connect with older operating systems that do not support 56-bit or 128-bit encryption keys (this includes older Windows operating systems and operating systems from companies other than Microsoft). Otherwise, use 128-bit encryption keys. Encryption strengths for L2TP/IPSec connections use 56-bit DES (the Basic or Strong setting) or 168-bit 3DES (the Strongest setting).

Encryption keys are determined at the time of the connection. By default, the highest key strength supported by the VPN client and VPN server is negotiated during the process of establishing a connection. If the VPN server requires a higher key strength than is supported by the VPN client, the connection attempt is rejected.

MPPE was originally designed for encryption across a point-to-point link where packets arrive in the same order in which they were sent with little packet loss. For this environment, the decryption of each packet depends on the decryption of the previous packet.

For VPN connections, however, IP datagrams sent across the Internet can arrive in a different order from the one in which they were sent, and a higher proportion of packets can be lost. Therefore, for VPN connections, MPPE changes the encryption key for each packet. The decryption of each packet is independent of the previous packet. MPPE includes a sequence number in the MPPE header. If packets are lost or arrive out of order, the encryption keys are changed relative to the sequence number.

**VPN Addressing and Routing**

Based on whether or not a route is added by default, a VPN client has broad access to Internet locations or to locations on the intranet, but not to both:

- If the currently active default route is pointing to the Internet (and the gateway on the remote network is not being used), Internet locations are reachable, but only intranet locations matching the network ID corresponding to the Internet address class of the assigned IP address can be reached.

- If the currently active default route is pointing to the intranet (and the gateway on the remote network is being used), all intranet locations are reachable, but only the IP address of the VPN server and locations available through other routes can be reached on the Internet.

For most VPN clients with an Internet connection, this does not present a problem, because the client is typically engaged in either intranet communication or Internet communication, but not both.

To work around this problem, instead of having the client create a new default route when a connection is made, administrators can configure the client's routing table with specific routes that direct packets to the organization's network over the VPN connection. While connected to the intranet, the client can obtain Internet access using the default route that points to the Internet. This configuration is known as split tunneling.

**Split Tunneling**
The VPN client can obtain the routes needed for split tunneling in several ways:

- If the VPN client has a configured connection without a default route, the client adds a route that it infers from the Internet address class of the IP address assigned to it for the current connection. For a simple target network, such as a small office, this one route is sufficient to allow packets to be routed to the target network. However, for a complex network, administrators need to configure multiple routes to successfully direct packets to the remote network.

- A client running the Microsoft Windows XP or Windows Server 2003 operating systems uses a DHCPINFORM message after the connection to request the DHCP Classless Static Routes option. This DHCP option contains a set of routes that are automatically added to the routing table of the requesting client. This additional information is available only if the Windows Server 2003 DHCP server has been configured to provide the DHCP Classless Static Routes option and if the VPN server has the DHCP Relay Agent routing protocol component configured with the IP address of the DHCP server.

- If the remote access client is managed using the Connection Manager component of Windows Server 2003, the network administrator can configure routing table updates from the Routing Table Update page of the Connection Manager Administration Kit when creating the Connection Manager profile.

If none of the approaches discussed above is an option, a batch file or program can be written that updates the routing table on the client with the necessary routes to the private intranet.

**Security Considerations for Split Tunneling**
When a VPN client computer is connected to both the Internet and a private intranet and has routes that allow it to reach both networks, the possibility exists that a malicious Internet user might use the connected VPN client computer to reach the private intranet through the authenticated VPN connection. This is possible if the VPN client computer has IP routing enabled. IP routing is enabled on Windows XP-based computers by setting the HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip \Parameters\IPEnableRouter registry entry to 1 (data type is REG_DWORD).

If split tunneling is required, administrators can help prevent a malicious user from gaining access over the Internet by doing the following:

- Use the Network Access Quarantine Control feature in Windows Server 2003 to check whether VPN clients have IP routing enabled and, if so, do not allow VPN access until it has been disabled.

- Use IP packet filters on the VPN remote access policy profile to discard both inbound traffic on the VPN connection that has not been sent from the VPN client and outbound traffic that is not destined to the VPN client. The default remote access policy, named "Connections to Microsoft Routing and Remote Access server in Windows Server 2003" has these packet filters configured and enabled by default.

  **Note**

  - Using the methods above does not prevent unwanted traffic if a malicious Internet user is remotely controlling the VPN client computer. To prevent this, ensure that the VPN client computer has a firewall enabled (such as Internet Connection Firewall in Windows XP) and an anti-virus program installed and running with the latest virus signature file installed. These are also settings that can be enabled and enforced when using Network Access Quarantine Control.

**DHCP Classless Static Routes Option**
Classless static routes are implemented using DHCP scope option 249. Using classless static routes, each DHCP client can be configured with the route to any destination on the network, and the subnet mask can be specified. Because each scope represents a physical subnet, the scope can be viewed as the start location for any message that is to be sent by a client to another subnet. The parameters used to configure option 249 are Destination, Mask, and Router. One or more static routes can be configured with option 249. All DHCP-enabled clients on the network can be provided with routes to all other subnets using option 249.

This option is configured as a scope option because the Router IP address, like the DHCP Router option that defines the default gateway for a DHCP client, is different for each subnet. For example, subnets A and D each use a router. The routers they use will be different, and the Router IP address will be different in each case.

**Static Routing**
Static routing requires that routing tables be configured and maintained manually. Static routers do not exchange information. Because of this limitation, when compared to dynamic routing, static routing is typically implemented in small networks or in networks that require the highest level of security.

**Auto-Static Updates**
If routing protocols are not used to update the routing tables, then the routes must be entered as static routes. The static routes that correspond to the network IDs available across the interface are entered manually or automatically. The automatic entering of static routes for demand-dial interfaces is known as making auto-static updates and is supported by the server running Routing and Remote Access. Auto-static updates are supported by Routing Information Protocol (RIP) for IP, but not by OSPF.

Auto-static refers to the automatic adding of the requested routes as static routes in the routing table. The sending of the request for routes is performed through an explicit action, either through Routing and Remote Access or the Netsh utility while the demand-dial interface is in a connected state. Auto-static updates are not automatically performed every time a demand-dial connection is made.

When instructed, a demand-dial interface that is configured for auto-static updates sends a request across an active connection to request all of the routes of the router on the other side of the connection. In response to the request, all of the routes of the requested router are automatically entered as static routes in the routing table of the requesting router. The static routes are persistent: They are kept in the routing table even if the interface becomes disconnected or the router is restarted. An auto-static update is a one-time, one-way exchange of routing information.

Administrators can automate and schedule auto-static updates by executing the update as a scheduled task. When an auto-static update is requested, the existing auto-static routes are deleted before the update is requested from other routers. If there is no response to the request, then the router cannot replace the routes it has deleted. This might lead to a loss of connectivity to remote networks.

**Dynamic Routing**
By implementing a dynamic routing protocol, such as RIP or Open Shortest Path First (OSPF), administrators can configure routers to exchange routing information with each other as needed.

**RIP**
The biggest advantage of RIP is that it is extremely simple to configure and deploy. The biggest disadvantage of RIP is its inability to scale to large or very large networks. The maximum hop count used by RIP routers is 15. Networks that are 16 hops or more away are considered unreachable. As networks grow larger in size, the periodic announcements by each RIP router can cause excessive traffic. Another disadvantage of RIP is its high recovery time. When the network topology changes, it might take several minutes before the RIP routers reconfigure themselves to the new network topology. While the network reconfigures itself, routing loops might form that result in lost or undeliverable data.

Initially, the routing table for each router includes only the networks that are physically connected. A RIP router periodically sends announcements that contain its routing table entries to inform other local RIP routers of the networks it can reach. RIP version 1 uses IP broadcast packets for its announcements. RIP version 2 can use multicast or broadcast packets for its announcements.

RIP routers can also communicate routing information through triggered updates. Triggered updates occur when the network topology changes and updated routing information is sent that reflects those changes. With triggered updates, the update is sent immediately rather than waiting for the next periodic announcement. For example, when a router detects a link or router failure, it updates its own routing table and sends updated routes. Each router that receives the triggered update modifies its own routing table and propagates the change.

Routing and Remote Access supports RIP versions 1 and 2. RIP version 2 supports multicast announcements, simple password authentication, and more flexibility in subnetted and Classless InterDomain Routing (CIDR) environments.

**OSPF**
The biggest advantage of OSPF is that it is efficient; OSPF requires very little network overhead even in very large networks. The biggest disadvantage of OSPF is its complexity; OSPF requires proper planning and is more difficult to configure and administer.

OSPF uses a Shortest Path First (SPF) algorithm to compute routes in the routing table. The SPF algorithm computes the shortest (least cost) path between the router and all the subnets of the network. SPF-calculated routes are always loop-free.

Changes to network topology are efficiently flooded across the entire network to ensure that the link state database on each router is synchronized and accurate at all times. Upon receiving changes to the link state database, the routing table is recalculated.

As the size of the link state database increases, memory requirements and route computation times increase. To address this scaling problem, OSPF divides the network into areas (collections of contiguous networks) that are connected to each other through a backbone area. Each router only keeps a link state database for those areas that are connected to the router. Area border routers (ABRs) connect the backbone area to other areas.

**Single-Adapter model**
With the single-adapter model, also known as the NBMA model, the network for the frame relay service provider (also known as the frame relay cloud) is treated as an IP network and the endpoints on the cloud are assigned IP addresses from a designated IP network ID. To ensure that OSPF traffic is received by all of the appropriate endpoints on the cloud, the frame relay interface must be configured to send unicast OSPF announcements to all of the appropriate endpoints. For the server running Routing and Remote Access, this is done by designating the interface as an NBMA network and adding OSPF neighbors.

In addition, in a spoke and hub frame relay topology, the frame relay interface for the hub router must have a router priority set to 1 or greater and the frame relay interfaces for the spoke routers must have a router priority set to 0. Otherwise, the hub router, which is the only router that can communicate with all of the spoke routers, cannot become the designated router and adjacencies cannot form across the frame relay network.

**Multiple-Adapter model**
With the multiple-adapter model, each frame relay virtual circuit appears as a point-to-point link with its own network ID, and the endpoints are assigned IP addresses from a designated IP network ID. Because each virtual circuit is its own point-to-point connection, administrators can configure the interface for the point-to-point network type.

**Virtual links**
An OSPF-routed network can be subdivided into areas, which are collections of contiguous networks. All areas are connected together through a common area called the backbone area. A router that connects an area to the backbone area is called an area border router (ABR). Normally, ABRs have a physical connection to the backbone area. When it is not possible or practical to have an ABR physically connected to the backbone area, administrators can use a virtual link to connect the ABR to the backbone.

A virtual link is a logical point-to-point connection between an ABR of an area and an ABR that is physically connected to the backbone area. For example, a virtual link is configured between the ABR of Area 2 and the ABR of Area 1. The ABR of Area 1 is physically connected to the backbone area. Area 1 is known as the transit area, the area across which the virtual link is created in order to logically connect Area 2 to the backbone.

To create a virtual link, both routers, called virtual link neighbors, are configured with the transit area, the router ID of the virtual link neighbor, matching hello and dead intervals, and a matching password.

**External routes and ASBRs**
The set of OSPF routers in an organization defines an OSPF autonomous system (AS). By default, only OSPF routes corresponding to directly-connected network segments are propagated within the AS. An external route is any route that is not within the OSPF AS. External routes can come from many sources:

- Other routing protocols such as RIP for IP (version 1 and version 2)
- Static routes
- Routes set on the router through SNMP

External routes are propagated throughout the OSPF AS through one or more autonomous system boundary routers (ASBRs). An ASBR advertises external routes within the OSPF AS. For example, if the static routes of a server running Routing and Remote Access need to be advertised, that router must be enabled as an ASBR.

**External route filters**
By default, OSPF routers acting as ASBRs import and advertise all external routes. Administrators might want to filter out external routes to keep the ASBR from advertising improper routes. External routes can be filtered on the ASBR by:

**External route source**
Administrators can configure the ASBR to accept or ignore the routes of certain external sources such as routing protocols (RIP version 2) or other sources (static routes or SNMP).

**Individual route**
Administrators can configure the ASBR to accept or discard specific routes by configuring one or multiple destination, network mask pairs.

**VPN and Firewalls**
A firewall uses packet filtering to allow or disallow the flow of specific types of network traffic. IP packet filtering provides a way for administrators to define precisely what IP traffic is allowed to cross the firewall. IP packet filtering is important when private intranets are connected to public networks, such as the Internet. There are two approaches to using a firewall with a VPN server:

- A firewall is between the VPN server and the Internet. In this configuration, the VPN server is behind the firewall.
- The VPN server is connected to the Internet and the firewall is between the VPN server and the intranet. In this configuration, the VPN server is in front of the firewall.

**VPN Server Behind a Firewall**
In the configuration shown in the following figure, the firewall is connected to the Internet and the VPN server is another intranet resource connected to the perimeter network, also known as a screened subnet or demilitarized zone (DMZ). The perimeter network is an IP network segment that typically contains resources available to Internet users such as Web servers and FTP servers. The VPN server has an interface on the perimeter network and an interface on the intranet.

In this approach, the firewall must be configured with input and output filters on its Internet and perimeter network interfaces to allow the passing of tunnel maintenance traffic and tunneled data to the VPN server. Additional filters can allow the passing of traffic to Web servers, FTP servers, and other types of servers on the perimeter network. As an added layer of security, the VPN server should also be configured with PPTP or L2TP/IPSec packet filters on its perimeter network interface as described in "VPN Server in Front of a Firewall" in this section.

Because the firewall does not have the encryption keys for each VPN connection, it can only filter on the plaintext headers of the tunneled data, meaning that all tunneled data passes through the firewall. However, this is not a security concern because the VPN connection requires an authentication process that prevents unauthorized access beyond the VPN server.

### VPN Server Behind the Firewall

**Packet Filters for a VPN Server Behind a Firewall**
If the VPN server is behind a firewall, packet filters must be configured for both an Internet interface and a perimeter network interface. In this scenario, the firewall is connected to the Internet, and the VPN server is an intranet resource that is connected to the perimeter network. The VPN server has an interface on both the perimeter network and the Internet.

**PPTP connections for the Internet interface of the firewall**
The following table shows the inbound and outbound PPTP filters on the firewall's Internet interface.

### VPN Server Behind a Firewall: PPTP Filters on the Firewall's Internet Interface

| Filter Type | Filter | Action |
|---|---|---|

| | | |
|---|---|---|
| Inbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**TCP destination port** = 1723 (0x6BB) | Allows PPTP tunnel maintenance traffic from the PPTP client to the PPTP server. |
| Inbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 47 (0x2F) | Allows tunneled PPTP data from the PPTP client to the PPTP server. |
| Inbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. If all traffic from TCP port 1723 is allowed to reach the VPN server, network attacks can emanate from sources on the Internet that use this port. Administrators should only use this filter in conjunction with the PPTP filters that are also configured on the VPN server. |
| Outbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Allows PPTP tunnel maintenance traffic from the PPTP server to the PPTP client. |
| Outbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 47 (0x2F) | Allows tunneled PPTP data from the PPTP server to the PPTP client. |
| Outbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**TCP destination port** = 1723 (0x6BB) | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. If all traffic from the VPN server is allowed to reach TCP port 1723, network attacks can emanate from sources on the Internet using this port. Administrators should only use this filter in conjunction with the PPTP filters that are also configured on the VPN server. |

**PPTP connections for the perimeter network interface of the firewall**

The following table shows the inbound and outbound PPTP filters on the firewall's perimeter network interface.

**VPN Server Behind a Firewall: PPTP Filters on the Perimeter Network Interface**

| Filter Type | Filter | Action |
|---|---|---|

| | | |
|---|---|---|
| Inbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Allows PPTP tunnel maintenance traffic from the VPN server to the VPN client. |
| Inbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 47 (0x2F) | Allows tunneled PPTP data from the VPN server to the VPN client. |
| Inbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**TCP destination port** = 1723 (0x6BB) | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. If all traffic from TCP port 1723 is allowed to reach the VPN server, network attacks can emanate from sources on the Internet using this port. |
| Outbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Allows PPTP tunnel maintenance traffic from the PPTP client to the PPTP server. |
| Outbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 47 (0x2F) | Allows tunneled PPTP data from the PPTP client to the PPTP server. |
| Outbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. If all traffic from the VPN server is allowed to reach TCP port 1723, network attacks can emanate from sources on the Internet using this port. |

**L2TP/IPSec connections for the Internet interface of the firewall**

The following table shows the inbound and outbound L2TP/IPSec filters on the firewall's Internet interface.

**VPN Server Behind a Firewall: L2TP/IPSec Filters on the Firewall's Internet Interface**

| Filter Type | Filter | Action |
|---|---|---|
| Inbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**UDP destination port** = 500 (0x1F4) | Allows IKE traffic to the VPN server. |
| Inbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**UDP destination port** = 4500 (0x1194) | Allows IPSec NAT-T traffic to the VPN server. |
| Inbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 50 (0x32) | Allows IPSec ESP traffic to the VPN server. |

| | | |
|---|---|---|
| Outbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**UDP source port** = 500 (0x1F4) | Allows IKE traffic from the VPN server. |
| Outbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**UDP source port** = 4500 (0x1194) | Allows IPSec NAT-T traffic from the VPN server. |
| Outbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 50 (0x32) | Allows IPSec ESP traffic from the VPN server. |

No filters are required for L2TP traffic at UDP port 1701. All L2TP traffic at the firewall, including tunnel maintenance and tunneled data, is encrypted with IPSec ESP.

**L2TP/IPSec connections for the perimeter network interface of the firewall**

The following table shows the inbound and outbound L2TP/IPSec filters on the firewall's perimeter network interface.

**VPN Server Behind a Firewall: L2TP/IPSec Filters on the Firewall's Perimeter Network Interface**

| Filter Type | Filter | Action |
|---|---|---|
| Inbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**UDP source port** = 500 (0x1F4) | Allows IKE traffic from the VPN server. |
| Inbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**UDP source port** = 4500 (0x1194) | Allows IPSec NAT-T traffic from the VPN server. |
| Inbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 50 (0x32) | Allows IPSec ESP traffic from the VPN server. |
| Outbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**UDP destination port** = 500 (0x1F4) | Allows IKE traffic to the VPN server. |
| Outbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**UDP destination port** = 4500 (0x1194) | Allows IPSec NAT-T traffic to the VPN server. |
| Outbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 50 (0x32) | Allows IPSec ESP traffic to the VPN server. |

**VPN Server in Front of a Firewall**

With the VPN server in front of the firewall and connected to the Internet, as shown in the following figure, administrators need to add packet filters to the Internet interface that allow only VPN traffic to and from the IP address of the VPN server's interface on the Internet.

For inbound traffic, when the tunneled data is decrypted by the VPN server it is forwarded to the firewall, which employs its filters to allow the traffic to be forwarded to intranet resources. Because the only traffic that is crossing the VPN server is traffic generated by authenticated VPN clients, firewall filtering in this scenario can be used to prevent VPN users from accessing specific intranet resources.

Because the only Internet traffic allowed on the intranet must go through the VPN server, this approach also prevents the sharing of intranet resources with non-VPN Internet users.

**VPN Server in Front of the Firewall**

**Packet Filters for a VPN Server in Front of a Firewall**

When a VPN server is in front of a firewall and connected to the Internet, inbound and outbound packet filters on the VPN server need to be configured to allow only VPN traffic to and from the IP address of the VPN server's Internet interface. Use this configuration if the VPN server is in a perimeter network, with one firewall positioned between the VPN server and the intranet and another between the VPN server and the Internet.

All of the following packet filters are configured, using the Routing and Remote Access snap-in, as IP packet filters on the Internet interface. Depending on the configuration decisions made when running the Routing and Remote Access Server Setup Wizard, these packet filters might already be configured.

**PPTP connections for the inbound and outbound filters**

The following table shows the VPN server's inbound and outbound filters for PPTP.

**VPN Server in Front of a Firewall: PPTP Packet Filters on the Internet Interface**

| Filter Type | Filter | Action |
|---|---|---|
| Inbound | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**TCP destination port** = 1723 | Allows PPTP tunnel maintenance to the VPN server. |
| Inbound | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**IP Protocol ID** = 47 | Allows tunneled PPTP data to the VPN server. |
| Inbound | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**TCP (established) source port** = 1723 | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. Accepts TCP traffic only when a VPN server initiates the TCP connection. |
| Outbound | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**TCP source port** = 1723 | Allows PPTP tunnel maintenance traffic from the VPN server. |

| | | |
|---|---|---|
| Outbound | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**IP Protocol ID** = 47 | Allows tunneled PPTP data from the VPN server. |
| Outbound | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**TCP (established) destination port** = 1723 | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. Sends TCP traffic only when a VPN server initiates the TCP connection. |

**L2TP/IPSec connections**

The following table shows the VPN server's inbound and outbound filters for L2TP/IPSec.

**VPN Server in Front of a Firewall: L2TP/IPSec Packet Filters on the Internet Interface**

| Filter Type | Filter | Action |
|---|---|---|
| Inbound | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP destination port** = 500 | Allows IKE traffic to the VPN server. |
| Inbound | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP destination port** = 1701 | Allows L2TP traffic from the VPN client to the VPN server. |
| Inbound | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP destination port** = 4500 | Allows IPSec NAT-T traffic from the VPN client to the VPN server. |
| Outbound | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP source port** = 500 | Allows IKE traffic from the VPN server. |
| Outbound | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP source port** = 1701 | Allows L2TP traffic from the VPN server to the VPN client. |
| Outbound | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP source port** = 4500 | Allows IPSec NAT-T traffic from the VPN server to the VPN client |

**VPN and NAT**

A network address translator (NAT) is a device that is typically used to provide shared access for private networks to a public network such as the Internet. Because NAT does not work with protocols that use encryption, a VPN solution that includes a NAT can add a layer of complexity to a VPN deployment.

**NAT with PPTP Connections**
If a VPN client that uses a PPTP connection is behind a NAT, the NAT must include a NAT editor that can translate PPTP traffic. The NAT editor is required because tunneled PPTP data has a GRE header rather than a TCP header or a UDP header. The NAT editor uses the Call ID field in the GRE header to identify the PPTP data stream and translate IP addresses and call IDs for PPTP data packets that are forwarded between a private network and the Internet.

**PPTP NAT editor**
The NAT/Basic Firewall routing protocol component of the Routing and Remote Access service and the Internet Connection Sharing feature of Network Connections includes a NAT editor for PPTP traffic.

**NAT with L2TP Connections**
To use L2TP-based VPN connections behind a NAT, IPSec NAT Traversal (NAT-T) must be implemented at both ends of the VPN connection.

**IPSec NAT-T**
IPSec NAT-T addresses the difficulty of using IPSec-based VPNs across a NAT. Windows Server 2003 allows an L2TP/IPSec connection to pass through a NAT. This capability is based on the latest IETF standards.

IPSec NAT-T enables IPSec peers to negotiate and communicate when they are behind a NAT. To use IPSec NAT-T, both the remote access VPN client and the remote access VPN server must support IPSec NAT-T. IPSec NAT-T is supported by the Windows Server 2003 Microsoft L2TP/IPSec VPN Client and by the L2TP/IPSec NAT-T Update for Windows XP and the L2TP/IPSec NAT-T Update for Windows 2000. During the IPSec negotiation process, IPSec NAT-T-capable peers automatically determine whether both the initiating IPSec peer (typically a client computer) and responding IPSec peer (typically a server) can perform IPSec NAT-T. In addition, IPSec NAT-T-capable peers automatically determine if there are any NATs in the path between them. If both of these conditions are true, the peers automatically use IPSec NAT-T to send IPSec-protected traffic.

**User Datagram Protocol-Encapsulating Security Payload (UDP-ESP)**
IPSec NAT-T provides UDP encapsulation of IPSec packets to enable IKE and ESP-protected traffic to pass through a NAT. IKE automatically detects that a NAT is present and uses UDP-ESP encapsulation to enable ESP-protected IPSec traffic to pass through the NAT.

**Related Information**
The following resources contain additional information that is relevant to this section.

- RFC 2637, 1701, 1702, 2661, 2865, 2866, 1213, 2284, 2716, 2138, and 2139 in the IETF RFC Database.

# VPN Tools and Settings

Updated: August 21, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**VPN Tools and Settings**

**In this section**

Windows Server 2003 provides the following tools to troubleshoot VPN connections:

- TCP/IP Troubleshooting Tools
- Authentication and Accounting Logging
- Event Logging
- IAS Event Logging
- PPP Logging
- Tracing
- Oakley Logging
- Network Monitor

**TCP/IP Troubleshooting Tools**

The **Ping**, **Tracert**, and **Pathping** tools use ICMP Echo and Echo Reply messages to verify connectivity, display the path to a destination, and test path integrity. The **route print** command can be used to display the IP routing table. Alternately, on the VPN server, you can use the **netsh routing ip show rtmroutes** command or the Routing and Remote Access snap-in. The Nslookup tool can be used to troubleshoot DNS and name resolution issues.

**Authentication and Accounting Logging**

A VPN server running Windows Server 2003 supports the logging of authentication and accounting information for remote access VPN connections in local logging files when Windows authentication or Windows accounting is enabled. This logging is separate from the events recorded in the system event log. You can use the information that is logged to track remote access usage and authentication attempts. Authentication and accounting logging is especially useful for troubleshooting remote access policy issues. For each authentication attempt, the name of the remote access policy that either accepted or rejected the connection attempt is recorded.

Enable authentication and accounting logging from the **Settings** tab on the properties of the **Local File** object in the **Remote Access Logging** folder in the Routing and Remote Access snap-in (if the Routing and Remote Access service is configured for Windows authentication and accounting) or the Internet Authentication Service snap-in (if the Routing and Remote Access service is configured for RADIUS authentication and accounting and the RADIUS server is an IAS server)

The authentication and accounting information is stored in a configurable log file or files stored in the *SystemRoot*\System32\LogFiles folder. The log files are saved in Internet Authentication Service (IAS) or database-compatible format, meaning that any database program can read the log file directly for analysis.

If the VPN server is configured for RADIUS authentication and accounting and the RADIUS server is a computer running Windows Server 2003 and IAS, the authentication and accounting logs are stored in the *SystemRoot*\System32\LogFiles folder on the IAS server computer.

IAS for Windows Server 2003 can also send authentication and accounting information to a Structured Query Language (SQL) database.

**Event Logging**

On the **Logging** tab in the properties of a VPN server in the Routing and Remote Access snap-in, there are four levels of logging. Select **Log all events**, and then try the connection again. After the connection fails, check the system event log for events logged during the connection process. After you are done viewing remote access events, select the **Log errors and**

**warnings** option on the **Logging** tab to conserve system resources.

#### IAS Event Logging

If your VPN servers are configured for RADIUS authentication and your RADIUS servers are computers running Windows Server 2003 and IAS, check the system event log for IAS events for rejected or accepted connection attempts. IAS system event log entries contain a lot of information about the connection attempt including the name of the remote access policy that accepted or rejected the connection attempt. IAS event logging for rejected or accepted connection attempts is enabled by default and configured from the **Service** tab from the properties of an IAS server in the Internet Authentication Service snap-in.

#### PPP logging

PPP logging records the series of programming functions and PPP control messages during a PPP connection and is a valuable source of information when you are troubleshooting the failure of a PPP connection. To enable PPP logging, select the **Log additional Routing and Remote Access information** option on the **Logging** tab on the properties of a remote access server.

By default, the PPP log is stored as the Ppp.log file in the *SystemRoot*\Tracing folder.

#### Tracing

The Windows Server 2003 Routing and Remote Access service has an extensive tracing capability that you can use to troubleshoot complex network problems. You can enable the components in Windows Server 2003 to log tracing information to files using the Netsh command or through the registry.

#### Enabling Tracing with Netsh

You can use the Netsh command to enable and disable tracing for specific components or for all components.

**To enable and disable tracing for a specific component, use the following syntax:**

**netsh ras set tracing** *Component* **enabled|disabled**

where *Component* is a component in the list of Routing and Remote Access service components found in the Windows Server 2003 registry under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing. For example, to enable tracing for the RASAUTH component, the command is:

**netsh ras set tracing rasauth enabled**

To enable tracing for all components, use the following command:

**netsh ras set tracing * enabled**

#### Enabling Tracing Through the Registry

**You can configure the tracing function by changing settings in the Windows Server 2003 registry under:**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing

You can enable tracing for each Routing and Remote Access service component by setting the registry values described later. You can enable and disable tracing for components while the Routing and Remote Access service is running. Each component is capable of tracing and appears as a subkey under the preceding registry key.

To enable tracing for each component, you can configure the following registry entries for each protocol key:

**EnableFileTracing** REG_DWORD *Flag*

You can enable logging tracing information to a file by setting **EnableFileTracing** to 1. The default value is 0.

**FileDirectory** REG_EXPAND_*SZ Path*

You can change the default location of the tracing files by setting **FileDirectory** to the path you want. The file name for the log file is the name of the component for which tracing is enabled. By default, log files are placed in the *SystemRoot*\Tracing folder.

**FileTracingMask** REG_DWORD *LevelOfTracingInformationLogged*

**FileTracingMask** determines how much tracing information is logged to the file. The default value is 0xFFFF0000.

**MaxFileSize** REG_DWORD *SizeOfLogFile*

You can change the size of the log file by setting different values for **MaxFileSize**. The default value is 0x10000 (64K).

**Note**

Tracing consumes system resources and should be used sparingly to help identify network problems. After the trace is captured or the problem is identified, you should immediately disable tracing. Do not leave tracing enabled on multiprocessor computers.

**Note**

Tracing information can be complex and very detailed. Most of the time this information is useful only to Microsoft support professionals or to network administrators who are very experienced with the Routing and Remote Access service. Tracing information can be saved as files and sent to Microsoft support for analysis.

**Oakley Logging**

You can use the Oakley log to view details about the SA establishment process. The Oakley log is enabled in the registry. It is not enabled by default. To enable the Oakley log, set the HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\PolicyAgent\Oakley\EnableLogging registry setting to 1. The Oakley key does not exist by default and must be created.

After it is enabled, the Oakley log, which is stored in the *SystemRoot*\Debug folder, records all IPSec SA negotiations. A new Oakley.log file is created each time the IPSec Policy Agent is started and the previous version of the Oakley.log file is saved as Oakley.log.sav.

To activate the new EnableLogging registry setting after modifying its value, stop and start the IPSec Policy Agent and related IPSec services by running the following sequence of commands:

1. Stop the Routing and Remote Access service using the **net stop remoteaccess** command.
2. Stop the IPSec services using the **net stop policyagent** command.
3. Start the IPSec services using the **net start policyagent** command.
4. Start the Routing and Remote Access service using the **net start remoteaccess** command.

**Network Monitor**

Use Network Monitor, a packet capture and analysis tool supplied with Windows Server 2003, to capture and view the traffic sent between a VPN server and VPN client during the VPN connection process and during data transfer. You cannot interpret the encrypted portions of VPN traffic with Network Monitor. Network Monitor is installed as an optional networking component.

The proper interpretation of the remote access and VPN traffic with Network Monitor requires an in-depth understanding of PPP, PPTP, IPSec, and other protocols. Network Monitor captures can be saved as files and sent to Microsoft support for analysis.

# 802.11 Wireless Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**802.11 Wireless Technical Reference**
The wireless local area network (WLAN) protocol, 802.11, and associated technologies, such as the 802.1X protocol, are Institute of Electrical and Electronic Engineers (IEEE) standards supported by Microsoft to provide secure wireless networking and extend your core network infrastructure.

The IEEE 802.11 wireless standard defines the specifications for the physical layer and the media access control (MAC) sublayer for wireless communications. The 802.1X standard defines port-based, network access control used to provide authenticated network access for Ethernet networks. Although this standard was originally designed for wired Ethernet networks, it has been adapted for use on 802.11 wireless LANs.

**In this subject**

- What Is 802.11 Wireless?
- How 802.11 Wireless Works
- 802.11 Wireless Tools and Settings

# What Is 802.11 Wireless?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is 802.11 Wireless?**
The wireless local area network (WLAN) protocol, IEEE 802.11, and associated technologies, such as the 802.1X protocol and Wi-Fi Protected Access (WPA), allow secure high-speed wireless network access and mobile access to a network infrastructure. Until the recent development and wide adoption of IEEE 802.11b, also known as *Wi-Fi*, in order to obtain high-speed network access to your local area network (LAN) your network client needed to be physically connected to the LAN with some type of wiring.

**Benefits**
Some of the specific benefits of implementing a WLAN are included in the following:

**Wireless connections can extend or replace a wired infrastructure**
In situations where it is costly, inconvenient, or impossible to lay cables, wireless connections can extend or replace a wired infrastructure. This benefit includes the following:

- To connect the networks in two buildings separated by a physical, legal, or financial obstacle, you can either use a link provided by a telecommunications vendor (for a fixed installation cost and ongoing recurring costs) or you can create a point-to-point wireless link using wireless LAN technology (for a fixed installation cost, but no recurring costs). Eliminating recurring telecommunications charges can provide significant cost savings.

- Wireless LAN technologies can be used to create a temporary network, which is in place for only a specific amount of time. For example, the network needed at a convention or trade show can be a wireless network, rather than deploying the physical cabling required for a traditional Ethernet network.

- Some types of buildings, such as historical buildings, might be governed by building codes that prohibit the use of wiring, making wireless networking an important alternative.

- The wiring-free aspect of wireless LAN networking is also very attractive to homeowners who want to connect the various computers in their home together without having to drill holes and pull network cables through walls and ceilings.

**Increased productivity for the mobile employee**
This benefit includes the following:

- The mobile user whose primary computer is a portable computer can change location and always remain connected to the network. This enables the mobile user to travel to various places — meeting rooms, hallways, lobbies, cafeterias, classrooms, and so forth — yet retain access to networked data. Without wireless access, the user has to carry cabling and is restricted to working near a network jack.

- Wireless LAN networking is a perfect technology for environments where movement is required. For example, retail environments can benefit when employees use a wireless portable computer or handheld device to enter inventory information directly into the store database from the sales floor.

- Even if no wireless infrastructure is present, wireless portable computers can still form their own ad hoc networks to communicate and share data with each other.

**Easy access to the Internet in public places**
Beyond the corporate workplace, access to the Internet and even corporate sites can be made available through public wireless "hot spot" networks. For example, many airports, conference centers, and hotels provide wireless access to the Internet for their visitors. When a traveling worker reaches his or her destination, perhaps meeting a client at a corporate office, limited access can be provided to the traveling worker through the local wireless network. The network can recognize the traveling worker from another corporation and create a connection that provides Internet access to the visiting user, but is isolated from the local corporate network.

### Note

- In all these wireless LAN scenarios, it is worth noting that today's standards-based wireless LANs operate at the same speeds that were considered state of the art for wired networks just a few years ago. For example, IEEE 802.11b, a prevalent wireless LAN technology, operates at a maximum of 11 megabits per second (Mbps), or about 30 to 100 times faster than standard dial-up technologies. This data transfer rate is adequate for running a number of applications or services. In addition, ongoing advancements of wireless standards continue to increase the data transfer rate, with speeds of up to 54 Mbps for IEEE 802.11g.

#### Dependencies and Associated Technologies

In a enterprise environment, secure 802.11 wireless technology has specific dependencies and other technologies with which it is typically associated.

#### Dependencies for a secure WLAN

The dependencies of a secure WLAN include the following:

- A standard TCP/IP network environment.
- Active Directory, to store account properties and validate password-based credentials.
- Remote Authentication Dial-In User Service (RADIUS) support, to provide centralized connection authentication, authorization, and accounting.
- A certificate infrastructure, also known as a public key infrastructure (PKI), to issue and validate the certificates required for Extensible Authentication Protocol–Transport Layer Security (EAP-TLS) and Protected EAP (PEAP)–TLS authentication. TLS can use either computer certificates for authenticating the wireless client computer or smart cards or registry-based user certificates for authenticating the user of a wireless client computer.
- For PEAP-Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAP v2) authentication, computer certificates for the RADIUS servers and root CA certificates of the issuing CAs on the wireless clients (if needed).

#### Associated Technologies

The associated technologies of a secure WLAN include the following:

- WPA, as agreed upon by wireless vendors, is an interoperable interim standard until the IEEE 802.11i standard is being ratified. WPA requires secure wireless networking, addresses the issues with WEP through a software upgrade, provides a secure wireless networking solution for small office/home office (SOHO) wireless users, and provides compatibility with the upcoming IEEE 802.11i standard.
- Dynamic Host Configuration Protocol (DHCP) services, to provide automatic Internet Protocol (IP) configuration to wireless clients.
- Domain Name System (DNS) and Windows Internet Name Service (WINS) services, to provide name resolution.

### Note

- For information about IEEE 802.11b wireless networks for the home and small business, see the Microsoft Wi-Fi Web page.

#### 802.11 Wireless Network Infrastructure

The following figure shows a simple example of a WLAN using a wireless access point and some of the Windows Server 2003 technologies on which a secure WLAN is dependent.

### Example Wireless Network Infrastructure

# How 802.11 Wireless Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How 802.11 Wireless Works**
The IEEE 802.11 protocol is a network access technology for providing connectivity between wireless stations and wired networking infrastructures.

By deploying the IEEE 802.11 protocol and associated technologies, you enable the mobile user to travel to various places — meeting rooms, hallways, lobbies, cafeterias, classrooms, and so forth — and still have access to networked data. Also, beyond the corporate workplace, you enable access to the Internet and even corporate sites can be made available through public wireless "hot spot" networks. Airports, restaurants, rail stations, and common areas throughout cities can be configured to provide this service.

This section provides an in-depth view of how IEEE 802.11 works, including the architecture, related protocols, and technologies.

**802.11 Architecture**
The 802.11 logical architecture contains several main components: station (STA), wireless access point (AP), independent basic service set (IBSS), basic service set (BSS), distribution system (DS), and extended service set (ESS). Some of the components of the 802.11 logical architecture map directly to hardware devices, such as STAs and wireless APs. The wireless STA contains an adapter card, PC Card, or an embedded device to provide wireless connectivity. The wireless AP functions as a bridge between the wireless STAs and the existing network backbone for network access.

An IBSS is a wireless network, consisting of at least two STAs, used where no access to a DS is available. An IBSS is also sometimes referred to as an ad hoc wireless network.

A BSS is a wireless network, consisting of a single wireless AP supporting one or multiple wireless clients. A BSS is also sometimes referred to as an infrastructure wireless network. All STAs in a BSS communicate through the AP. The AP provides connectivity to the wired LAN and provides bridging functionality when one STA initiates communication to another STA or a node on the DS.

An ESS is a set of two or more wireless APs connected to the same wired network that defines a single logical network segment bounded by a router (also known as a *subnet*).

The APs of multiple BSSs are interconnected by the DS. This allows for mobility, because STAs can move from one BSS to another BSS. APs can be interconnected with or without wires; however, most of the time they are connected with wires. The DS is the logical component used to interconnect BSSs. The DS provides distribution services to allow for the roaming of STAs between BSSs.

The following figure shows the 802.11 architecture.

**802.11 Architecture**

**802.11 Operating Modes**
IEEE 802.11 defines the following operating modes:

- Infrastructure mode

- Ad hoc mode

In both operating modes, a Service Set Identifier (SSID), also known as the *wireless network name*, identifies the wireless network. The *SSID* is a name configured on the wireless AP (for infrastructure mode) or an initial wireless client (for ad hoc mode) that identifies the wireless network. The SSID is periodically advertised by the wireless AP or the initial wireless client using a special 802.11 MAC management frame known as a *beacon frame*.

**802.11 Infrastructure Mode**

In *infrastructure mode*, there is at least one wireless AP and one wireless client. The wireless client uses the wireless AP to access the resources of a traditional wired network. The wired network can be an organization intranet or the Internet, depending on the placement of the wireless AP. An extended service set (ESS) is shown in the following figure.

**802.11 Infrastructure Mode**

**802.11 Ad Hoc Mode**

In *ad hoc mode*, wireless clients communicate directly with each other without the use of a wireless AP, as shown in the following figure.

**802.11 Wireless Clients in Ad Hoc Mode**

Ad hoc mode is also called *peer-to-peer mode*. Wireless clients in ad hoc mode form an independent basic service set (IBSS). One of the wireless clients, the first wireless client in the IBSS, takes over some of the responsibilities of the wireless AP. These responsibilities include the periodic beaconing process and the authentication of new members. This wireless client does not act as a bridge to relay information between wireless clients. Ad hoc mode is used to connect wireless clients together when there is no wireless AP present. The wireless clients must be explicitly configured to use ad hoc mode. There can be a maximum of nine members in an ad hoc 802.11 wireless network.

**802.11 Protocols and Technologies**

The 802.11-related protocols and technologies are discussed in detail in the following section:

- **802.11.** The IEEE 802.11 wireless standard defines the specifications for the physical layer and the media access control (MAC) layer.

- **802.1X.** The IEEE 802.1X standard defines port-based, network access control used to provide authenticated network access for Ethernet networks.

- **Extensible Authentication Protocol (EAP) over LAN (EAPOL).** EAP is a Point-to-Point Protocol (PPP)-based authentication mechanism that was adapted for use on point-to-point local area network (LAN) segments.

- **Wired Equivalent Privacy (WEP).** WEP provides data confidentiality services by encrypting the data sent between wireless nodes.

- **Wi-Fi Protected Access (WPA).** WPA is an interim standard until the IEEE 802.11i standard is ratified. These standards, intended to be a replacement for the WEP standard, offer more robust methods of data encryption and network authentication.

- **Wireless Auto Configuration.** The Wireless Auto Configuration feature of Windows XP and Windows Server 2003 dynamically selects the wireless network to which a connection is attempted, based either on configured preferences or default settings.

**802.11 Protocol**

The IEEE 802 standards committee defines two separate layers, the Logical Link Control (LLC) and media access control, for the Data-Link layer of the OSI model. The IEEE 802.11 wireless standard defines the specifications for the physical layer and the media access control (MAC) layer that communicates up to the LLC layer, as shown in the following figure.

**802.11 and OSI Model**

All of the components in the 802.11 architecture fall into either the media access control (MAC) sublayer of the data-link layer or the physical layer.

**802.11 MAC Frame**

The 802.11 MAC frame, as shown in the following figure, consists of a MAC header, the frame body, and a frame check sequence (FCS). The numbers in the following figure represent the number of bytes for each field.

**802.11 MAC Frame Format**

**Frame Control Field**

The Frame Control field, shown in the following figure, contains control information used for defining the type of 802.11 MAC frame and providing information necessary for the following fields to understand how to process the MAC frame. The numbers in the following figure represent the number of bits for each field.

**Frame Control Field**

A description of each Frame Control field subfield are as follows:

- **Protocol Version** provides the current version of the 802.11 protocol used. Receiving STAs use this value to determine if the version of the protocol of the received frame is supported.

- **Type and Subtype** determines the function of the frame. There are three different frame type fields: control, data, and management. There are multiple subtype fields for each frame type . Each subtype determines the specific function to perform for its associated frame type.

- **To DS and From DS** indicates whether the frame is going to or exiting from the DS (distributed system), and is only used in data type frames of STAs associated with an AP.

- **More Fragments** indicates whether more fragments of the frame, either data or management type, are to follow.

- **Retry** indicates whether or not the frame, for either data or management frame types, is being retransmitted.

- **Power Management** indicates whether the sending STA is in active mode or power-save mode.

- **More Data** indicates to a STA in power-save mode that the AP has more frames to send. It is also used for APs to indicate that additional broadcast/multicast frames are to follow.

- **WEP** indicates whether or not encryption and authentication are used in the frame. It can be set for all data frames and management frames, which have the subtype set to authentication.

- **Order** indicates that all received data frames must be processed in order.

**Duration/ID Field**
This field is used for all control type frames, except with the subtype of Power Save (PS) Poll, to indicate the remaining duration needed to receive the next frame transmission. When the sub-type is PS Poll, the field contains the association identity (AID) of the transmitting STA.

**Address Fields**
Depending upon the frame type, the four address fields will contain a combination of the following address types:

- **BSS Identifier (BSSID).** BSSID uniquely identifies each BSS. When the frame is from an STA in an infrastructure BSS, the BSSID is the MAC address of the AP. When the frame is from a STA in an IBSS, the BSSID is the randomly generated, locally administered MAC address of the STA that initiated the IBSS.

- **Destination Address (DA).** DA indicates the MAC address of the final destination to receive the frame.

- **Source Address (SA).** SA indicates the MAC address of the original source that initially created and transmitted the frame.

- **Receiver Address (RA).** RA indicates the MAC address of the next immediate STA on the wireless medium to receive the frame.

- **Transmitter Address (TA).** TA indicates the MAC address of the STA that transmitted the frame onto the wireless medium.

For more information about the address types and the contents of the address fields in the 802.11 MAC header, see the IEEE 802.11 standard at the IEEE Web site.

**Sequence Control**
The Sequence Control field contains two subfields, the Fragment Number field and the Sequence Number field, as shown in the following figure.

Sequence Control Field

A description of each Sequence Control field subfield are as follows:

- **Sequence Number** indicates the sequence number of each frame. The sequence number is the same for each frame sent for a fragmented frame; otherwise, the number is incremented by one until reaching 4095, when it then begins at zero again.

- **Fragment Number** indicates the number of each frame sent of a fragmented frame. The initial value is set to 0 and then incremented by one for each subsequent frame sent of the fragmented frame.

**Frame Body**
The frame body contains the data or information included in either management type or data type frames.

**Frame Check Sequence**
The transmitting STA uses a cyclic redundancy check (CRC) over all the fields of the MAC header and the frame body field to generate the FCS value. The receiving STA then uses the same CRC calculation to determine its own value of the FCS field to verify whether or not any errors occurred in the frame during the transmission.

**802.11 PHY Sublayer**
At the physical (PHY) sublayer, IEEE 802.11 defines a series of encoding and transmission schemes for wireless communications, the most common of which are the Frequency Hopping Spread Spectrum (FHSS), Direct Sequence Spread Spectrum (DSSS), and Orthogonal Frequency Division Multiplexing (OFDM) transmission schemes. The following figure shows the 802.11, 802.11b, 802.11a, and 802.11g standards that exist at the PHY sublayer. These standards are described in the sections that follow.

### Standards for 802.11 at the PHY Layer

| | 802.2 Logical Link Control (LLC) | | | |
|---|---|---|---|---|
| MAC | CSMA/CA | | | |
| PHY | **802.11**<br>2 Mbps<br>S-Band ISM<br>FHSS | **802.11b**<br>11 Mbps<br>S-Band ISM<br>DSSS | **802.11a**<br>54 Mbps<br>C-Band ISM<br>OFDM | **802.11g**<br>54 Mbps<br>S-Band ISM<br>OFDM |

**IEEE 802.11**
The bit rate for the original IEEE 802.11 standard is 2 Mbps using the FHSS transmission scheme and the S-Band Industrial, Scientific, and Medical (ISM) frequency band, which operates in the frequency range of 2.4 to 2.5 GHz. However, under less-than-ideal conditions, a lower bit rate speed of 1 Mbps is used.

**802.11b**
The major enhancement to IEEE 802.11 by IEEE 802.11b is the standardization of the physical layer to support higher bit rates. IEEE 802.11b supports two additional speeds, 5.5 Mbps and 11 Mbps, using the S-Band ISM. The DSSS transmission scheme is used in order to provide the higher bit rates. The bit rate of 11 Mbps is achievable in ideal conditions. In less-than-ideal conditions, the slower speeds of 5.5 Mbps, 2 Mbps, and 1 Mbps are used.

### Note

- 802.11b uses the same frequency band as that used by microwave ovens, cordless phones, baby monitors, wireless video cameras, and Bluetooth devices.

**802.11a**
IEEE 802.11a (the first standard to be ratified, but just now being widely sold and deployed) operates at a bit rate as high as 54 Mbps and uses the C-Band ISM, which operates in the frequency range of 5.725 to 5.875 GHz. Instead of DSSS, 802.11a uses OFDM, which allows data to be transmitted by subfrequencies in parallel and provides greater resistance to interference and greater throughput. This higher-speed technology enables wireless LAN networking to perform better for video and conferencing applications.

Because they are not on the same frequencies as other S-Band devices (such as cordless phones), OFDM and IEEE 802.11a provide both a higher data rate and a cleaner signal. The bit rate of 54 Mbps is achievable in ideal conditions. In less-than-ideal conditions, the slower speeds of 48 Mbps, 36 Mbps, 24 Mbps, 18 Mbps, 12 Mbps, and 6 Mbps are used.

**802.11g**
IEEE 802.11g operates at a bit rate as high as 54 Mbps, but uses the S-Band ISM and OFDM. 802.11g is also backward-compatible with 802.11b and can operate at the 802.11b bit rates and use DSSS. 802.11g wireless network adapters can connect to an 802.11b wireless AP, and 802.11b wireless network adapters can connect to an 802.11g wireless AP. Thus, 802.11g provides a migration path for 802.11b networks to a frequency-compatible standard technology with a higher bit rate. Existing 802.11b wireless network adapters cannot be upgraded to 802.11g by updating the firmware of the adapter — they must be replaced. Unlike migrating from 802.11b to 802.11a (in which all the network adapters in both the wireless clients and the wireless APs must be replaced at the same time), migrating from 802.11b to 802.11g can be done incrementally.

Like 802.11a, 802.11g uses 54 Mbps in ideal conditions and the slower speeds of 48 Mbps, 36 Mbps, 24 Mbps, 18 Mbps, 12 Mbps, and 6 Mbps in less-than-ideal conditions.

**802.1X Protocol**
The IEEE 802.1X standard defines port-based, network access control used to provide authenticated network access for Ethernet networks. This port-based network access control uses the physical characteristics of the switched LAN infrastructure to authenticate devices attached to a LAN port. Access to the port can be denied if the authentication process fails. Although this standard was designed for wired Ethernet networks, it has been adapted to 802.11 wireless LANs.

**Components of 802.1X**

IEEE 802.1X defines the following terms, as described in the following sections:

- **Port access entity.** A LAN port, also known as *port access entity (PAE)*, is the logical entity that supports the IEEE 802.1X protocol that is associated with a port. A PAE can adopt the role of the authenticator, the supplicant, or both.

- **Authenticator.** An *authenticator* is a LAN port that enforces authentication before allowing access to services accessible using that port. For wireless connections, the authenticator is the logical LAN port on a wireless AP through which wireless clients in infrastructure mode gain access to other wireless clients and the wired network.

- **Supplicant.** The *supplicant* is a LAN port that requests access to services accessible on the authenticator. For wireless connections, the supplicant is the logical LAN port on a wireless LAN network adapter that requests access to the other wireless clients and the wired network by associating with and then authenticating itself to an authenticator.

  Whether for wireless connections or wired Ethernet connections, the supplicant and authenticator are connected by a logical or physical point-to-point LAN segment.

- **Authentication server.** To verify the credentials of the supplicant, the authenticator uses an *authentication server*, which checks the credentials of the supplicant on behalf of the authenticator and then responds to the authenticator, indicating whether or not the supplicant is authorized to access the authenticator's services.

The following figure shows these components for a wireless LAN network.

**Components of IEEE 802.1X Authentication**

The authentication server can be the following:

- **A component of the access point.** In this case, the AP must be configured with the sets of user credentials corresponding to the supplicants that will be attempting to connect (it is typically not implemented for wireless APs).

- **A separate entity.** In this case, the AP forwards the credentials of the connection attempt to a separate authentication server. Typically, a wireless AP uses the Remote Authentication Dial-In User Service (RADIUS) protocol to send a connection request message to a RADIUS server.

#### Controlled and Uncontrolled Ports

The authenticator's port-based access control defines the following different types of logical ports that access the wired LAN by means of a single physical LAN port:

- **Uncontrolled Port.** The uncontrolled portallows an uncontrolled exchange between the authenticator (the wireless AP) and other networking devices on the wired network — regardless of any wireless client's authorization state. Frames sent by the wireless client are never sent using the uncontrolled port.

- **Controlled Port.** The controlled portallows data to be sent between a wireless client and the wired network only if the wireless client is authorized by 802.1X. Before authentication, the switch is open and no frames are forwarded between the wireless client and the wired network. When the wireless client is successfully authenticated using IEEE 802.1X, the switch is closed, and frames can be sent between the wireless client and nodes on the wired network.

The different types of ports are shown in the following figure.

**Controlled and Uncontrolled Ports for IEEE 802.1X**

On an authenticating Ethernet switch, the wired Ethernet client can send Ethernet frames to the wired network as soon as authentication is complete. The switch identifies the traffic of a specific wired Ethernet client using the physical port to which the Ethernet client is connected. Typically, only a single Ethernet client is connected to a physical port on the Ethernet switch.

Because multiple wireless clients contend for access to the same frequency channel and send data using the same channel, an extension to the basic IEEE 802.1X protocol is required to allow a wireless AP to identify the secured traffic of a particular wireless client. The wireless client and wireless AP do this through the mutual determination of a per-client unicast session key. Only authenticated wireless clients have knowledge of their per-client unicast session key. Without a valid unicast session key tied to a successful authentication, a wireless AP discards the traffic sent from the wireless client.

**EAP over LAN**

To provide a standard authentication mechanism for IEEE 802.1X, the Extensible Authentication Protocol (EAP) was chosen. EAP is a Point-to-Point Protocol (PPP)-based authentication mechanism that was adapted for use on point-to-point LAN segments. EAP messages are normally sent as the payload of PPP frames. To adapt EAP messages to be sent over Ethernet or wireless LAN segments, the IEEE 802.1X standard defines EAP over LAN (EAPOL), a standard encapsulation method for EAP messages.

**WEP**

WEP provides data confidentiality services by encrypting the data sent between wireless nodes. Setting a WEP flag in the MAC header of the 802.11 frame indicates that the frame is encrypted with WEP encryption. WEP provides data integrity by including an integrity check value (ICV) in the encrypted portion of the wireless frame.

WEP defines two shared keys:

- **Multicast/global key.** The *multicast/global key* is an encryption key that protects multicast and broadcast traffic from a wireless AP to all of its connected wireless clients.

- **Unicast session key.** The *unicast session key* is an encryption key that protects unicast traffic between a wireless client and a wireless AP and multicast and broadcast traffic sent by the wireless client to the wireless AP.

WEP encryption uses the RC4 symmetric stream cipher with 40-bit and 104-bit encryption keys. Although 104-bit encryption keys are not specified in the 802.11 standard, many wireless AP vendors support them.

**Note**

- Some implementations that advertise the use of 128-bit WEP encryption keys are just adding a 104-bit encryption key to the 24-bit initialization vector (IV) and calling it a 128-bit key. The IV is a field in the header of each 802.11 frame that is used during the encryption and decryption process.

**WEP Encryption**

The WEP encryption process is shown in the following figure.

**WEP Encryption Process**

To encrypt the payload of an 802.11 frame, the following process is used:

1. A 32-bit integrity check value (ICV) is calculated for the frame data.

2. The ICV is appended to the end of the frame data.

3. A 24-bit initialization vector (IV) is generated and appended to the WEP encryption key.

4. The combination of initialization vector and WEP encryption key is used as the input of a pseudo-random number generator (PRNG) to generate a bit sequence that is the same size as the combination of data and ICV.

5. The PRNG bit sequence, also known as the *key stream*, is bit-wise exclusive ORed (XORed) with the combination of data and ICV to produce the encrypted portion of the payload that is sent between the wireless access point (AP) and the wireless client.

6. To create the payload for the wireless MAC frame, the IV is added to the front of the encrypted combination of the data and ICV, along with other fields.

**WEP Decryption**

The WEP decryption process is shown in the following figure.

**WEP Decryption Process**

To decrypt the 802.11 frame data, the following process is used:

1. The initialization vector (IV) is obtained from the front of the MAC payload.

2. The IV is appended to the WEP encryption key.

3. The combination of initialization vector and WEP encryption key is used as the input of the same PRNG to generate a bit sequence of the same size as the combination of the data and the ICV. This process produces the same key stream as that of the sending wireless node.

4. The PRNG bit sequence is XORed with the encrypted combination of the data and ICV] to decrypt the combined data and ICV portion of the payload.

5. The ICV calculation for the data portion of the payload is run, and its result is compared with the value included in the incoming frame. If the values match, the data is considered to be valid (sent from the wireless client and unmodified in transit). If they do not match, the frame is silently discarded.

**Security Issues with WEP and IEEE 802.11**

The main problem with WEP is that the determination and distribution of WEP encryption keys are not defined. WEP keys must be distributed by using a secure channel outside of the 802.11 protocol. In practice, WEP keys are text strings that must be manually configured using a keyboard for both the wireless AP and wireless clients. However, this key distribution system does not scale well to an enterprise organization and is not secure.

Additionally, there is no defined mechanism for changing the WEP encryption keys either per authentication or periodically for an authenticated connection. All wireless APs and clients use the same manually configured WEP key for multiple sessions. With multiple wireless clients sending a large amount of data, an attacker can remotely capture large amounts of WEP ciphertext and use cryptanalysis methods to determine the WEP key.

The lack of a WEP key management protocol is a principal limitation to providing 802.11 security, especially in infrastructure mode with a large number of stations. Some examples of this type of network include corporate and educational institutional campuses and public places such as airports and malls. The lack of automated authentication and key determination services also affects operation in ad hoc mode, in which users might want to use in peer-to-peer collaborative communication in areas such as conference rooms.

**WPA**

Although 802.1X addresses many of the security issues of the original 802.11 standard, issues still exist with regard to weaknesses in the WEP encryption and data integrity methods. The long-term solution to these problems is the IEEE 802.11i standard, which is currently in draft form.

Until the IEEE 802.11i standard is ratified, wireless vendors have agreed on an interoperable interim standard known as Wi-Fi Protected Access (WPA). The goals of WPA are the following:

- **To require secure wireless networking.** WPA requires secure wireless networking by requiring 802.1X authentication, encryption, and unicast and multicast/global encryption key management.

- **To address WEP issues with a software upgrade.** The implementation of the RC4 stream cipher within WEP is vulnerable to known plaintext attacks. Additionally, the data integrity provided with WEP is relatively weak. WPA solves all the remaining security issues with WEP, yet only requires firmware updates in wireless equipment and an update for wireless clients. Existing wireless equipment is not expected to require replacement.

- **To provide a secure wireless networking solution for small office/home office (SOHO) wireless users.** For the SOHO, there is no RADIUS server to provide 802.1X authentication with an EAP type. SOHO wireless clients must use either shared key authentication (highly discouraged) or open system authentication (recommended) with a single static WEP key for both unicast and multicast traffic. WPA provides a pre-shared key option intended for SOHO configurations. The pre-shared key is configured on the wireless AP and each wireless client. The initial unicast encryption key is derived from the authentication process, which verifies that both the wireless client and the wireless AP have the pre-shared key.

- **To be compatible with the upcoming IEEE 802.11i standard.** WPA is a subset of the security features in the proposed IEEE 802.11i standard. All the features of WPA are described in the current draft of the 802.11i standard.

- **To be available today.** WPA upgrades to wireless equipment and for wireless clients were available beginning in February 2003.

**WPA Security Features**

WPA contains enhancements or replacements for the following security features:

- Authentication

- Encryption

- Data integrity

**Authentication**

With 802.11, 802.1X authentication is optional; with WPA, 802.1X authentication is required. Authentication with WPA is a combination of open system and 802.1X authentication, which uses the following phases:

- The first phase uses open system authentication to indicate to the wireless client that it can send frames to the wireless AP.

- The second phase uses 802.1X to perform a user-level authentication. For environments without a RADIUS infrastructure, WPA supports the use of a pre-shared key; for environments with a RADIUS infrastructure, WPA supports EAP and RADIUS.

**Encryption**

With 802.1X, rekeying of unicast encryption keys is optional. Additionally, 802.11 and 802.1X provide no mechanism to change the global encryption key that is used for multicast and broadcast traffic. With WPA, rekeying of both unicast and global encryption keys is required. The Temporal Key Integrity Protocol (TKIP) changes the unicast encryption key for every frame, and

each change is synchronized between the wireless client and the wireless AP. For the multicast/global encryption key, WPA includes a facility for the wireless AP to advertise changes to the connected wireless clients.

**TKIP**
For 802.11, WEP encryption is optional. For WPA, encryption using TKIP is required. TKIP replaces WEP with a new encryption algorithm that is stronger than the WEP algorithm, yet can be performed using the calculation facilities present on existing wireless hardware. TKIP also provides for the following:

- The verification of the security configuration after the encryption keys are determined.
- The synchronized changing of the unicast encryption key for each frame.
- The determination of a unique starting unicast encryption key for each pre-shared key authentication.

**AES**
WPA defines the use of the Advanced Encryption Standard (AES) as an optional replacement for WEP encryption. Because adding AES support by using a firmware update might not be possible for existing wireless equipment, support for AES on wireless network adapters and wireless APs is not required.

**Data Integrity**
With 802.11 and WEP, data integrity is provided by a 32-bit ICV that is appended to the 802.11 payload and encrypted with WEP. Although the ICV is encrypted, it is possible through cryptanalysis to change bits in the encrypted payload and update the encrypted ICV without being detected by the receiver.

With WPA, a method known as *Michael* specifies a new algorithm that calculates an 8-byte message integrity code (MIC) with the calculation facilities available on existing wireless hardware. The MIC is placed between the data portion of the 802.11 frame and the 4-byte ICV. The MIC field is encrypted along with the frame data and the ICV.

Michael also provides replay protection through the use of a frame counter field in the 802.11 MAC header.

### Note

- WPA requires software changes to the following:
- Wireless APs
- Wireless network adapters
- Wireless client software

**Wireless Auto Configuration**
Wireless Auto Configuration dynamically selects the wireless network to which a connection is attempted, based either on configured preferences or default settings. This process includes automatically selecting and connecting to a more preferred wireless network when it becomes available. If none of the preferred wireless networks is found nearby, Wireless Auto Configuration configures the wireless adapter so that there is no accidental connection until the wireless client roams within the range of a preferred network.

Wireless Auto Configuration corresponds to the Wireless Configuration service in Windows Server 2003 and the Wireless Zero Configuration service in Windows XP. You can use the Services snap-in (available in the Administrative Tools folder) to view the current status of (as well as stop, start, and restart) either service. You can also manage either service from the command prompt by using the **net** command. For example, to stop either service, type **net stop wzcsv** at a command prompt.

Wireless Auto Configuration minimizes the configuration that is required to access wireless networks and allows you to travel to different wireless networks without reconfiguring the network connection settings on your computer for each location. For the initial scan of available wireless networks, Wireless Auto Configuration performs the following process:

1. Wireless Auto Configuration attempts to connect to the preferred networks that appear in the list of available networks in the preferred networks preference order.
2. If there are no successful connections, Wireless Auto Configuration attempts to connect to the preferred networks that do not appear in the list of available networks in the preferred networks preference order. Thus, it can connect even when the wireless APs are configured to suppress the beaconing of the SSID of the wireless network.

3. If there are no successful connections and there is an ad hoc network in the list of preferred networks that is available, Wireless Auto Configuration tries to connect to it.

4. If there are no successful connections, and there is an ad hoc network in the list of preferred networks that is not available, Wireless Auto Configuration configures the wireless network adapter to act as the first node in the ad hoc network.

5. If there are no successful connections to preferred networks, and there are no ad hoc networks in the list of preferred networks, Wireless Auto Configuration determines the **Automatically Connect To Non-Preferred Networks** setting (located on the **Wireless Networks** tab of the wireless network connection).

6. If the **Automatically Connect To Non-Preferred Networks** setting is disabled, Wireless Auto Configuration creates a random network name and places the wireless network adapter in infrastructure mode.

   This behavior prevents the Windows XP wireless client from accidentally connecting to a wireless network that does not appear in the list of preferred networks. You then see the **One Or More Wireless Networks Are Available** message in the notification area. The wireless adapter is not connected to any wireless network, but continues to scan for preferred wireless networks every 60 seconds.

7. If the **Automatically Connect To Non-Preferred Networks** setting is enabled, Wireless Auto Configuration attempts to connect to the available networks in the order in which the wireless adapter sensed them.

   If all connection attempts fail, Wireless Auto Configuration creates a random network name and places the wireless network adapter in infrastructure mode. You then see the **One Or More Wireless Networks Are Available** message in the notification area.

For subsequent scans, Wireless Auto Configuration determines whether there are any changes in the wireless environment that require switching the connection. If the Windows wireless client is already connected to a wireless network and there is no other preferred network higher in the preference list that has not been attempted already, Wireless Auto Configuration maintains the existing connection. If the Windows wireless client is already connected to a wireless network, but a more preferred wireless network becomes available, Wireless Auto Configuration disconnects from the currently connected wireless network and attempts to connect to the more preferred wireless network.

The operation of Wireless Auto Configuration provides the following:

- The first time a wireless adapter is added to a computer running Windows XP or Windows Server 2003 and a wireless network is available, Wireless Auto Configuration prompts you with the **One Or More Wireless Networks Are Available** message in the notification area, which leads you to select a wireless network in the **Connect To Wireless Network** dialog box.

  After you select a wireless network and the connection is successful, the selected network is automatically added as a preferred network, and you are no longer prompted whenever you are within range of it. For an organization, this is the typical process for configuring the initial connection to a private wireless network. After the initial configuration, Wireless Auto Configuration connects (and then maintains the connection) to the organization's wireless network.

  When you take your portable computer to your home wireless network, to an airport, or to another location with public wireless access, Wireless Auto Configuration first attempts to connect to your preferred network. When that connection attempt fails, you are prompted again to connect to your home wireless network or to the public access wireless network.

- If there are two preferred wireless networks, and the most preferred one is not initially available, Wireless Auto Configuration configures a wireless connection to the next most preferred network. When the most preferred network eventually becomes available, Wireless Auto Configuration automatically switches the wireless client connection to it after the next scan.

- If there are no preferred networks in the list of those available, Wireless Auto Configuration attempts to configure connections to the preferred networks in their configured order, in case the wireless APs for the wireless network are configured to prohibit the beaconing of their SSID.

**Related Information**

For more information about 802.11 and related technologies, see the Microsoft Wi-Fi Web site.

# 802.11 Wireless Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**802.11 Wireless Tools and Settings**

**In this section**

- Windows Wireless Client
- Wireless AP
- 802.11 Wireless Authentication Infrastructure
- 802.11 Wireless Registry Entries

This section contains information about the tools and settings available for configuring, managing, and customizing wireless clients, and for troubleshooting wireless connectivity.

**Windows Wireless Client**

The following services and features are associated with Windows wireless clients and wireless client connections.

**Network Connections Folder**

The Network Connections folder and the messages displayed in the notification area of the task bar provide information about the state of the wireless network availability as well as client authentication and connection status. If authentication of a client requires additional information from the user, such as selecting one of multiple user certificates, a text balloon appears to instruct the user. Within the Network Connections folder, the text under the name of the connection corresponding to the wireless network adapter describes the state of the authentication.

For wireless clients running Windows XP, when you click the wireless connection, the Details dialog box displays the authentication status, the Internet Protocol (IP) address configuration, and information about the connected wireless network and the current association. When you obtain status on the connection, you can view information such as the signal speed on the **General** tab and the IP address configuration on the **Support** tab.

If the wireless adapter is assigned an Automatic Private IP Addressing (APIPA) address in the range 169.254.0.0/16 or the configured alternate static IP address, the wireless client is still associated with the wireless AP, but either authentication has failed or the Dynamic Host Configuration Protocol (DHCP) server is not available. If the authentication fails and the association is still in place, the wireless adapter is enabled and Transmission Control Protocol/Internet Protocol (TCP/IP) performs its normal configuration process. If a DHCP server is not found (either authenticated or not), Windows XP automatically configures an APIPA or alternate static address.

For a wireless client running Windows 2000, you can use the **Network and Dial-up Connections** folder to view whether the connection corresponding to your wireless network adapter is authenticated. If authentication is successful, the connection icon appears normal. If authentication has failed, the connection icon has a red X through it. To view the IP address configuration of the connection corresponding to the wireless network adapter, type **ipconfig** at a command prompt.

**Netsh**

Windows XP, Windows Server 2003, and Windows 2000 have an extensive tracing capability that you can use to troubleshoot complex problems for specific components related to wireless client authentication. You can enable the components in Windows to log tracing information to files using the **netsh** command for specific components or for all components. For more detailed information, see “Netsh,” in the section “802.11 Wireless Authentication Infrastructure” later in this document.

**Network Monitor**

You can use Microsoft Network Monitor, available in Microsoft Systems Management Server, Windows 2000 Server, and Windows Server 2003, or a commercial packet analyzer (also known as a network sniffer), to capture and view the authentication and data traffic sent and received by a wireless network adapter.

For Windows wireless client authentication, you can use Network Monitor to capture the set of frames exchanged between the wireless client computer and the wireless AP during the wireless authentication process. You can then use Network Monitor to view the individual frames and determine why the authentication failed.

Network Monitor includes 802.1X, EAPOL, and EAP parsers. A *parser* is a component included with Network Monitor that can separate the fields of a protocol header and display their structure and values. Without a parser, Network Monitor displays the hexadecimal bytes of a header, which you must parse manually.

In Windows 2000 Server and Windows Server 2003, Network Monitor is installed as an optional management and monitoring tool using Control Panel's Add or Remove Programs. After it is installed, you can run Network Monitor from the Administrative Tools folder.

**Wireless Monitor snap-in**
In Windows Server 2003, you can use the new Wireless Monitor snap-in to view wireless AP or wireless client information. There are two main views of information in the Wireless Monitor snap-in:

- Access Point Information
- Wireless Client Information

When you click Access Point Information in the console tree, the wireless network adapter scans for the available wireless APs within range and then displays them in the details pane.

You can use the list of wireless APs to determine the visibility and parameters (such as signal strength, channel, and data rates) of specific wireless APs for a specific location.

When you click Wireless Client Information in the console tree, the list of wireless events for the Wireless Zero Configuration service and the EAPOL component displays in the details pane.

You can use these events to determine how the Wireless Zero Configuration service chooses to connect to a specific wireless AP and explore the details of the authentication process.

**Wireless AP**
The following services and features are associated with wireless access points (APs). Consult your wireless AP documentation for information about the set of troubleshooting tools provided with your wireless AP.

**Panel Indicators**
Most wireless APs have one or more indicators, status lights that are visible on the housing of the wireless AP, from which you can obtain a quick assessment of the wireless AP's hardware status. For example, you might see the following:

- An indicator to show that the wireless AP has electrical power.
- An indicator to show general operation status. For example, the indicator might show whether the wireless AP is associated with any wireless clients.
- An indicator to show wireless network traffic. This indicator might blink for each frame received on the wireless network.
- An indicator to show data collisions. If the blinking of this indicator seems excessive, evaluate the performance of the link by using methods suggested by the wireless AP vendor.
- An indicator to show wired network traffic. This indicator might blink for each frame received on the wired network.

Alternatively, the wireless AP might have a liquid crystal display (LCD) panel display that shows icons indicating its current status. Consult your wireless AP documentation for information about panel indicators and their interpretation.

**Site Survey Software**
Site survey software is used to determine the coverage volume and where the data rate changes for each wireless AP. An administrator can use site survey software during the deployment of wireless APs to determine their optimal placement. It is typically installed on a wireless-capable portable computer from a CD provided by the wireless AP vendor or the wireless network adapter vendor.

If wireless clients cannot connect to a specific wireless AP, use the site survey software to perform a site survey for that wireless AP. There might have been a change in the devices that create interference and objects that interfere with signal propagation because the original site survey and wireless AP placement was done.

**SNMP support**
Many wireless APs include a Simple Network Management Protocol (SNMP) agent that supports the following SNMP

Management Information Bases (MIBs):

- IEEE 802.11 MIB
- IEEE 802.1 Port Access Entity (PAE ) MIB
- SNMP MIB (described in RFC 1157)
- SNMP MIB II (described in RFC 1213)
- Ethernet Interface MIB (described in RFC 1398)
- SNMP Bridge MIB (described in RFC 1493)
- Remote Network Monitoring MIB (described in RFC 1757)
- RADIUS Authentication Client MIB (described in RFC 2618)

The SNMP agent on the wireless AP can be used in conjunction with your existing SNMP-based network management infrastructure to monitor your wireless APs, set trap conditions, and monitor loads on your wireless APs. In SNMP, trap conditions specify which events will trigger a message to be sent by the SNMP agent to a management system, indicating that the event has occurred on the host running the agent.

**Diagnostics**
The purpose of the diagnostics is to ensure that the wireless AP is operating properly (from a hardware standpoint) and to validate its current configuration. However, the exact diagnostic facilities of a wireless AP vary from one wireless AP to another.

Diagnostics for wireless APs can be of the following forms:

- Software or a Web site provided by the wireless AP vendor.
- A command-line tool or facility, such as terminal access to the wireless AP.

**802.11 Wireless Authentication Infrastructure**
Wireless 802.11 clients and APs can use Internet Authentication Service (IAS) — the Microsoft implementation of RADIUS — to enforce authentication in an enterprise environment. The following services and features are associated with authentication infrastructure of Wireless 802.11.

**IAS Event Logging**
To troubleshoot IAS authentication attempts, view events in the Windows event logs. Ensure that event logging is enabled for all types of IAS events (such as rejected, discarded, and successful authentication events). Event logging for all these types of events are enabled by default for both Windows Server 2003 IAS and Windows 2000 IAS.

IAS events are stored in the system event log, which can be viewed in the Event Viewer snap-in. Here is an example of a successful IAS authentication event (Event ID 1).

```
User client@example.com was granted access.
Fully-Qualified-User-Name =example.com/Users/Client
NAS-IP-Address =10.7.0.4
NAS-Identifier =<not present>
Client-Friendly-Name =Building 7 Wireless AP
Client-IP-Address =10.7.0.4
NAS-Port-Type =Wireless-IEEE 802.11
NAS-Port =6
Policy-Name =Wireless Remote Access Policy
Authentication-Type =EAP
EAP-Type =Smart Card or other Certificate
```

To view s failed IAS authentication event, view all events that have Event ID 2.

Viewing the IAS events in the system event log is one of the most useful troubleshooting tools for obtaining information about failed authentications. The IAS events are also helpful when troubleshooting remote access policies. When you have multiple

remote access policies configured, the Policy-Name field in the event description records the name of the remote access policy that either accepted or rejected the connection attempt.

**Network Monitor**
Network Monitor is useful for checking whether RADIUS messages are being exchanged, and for determining the RADIUS attributes of each message.

You can use Microsoft Network Monitor—available in Microsoft Systems Management Server, Windows 2000 Server, and Windows Server 2003 — or a commercial packet analyzer (also known as a *network sniffer*) to capture and view RADIUS authentication and accounting messages that are sent to and from the IAS RADIUS server or an IAS RADIUS proxy. Network Monitor includes a RADIUS parser that you can use to view the attributes of a RADIUS message and trouble-shoot connection issues.

**SChannel Logging**
Secure channel (SChannel) is a Security Support Provider (SSP) that implements the Secure Sockets Layer (SSL) and Transport Layer Security (TLS) authentication protocols. SSL and TLS are the Internet standard for secure transactions.

By default, SChannel logs only error messages in the system event log. To log errors, warnings, informational, and successful events, set the HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\SecurityProviders\SCHANNEL\EventLogging registry value to 4 (as a DWORD type). With SChannel logging recording all events, it is possible to obtain more information about the certificate exchange and validation process on the IAS server during EAP-TLS authentication.

**Netsh**
Windows Server 2003 and Windows 2000 have an extensive tracing capability that creates tracing files that describe the internal behavior of Windows components during the wireless client authentication and authorization process. This information is typically most useful to Microsoft support engineers, who might request that you create trace files for a connection attempt during their investigation of a support issue. You can enable the components in Windows Server 2003 to log tracing information to files by using the **netsh** command for specific components or for all components. To enable and disable tracing for a specific component, use the following command:

```
netsh ras set tracing
component
 enabled|disabled
```

In the preceding command, *component* is any of the items in the list of components found in the registry under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tracing. For example, to enable tracing for the IASRAD component, use the following command:

```
netsh ras set tracing iasrad enabled
```

To obtain detailed information about the EAP authentication process for Windows XP or Windows Server 2003, enable tracing for only the EAP over LAN (EAPOL) and Remote Access Service Transport Level Security (RASTLS) components. To enable tracing for EAPOL, use the following command:

```
netsh ras set tracing eapol enabled
```

To enable tracing for RASTLS, use the following command:

```
netsh ras set tracing rastls enabled
```

After these commands are issued, try the authentication process again and view the Eapol.log and Rastls.log files in the *SystemRoot*\Tracing folder. To disable tracing for EAPOL and RASTLS, use the following respective commands:

```
netsh ras set tracing eapol disabled
netsh ras set tracing rastls disabled
```

To obtain detailed information about the EAP authentication process for Windows 2000, enable tracing for the RASTLS component.

Although you can enable tracing for individual components of IAS, it is generally easier to turn tracing on for all the IAS

components at once; and Microsoft support engineers typically want to see all the trace files, rather than the trace file for an individual component. To enable tracing for all components, use the following command:

```
netsh ras set tracing * enabled
```

To disable tracing for all components, use the following command:

```
netsh ras set tracing * disabled
```

The log files that are generated are stored in the *SystemRoot*\tracing folder.

**Note**

- Tracing consumes system resources and should be used sparingly during the investigation of a support issue. After the trace is done or the problem is identified, you should disable tracing. Do not leave tracing enabled on multiprocessor computers.

**SNMP Agent**

You can use the Simple Network Management Protocol (SNMP) agent software included with Windows 2000 Server and Windows Server 2003 to monitor status information for your IAS server from an SNMP snap-in. IAS supports the RADIUS Authentication Server MIB (RFC 2619) and the RADIUS Accounting Server MIB (RFC 2621). Use **AddRemove Programs** in Control Panel to install the SNMP agent. The SNMP agent can be used in conjunction with your existing SNMP-based network management infrastructure to monitor your IAS RADIUS servers or proxies.

**Performance Logs And Alerts Snap-in**

You can use the Performance Logs And Alerts snap-in to monitor counters, create logs, and set alerts for specific IAS components and program processes. You can also use charts and reports to determine how efficiently your server uses IAS and to both identify and troubleshoot potential problems.

You can use the Performance Logs And Alerts snap-in to monitor counters within the following IAS-related performance objects:

- IAS Accounting Clients
- IAS Accounting Proxy
- IAS Accounting Server
- IAS Authentication Clients
- IAS Authentication Proxy
- IAS Authentication Server
- IAS Remote Accounting Servers
- IAS Remote Authentication Servers

For more information about how to use the Performance Logs And Alerts snap-in, see Help and Support Center for Windows Server 2003.

**802.11 Wireless Registry Entries**

Controlling the computer and user authentication behavior of Windows XP and Windows Server 2003 can be configured by using either the AuthMode registry setting or in a Windows Server 2003 Active Directory environment by using the Wireless Network (IEEE 802.11) Policies Group Policy extension. Controlling the transmission behavior of the EAPOL-Start message when authenticating can be configured by using either the SupplicantMode registry setting or the Wireless Network (IEEE 802.11) Policies Group Policy extension.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**AuthMode Registry Entry**
The setting of the AuthMode registry entry controls the computer and user authentication behavior of Windows XP and Windows Server 2003.

**Registry path**
HKEY_LOCAL_MACHINE\Software\Microsoft\EAPOL\Parameters\General\Global\AuthMode

**Version**
Windows XP and Windows Server 2003

AuthMode has the following values:

- **0 - Computer authentication mode.** If computer authentication is successful, no user authentication is attempted. If the user logon is successful before computer authentication, user authentication is performed. This is the default setting for Windows XP (prior to Service Pack 1).

- **1 - Computer authentication with re-authentication.** If computer authentication is successful, a subsequent user logon results in a re-authentication with user credentials. The user logon has to complete in 60 seconds or the existing network connectivity is terminated. The user credentials are used for subsequent authentication or re-authentication. Computer authentication is not attempted again until the user logs off the computer. This is the default setting for Windows XP Service Pack 1 (SP1) and Windows Server 2003.

- **2 - Computer authentication only.** When a user logs on, it has no effect on the connection. Only computer authentication is performed. The exception to this behavior is when a user successfully logs on, and then roams between wireless APs. In that case, user authentication is performed. For changes to this setting to take effect, restart the Wireless Zero Configuration service for Windows XP or Windows Server 2003.

**SupplicantMode Registry Entry**
The setting of the SupplicantMode registry entry specifies the transmission behavior of the EAPOL-Start message when authenticating.

**Registry path**
HKEY_LOCAL_MACHINE\Software\Microsoft\EAPOL\Parameters\General\Global\SupplicantMode

**Version**
Windows XP and Windows Server 2003

SupplicantMode has the following values:

- **1 - Do not transmit.** Specifies that EAPOL-Start messages are not sent.

- **2 - Transmit.** Determines when to send EAPOL-Start messages and, if needed, sends an EAPOL-Start message.

- **3 - Transmit per 802.1x.** Sends an EAPOL-Start message upon association to initiate the 802.1X authentication process.

**Wireless 802.11 Group Policy Settings**
To automate the configuration of network settings on wireless clients running Windows XP SP1 and Windows Server 2003, Windows Server 2003 Active Directory domains support a new Wireless Network (IEEE 802.11) Policies Group Policy extension that allows you to configure wireless network settings that are part of Computer Configuration Group Policy. The Wireless Network (IEEE 802.11) Policies Group Policy extension is found in the Group Policy Object Editor by navigating to Default Domain Policy/Computer Confiuration/Windows Settings/Security Settings/Wireless.

Wireless network settings include the list of preferred networks, WEP settings, and IEEE 802.1X settings. These settings encompass all of the items on the Association and Authentication tabs of the properties of a wireless network and additional settings. The Association and Authentication tabs on Windows XP or Windows Server 2003 computers can be found by

opening **Network Connections**, right-clicking on the wireless connection icon and clicking **Properties**, then on the Wireless Network tab, click **Properties**. The settings are downloaded to wireless client computers running Windows XP SP1 or Windows Server 2003 that are members of a Windows Server 2003 Active Directory domain, making it much easier to deploy a specific configuration for secure wireless connections.

**Wireless Network (IEEE 802.11) Policy Settings**

In the Group Policy snap-in, you can configure wireless policies by using the Computer Configuration/Windows Settings/Security Settings/Wireless Network (IEEE 802.11) Policies node.

**Note**

- These policy settings do not apply to wireless clients running Windows XP (prior to SP1) or Microsoft 802.1X Authentication Client.

By default, there are no Group Policy objects (GPOs) in the Wireless Network (IEEE 802.11) Policies node. You can create only a single wireless network policy for each Group Policy object.

The properties of a wireless network policy consist of a General tab and a Preferred Networks tab.

On the General tab, you can view the options as described in the following table.

**General Settings of a Wireless Network Policy**

| Setting | Description |
|---|---|
| **Name** | This option allows you to type a friendly name for the wireless network policy. |
| **Description** | This option allows you to type a description for the wireless network policy. |
| **Check For Policy Changes Every** | This option allows you to specify the interval in minutes after which wireless clients that are Active Directory members check for changes in the wireless network policy. |
| **Networks To Access** | This option selects the types of wireless networks with which the wireless network is allowed to create connections:<br>• Any Available Network (Access Point Preferred)<br>• Access Point (Infrastructure) Networks Only<br>• Computer-To-Computer (Ad Hoc) Networks Only |
| **Use Windows To Configure Wireless Network Settings for Clients** | This option enables Wireless Auto Configuration. |
| **Automatically Connect to Non-preferred Networks** | This option enables automatic connections to wireless networks that are not configured as preferred networks. |

On the **Preferred Networks** tab, you can view the options as described in the following table.

**Preferred Network Options of a Wireless Network Policy**

| Option | Description |
|---|---|
| **Networks** | This option displays the list of preferred wireless networks. |
| **Add/Edit/Remove** | These buttons create a new preferred wireless network, modify the settings of the selected preferred wireless network, and delete the selected preferred wireless network. |
| **Move Up/Move Down** | These buttons move the selected preferred wireless network up or down in the Networks list. |

The properties of a preferred wireless network consist of a Network Properties tab and an IEEE 802.1X tab.

On the **Network Properties** tab, you can view and configure the settings of a wireless network for a Windows wireless client that supports the Wireless Zero Configuration service. The settings are:

- **Network Name (SSID).** Displays the names of networks that are within the reception range of the wireless adapter on your computer. If selected, a network key is used to encrypt data while it is transmitted over the network.

- **Description.** This option allows you to type a description for the preferred wireless network.

- **Data Encryption (WEP Enabled).** Specifies whether Wired Equivalent Privacy (WEP) is enabled for this preferred wireless network.

- **Network Authentication (Shared Mode).** Specifies whether a network key is used to authenticate to this preferred wireless network. Under the 802.11 standard for wireless networks, when a network key is used for authentication, the network is operating in shared key authentication mode. If a network key is not used for authentication, the network is operating in open system mode.

- **The Key Is Provided Automatically.** Specifies whether a network key is automatically provided for this preferred wireless network. For example, if 802.1X is being used for dynamic key distribution.

- **This Is A Computer-to-Computer (Ad Hoc) Network; Wireless Access Points Are Not Used.** Specifies whether the preferred wireless network is a computer-to-computer (ad hoc) network, not an access point (infrastructure) network.

On the **IEEE 802.1X** tab, you can view and configure the following settings (which are equivalent to the authentication settings of a Windows wireless client):

- **Enable Network Access Control Using IEEE 802.1X.** Specifies whether 802.1X authentication is enabled. If selected, credentials such as smart cards, certificates, and passwords are used for authentication.

- **EAP Type and Settings.** Specifies the Extensible Authentication Protocol (EAP) type that is to be used.

- **Authenticate As Guest When User Or Computer Information Is Unavailable.** Specifies whether the computer attempts authentication to the network when a user is not logged on.

- **Authenticate As Computer When Computer Information Is Available.** Specifies whether the computer attempts authentication to the network as a guest when user or computer information is not available.

The following are additional settings on the IEEE 802.1X tab that do not appear on authentication settings of a Windows wireless client:

- **EAPOL-Start Message.** This option allows you to specify the transmission behavior of the EAPOL-Start message when authenticating. These settings set the SupplicantMode registry setting. You can select from the following:

    - Do Not Transmit

    - Transmit

    - Transmit Per 802.1X

- **Max Start.** This option allows you to specify the number of successive EAPOL-Start messages that are sent out when no response is received to the initial EAPOL-Start messages.

- **Start Period.** This option allows you to specify the interval, in seconds, between the retransmission of EAPOL-Start messages when no response is received to the previously sent EAPOL-Start message.

- **Held Period.** This option allows you to specify the period, in seconds, for which the authenticating client will not perform any 802.1X authentication activity after it has received an authentication failure indication from the authenticator.

- **Authentication Period.** This option allows you to specify the interval, in seconds, for which the authenticating client will wait before retransmitting any 802.1X requests after end-to-end 802.1X authentication has been initiated.

- **Computer Authentication.** This option allows you to specify how computer authentication works with user authentication. These settings set the AuthMode registry setting. There are three possible settings:

    - **With User Authentication.** When users are not logged on to the computer, authentication is performed using the computer credentials. After a user logs on to the computer, authentication is maintained using the computer credentials. If a user travels to a new wireless access point, authentication is performed using the user credentials.

    - **With User Re-Authentication.** When users are not logged on to the computer, authentication is performed using the computer credentials. After a user logs on to the computer, authentication is performed using the user credentials. When a user logs off of the computer, authentication is performed with the computer credentials. This is the recommended setting because it ensures that the connection to the wireless AP is always using the security credentials of the computer's current security context (computer credentials when no user is logged on and user credentials when a user is logged on).

    - **Computer Only.** Authentication is always performed using the computer credentials. User authentication is never performed.

For more information about Group Policy settings, see the Group Policy Settings Reference for Windows Server 2003.

**WPA upgrade**

To use the new Wi-Fi Protected Access (WPA) standard for wireless clients running Windows XP (SP1 and later) and Windows Server 2003 that are using a wireless network adapter that supports the WZC service, you must obtain and install the free download WPA Wireless Security Update. It updates the wireless network configuration dialog boxes to support new WPA options. An update to the properties of the Wireless Network (IEEE 802.11) Policies to allow configuration of WPA options is being investigated.

# Network Interoperability Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Interoperability Technologies**
Microsoft Windows Server 2003 interoperability technologies provide the core functionality that enables remote administration and directory service synchronization. The Remote Procedure Call (RPC) functionality in Windows Server 2003 enables the implementation of a comprehensive network access solution. The Directory Synchronization Services (MSDSS) and the File Migration Utility (FMU) components in Services for Netware 5.03 (SFN) enable computers running Windows Server 2003 to interoperate with computers running Novell NetWare.

**Network Interoperability Technologies Components**
The following network access technologies provide options for secure client access to an organization's network.

**Remote Procedure Call**
RPC is technology for creating distributed client/server programs. RPC is an efficient and secure interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality residing in a different process. That process can be on the same computer, on the local area network (LAN), or across the Internet.

For more information, see "RPC Technical Reference.

**Services for NetWare**
SFN provides directory object migration and synchronization between computers that are running Windows Server 2003 with Microsoft Active Directory and computers that are running Novell's NetWare operating system with NDS, eDirectory, and Bindery directory services.

For more information, see "Services for Netware Technical Reference.

**Network Interoperability Technologies Scenarios**
RPC is an IPC technique that allows client and server software to communicate. The Microsoft RPC facility is compatible with the Open Group's Distributed Computing Environment (DCE) specification for remote procedure calls and is interoperable with other DCE-based RPC systems, such as those for HP-UX and IBM AIX UNIX–based operating systems.

SFN is a synchronization, migration, and interoperability utility that enables the migration of objects from Novell's NetWare operating system with NDS, eDirectory, and Bindery directory services, to Windows Server 2003 with the Active Directory directory service.

# RPC Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**RPC Technical Reference**
Microsoft Remote Procedure Call (RPC) is a powerful, robust, efficient, and secure interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality residing in a different process. That process can be on the same computer, on the local area network (LAN), or across the Internet.

In Microsoft Windows Server 2003 and Windows XP, there are three types of processes: native 32-bit processes, native 64-bit processes, and 32-bit processes running under the 32-bit process emulator on a 64-bit system (often referred to as WOW6432 processes). RPC fully supports the 64-bit version of Windows.

Microsoft RPC was initially developed as an extension to Open Software Foundation (OSF) RPC. With the exception of some of its advanced features, Microsoft RPC is interoperable with other vendors' implementations of OSF RPC.

# What Is RPC?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is RPC?**

**In this section**

- Terms and Definitions
- RPC Dependencies and Interactions

Microsoft Remote Procedure Call (RPC) is a powerful technology for creating distributed client/server programs. RPC is an interprocess communication technique that allows client and server software to communicate. The Microsoft RPC facility is compatible with the Open Group's Distributed Computing Environment (DCE) specification for remote procedure calls and is interoperable with other DCE-based RPC systems, such as those for HP-UX and IBM AIX UNIX–based operating systems.

Computer operating systems and programs have steadily gotten more complex over the years. With each release, there are more features. The growing intricacy of systems makes it more difficult for developers to avoid errors during the development process. Often, developers create a solution for their system or application when a nearly identical solution has already been devised. This duplication of effort consumes time and money and adds complexity to already complex systems.

RPC is designed to mitigate these issues by providing a common interface between applications. RPC serves as a go–between for client/server communications. RPC is designed to make client/server interaction easier and safer by factoring out common tasks, such as security, synchronization, and data flow handling, into a common library so that developers do not have to dedicate the time and effort into developing their own solutions.

**Terms and Definitions**

The following terms are associated with RPC.

**Client**

A process, such as a program or task, that requests a service provided by another program. The client process uses the requested service without having to "deal" with many working details about the other program or the service.

**Server**

A process, such as a program or task, that responds to requests from a client.

**Endpoint**

The name, port, or group of ports on a host system that is monitored by a server program for incoming client requests. The endpoint is a network-specific address of a server process for remote procedure calls. The name of the endpoint depends on the protocol sequence being used.

**Endpoint Mapper (EPM)**

Part of the RPC subsystem that resolves dynamic endpoints in response to client requests and, in some configurations, dynamically assigns endpoints to servers.

**Client Stub**

Module within a client application containing all of the functions necessary for the client to make remote procedure calls using the model of a traditional function call in a standalone application. The client stub is responsible for invoking the marshalling engine and some of the RPC application programming interfaces (APIs).

**Server Stub**

Module within a server application or service that contains all of the functions necessary for the server to handle remote requests using local procedure calls.

**RPC Dependencies and Interactions**

RPC is a client/server technology in the most generic sense. There is a sender and a receiver; data is transferred between them. This can be classic client/server (for example, Microsoft Outlook communicating with a server running Microsoft Exchange Server) or system services within the computer communicating with each other. The latter is especially common. Much of the Windows architecture is composed of services that communicate with each other to accomplish a task. Most services built into the Windows architecture use RPC to communicate with each other.

The following table briefly describes the services in Windows Server 2003 that depend on the RPC system service (RPCSS).

**Services That Depend on RPCSS**

| Service | Description |
|---|---|
| Background Intelligent Transfer Service | Transfers data between clients and servers in the background. |
| COM+ Event System | Supports System Event Notification Service (SENS), which provides automatic distribution of events to subscribing Component Object Model (COM) components. |
| COM+ System Application | Manages the configuration and tracking of COM+-based components. |
| Cryptographic Services | Provides three management services: Catalog Database Service, which confirms the signatures of Windows files; Protected Root Service, which adds and removes Trusted Root Certification Authority certificates from this computer; and Key Service, which helps enroll this computer for certificates. |
| DHCP Server | Performs TCP/IP configuration for DHCP clients, including dynamic assignments of IP addresses, specification of the WINS and DNS servers, and connection–specific Domain Name System (DNS) names. |
| Distributed Link Tracking Client | Enables client programs to track linked files that are moved within an NTFS volume to another NTFS volume on the same computer or to an NTFS volume on another computer. |
| Distributed Link Tracking Server | Enables the Distributed Link Tracking Client service within the same domain to provide more reliable and efficient maintenance of links within the domain. |
| Distributed Link Transaction Coordinator | Coordinates transactions that span multiple resource managers, such as databases, message queues, and file systems. |
| DNS Server | Enables DNS clients to resolve DNS names by answering DNS queries and dynamic update requests. |
| Error Reporting Service | Collects, stores, and reports unexpected application failures to Microsoft. |
| File Replication Service | Allows files to be automatically copied and maintained simultaneously on multiple servers. |
| Help and Support | Enables Help and Support Center to run on the computer. |
| Human Interface Device Access | Enables generic input access to Human Interface Devices (HID), which activates and maintains the use of predefined hot buttons on keyboards, remote controls, and other multimedia devices. |
| Indexing Service | Indexes contents and properties of files on local and remote computers; provides rapid access to files through flexible querying language. |
| IPSec Services | Provides end-to-end security between clients and servers on TCP/IP networks. |
| Kerberos Key Distribution Center | On domain controllers, enables users to log on to the network using the Kerberos authentication protocol. |
| Logical Disk Manager | Detects and monitors new hard disk drives and sends disk volume information to Logical Disk Manager Administrative Service for configuration. |
| Logical Disk Manager Administrative Service | Configures hard disk drives and volumes. |

| | |
|---|---|
| Messenger | Transmits net send and Alerter service messages between clients and servers. This service is not related to Windows Messenger. |
| Microsoft Software Shadow Copy Provider | Manages software-based volume shadow copies taken by the Volume Shadow Copy service. |
| Network Connections | Manages objects in the Network and Dial-Up Connections folder in which you can view local area network (LAN) and remote connections. |
| Print Spooler | Manages all local and network print queues and controls all printing jobs. |
| Protected Storage | Protects storage of sensitive information, such as private keys and prevents access by unauthorized services, processes, or users. |
| Remote Desktop Help Session Manager | Manages and controls Remote Assistance. |
| Remote Registry | Enables remote users to modify registry settings on a computer. |
| Removable Storage | Manages and catalogs removable media and operates automated removable media devices. |
| Resultant Set of Policy Provider | Enables a user to connect to a remote computer, access the Windows Management Instrumentation (WMI) database for that computer, and either verify the current Group Policy settings made for the computer or check settings before they are applied. |
| Routing and Remote Access | Enables multi-protocol LAN-to-LAN, LAN-to-wide area network (WAN), virtual private network (VPN), and network address translation (NAT) routing services for clients and servers on the network. |
| Security Accounts Manager | Upon startup, signals other services that the Security Accounts Manager (SAM) is ready to accept requests. |
| Shell Hardware Detection | Provides notifications for AutoPlay hardware events. |
| Task Scheduler | Enables a user to configure and schedule automated tasks on the computer. |
| Telephony | Provides Telephony API (TAPI) support for clients using programs that control telephony devices and IP-based voice connections. |
| Telnet | Enables a remote user to log on to a computer and run programs; supports various TCP/IP Telnet clients, including UNIX-based and Windows-based computers. |
| Terminal Services | Allows users to connect interactively to a remote computer. Remote Desktop, Fast User Switching, Remote Assistance, and Terminal Server depend on this service. |
| Terminal Services Session Directory | Enables a user connection request to be routed to the appropriate terminal server in a cluster. |
| Upload Manager | Manages the synchronous and asynchronous file transfers between clients and servers on the network. |
| Virtual Disk Service | Provides software volume and hardware volume management service. |

| | |
|---|---|
| Volume Shadow Copy | Manages and implements Volume Shadow Copies used for backup and other purposes. |
| Windows Audio | Manages audio devices for Windows-based programs. |
| Windows Image Acquisition (WIA) | Provides image acquisition services for scanners and cameras. |
| Windows Installer | Installs, repairs, and removes software according to instructions contained in .MSI files. |
| Windows Internet Name Service (WINS) | Resolves NetBIOS names for TCP/IP clients by locating network services that use NetBIOS names. |
| Windows Management Instrumentation | Provides a common interface and object model to access management information about operating system, devices, applications, and services. If this service is stopped, most Windows-based software will not function properly. |
| Wireless Configuration | Enables automatic configuration for IEEE 802.11 adapters. |
| WMI Performance Adapter | Provides performance library information from WMI providers to clients on the network. |

# How RPC Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How RPC Works**
**In this section**

- RPC Architecture
- RPC Processes and Interactions
- Network Ports Used by RPC

Microsoft Remote Procedure Call (RPC) is an interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality residing in a different process. That process can be on the same computer, on the local area network (LAN), or across the Internet. The Microsoft RPC mechanism uses other IPC mechanisms, such as named pipes, NetBIOS, or Winsock, to establish communications between the client and the server. With RPC, essential program logic and related procedure code can exist on different computers, which is important for distributed applications.

This section covers the architecture of RPC and the way in which RPC communication takes place.

**RPC Architecture**
By replacing dedicated protocols and communication methods with a robust and standardized interface, RPC is designed to facilitate communication between client and server processes. The functions contained within RPC are accessible by any program that must communicate using a client/server methodology. The following figure shows the RPC architecture.

**RPC Architecture**

The following table lists and describes the components and functions of the RPC architecture.

**RPC Components**

| Component | Description |
|---|---|
| Client or server process | Program or service that initiates or responds to an RPC request. |
| RPC stubs | Program subsystems used by a client or server to initiate an RPC request. |

| | |
|---|---|
| Marshalling engine<br><br>(NDR20 or NDR64) | Provides a common RPC interface between RPC clients and servers. NDR20 is used in a 32-bit architecture and NDR64 is optimized for a 64-bit architecture. The client and the server negotiate which marshalling engine is used for the communication. |
| Runtime application programming interface (API) | Provides a direct interface for RPC to clients or servers. RPC clients and servers typically call the runtime API to initialize RPC and prepare the data structure that is used to make RPC calls. This runtime API layer also determines if an RPC request coming from a marshalling engine or directly from a client or server is going to a local server or a remote server. The runtime API layer then routes the RPC to the Connection RPC, Datagram RPC, or Local RPC layers. |
| Connection RPC protocol engine | Used when the RPC requires a connection–oriented protocol. This layer designates the connection–oriented protocol to use if the RPC is outgoing or receives an incoming connection–oriented RPC. |
| Datagram RPC protocol engine | Used when the RPC requires a connectionless protocol. This layer designates the connectionless protocol to use if the RPC is outgoing or receives an incoming connectionless RPC. |
| Local RPC protocol engine | Used when the server and client are located on the same host. |
| Registry | Accessed when the RPC service first loads. Registry keys may specify IP port ranges and the device names of network cards that RPC should bind to. Unless APIs force its use, the registry is not used in normal RPC operations. |
| Win32 APIs<br><br>(kernel32.dll, advapi32.dll, ntdll.dll) | Kernel32.dll is a Windows NT base API client dynamic-link library (DLL) file that provides system services for managing threads, memory, and resources.<br><br>Advapi32.dll is an advanced Windows 32 base API DLL file; it is an API services library that supports security and registry calls.<br><br>Ntdll.dll is an NT layer DLL file that controls Windows NT system functions. |
| SSPI<br><br>(secur32.dll) | Provides a security interface for RPC. Negotiates the use of Kerberos, NTLM, or Secure Sockets Layer (SSL) for authentication and encryption. |
| Endpoint Mapper (EPM)<br><br>(rpcss.dll) | Rpcss.dll primarily provides the infrastructure for COM, but a portion of rpcss.dll is used for the EPM. An RPC server contacts the EPM to receive dynamic endpoints and register those endpoints in the EPM database. RPC clients contact the EPM from the protocol-engine level to resolve endpoints when establishing a connection with an unknown RPC server endpoint. |
| Active Directory | Used in the RPC client process only when the security interface specifies Kerberos or Negotiate as the security provider or when the server uses NTLM as the security provider. |
| Network stack | Used to pass RPC requests and replies between a client and a remote server. |
| Kernel | Used to pass RPC requests and replies between a client and a local server. |

**RPC Processes and Interactions**

The RPC components make it easy for clients to call a procedure located in a remote server program. The client and server each have their own address spaces; that is, each has its own memory resource allocated to data used by the procedure. The following figure shows the RPC process.

**RPC Process**

The RPC process starts on the client side. The client application calls a local stub procedure instead of code implementing the procedure. Stubs are compiled and linked with the client application during development. Instead of containing code that implements the remote procedure, the client stub code retrieves the required parameters from the client address space and delivers them to the client runtime library. The client runtime library then translates the parameters as needed into a standard Network Data Representation (NDR) format for transmission to the server.

**Note**

- There are two NDR marshalling engines within the RPC runtime library: NDR20 and NDR64. A 32-bit client initiating the communication uses the NDR20 marshalling engine; a 64-bit client can use either the NDR20 or the NDR64 marshalling engine. The same marshalling engine is used on both the client and the server side, regardless of program architecture. There is a slight decline in performance when either the client or server uses an architecture different from the other because the marshalling engine must do additional translation during the communication.

The client stub then calls functions in the RPC client runtime library (rpcrt4.dll) to send the request and its parameters to the server. If the server is located on the same host as the client, the runtime library can use the Local RPC (LRPC) function and pass the RPC request to the Windows kernel for transport to the server. If the server is located on a remote host, the runtime library specifies an appropriate transport protocol engine and passes the RPC to the network stack for transport to the server. RPC can use other IPC mechanisms, such as named pipes and Winsock, to accomplish the transport. The other IPC mechanisms allow RPC more flexibility in the way in which it completes its communications tasks. For more information about IPC mechanisms, see “Interprocess Communications” on MSDN.

The following table lists the network protocols supported by RPC and the type of RPC connection for which the protocol is used.

**RPC-Supported Network Protocols**

| Protocol | RPC Type |
|---|---|
| Transmission Control Protocol (TCP) | Connection–oriented |
| Sequenced Packet Exchange (SPX) | Connection–oriented |
| Named Pipe | Connection–oriented |
| HTTP | Connection–oriented |
| User Datagram Protocol (UDP) | Connectionless |
| Cluster Datagram Protocol (CDP) | Connectionless |

When the server receives the RPC, either locally or from a remote client, the server RPC runtime library functions accept the request and call the server stub procedure. The server stub retrieves the parameters from the network buffer and, using one of the NDR marshalling engines, converts them from the network transmission format to the format required by the server. The server stub calls the actual procedure on the server. The remote procedure then runs, possibly generating output parameters and a return value. When the remote procedure is complete, a similar sequence of steps returns the data to the client.

The remote procedure returns its data to the server stub which, using one of the NDR marshalling engines, converts output parameters to the format required for transmission back to the client and returns them to the RPC runtime library functions. The server RPC runtime library functions transmit the data to the client computer using either LRPC or the network.

The client completes the process by accepting the data over the network and returning it to the calling function. The client RPC runtime library receives the remote-procedure return values, converts the data from its NDR to the format used by the client computer, and returns them to the client stub.

For Microsoft Windows, the runtime libraries are provided in two parts: an import library, which is linked to the application, and the RPC runtime library, which is implemented as a DLL.

The server application contains calls to the server runtime library functions, which register the server's interface with the RPC runtime and, optionally, the EPM, and allow the server to accept remote procedure calls. The server application also contains the application-specific remote procedures that are called by the client applications.

**RPC Security Context Multiplexing**

Windows Server 2003 Service Pack 1 (SP1) provides RPC security context multiplexing for connection-oriented connections, such as those that use Transmission Control Protocol (TCP). This allows the RPC server to negotiate multiple security contexts over a single connection. For example, when multiple RPC clients establish a connection to an RPC server and a middle-tier RPC server resides between the clients and the destination server, the middle-tier server multiplexes the security context of the additional clients over an already established connection to the destination server. This eliminates the need for the middle-tier RPC server to use one of the exhaustible TCP ports to establish a new connection for each RPC client connecting to the RPC server

**Network Ports Used by RPC**

RPC server programs typically use dynamic port mappings to avoid conflicts with programs and protocols registered in the range of well-known TCP ports. RPC server programs associate their universally unique identifier (UUID) with a dynamic port and register the combination with the RPC EPM. The EPM provides a single point of contact for RPC clients. The RPC clients contact the EPM and use the server program's UUID to determine the port being used by the server program. The following table indicates the network ports normally used by RPC.

**Port Assignments for RPC**

| Service Name | UDP | TCP |
|---|---|---|
| HTTP | 80, 443, 593 | 80, 443, 593 |
| Named Pipes | 445 | 445 |
| RPC Endpoint Mapper | 135 | 135 |
| RPC Server Programs | <Dynamically assigned> | <Dynamically assigned> |

# Services for Netware Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Services for NetWare Technical Reference**
Microsoft Services for NetWare 5.03 is a synchronization, migration, and interoperability tool made up of the following components: Directory Synchronization Services (MSDSS) and File Migration Utility (FMU).

Services for NetWare enables an organization to migrate objects from Novell's NetWare operating system with NDS, eDirectory, and Bindery directory services to the Microsoft Windows Server 2003 operating system with the Active Directory directory service. Services for NetWare also enables short-term directory service interoperability and bi-directional synchronization.

**In this subject**

- How Services for Netware Works
- Services for Netware Tools and Settings

# What Is Services for Netware

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Services for NetWare Scenarios**
To enhance interoperability with NetWare networks, Services for NetWare 5.03 includes Directory Synchronization Services (MSDSS) and the File Migration Utility (FMU):

- **Directory Synchronization Services** — Enables you to migrate and synchronize directory resources from NetWare servers.
- **File Migration Utility** — Enables you to migrate files from NetWare servers.

Services for NetWare 5.03 also provides Active Directory and NDS interoperability. This functionality enables you to add Active Directory to a Bindery or NDS environment. In addition, Services for NetWare provides tools that enable you to troubleshoot connectivity problems, login scripts, and password synchronization. Services for NetWare also provides utilities for monitoring network traffic.

Services for NetWare 5.03 requires Novell Client for Windows.

**Note**

- File and Print Services for NetWare (FPNW) has been removed from Services for NetWare 5.03.

**Synchronization Overview**
Directory Synchronization Services (MSDSS) performs the following functions:

- Simplifies the integration of NDS/eDirectory and Active Directory.
- Reduces directory management overhead by enabling two-way synchronization.
- Speeds the migration of NDS/eDirectory and NetWare bindery information to Windows Server 2003.

To enable these capabilities, MSDSS bi-directionally synchronizes data stored in Active Directory with NDS or eDirectory.

To provide interoperability between Windows Server 2003 directory services and NetWare 3.x bindery services, MSDSS synchronizes data stored in Active Directory with all NetWare 3.x bindery services on a one-way basis. Bindery does not support two-way synchronization. You can also establish a one-way synchronization session with NDS or eDirectory.

For more information about the following synchronization methods used by MSDSS, see "How Services for Netware Works:"

- Forward Synchronization
- Reverse Synchronization
- One-Way Synchronization
- Two-Way Synchronization
- Scheduled Synchronization
- Manual Synchronization
- Synchronization Filtering
- Password Synchronization

**Migration Overview**
The File Migration Utility (FMU) enables you to migrate files from NetWare servers to Windows Server 2003. FMU can copy files from multiple NetWare file servers to multiple file servers running Windows Server 2003.

FMU is integrated with MSDSS and enables the migration of large amounts of file data from supported versions of NetWare over to Windows Server 2003, while preserving unique file-security permissions during the migration. In addition, users can access their files during the migration process.

Before you use FMU to translate the NDS, eDirectory, or Bindery file system rights and permissions to the equivalent rights and permissions in the NTFS file system, you must run a one-time migration of NDS or Bindery directory objects to Active Directory. After you have performed the one-time migration and selected the option to migrate files, a migration log will be created that can be used later by FMU. This migration log serves as a mapping file that maps user objects in NDS to Active Directory.

For each NDS or Bindery volume, FMU calculates the effective rights, starting at the root, and tracks inheritance and filters as the migration continues through the tree. Like Novell NetWare, Microsoft Windows secures folders and files by controlling group and user access. Windows security is supported through the NTFS file system. To help preserve security on transferred NetWare files, you must transfer the NetWare files to an NTFS volume, where the effective rights of the NetWare files are converted to permissions.

**Interoperability Overview**
If you want to maintain an environment that contains both Active Directory and Bindery/NDS directory services, you can perform a phased migration and run the two systems in parallel. If you choose to run the two systems in parallel, you will be able to perform additional migration tasks (other than synchronizing the two directory services), such as replacing applications that are dependent on Novell services with applications that are compatible with Active Directory.

# How Services for Netware Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Services for NetWare Architecture**
Services for NetWare 5.03 includes two components: Directory Synchronization Services and the File Migration Utility (FMU).

**Directory Synchronization Services**
Using Directory Synchronization Services (MSDSS) an organization can retain an existing Novell directory in an environment that includes computers running Windows Server 2003 and Active Directory. MSDSS synchronization enables you to choose:

- One-way synchronization to centralize directory management from Active Directory.
- Two-way synchronization to manage data from either Active Directory or a Novell directory.

**File Migration Utility**
Using FMU, an organization can migrate a Novell Bindery or NDS directory to Windows Server 2003 Active Directory.

**MSDSS**
The following sections summarize the synchronization methods that are available with Directory Synchronization Services (MSDSS):

- Forward Synchronization
- Reverse Synchronization
- One-Way Synchronization
- Two-Way Synchronization
- Scheduled Synchronization
- Manual Synchronization
- Synchronization Filtering
- Password Synchronization

**Forward Synchronization**
The process of synchronizing data from Active Directory to Novell directories is referred to as forward synchronization. The forward synchronization process efficiently queries Active Directory for any new objects and alterations to existing objects. If an existing object is modified, only its changes, not the entire object, are synchronized with NDS, eDirectory, or Bindery directory services objects. If a new object is created, then only the new object and its attributes are synchronized with NDS, eDirectory, or Bindery directory services objects. Synchronization takes place during the scheduled synchronization or when you initiate a manual synchronization.

**Reverse Synchronization**
The process of synchronizing data from Novell directories to Active Directory is referred to as reverse synchronization. Reverse synchronization is less efficient than forward synchronization. This means that network utilization during reverse synchronization is higher than it is during forward synchronization.

NDS does not currently provide a comprehensive mechanism to query changes to objects. Therefore, during reverse synchronization, an MSDSS algorithm compares all of the objects residing in the NDS directory to the objects residing in Active Directory. Only changed objects and newly created objects in NDS are copied to Active Directory.

Because network utilization during reverse synchronization can be higher, it should be scheduled to run less frequently than forward synchronization. However, if you decrease the frequency of directory synchronization in either direction, you will increase the likelihood of inconsistencies between Active Directory and NDS.

**One-Way Synchronization**
Using one-way synchronization, you can deploy Active Directory in a Novell environment without replacing existing directories or having to manage two directories. This enables you to:

- Consolidate network management where multiple directories are required.
- Manage accounts from a single directory.
- Use directory-enabled applications, devices, and services based on Active Directory.

After an initial reverse synchronization is performed (from NDS, eDirectory, or Bindery directories to Active Directory), the NDS, eDirectory, or Bindery directory objects that reside in Active Directory can be forward-synchronized on a one-way basis. When users, groups, organizational units (OUs), or any of their applicable attributes are modified in Active Directory, they will be synchronized with the NDS, eDirectory, or Bindery directories during the next scheduled synchronization.

Setting up a one-way synchronization session provides an administrator with a central directory management solution and supports additions or modifications to NDS, eDirectory, or Bindery directory services objects from Active Directory only.

**Two-Way Synchronization**
Using two-way synchronization, you can create or change objects in either Active Directory or NDS and the partner directory will be updated at the next scheduled synchronization.

You can use two-way synchronization to enable interoperability between NDS and Active Directory and to maintain an existing NDS directory and add Active Directory.

**Scheduled Synchronization**
During a scheduled synchronization, changes from one directory are replicated to another directory at scheduled intervals that are set by an administrator. The default interval for forward synchronization is every 15 minutes, 24 hours a day. The default interval for reverse synchronization is every hour, from midnight to 06:00. If a two-way synchronization session has been configured, you can define a separate schedule for each direction of the synchronization.

**Manual Synchronization**
When you manually synchronize directories, you have the option of copying recent changes from one directory to another immediately, without waiting for the next scheduled synchronization.

Usually, it is safe to let synchronization occur during the normally scheduled times. However, a security-related situation might call for an immediate manual synchronization. For example, users with access to both directory platforms might request a password reset or logon change, or user accounts might need to be immediately disabled.

When user accounts are disabled in Active Directory, access to those accounts from Active Directory is immediately restricted. However, users will still have access to their accounts from NDS until a scheduled synchronization takes place. To prevent this situation from occurring, you can perform a manual synchronization.

**Synchronization Filtering**
Using synchronization filtering, administrators can define an explicit set of object types within a session to be read during the synchronization process. Object types are collections of attributes. When a synchronization filter is applied, changes to a defined object type are synchronized on the next scheduled synchronization.

**Password Synchronization**
Password synchronization can occur only if passwords are changed from Active Directory. Passwords are synchronized when an administrator performs any of the following administrative functions:

- Initial reverse synchronization
- User creation in NDS or eDirectory
- Password changes in Active Directory

**Initial Reverse Synchronization**
Users that have been copied from NDS, eDirectory, or Bindery to Active Directory through initial reverse synchronization will be prompted to change their passwords the first time they log on to Active Directory. This new password will then be synchronized with the password attribute in NDS, eDirectory, or Bindery.

**User Creation in NDS or eDirectory**
If users are created in NDS or eDirectory (in a two-way synchronization), the new user objects are copied to Active Directory on the next scheduled reverse synchronization. When the new users successfully log on to Active Directory, they are prompted to change their passwords. The new passwords are copied to NDS or eDirectory on the next scheduled forward synchronization.

**Password Changes in Active Directory**
When users change their passwords or when an administrator resets user passwords in Active Directory, the new passwords overwrite the existing NDS, eDirectory, or Bindery passwords. This password synchronization process occurs during the next scheduled forward synchronization.

### Note

- If the **User must change password at next logon** check box is selected for any user, the password will not be synchronized from Active Directory to the Novell directory until the user logs on to Active Directory and changes the password.

Because it is impossible to access encrypted passwords stored in NDS, eDirectory, and Bindery, new user passwords are created when user objects are migrated to Active Directory. Any password changes made from NDS or eDirectory will not be synchronized with Active Directory. The new password is generated using password generation schemes that are specified by Services for NetWare.

The password scheme is applied and then copied to Active Directory before the user object is migrated. When the user accounts exist in Active Directory, users will be prompted to create new passwords when logging on to Active Directory.

Changes made to user passwords in Active Directory will be synchronized with the respective Novell user objects at the next scheduled synchronization.

User password schemes only affect user objects that exist in NDS, and use of a password scheme will not overwrite a valid user password in Active Directory. Because of this password scheme rule, it is recommended that all future password changes occur in Active Directory. Otherwise, if a user password is changed in NDS, the passwords in both directories will be inconsistent until it is changed in Active Directory.

The following table lists and describes the password schemes that are available to administrators.

**Password Schemes Available to Administrators**

| Password Schemes | Description |
|---|---|
| Set passwords to blank. | Clears all passwords. Users logging on to Active Directory for the first time will not need to specify a password. |
| Set passwords to the name of the user. | Sets passwords to user names after migration has taken place. This is the default scheme. |
| Set passwords to a random value. | Creates random passwords for each user migrated to Active Directory. The password generated by SFN does meet Windows Server 2003 default password policy. |
| Set all passwords to the following value. | Provides an option to specify and confirm the password value for all users migrating to Active Directory. |

**MSDSS Directory Schema Extensions**
Extensions to the Active Directory and NDS directory schemas are required for full MSDSS functionality.

### Note

- MSDSS directory schema extensions are implemented once and are irreversible.

A directory schema provides a description of object classes and associated attributes that can be placed in a directory. For each object class, the directory schema defines:

- The required attributes of the object class
- Any additional attributes of the object class

- The parent object class of the defined object class

**Active Directory Schema Extensions**
Extensions to the Active Directory schema are required for:

- Migration
- One-way synchronization
- Two-way synchronization

If a user who is installing MSDSS has the necessary permissions to extend the Active Directory schema, MSDSS automatically updates the Active Directory schema during the setup process. The schema update process is required only once for each Active Directory forest. If a user who is installing MSDSS does not have the necessary permissions to extend the Active Directory schema, the schema can be updated manually by a user with the appropriate schema credentials. To manually update the schema, log on to the schema master in the Active Directory forest in which MSDSS is to be installed with the appropriate schema credentials, then open a command prompt and type:

```
msiexec /I Path \msdss.msi SCHEMAONLY=1
```

**NDS Directory Schema Extensions**
Extensions to the NDS directory schema are required for two-way synchronization.

To support two-way synchronization, you must also extend the NDS schema. If you are required to extend the NDS schema when you create a new session, the system prompts you. Extending the NDS schema requires the following:

- Installation of Novell Client for Windows (also a requirement for MSDSS).
- Administrator permission to access the root object of the NDS tree.
- Access to the server that stores the master replica of the root partition (this server propagates the changes to all the servers in the NDS tree).

You can also extend the NDS or eDirectory schema manually by using the MSDSS command-line NDS schema extension tool NDSext.exe (available in the *systemroot*\System32\Directory Synchronization\Client folder). Use the following syntax:

```
ndsext extend Treename Username.Context Password
```

This command enables you to extend the NDS schema of a specified tree.

**File Migration Utility**
The File Migration Utility (FMU) enables you to migrate files from NetWare servers to Windows Server 2003. FMU can copy files from multiple NetWare file servers to multiple file servers running Windows Server 2003.

FMU is integrated with MSDSS and enables the migration of large numbers of data files from all versions of NetWare over to Windows Server 2003, while preserving unique file-security permissions during the migration. In addition, users can access their files during the migration process.

Before using FMU to translate the NDS, eDirectory, or Bindery file system rights and permissions to the equivalent rights and permissions in the NTFS file system, you must run a one-time migration of NDS or Bindery directory objects to Active Directory. This operation creates the mapping file used by FMU to map user rights to folders. After a scan confirms that all files, subdirectories, and permissions will migrate successfully, you can perform the migration process. Each source directory and file is copied to the selected target. Each migrated trustee is translated with its associated rights to the equivalent NTFS permissions and then added to the security descriptor for the migrated directory or file.

For each NDS or Bindery volume, FMU calculates the effective rights, starting at the root, and tracks inheritance and filters as the migration continues through the tree. Like Novell NetWare, Microsoft Windows secures folders and files by controlling group and user access. Windows security is supported through the NTFS file system. To help preserve security on transferred NetWare files, you must transfer the NetWare files to an NTFS volume, where the effective rights of the NetWare files are converted to permissions.

After you have performed the one-time migration and selected the option to migrate files, a migration log will be created that can be used later by FMU. This migration log serves as a mapping file that maps user objects in NDS to Active Directory.

**Accounts Required for FMU**
FMU requires the following accounts for its security context:

- The account that the user provides for NDS or Bindery access. The security context of this account is used to read the directories, files, and associated trustees that reside on the source Novell system.

- The user accounts accessed through Active Directory for users who are logged on. The security context of this account is used for creating directories and files and setting the associated security descriptor on the targeted Active Directory domain.

**Sources and Targets**
During a migration, the source is always either a volume or a directory from an NDS or Bindery server. You can have multiple mappings in any migration. One source can be mapped to multiple targets or multiple sources can be mapped to a single target. The migration target must be a shared folder on Microsoft Windows 2000 or Windows Server 2003.

You can display the source and target listings by using Active Directory Service Interfaces (ADSI) calls and then use the Lightweight Directory Access Protocol (LDAP), NDS, and NWCOMPAT providers to populate the lists. If any of these providers are missing, you might get blank listings.

**FMU and MSDSS**
MSDSS is an essential part of the file migration process because MSDSS informs FMU of the user and group relationships with the corresponding objects in NDS or Bindery. Within NDS, users, groups, organizational units, and organizations can all be trustees to directories and files.

**Note**

- Trustees are granted rights to work with directories, files, or objects. Active Directory does not support a container such as an organization to be the trustee of a directory or file. For more information about NDS or Bindery inheritance, see Novell documentation.

To maintain these rights throughout the migration of files from Novell NetWare to Microsoft Windows, MSDSS maps organizational units and organizations to Active Directory groups by creating local domain security groups for each NDS organizational unit and organization.

**MSDSS Migration Logs for FMU**
FMU requires the MSDSS-generated migration log to determine where each Novell trustee has been mapped in Active Directory. The migration log contains a list of trustee objects that were migrated to Active Directory during the MSDSS one-time migration process, and the log also lists the groups of trustees that were made members in Active Directory. Only trustees and their group associations that are listed in the migration log will be used to ensure equivalent security for files during the file migration process. The migration log contains a list of trustee objects that were migrated to Active Directory during the MSDSS one-time migration process. MSDSS can recognize the following NDS, eDirectory, or Bindery trustee objects:

- Users

- Groups

- Organizational units

- Organizations

Because only the trustee objects from NDS or eDirectory organizational units or organizations that you selected during the MSDSS one-time migration process will appear in the migration log, you will need to know which trustees have restrictions to the files you will be migrating to Windows and where these trustees reside in your NDS or eDirectory hierarchy.

You can use the migration log **Maps** option to display the maps that are loaded with the migration log. You can use **Maps** to confirm the trustee relationships to their corresponding objects in Active Directory before you perform a file migration. You can view the following maps:

- NDS Organizations and organizational units to Active Directory Group Mappings
- NDS Group to Active Directory Group Mappings
- NDS User to Active Directory User Mappings

You can use the migration log **Access Rights** option to view NetWare rights that are equivalent to NTFS permissions.

**Note**

- The NDS **Modify** right does not have an equivalent NTFS permission.

**Directory Service Interoperability**

Using the Services for NetWare directory service interoperability features, an organization can establish a synchronization strategy over a period of weeks or months, during which Active Directory interoperates with Novell Bindery, NDS, or eDirectory. This enables an organization to perform a migration to Windows Server 2003 in planned stages.

To maintain an environment that contains both Active Directory and Bindery/NDS directory services, you can perform a phased migration and run the two systems in parallel. A phased migration reduces the risk of data loss because you can migrate in managed stages and you can reverse the process if necessary. However, maintaining two separate directory services can, over time, add additional administrative costs to the migration.

In a phased migration, you use MSDSS to copy all Bindery or NDS user accounts, groups, and distribution lists, and (for NDS only) organizational units and organizations to Active Directory, while you maintain these objects in NDS or Bindery. While you gradually move resources to the Windows Server 2003-based environment, the MSDSS-provided directory synchronization enables users to continue to access those resources that remain on NetWare servers. As the changeover continues, users begin to access resources on computers running Windows Server 2003.

If you plan to perform a migration over several months or longer, two-way synchronization is recommended. Two-way synchronization should be used if the long-term goal is to interoperate using the two directory services. In this scenario, you can replace existing NetWare technologies with the latest comparable Microsoft technologies over a period of time.

After you have moved all resources to Windows Server 2003, converted all Novell services and applications to their counterparts in Active Directory, and moved object security permissions and objects that MSDSS does not migrate (such as computer accounts, printer objects, and application objects), synchronization between the two directory services might not be necessary. If not, you can delete the synchronization sessions and decommission remaining NetWare servers.

**Services for NetWare and MIIS**

Microsoft Identity Integration Server 2003 (MIIS) enables the integration and management of identity information across multiple repositories, systems, and platforms. MIIS augments Active Directory by providing broad interoperability capabilities, including: integration with a wide range of identity repositories; provisioning and synchronizing identity information, including password management, across multiple stores; and brokering changes to identity information by automatically detecting updates and sharing the changes across systems.

- MIIS also provides cross-platform identity synchronization across many different identity stores, including Novell's eDirectory. MIIS is a much more robust long-term cross-platform interoperability solution than Services for NetWare; however, MIIS does not support NDS. MIIS supports Novell's eDirectory version 8.6.2 and later.

  **Note**

  - NetWare 5.x and NetWare 6.x are supported by MIIS if the NDS directory has been upgraded to Novell's eDirectory:

MIIS currently supports the following versions of Novell's eDirectory:

- eDirectory 8.6.2
- eDirectory 8.7
- eDirectory 8.7.x

**Note**

- Support for eDirectory 8.7.x is included with Microsoft Identity Integration Server 2003, SP1.

For NetWare administrators who manage networks that include Novell software not supported by MIIS, Services for NetWare 5.03 can provide an interim Active Directory/NDS interoperability solution. For all other Novell customers, MIIS is the recommended long-term interoperability solution.

**Services for NetWare Troubleshooting**

Windows Server 2003 includes tools to help you monitor network traffic and to troubleshoot connectivity-related problems, including problems with routers, login scripts, client/server installation and configuration, and password synchronization. Among the troubleshooting tools provided with Windows Server 2003 are:

- **Netdiag** to help isolate TCP/IP-related connectivity problems.
- **Netstat** to display active TCP/IP connections, ports on which the computer is listening, Ethernet statistics, the IP routing table, IPv4 statistics (for the IP, ICMP, TCP, and UDP protocols), and IPv6 statistics (for the IPv6, ICMPv6, TCP over IPv6, and UDP over IPv6 protocols).
- **Ping** for troubleshooting IP-level connectivity between two TCP/IP computers.
- **Tracert** to trace routes and display the path between the sending host and a destination.
- **Pathping** to identify the path to a remote host and then ping the remote host for a period of time to collect and report statistics.
- **Event Viewer** to track errors and events recorded in Application, Security, and System logs.
- **Ipxroute** to display and modify information about the routing tables used by the IPX protocol.
- **Network Monitor** to monitor, record, and analyze network traffic.

For more detailed information about these and other troubleshooting tools, see "TCP/IP Tools and Settings" and "Services for Netware Tools and Settings."

**Connectivity Problems**

Most connectivity problems between computers running Windows Server 2003 and NetWare are caused by invalid configurations. If these systems are incorrectly configured, NetWare might not be able to access resources or it might access them inconsistently. Because resource access involves interaction between both Windows Server 2003-based and NetWare-based computers, you must be sure that resource access configurations are accurate on these computers.

In general, any of the following conditions could be symptomatic of protocol related issues, such as a scenario that includes IPX configured on a NetWare server while a computer running Windows Server 2003 is using IP.

- Access is denied to applications residing on NetWare servers.
- Programs fail to run and display error messages.
- Data throughput is slow.
- Users see the error message "Server not found."
- Users are denied access to network resources located on NetWare servers.
- Access to NetWare resources is limited.
- Some clients have some access to NetWare services, while others have none.

- Users can connect to servers running Windows Server 2003, but not to NetWare servers.
- Users can connect to some NetWare servers, but not to others.

To resolve some of the connectivity issues, you can verify that NetWare rights and user credentials are configured correctly by asking the following questions:

- Have you configured user accounts correctly on the NetWare file server?
- Have you set up the appropriate groups?
- Is group membership correctly configured?
- Have you set up user rights correctly for required resources?

**Note**

- For more information about NetWare configuration procedures, contact your NetWare administrator or refer to the Novell NetWare documentation.

**Router Problem**

In addition to potential NetWare and Windows Server 2003 connectivity problems, you might also experience the following router problem: NetBIOS-over-IPX packets do not propagate across routers.

If an incomplete browse list is displayed for a NetWare directory, or you cannot browse a server across a WAN link, you might have a problem with propagating packets using NetBIOS over IPX.

To facilitate the communication of a LAN-based protocol (such as NetBIOS) across an IPX network, IPX routers must be capable of propagating NetBIOS-over-IPX broadcast packets (type 20 packets), also known as IPX WAN broadcast packets. However, many router manufacturers set router parameters that prevent passing type 20 packets by default. If your router is not configured to pass type 20 packets, contact the router manufacturer for reconfiguration procedures.

**Services for NetWare Protocols**

NWLink, the IPX/SPX/NetBIOS-Compatible Transport Protocol, is Microsoft's 32-bit implementation of Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX). NWLink is included with Windows Server 2003.

NWLink provides the transport protocol to support communications with NetWare file servers. To log on to a NetWare network from Windows Server 2003, you must use a NetWare client such as Novell Client for Windows XP Professional.

**Note**

- You can also use NWLink to enable NetWare clients to connect to Windows Server 2003, Windows XP Professional, or Windows 2000 resources.

Because NWLink is Network Driver Interface Specification (NDIS)-compliant, a computer running Windows Server 2003 can also simultaneously run other protocol stacks, such as TCP/IP, for communication with computers running Windows with TCP/IP. In addition, you can bind NWLink to multiple network adapters with multiple frame types.

NWLink supports the networking application programming interfaces (APIs) NetBIOS and Windows Sockets (Winsock). These APIs enable communication among computers running Windows Server 2003 and between computers running Windows Server 2003 and NetWare bindery or NDS-based servers.

In addition to using NWLink to connect computers running Windows Server 2003 and NetWare, you can use NWLink whenever you need IPX/SPX. For example, when an IPX/SPX-based protocol is required, you can use NWLink as an alternative protocol to connect computers running Microsoft Proxy Server for Windows, Microsoft Systems Management Server (SMS), Microsoft Host Integration Server, Microsoft SQL Server, or Microsoft Exchange Server.

NWLink requires no initial client configuration on small non-routed networks.

**Note**

- The 64-bit versions of the Windows XP and Windows Server 2003 family do not support NWLink.

When used in combination with a redirector, NWLink can also function as a protocol that connects computers running the following Microsoft operating systems, if they are also running IPX/SPX:

- Windows 2000 Server
- Windows XP Professional
- Windows 2000 Professional
- Windows NT
- Windows for Workgroups 3.11
- Windows 98
- Windows 95
- Microsoft MS-DOS

**NWLink Architecture**

The following figure shows NWLink in the Windows Server 2003 architecture and the files in which each of the NWLink protocols are implemented.

**NWLink in Windows Server 2003 Architecture**

**NWLink Protocols**

NWLink provides a comprehensive set of transport and network layer protocols that enable integration with the NetWare environment. The following table shows NWLink protocols, defines their functions, and lists the associated drivers.

**NWLink Protocols**

| Protocol | Function | Driver |
|---|---|---|
| IPX | Provides connectionless datagram transfer services. | Nwlnkipx.sys |
| SPX and SPXII | Provides connection-oriented transfer services. | Nwlnkspx.sys |
| RIP | Provides route and router discovery services. | Nwlnkipx.sys |
| SAP | Collects and distributes service names and addresses. | Nwlnkipx.sys |
| NetBIOS | Provides compatible support with NetBIOS, for IPX/SPX on NetWare servers. | Nwlnknb.sys |

**IPX**

IPX is a peer-to-peer networking protocol that provides connectionless datagram transfer services and controls addressing and routing of packets of data within, and between, network segments. With connectionless transmission, it is unnecessary to set up a session each time packets are to be transmittedpackets are simply sent out on the network media. This requires less overhead than connection-oriented transmission, where it is necessary to establish a session each time packets are

transmitted. Connectionless transmission works best when data is generated intermittently, in short bursts.

Because IPX is a connectionless protocol, it does not provide for flow control or acknowledgment when the destination node receives the datagram packet. Instead, individual datagram packets travel independently to their destination. There is no guarantee that packets arrive at their destination or that they arrive in sequence. However, because transmission on local area networks (LANs) is relatively error-free, IPX is efficient in delivering short-burst data on LANs.

NWLink enables application programming for Winsock and remote procedure calls (RPCs) over Windows Sockets. IPX supports Windows Socket IDs for use by Windows Sockets applications. IPX enables NetBIOS, named pipes, mailslot, network dynamic data exchange (network DDE), RPC over NetBIOS, and RPC over named pipes. Through direct hosting, NWLink also supports other applications that use IPX. Direct hosting is a feature that enables computers to communicate over IPX while bypassing the NetBIOS layer. Direct hosting can lower overhead and increase throughput.

**IPX Frame Structure**

An IPX packet is encapsulated within the data field of an Institute of Electrical and Electronic Engineers (IEEE) frame, such as Ethernet, Token Ring, or Fiber Distributed Data Interface (FDDI), and immediately follows the media and data-link layer headers. The following figure shows the structure of an IPX header. The first 30 bytes of an IPX frame contain the header information while the remaining bytes contain the actual IPX packet data. For example, the packet data might signify a client request for a service or the data might be a server response.

**IPX Packet Header Structure for IPX**

**SPX**

SPX is a transport protocol that offers connection-oriented services over IPX. Although connection-oriented services require overhead for session setup, when a session is established, connection-oriented services require less overhead for data transmission than connectionless services. SPX works best for applications that require a continuous connection. SPX provides reliable delivery through sequencing and acknowledgments and also verifies successful packet delivery to any network destination by requesting verification from the destination node upon receipt of the data. SPX can track data transmissions consisting of a series of separate packets. If an acknowledgment request brings no response within a specified time, SPX retransmits the request eight times. If no response is received, SPX assumes the connection has failed.

**SPXII**

SPXII improves upon SPX in the following ways:

- **SPXII allows more outstanding unacknowledged packets than SPX.** SPX permits only one outstanding unacknowledged packet at a time, while SPXII allows as many outstanding packets as negotiated by the networked peers at connection setup time.

- **SPXII allows larger packets.** SPX has a maximum packet size of 576 bytes, while SPXII can use the maximum packet size of the underlying LAN. For example, SPXII can use a packet size of 1518 bytes on an Ethernet network.

- **SPXII provides a packet burst mechanism.** Packet burst, also known as burst mode, allows the transfer of multiple data packets without requiring that each packet be sequenced and acknowledged individually. By allowing multiple packets to be acknowledged once, burst mode can reduce network traffic on most IPX networks. Additionally, the packet burst mechanism monitors for dropped packets and retransmits only the missing packets.

**Note**

- In Windows Server 2003, burst mode is enabled by default.

**RIP**

NWLink uses Routing Information Protocol (RIP) over IPX (RIPX) to implement route and router discovery services used by SPX and NetBIOS/IPX (NBIPX). RIP runs on a layer equivalent to the OSI Application layer and determines the forwarding media access control (MAC) address for outbound traffic. RIP code is implemented within the file Nwlnkipx.sys.

NWLink includes the RIP protocol for Windows-based clients and for computers running Windows Server 2003 that do not have the Routing and Remote Access service installed. These computers do not forward packets as routers do, but rather use a RIP table to determine where to send packets. RIP clients, such as workstations, can locate the optimal route to an IPX network number by broadcasting a RIP GetLocalTarget route request. Each router that can reach the destination responds to the GetLocalTarget route request with a single route. Based on the RIP responses from the local routers, the sending node chooses the best router to forward the IPX packet. However, clients using the RIP protocol without Routing and Remote Access do not forward packets.

The RIPX packet header immediately follows the IPX packet header. The following figure shows the packet header for RIPX.

**IPX Packet Header Structure for RIPX**

**SAP**

Service Advertising Protocol (SAP) is the protocol that routers use to distribute the names and addresses of services running on IPX nodes. When bindery-based or NDS queries fail, SAP clients use SAP broadcasts to send the following types of messages:

- SAP GetNearestServer request for the name and address of the nearest server of a specific type.
- SAP general service request for the names and addresses of all services or of all services of a specific type.

NWLink includes a subset of the SAP protocol for Windows-based clients and for computers running Windows Server 2003 that do not have an IPX router installed.

The SAP header immediately follows the IPX header. The following figure shows the SAP header.

**IPX Packet Header Structure for SAP**

**NetBIOS over IPX**

To facilitate the operation of NetBIOS-based applications on an IPX network, NetBIOS over IPX provides the following standard NetBIOS services:

- **Datagrams.** Single packets sent without acknowledgment, for example, broadcasts.
- **Sessions.** Multiple packets sent with acknowledgments between two endpoints.
- **Name management.** Registering, querying, and releasing NetBIOS names.

The following figure shows the packet structure for NetBIOS over IPX.

**IPX Packet Header Structure for NetBIOS over IPX**

The module NWLnkNB.sys formats NetBIOS-level requests and passes them to NWLink for transmission over the network. NWLnkNB.sys includes the following performance enhancements:

- **PiggyBackAck.** A feature that facilitates acknowledgment of previous frames within the response frames.

- **Sliding window acknowledgment mechanism.** A dynamic window–sizing algorithm that enables burst mode to adjust the number of frames it can send.

As an alternative to NetBIOS over IPX, computers can communicate directly over IPX through direct hosting.

**Protocol Priority Setting**

When multiple transport protocols exist on a computer's network adapter, Windows Server 2003 negotiates network connections in the order that the network services binding list prioritizes the protocols. For example, if TCP/IP is ranked at the top of the network services binding list, Windows Server 2003 attempts to make network connections with TCP/IP before attempting to use other transport protocols. If users require network connections to servers using TCP/IP, setting the highest priority to this protocol provides the best overall performance. However, if users need connections to NetWare servers using IPX/SPX, you can improve overall performance for those users by changing the protocol priorities in their network services binding list, so that Windows Server 2003 attempts to make network connections with IPX/SPX before using the other protocols.

**NWLink Forwarder**

The forwarder component provides IPX router support. The name of the forwarder component driver is **Nwlnkfwd.sys**. This component is installed with NWLink but is used only when a computer running Windows Server 2003 is acting as an IPX router running the Routing and Remote Access service. This component operates in kernel mode.

When the IPX router software is activated, the forwarder component works with the IPX Router Manager and the filtering component to forward packets. The forwarder component obtains configuration information from the IPX Router Manager and stores a table of the best routes. When the forwarder component receives an incoming packet, it passes the packet to the filtering driver, which checks for input filters. When the component receives an outgoing packet, it passes the packet to the filtering driver, and if no outgoing filters prevent the packet from being transmitted, the filtering component passes the packet back to the forwarder component. The forwarder component then forwards the packet over the appropriate interface.

**Frame Types and Network Numbers**

NWLink uses frame types and network numbers to communicate with other computers on the same network segment and to provide correct packet routing.

**Determining Frame Type and Network Number with NWLink Auto Detect**

To connect a computer running Windows Server 2003 to a computer running IPX/SPX, a network number and frame type must be configured for each computer. The frame type and network number must be identical to the frame type and network number used on the local network segment. The NWLink Auto Detect feature automatically detects the internal network number and frame type. The Auto Detect feature, which is the recommended method for configuring network number and frame type, works in the following manner:

- When the NWLink protocol is initialized, it sends a RIPX request using a specific frame type. The RIPX request is a broadcast request for the local network. If a response is not received, NWLink sends additional requests.

- When a response to a RIPX request is received, the frame type for NWLink is set to the frame type of the response, and the IPX network number is set to the value of the Source Network number in the IPX header of the RIP response.

  **Note**

- If a computer has multiple network adapters attached to different networks, such as Token Ring, FDDI, and Ethernet, you can run Auto Detect for each adapter.

- If there are multiple RIPX responses containing multiple network numbers, Auto Detect uses a counting algorithm to determine the most likely network number.

- If there is no RIPX response to any request, NWLink sets the frame type to Ethernet 802.2 (for Ethernet network adapters) and the network number to 0.

AutoDetect uses the RIPX response to select the frame type and network number. If a network computer has an incorrect manual setting, AutoDetect will select an inappropriate frame type and network number combination for the network adapter. For example, if a computer replies with an incorrect frame type and network number, Auto Detect detects the incorrect configuration and uses it. Auto Detect might also select an incorrect network number if multiple computers respond. In that case, Auto Detect uses a heuristic algorithm to determine the most likely network number, but Auto Detect does not validate the packet information that it receives.

**Understanding Network Numbers**
You can configure NWLink with two distinctly different types of network numbers for routing purposes: the external network number and the internal network number. NWLink uses an IPX external network number to identify the computer's local network segment within the routed environment. In addition, NWLink uses a virtual network number, also known as an internal network number, to identify a logical network inside the computer. The purpose of the logical network inside the computer is to provide optimal routing to services running on the computer.

In Windows Server 2003 you can change both the external network number and internal network number from Control Panel.

**External network number**
The external network number is associated with the physical network adapter and the local area network segment (a segment in a NetWare network is analogous to a TCP/IP subnet). The external network number identifies the computer's local segment and facilitates communications within the routed environment. Accordingly, packets transmitted across the network contain the computer's external network number. Otherwise, if an internal number exists, the packets must contain the internal network number along with an appended MAC address to identify individual computers. All computers on the same network segment that use a given frame type must have the same external network number that must also be unique for each network segment.

If you replace a network adapter or connect the computer to a different segment, or if the external network number on a segment changes, you might not be able to communicate over IPX. If you lose IPX connectivity, you must reset the external network number and reboot the computer, when prompted to do so.

- To determine the external network number and frame type that have been set on a computer running Windows Server 2003, run the **ipxroute config** command at the command-line interface of that computer.

- To determine the external network number and frame type that have been set on a server running NetWare, enter **config** at the command-line interface of the NetWare server or inspect the Autoexec.ncf file.

### Note

- It is possible to run multiple IPX networks over the same physical network segment if those networks use different frame types.

**Internal Network Number**
Internal network numbers are necessary for internal routing purposes. Service-supporting hosts, which are hosts running services that SAP-based clients need to access, use internal network numbers. Service-supporting hosts use these numbers to help clients determine the optimal route for transmitting packets to services running on the service-supporting hosts. If only external network numbers are used, different routers might send a client multiple routes with the same route metrics, when only one route is actually optimal. However, if you specify an internal network number, you create a virtual network inside the service-supporting host and packets are always forwarded to the services running on the service-supporting host using an optimal path.

By default, NWLink does not identify internal network numbers. For example, when NWLink is installed, the Auto Detect feature does not detect the internal network number automatically. Instead, NWLink sets an internal network number of

00000000 on the computer's network adapter. When set to 00000000, the internal network number is not in use for that computer. This default behavior works whether NWLink is bound to a single network adapter or to multiple network adapters. However, an internal network number is required if the computer running Windows Server 2003 is acting as a server for applications that use NetWare SAP. This includes applications such as SQL Server, Exchange Server, SNA Server, or Host Integration Server (HIS) 2000.

Depending on your configuration, you might already have an internal network number. The Routing and Remote Access service and the SAP agent automatically install a unique internal network number during setup procedures. If you previously installed any of these services, you might already have a unique internal network number set for your computer's network adapter.

The default value of zero (00000000) for the internal network number is not returned when you type **ipxroute config** at the command-line interface. However, if you configure an internal network number, you can view the number using either **ipxroute config**, or by monitoring a trace of a RIP or SAP broadcast from the computer where the number is set.

**Supporting IPX Frame Types with NWLink**

Both Windows Server 2003 and NetWare support frame types for Ethernet, Token Ring, and FDDI topologies. The following table lists the frame types that Windows Server 2003 supports:

**Frame Types Supported by Windows Server 2003**

| Network Type | Supported Frame Types |
|---|---|
| Ethernet | Ethernet II, 802.2, 802.3, Ethernet Subnetwork Access Protocol (SNAP) |
| Token Ring | 802.5 and 802.5 SNAP |
| FDDI | 802.2, 802.3, and SNAP |

Frame types are based upon IEEE standards and define packet formats used by various topologies.

**Ethernet II**

The Ethernet II frame includes a 2-byte Type field that immediately follows the source address. The Type field contains a unique value, called an **EtherType**, which identifies the receiving computer for which the upper-layer protocol handles Data field contents.

**Ethernet 802.2**

Several frame types are based on the IEEE 802.3 standards, which define operations for the physical layer and the MAC sublayer. NetWare combines the IEEE 802.3 standard for the physical layer and the IEEE 802.2 standard for operations of the Logical Link Control (LLC) sublayer and refers to this combination as the Ethernet 802.2 frame type.

Ethernet II and Ethernet 802.2 frames can run on the same network. Because the value in the Ethernet II Type field always equals a number greater than 1,500 and the value in the Ethernet 802.2 Length field always equals a number of 1,500 or less, network hardware and software can distinguish between these frame types. This makes it possible for both frame types to coexist on the same network.

**Subnetwork Access Protocol**

The Subnetwork Access Protocol (SNAP) frame type is derived from the Ethernet 802.2 frame type. The SNAP portion of the frame is carried in the Data field. This frame type gives individual vendors the ability to assign unique values for protocols running on their hardware.

**Ethernet 802.3**

Like the 802.2 frame, the 802.3 frame differs from the Ethernet II frame because the 802.3 frame uses a Length field in place of the Type field in Ethernet II. It is often called 802.3 raw because it does not use the 802.2 LLC header in the Data field.

**Token Ring 802.5**

The Token Ring protocol is composed of two distinct frame subtypes, the MAC frames and non-MAC frames:

- **MAC frames.** These transmit management information for the Token Ring network. MAC frames carry signaling information and are not passed on by bridges and routers. They reside only on the LAN ring segment where the packets originate.

- **Non-MAC frames.** These transmit data for Token Ring networks. Non-MAC frames transmit data between computer stations on the ring and are passed on by bridges and routers.

**Note**

- The content of fields at the beginning of a Token Ring frame can redefine the composition of fields later in the frame.

# Services for Netware Tools and Settings

Updated: June 7, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

### In this section

- Services for NetWare Tools
- Services for NetWare Registry Entries

The "Services for NetWare Tools" section describes tools that are useful for troubleshooting Services for NetWare.

The "Services for NetWare Registry Entries" section describes the registry entries that can be configured to use the advanced features of MSDSS, such as modifying wakeup interval values and setting the maximum number of failed objects.

**Services for NetWare Tools**
Windows Server 2003 includes several tools that allow you to determine computer configuration settings and perform diagnostic tests to resolve communication problems in an IPX/SPX network environment used for Services for NetWare 5.03.

**Dsa.msc: Active Directory Users and Computers**
**Category**
An Active Directory Administrative Tools MMC snap-in that is automatically installed on all Windows Server 2003 domain controllers running Windows Server 2003.

### Version compatibility

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Active Directory Users and Computers provides a graphical user interface that can be used to manage users and computers in Active Directory domains.

**Ipxroute**
**Category**
**Ipxroute** can be used to display and modify information about the routing tables used by the IPX protocol.

**Version compatibility**

**Ipxroute** is available in Windows Server 2003, Windows 2000 Server, and Windows XP Professional.

Ipxroute enables you to troubleshoot IPX connectivity problems and provides information about the current state of the stack. Ipxroute also displays information such as current IPX status, network number, MAC address, interface name, frame type, and so on.

For example, to display information at the command-line interface for all bindings on which IPX is configured, use the ipxroute command with the **config** argument, as follows:

```
C:\>ipxroute config
```

To determine if there is connectivity to a specific network, use the **ipxroute** command with the **ripout** argument as follows:

```
C:\>ipxroute ripout <network number>
```

where <*network number*> is the 8-digit hexadecimal network number.

You can also view additional information about **ipxroute** options, which might assist you in troubleshooting connectivity problems. To do this, use the help switch for **ipxroute**, as follows:

```
C:\>ipxroute /?
```

**Network Monitor**
**Category**
**Network Monitor** is a utility for monitoring, recording, and analyzing network traffic.

**Version compatibility**
Network Monitor is part of the Microsoft Systems Management Server (SMS) product. A limited version, which can capture frames that are sent to or from the network adapter of the computer on which Network Monitor is installed, is included with Windows Server 2003 and can be installed as an optional networking component. You can use NetMon to identify network traffic patterns and to perform other tasks associated with finding network problems, such as the following:

- Locating client-to-server connection problems.
- Identifying computers that make a disproportionate number of service requests.
- Capturing frames (packets) directly from the network.
- Displaying and filtering captured frames.
- Identifying unauthorized users on a network.

**Services for NetWare Registry Entries**
The following registry entries are associated with Services for NetWare.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**Note**

- For information about additional Services for NetWare registry entries for MSDSS and FMU, see the Services for Netware 5.03 online Help.

**HKEY_LOCAL_MACHINE\SYSTEM**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM CurrentControlSet\Services\MSDSS\Parameters.

**UseMemberAttribute**
**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\ CurrentControlSet\Services\MSDSS\Parameters

**Version**
The UseMemberAttribute registry setting is available in Microsoft Services for NetWare 5.03 on Windows Server 2003.

Set this value to 1 to migrate group "member"ships using the "member" attribute of the group object. If you set the value to 0, you use the "security equal to me" attribute.

When migrating groups from NDS to Active Directory, MSDSS reads the "security equal to me" attribute by default and migrates those group members to Active Directory. Some NetWare administration tools (particularly those that operate in Bindery mode) add "member"s only to the "member" attribute. This causes a discrepancy between the group memberships displayed in NDS, eDirectory, and Active Directory after some migrations. If you experience this, set the value to 1 to allow NDS and eDirectory group members that are not marked as "security equal to me" to be migrated to Active Directory.

**SyncIntervalForward or SyncIntervalReverse**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\MSDSS\Parameters

**Version**
The SyncIntervalForward and SyncIntervalReverse registry settings are available in Microsoft Services for NetWare 5.03 running on Windows Server 2003.

To modify the wakeup interval values, you can add the DWORD values SyncIntervalForward and SyncIntervalReverse to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\MSDSS\Parameters.

After these values have been added, you can indicate the wakeup interval time in seconds.

**MaxFailedObjects**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\MSDSS\Parameters

**Version**
The MaxFailedObjects registry setting is available in Microsoft Services for NetWare 5.03 running on Windows Server 2003.

To modify the default value of objects that cannot be retried, you can add the DWORD value MaxFailedObjects to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\MSDSS\Parameters.

A value of 0 in MaxFailedObjects means there is no limit for the number of failed objects.

**BackupInterval**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\MSDSS\Parameters

**Version**
The BackupInterval registry setting is available in Microsoft Services for NetWare 5.03 running on Windows Server 2003.

To modify the default backup interval, create a DWORD value named BackupInterval and specify a custom interval, in seconds.

**SyncEmailAddress**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\MSDSS\Parameters

**Version**
The SyncEmailAddress registry setting is available in Microsoft Services for NetWare 5.03 running on Windows Server 2003.

You can disable the "mail" synchronization attribute by setting the DWORD value to 0 in the SyncEmailAddress registry key.

**SamRename**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\\CurrentControlSet\Services\MSDSS\Parameters

**Version**
The SamRename registry setting is available in Microsoft Services for NetWare 5.03 running on Windows Server 2003.

Active Directory, NDS, and eDirectory handle logon names differently. Active Directory provides separate attributes for logon name (samAccountName) and object naming in the directory hierarchy (that is, the relative distinguished name). NDS and eDirectory use the same attribute (that is, CN) for both purposes. The initial release of MSDSS synchronizes the directory object name (that is, the relative distinguished name maps to the CN) but does not synchronize the logon names. MSDSS in Services for NetWare 5.03 provides an option for synchronizing logon names between Active Directory, NDS, and eDirectory.

Setting the value to 1 enables MSDSS to keep both the samAccountName and relative distinguished name attributes of a user object in Active Directory synchronized with the CN attribute of the corresponding NDS or eDirectory user object.

**Note**

- The session must be a two-way synchronization session to synchronize changes in NDS or eDirectory to Active Directory.

# Remote Access Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote Access Technologies**
In the Microsoft Windows Server 2003 operating system, remote access technologies allow IT professionals to perform administrative tasks and users to run programs on a remote computer as if they were working locally.

**Remote Access Technologies Components**
Dial-up Remote Access, Telnet, and Terminal Services are included in Windows Server 2003 as remote access technologies.

**Dial-up Remote Access**
Dial-up Remote Access is a remote access technology that is available as part of the Routing and Remote Access services included in Microsoft Windows Server 2003. A dial-up remote access client uses the telecommunications infrastructure to create a temporary physical circuit or a virtual circuit to a port on a remote access server. If the remote access server accepts the dial-up connection from the client, the server forwards packets between the client and the network to which the remote access server is attached.

**Telnet**
Windows Server 2003 and Windows XP Professional include Telnet Client and Telnet Server components, which allow users to make remote connections based on the Telnet protocol. By using Telnet Client and Telnet Server, you can create a remote command console session on a host. Using a local command prompt, you can run command-line programs, shell commands, and scripts in a remote command console session just as though you were locally logged on to the host.

**Terminal Services**
The Terminal Services component of the Windows Server 2003 operating system delivers the Windows Server 2003 desktop and the latest Windows-based applications to a variety of desktops, including those that normally cannot run Windows.

Terminal Services provides the ability to host multiple, simultaneous client sessions on Windows Server 2003. Through terminal emulation, Terminal Services allows the same set of applications to run on diverse types of desktop hardware. For organizations wanting to more flexibly deploy applications and control desktop management costs, a Terminal Services architecture offers an important enhancement to the traditional two- or three-tier client-server architecture based on servers and full-scale personal computers.

Terminal Services also provides Remote Desktop for Administration, which can greatly reduce the overhead associated with remote administration. Enabled by Terminal Services technology, Remote Desktop for Administration is specifically designed for server management. Therefore, it does not install the application-sharing and multi-user capabilities or the process scheduling of the full Terminal Server component (formerly called Terminal Services in Application Server mode).

**Remote Access Technologies Scenarios**
In a dial-up remote access scenario, a remote access client uses the telecommunications infrastructure to create a temporary physical or virtual circuit to transparently connect the remote access client to a network. The physical or logical connection between the remote access server and the remote access client is created using available dial-up equipment. The dial-up equipment and network infrastructure can vary, depending on the type of connection used. For example, a dial-up connection can be made using the Public Switched Telephone Network (PSTN), Integrated Services Digital Network (ISDN), X.25, or Asynchronous Transfer Mode (ATM) over asymmetric digital subscriber line (ADSL).

Telnet Client and Telnet Server are well suited for troubleshooting and configuring remote computers, especially in mixed environments that require interoperability between different operating systems. For example, you can use Windows Server 2003 Telnet Client to connect to a Telnet server that is running another operating system, such as UNIX. Likewise, you can use a Telnet client that is running UNIX to connect to a computer running Windows Server 2003 Telnet Server. Telnet Client and Telnet Server are also ideal in situations in which memory and processor resources are minimal on a client or host or in which network bandwidth is limited. This is because Telnet Clients and Telnet Server use less memory and processor time than other remote management tools, and Telnet clients and servers transmit only plaintext (unencrypted characters) across the network.

Organizations are always searching for ways to reduce the costs of ownership and this is one of the major goals of Terminal Services. Terminal Services lets enterprises more easily and cost-effectively accomplish this goal by allowing organizations to:

- Centrally deploy and manage Windows-based applications.
- Remotely administer Windows Server 2003-based computers.

Terminal Services extends the model of distributed computing by allowing computers to operate in a server-based computing environment. With Terminal Services running on a Windows Server 2003-based computer, all client application execution, data processing, and data storage occur on the server. Applications and user desktops are transmitted over the network and displayed through terminal emulation software. Similarly, print streams, keyboard input, and mouse clicks are also transmitted over the network between the server and the terminal emulation software. Users log on and see only their individual session, which is managed transparently by the server operating system and is independent of any other client session.

Remote Desktop for Administration allows for the management of servers from any location without affecting server performance or application compatibility. In addition to the console session, up to two remote administration sessions are supported. Because it is meant as a single-user remote access solution, no Terminal Server Client Access License (CAL) is required to use Remote Desktop for Administration.

Administrators can also fully administer computers running Windows Server 2003 from computers running earlier versions of Windows by installing Remote Desktop Connection.

# Dial-up Remote Access Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft® Windows Server™ 2003 provides extensive support for technology that connects remote clients to corporate networks or the Internet. This technical reference describes the remote access connectivity type known as dial-up remote access.

Dial-up remote access is a remote access technology that is available as part of Routing and Remote Access that is included in Windows Server 2003. With dial-up remote access, a remote access client uses the telecommunications infrastructure to create a temporary physical or virtual circuit to a port on a remote access server, which is typically attached to a corporate network.

# What Is Dial-up Remote Access?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Dial-up Remote Access?**

**In this section**

- Dial-up Remote Access vs. VPN
- Components of a Dial-up Remote Access Connection
- Components of Secure Remote Access
- Dial-up Remote Access Dependencies
- Related Information

Dial-up remote access is a remote access technology that is available as part of Routing and Remote Access that is included in Microsoft Windows Server 2003.

Organizations require a simple solution that allows employees to remotely access their corporate e-mail accounts and shared files from home or from other locations outside the corporate network. Dial-up remote access provides the solution by enabling a remote access client to use the wide area network (WAN) infrastructure to connect to a remote access server.

**Dial-up Remote Access vs. VPN**

Windows Server 2003 remote access provides two different types of remote access connectivity: dial-up remote access and virtual private network (VPN) remote access.

- With dial-up remote access, a remote access client uses the telecommunications infrastructure to create a temporary physical circuit or a virtual circuit to a port on a remote access server. After the physical or virtual circuit is created, the rest of the connection parameters can be negotiated.
- With virtual private network remote access, a VPN client uses an IP internetwork to create a virtual point-to-point connection with a remote access server acting as the VPN server. After the virtual point-to-point connection is created, the rest of the connection parameters can be negotiated.

**Demand-Dial Routing**

Demand-dial routing is not a technology, but a process by which packets are forwarded across a Point-to-Point Protocol (PPP) link. Demand-dial routing is used by remote access technologies—dial-up remote access and VPN, as well as routing technologies—unicast routing, multicast routing, and network address translation (NAT). For more information about demand-dial routing, see "Demand Dial Routing Technical Reference."

**Components of a Dial-up Remote Access Connection**

A dial-up remote access connection contains the following components:

- Remote access client
- Remote access server
- WAN infrastructure.

**Components of a Dial-up Remote Access Connection**

**Remote Access Client**

Remote access clients running Windows Server 2003, Windows XP, Windows 2000, Windows NT 4.0, Windows Millennium Edition, and Windows 98 can connect to a Windows Server 2003 remote access server. Almost any PPP remote access client, including UNIX and Macintosh, can connect to a Windows Server 2003 remote access server.

**Remote Access Server**

The Windows Server 2003 remote access server accepts dial-up connections and forwards packets between remote access clients and the network to which the remote access server is attached.

### Note

- The term remote access server as it is used in this section refers to a Windows Server 2003 computer running Routing and Remote Access and configured to provide remote access.

**Dial-up Equipment and the WAN Infrastructure**

The physical or logical connection between the remote access server and the remote access client is facilitated by dial-up equipment installed at the remote access client, the remote access server, and the WAN infrastructure. The nature of the dial-up equipment and WAN infrastructure varies, depending on the type of connection.

The following telecommunications technologies can make up the WAN infrastructure:

- Public Switched Telephone Network (PSTN)
- Integrated Services Digital Network (ISDN)
- X.25
- Asynchronous Transfer Mode (ATM) over asymmetric digital subscriber line (ADSL)

**PSTN**

PSTN, also known as Plain Old Telephone Service (POTS), is the most common network used for dial-up remote access. PSTN is the analog phone system designed to carry the minimum frequencies required to distinguish human voices.

Dial-up equipment consists of an analog modem at the remote access client and at least one analog modem at the remote access server. For large organizations, the remote access server is attached to a modem bank containing up to hundreds of modems. Because PSTN was not designed for data transmission, there are limits to the maximum bit rate of a PSTN connection. The maximum bit rate supported by PSTN connections is 33,600 bits per second or 33.6 kilobits per second (Kbps).

### Standard PSTN Connection

**Digital Links and V.90**

The maximum bit rate of PSTN depends on the range of frequencies being passed by PSTN switches and the signal-to-noise ratio of the connection. The modern-day analog phone system is only analog on the local loop, the set of wires that connect the customer to the central office (CO) PSTN switch. After the analog signal reaches the PSTN switch, it is converted to a digital signal. The analog-to-digital conversion introduces noise on the connection known as quantization noise.

When a remote access server is connected to a CO by using a digital switch based on T-Carrier or ISDN rather than an analog PSTN switch, there is no analog-to-digital conversion when the remote access server sends information to the remote access client. Because there is no quantization noise in the path back to the remote access client, there is a higher signal-to-noise ratio and, therefore, a higher maximum bit rate.

With this technology, called V.90, remote access clients can send data at 33.6 Kbps and receive data at 56 Kbps. In North America, the maximum receive bit rate is 53 Kbps due to Federal Communications Commission (FCC) power rules.

To obtain V.90 speeds, the following must be true:

- The remote access client must be using a V.90 modem.
- The remote access server must be using a V.90 digital switch and be connected to PSTN using a digital link, such as T-Carrier or ISDN.
- There cannot be any analog-to-digital conversions in the path from the remote access server to the remote access client.

**PSTN Connection with V.90**

**ISDN**

ISDN is a set of international specifications for a digital replacement of PSTN. ISDN provides a single digital network to handle voice, data, fax, and other services over existing local loop wiring. ISDN behaves like an analog phone line except that it is a digital technology with higher data rates and a much lower connection time. ISDN offers multiple channels, with each channel operating at 64 Kbps. Because the network is digital from end to end, there are no analog-to-digital conversions.

Dial-up equipment consists of an ISDN adapter for the remote access client and the remote access server. Remote access clients typically use Basic Rate ISDN (BRI) with two 64-Kbps channels; large organizations typically use Primary Rate ISDN (PRI) with 23 64-Kbps channels.

**ISDN Connection**

**X.25**

X.25 is an international standard for sending data across public packet-switching networks. Windows Server 2003 remote access supports X.25 in the following ways:

- The remote access client supports the use of X.25 smart cards, which can connect directly to the X.25 data network and use the X.25 protocol to establish connections and send and receive data. The remote access client also supports dialing into a packet assembler and disassembler (PAD) of an X.25 carrier using an analog modem.
- A remote access server only supports direct connections to X.25 networks by using an X.25 smart card.

**Note**

- X.25 smart cards are adapters that use the X.25 protocol and can directly connect to an X.25 public data network. X.25 smart cards are not related to smart cards used for authentication and secure communications. For more information about smart cards used for authentication, see "IAS Technical Reference."

**X.25 Connection**

**ATM over ADSL**

ATM is a fixed-length, cell-based, packet-switching technology that transmits data across an ATM network. Routing and Remote Access supports PPP connections over switched virtual circuit (SVC) or permanent virtual circuit (PVC) ATM connections. PPP connections over ATM require an ATM adapter with support for the physical connection to the ATM network. After it is installed, the ATM adapter appears as a dial-up device.

ADSL is a local loop technology for small business and residential customers. Although ADSL provides higher bit rates than PSTN and ISDN connections, the bit rate is not the same in the upstream and downstream directions. Typical ADSL connections offer 64 Kbps from the customer and 1.544 megabits per second (Mbps) to the customer. The asymmetric nature of the connection fits well with typical Internet use. Most Internet users receive a lot more information than they send.

ADSL equipment can appear to Windows Server 2003 as either an Ethernet interface or a dial-up interface. When an ADSL adapter appears as an Ethernet interface, the ADSL connection operates in the same way as an Ethernet connection to the Internet.

When an ADSL adapter appears as a dial-up device, ADSL provides a physical connection and the individual local area network (LAN) protocol packets are sent using ATM. An ATM adapter with an ADSL port is installed in both the remote access client and remote access server.

### ATM over ADSL Connection

**Remote Access Protocols**

Windows Server 2003 supports the following remote access protocols:

- PPP
- SLIP

**PPP**

PPP is an industry standard method of using point-to-point links to transport multi-protocol datagrams. A PPP-enabled connection can dial into remote networks through any industry-standard PPP server. PPP also permits a remote access server to receive calls from, and provide network access to, other vendors' remote access software that complies with the PPP standards. For more information about PPP, see "How Dial-up Remote Access Works." PPP is documented in RFC 1661.

**SLIP**

Serial Line Internet Protocol (SLIP) is an older remote access standard typically used by UNIX remote access servers. Routing and Remote Access supports SLIP for dial-up connections. Support for SLIP is included in the Windows remote access client to ensure interoperability with other remote access software. For more information about SLIP, see RFC 1055, A Nonstandard for Transmission of IP Datagrams Over Serial Lines: SLIP and RFC 1144, "Compressing TCP/IP Headers for Low-Speed Serial Links."

### Notes

- Windows Server 2003 and Microsoft Windows XP do not support SLIP for incoming connections.
- You must use the TCP/IP protocol and a serial COM port to connect to a SLIP server.

**LAN Protocols**
LAN protocols are the protocols used by the remote access client to access resources on the network connected to the remote access server. Windows Server 2003 remote access supports TCP/IP and AppleTalk. For more information about these protocols, see "How Dial-up Remote Access Works."

**Components of Secure Remote Access**
Because remote access is designed to transparently connect a remote access client to a network and its potentially sensitive data, the security of remote access connections is an important consideration. Windows Server 2003 remote access offers security features, such as secure user authentication, mutual authentication, data encryption, callback, caller ID, and smart card authentication. For more information about smart card authentication, see "IAS Technical Reference."

**Authentication vs. Authorization**
To understand why connection attempts are either accepted or denied, it is important to understand the distinction between authentication and authorization:

- Authentication is the verification of the credentials of the connection attempt. This process consists of sending the credentials from the remote access client to the remote access server in either plain text or an encrypted form by using an authentication protocol.

- Authorization is the determination that the connection attempt is allowed. Authorization occurs after successful authentication.

To be accepted, the connection attempt must be both authenticated and authorized. It is possible for the connection attempt to be authenticated by using valid credentials, but not authorized. In this case, the connection attempt is denied.

If a remote access server is configured for Windows Authentication, the security features of Windows Server 2003 are used to verify the credentials for authentication, and the dial-in properties of the user account and locally stored remote access policies are used to authorize the connection. If the connection attempt is both authenticated and authorized, the connection attempt is accepted. For more information, see "Remote Access Policies" later in this section.

If the remote access server is configured for Remote Authentication Dial-In User Service (RADIUS) authentication, the credentials of the connection attempt are passed to the RADIUS server for authentication and authorization. If the connection attempt is both authenticated and authorized, the RADIUS server sends an accept message back to the remote access server and the connection attempt is accepted. If the connection attempt is either not authenticated or not authorized, the RADIUS server sends a reject message back to the remote access server and the connection attempt is rejected.

If the RADIUS server is a computer running Internet Authentication Service (IAS), the IAS server performs authentication through selected authentication features and authorization through the dial-in properties of the user account and remote access policies stored on the IAS server.

**Secure User Authentication**
Secure user authentication is obtained through the encrypted exchange of user credentials. This is possible with the PPP remote access protocol using either the Challenge Handshake Authentication Protocol (CHAP), Shiva Password Authentication Protocol (SPAP), Microsoft Challenge Handshake Authentication Protocol version 1 (MS-CHAP), Challenge Handshake Authentication Protocol version 2 (MS-CHAP v2), or Extensible Authentication Protocol (EAP) authentication protocols. MS-CHAP, MS-CHAP v2, and EAP offer the most security. The remote access server can be configured to require a secure authentication method; if the remote access client cannot perform the required secure authentication, the connection is denied.

For more information about PPP authentication protocols, see "PPP Authentication Protocols" in How Dial-up Remote Access Works.

**Secure Authentication Scheme**
A secure authentication scheme provides protection against replay attacks, remote access client impersonation, and remote access server impersonation.

- A replay attack occurs when a person captures the packets of a successful connection attempt and then replays those packets in an attempt to obtain an authenticated connection.

- Remote access client impersonation occurs when a person takes over an existing authenticated connection. The intruder waits until the connection is authenticated and then obtains the connection parameters, disconnects the user, and takes control of the authenticated connection.

- Remote server impersonation occurs when a computer appears as the remote access server to the remote access client.

The impersonator appears to verify the remote access client credentials and then captures all of the traffic from the remote access client.

**Mutual Authentication**

Mutual authentication is obtained by authenticating both ends of the connection through the encrypted exchange of user credentials. This is possible with the PPP remote access protocol using either the EAP-Transport Level Security (EAP-TLS) or MS-CHAP v2 authentication protocols. If smart cards are used for remote access authentication, EAP-TLS is the required authentication method. During mutual authentication, the remote access client authenticates itself to the remote access server, and then the remote access server authenticates itself to the remote access client.

For more information about smart card authentication, see "IAS Technical Reference."

A remote access server does not always request authentication from the remote access client. However, in the case of a Windows Server 2003 remote access client configured for MS-CHAP v2 only or EAP-TLS only, the remote access client will force the mutual authentication of the client and server. If the remote access server does not respond to the authentication request, the connection is terminated by the client.

For more information about EAP-TLS, see "How Dial-up Remote Access Works."

**Data Encryption**

Data encryption protects the data sent between the remote access client and the remote access server. Remote access data encryption does not provide end-to-end data encryption. End-to-end encryption is data encryption between the client application and the server that hosts the resource or service being accessed by the client application. If end-to-end encryption is required, use Internet Protocol security (IPSec) to create an encrypted end-to-end connection after the remote access connection has been made.

### Note

- IPSec can also be used for encrypting a Layer Two Tunneling Protocol (L2TP) virtual private network connection. For more information, see "VPN Technical Reference."

Data encryption on a remote access connection is based on a secret encryption key known to the remote access server and remote access client. This shared secret key is generated during the user authentication process.

Data encryption is possible over dial-up remote access links when using the PPP remote access protocol and the EAP-TLS or MS-CHAP authentication protocols.

The remote access server can be configured to require data encryption. The remote access client can be configured to request the following levels of data encryption:

- No encryption (the server disconnects if it requires encryption).
- Optional encryption (connect even if there is no encryption).
- Require encryption (disconnect if the server declines).
- Maximum-strength encryption (disconnect if the server declines).

If the remote access client cannot perform the required encryption, the connection attempt is rejected.

Remote access clients and remote access servers running Windows Server 2003, Windows 2000, Windows NT 4.0, Windows 98, and Windows 95 use the Microsoft Point-to-Point Encryption (MPPE) Protocol. MPPE uses the Rivest-Shamir-Adleman (RSA) RC4 stream cipher and either 40-bit, 56-bit, or 128-bit secret keys. MPPE keys are generated from the MS-CHAP and EAP-TLS user authentication process.

**Callback**

With callback, the remote access server calls the remote access client after the user credentials have been verified. Callback is configured as part of the dial-in properties of the user account. Callback can also be configured on the server to call the remote access client back at a number specified by the user during the time of the call. A traveling user can reduce phone charges by dialing in and having the remote access server call back at the user's current location. Callback can also be configured to always call the remote access client back at a specific location, which is the secure form of callback.

**Caller ID**
Caller ID can be used to verify that the incoming call is coming from a specified phone number. Caller ID is configured as part of the dial-in properties of the user account. If the Caller ID number of the incoming connection for that user does not match the configured Caller ID, the connection is denied.

Caller ID requires that the caller's phone line, the phone system, the remote access server's phone line, and the Windows Server 2003 driver for the dial-up equipment all support Caller ID. If a Caller ID is configured for a user account and the Caller ID is not being passed from the caller to Routing and Remote Access, then the connection is denied.

Caller ID is a feature designed to provide a higher degree of security for networks that support telecommuters. The disadvantage of configuring Caller ID is that the user can dial in from a single phone line only.

**Secure Remote Access and IAS**
Internet Authentication Service (IAS) is the Microsoft implementation of a Remote Authentication Dial-In User Service (RADIUS) server and proxy. RADIUS is an industry standard for the client-server protocol. For more information about RADIUS, see RFC 2865, "Remote Authentication Dial-In User Service (RADIUS)" and RFC 2866, "RADIUS Accounting."

As a RADIUS server, IAS performs centralized connection authentication, authorization, accounting, and auditing (AAAA) for network access types that include dial-up remote access, VPN, wireless, and authenticating switch connections.

**Network Access Quarantine Control**
IAS Network Access Quarantine Control provides phased network access, which restricts remote clients to quarantine mode until each client is either verified as meeting, or configured according to, organization network access policy. Quarantine control can be applied when:

- The user connects directly to a dial-up remote access server on a private network.
- The user connects to an Internet Service Provider (ISP) through a modem, and then connects to a private network through a VPN connection over the Internet.

To implement Network Access Quarantine Control, you must use Connection Manager Administration Kit (CMAK), Routing and Remote Access, and additional components that include servers that perform name resolution (such as Domain Name System [DNS] servers), obtain the latest version of the Connection Manager profile, or access instructions and components required to make the remote access client comply with network policies.

For more information about Network Access Quarantine Control, see Network Access Quarantine Control in Windows Server 2003.

**Remote Access Policies**
In Windows Server 2003, remote access connections are accepted based on the dial-in properties of a user account and remote access policies. A remote access policy is a set of conditions and connection parameters that define the characteristics of the incoming connection and the set of constraints imposed on it. Remote access policies can be used to specify allowed connections conditioned by the time of day and day of the week, the Windows Server 2003 group to which the dial-in user belongs, the type of remote access client (dial-up or VPN), and so on. Remote access policies can be used to impose connection parameters such as maximum session time, idle disconnect time, required secure authentication methods, required encryption, and so on.

For information about how the processing of connection attempts involves remote access policies, see "How Dial-up Remote Access Works."

With multiple remote access policies, different sets of conditions can be applied to different remote access clients or different requirements can be applied to the same remote access client based on the parameters of the connection attempt. For example, multiple remote access policies can be used to:

- Allow or deny connections if the user account belongs to a specified group.
- Define different days and times for different user accounts based on group membership.
- Configure different authentication methods for dial-up and VPN remote access clients.
- Configure different authentication or encryption settings for Point-to-Point Tunneling Protocol (PPTP) or L2TP connections.

- Configure different maximum session times for different user accounts based on group membership.
- Send network access server-specific RADIUS attributes to a RADIUS client.
- When you have multiple Windows Server 2003 remote access or VPN servers and you want all of the servers to use a centralized set of remote access policies to authorize incoming connections, you must configure a computer to run Windows Server 2003 and IAS and then configure each remote access or VPN server as a RADIUS client to the IAS server computer.

For more information about remote access policies, see "IAS Technical Reference."

**Unauthenticated Connections**
Windows Server 2003 also supports unauthenticated PPP connections. In an unauthenticated PPP connection, the authentication phase of the PPP connection establishment is skipped. Neither the remote access client nor the remote access server exchange credentials. The use of unauthenticated PPP connections must be carefully considered because connections are allowed without verification of the identity of the remote access client.

There are two common cases in which unauthenticated connections are desired:

- When using Automatic Number Identification/Calling Line Identification (ANI/CLI) authentication, the authentication of a connection attempt is based on the phone number of the caller. ANI/CLI service returns the number of the caller to the receiver of the call and is provided by most standard telephone companies.

  ANI/CLI authentication is different from caller ID authorization. In caller ID authorization, the caller sends a valid user name and password. The caller ID that is configured for the dial-in property on the user account must match the connection attempt; otherwise, the connection attempt is rejected. In ANI/CLI authentication, a user name and password are not sent.

- When using guest authentication, the Guest account is used as the identity of the caller.

**Dial-up Remote Access Dependencies**
Dial-up remote access requires one of the following operating systems for the remote access server:

- Windows 2000 Server
- Windows Server 2003
- Windows XP (appropriately configured for incoming connections)

Dial-up remote access requires one of the following operating systems for the remote access client:

- Windows 98
- Windows Millennium Edition
- Windows 2000
- Windows 2000 Server
- Windows XP
- Windows Server 2003

Dial-up remote access requires the following protocols and interfaces:

- PPP

- Either TCP/IP or AppleTalk

# How Dial-up Remote Access Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Dial-up Remote Access Works**

**In this section**

- Remote Access Server Architecture
- Dial-up Remote Access Protocols
- Dial-up Remote Access Processes and Interactions
- Related Information

Dial-up remote access is a remote access technology that is available as part of Routing and Remote Access that is included in Windows Server 2003. With dial-up remote access, a remote access client uses the telecommunications infrastructure to create a temporary physical or virtual circuit to a port on a remote access server, which is typically attached to a corporate network.

The physical or logical connection between the remote access server and the remote access client is made possible through dial-up equipment installed at the remote access client, the remote access server, and the wide area network (WAN) infrastructure. The nature of the dial-up equipment and WAN infrastructure varies, depending on the type of connection.

The following telecommunications technologies can make up the WAN infrastructure:

- Public Switched Telephone Network (PSTN)
- Integrated Services Digital Network (ISDN)
- X.25
- Asynchronous Transfer Mode (ATM) over asymmetric digital subscriber line (ADSL)

For more information about dial-up remote access configurations with each of these telecommunications technologies, see "What Is Dial-up Remote Access?."

**Remote Access Server Architecture**

To understand how dial-up remote access works in Windows Server 2003, you must first understand the architecture of the remote access server. The following figure illustrates how the remote access server components work together.

**Remote Access Server Architecture**

The following table describes the remote access server components.

**Remote Access Server Components**

| Component | Description |
|---|---|

| | |
|---|---|
| Ndis.sys | The Network Driver Interface Specification (NDIS) wrapper provides the NDIS packet-level interface to the TCP/IP and AppleTalk protocols. |
| Ndiswan.sys | The NDISWAN driver is an intermediate NDIS driver that provides an IEEE 802.3 miniport interface to protocol drivers and a protocol interface to WAN miniport drivers. NDISWAN provides framing, compression, and encryption services for remote access connections. |
| WAN miniport driver | The WAN miniport driver contains the code required to operate the dial-up equipment. To use an adapter supporting WAN media, such as Integrated Services Digital Network (ISDN) or asynchronous transfer mode (ATM) with Windows Server 2003 remote access, the adapter vendor must create a WAN miniport driver. |
| Remote access components | These components are libraries that provide remote access programming interface for applications, Point-to-Point (PPP) protocols (link control, authentication, and network control protocols), and so on. Remote access components can communicate directly with the NDISWAN driver or by accessing the Telephony API (TAPI). |
| TAPI components | These components are libraries that provide a call control programming interface for all TAPI-aware applications. TAPI components communicate directly with the NDISWAN driver to manage connections. |

Routing and Remote Access can be invoked from the command line and is available to the following application programming interfaces (APIs):

- For the remote access server, MultiProtocol Routing (MPR) API.
- For the remote access client, remote access API.

For more information about the APIs associated with remote access, see the Windows Server 2003 Software Development Kit (SDK).

**Dial-up Remote Access Protocols**

Dial-up remote access uses PPP, a data link layer protocol that uses network layer protocols, including TCP/IP and AppleTalk, to transmit data across a WAN infrastructure.

This section describes PPP and the following protocols and methods that are part of the process when using PPP.

- PPP encapsulation, including PPP over Ethernet (PPPoE)
- PPP Link Control Protocol (LCP)
- Multilink Protocol (MP), Bandwidth Allocation Protocol (BAP), and Bandwidth Allocation Control Protocol (BACP)
- PPP Network Control Protocols (NCPs)
- PPP authentication protocols

PPP performs the following functions:

- Provides multiprotocol data-link layer encapsulation.

  PPP creates frames that contain separate Internet Protocol (IP) datagrams.

- Establishes, maintains, and ends the logical link.

  The PPP protocol uses LCP to establish and configure the parameters of the data-link connection. LCP negotiation includes the authentication of the credentials of the remote access client.

- Provides protocol configuration.

  After the data-link connection has been negotiated, NCPs such as Internet Protocol Control Protocol (IPCP) and AppleTalk Control Protocol (ATCP) negotiate parameters to configure PPP peers. For example, for IPCP, an IP address is allocated to

the remote access client by the remote access server. Compression and encryption are also negotiated.

**Note**

- PPP can terminate the link at any time. Termination generally occurs due to carrier loss, authentication failure, link quality failure, time-out, or link closure by the dial-up client or system administrator. When the link is closing, PPP informs the network layer protocols so that they can take appropriate action.

**PPP Encapsulation**

PPP encapsulation uses a variant of the International Organization for Standardization (ISO) High-Level Data Link Control (HDLC) protocol to encapsulate multiprotocol datagrams as the payload of PPP frames. The PPP header and trailer are shown in the following figure.

**PPP Encapsulation**

The fields are described as follows:

- **Flag** - Set to 0x7E (bit sequence 011111110) to signify the beginning and end of a PPP frame. In successive PPP frames, only a single Flag character is used.

  **Note**

  - The Flag character must not occur in the middle of the PPP frame. Character stuffing and bit stuffing are used to ensure that the Flag character occurs at the beginning and the end of the frame. For more information, see "Dial-up Remote Access Processes and Interactions" later in this section.

- **Address** - In HDLC environments, the Address field is used to address the frame to the destination node. On a point-to-point link, the destination node does not need to be addressed. Therefore, for PPP, the Address field is set to 0xFF, the broadcast address. If both PPP peers agree to perform address and control field compression during LCP negotiation, the Address field is not included.

- **Control** - In HDLC environments, the Control field is used for data-link layer sequencing and acknowledgments. PPP does not provide link-to-link reliable data transfer. Therefore, for all PPP frames, the Control field is set to 0x03 to indicate an unnumbered information frame. If both PPP peers agree to perform address and control field compression during LCP negotiation, the Control field is not included.

- **Protocol ID** - The 2-byte Protocol ID field identifies the protocol of the PPP payload. If both PPP peers agree to perform protocol field compression during LCP negotiation, the Protocol ID field is one byte for Protocol IDs in the range of 0x00-00 to 0x00-FF.

- **PPP Payload** - An encapsulation of IP datagrams or AppleTalk datagrams.

- **Frame Check Sequence (FCS)** - A 16-bit checksum that is used to check for bit-level errors in the PPP frame. If the receiver's calculation of the FCS does not match the FCS in the PPP frame, the PPP frame is silently discarded.

The maximum size of a PPP frame, known as the maximum receive unit (MRU), is determined during the negotiation of the logical link. The default MRU is 1,500 bytes. If the MRU is negotiated lower than 1,500 bytes, a PPP host must still have the ability to receive 1,500-byte frames in the event of link synchronization failure.

The following table lists typical values for the PPP Protocol ID.

**PPP Protocol IDs**

| Protocol | Protocol ID/Compressed Value |
|---|---|
| IP | 0x00-21 / 0x21 |
| AppleTalk | 0x00-29 / 0x29 |
| Van Jacobsen Compressed TCP/IP | 0x00-2D / 0x2D |
| Multilink | 0x00-3D / 0x3D |
| Microsoft Point-to-Point Compression Protocol (MPPC) | 0x00-FD / 0xFD |
| Microsoft Point-to-Point Encryption Protocol (MPPE) | 0x00-FD / 0xFD |

If MPPE or MPPC are negotiated, then the PPP Protocol ID is set to 0x00-FD. With MPPE and MPPC both using the same PPP Protocol ID, each peer must know that the resulting PPP payload either is encrypted or compressed, or both.

- If only MPPC is negotiated, then the PPP Protocol ID is set to 0x00-FD and the PPP payload is compressed.
- If only MPPE is negotiated, then the PPP Protocol ID is set to 0x00-FD and the PPP payload is encrypted.
- If both MPPC and MPPE are negotiated, then compression always occurs before encryption. The compressed PPP frame, consisting of the PPP protocol ID field set to 0xFD and the compressed data, is then encrypted and encapsulated with another PPP header consisting of the protocol ID field set to 0xFD and a 2-byte MPPE header.

**PPPoE**

PPPoE (PPP over Ethernet) is a method of encapsulating PPP frames so that they can be sent over an Ethernet network. PPPoE was created so that Internet service providers (ISPs) that deploy a broadband Internet access technology in a bridged Ethernet topology, such as cable modems or Digital Subscriber Line (DSL), can use the per-user authentication and connection identification facilities of PPP to identify individual customer connections for accounting and billing purposes. For more information about PPPoE, see RFC 2516.

The following figure shows a PPPoE frame.

**PPPoE Frame Structure**

The following are the fields in the PPPoE frame:

- **Preamble** - An 8-byte field that consists of 7 bytes of alternating 1s and 0s (each byte is the bit sequence 10101010) to synchronize a receiving station and a 1-byte 10101011 sequence that indicates the start of a frame. The Preamble provides receiver synchronization and frame delimitation services.
- **Destination Address** - A 6-byte field that indicates the destination's address. The destination can be a unicast, a multicast, or the Ethernet broadcast address. The unicast address is also known as an individual, physical, hardware, or media access control (MAC) address. For the Ethernet broadcast address, all 48 bits are set to 1 to create the address 0xFF-FF-FF-FF-FF-FF.
- **Source Address** - A 6-byte field that indicates the sending node's unicast address.

- **EtherType** - The Ethernet II header for PPPoE frames. EtherType is set to 0x88-63 for PPPoE discovery frames and 0x88-64 for PPP session frames. For more information about Ethernet II, see RFC 894.

- **Version** - A 4-bit field that is set to the value of 1.

- **Type** - A 4-bit field that is set to the value of 1.

- **Code** - A 1-byte field that is used to identify the type of PPPoE message. There are defined values for the PPPoE frames exchanged during the discovery phase. For PPP session frames, the Code field is set to 0.

- **Session_ID** - A 2-byte field that identifies the PPPoE session ID. This field is set to 0 until a session ID is negotiated with the access concentrator (AC) during the discovery phase of the PPPoE connection.

- **Length** - A 2-byte field that is used to indicate the size, in bytes, of the PPPoE payload.

- **PPPoE Payload** - A variable-sized payload that can contain either one or more PPPoE tags for PPPoE frames sent during the discovery phase or PPP frames for the PPP session phase. PPPoE tags are information elements in type-length-value (TLV) format. Typical PPPoE tags used during the discovery phase are Service-Name (the name of the ISP or service offered by the AC) and AC-Name (the name of the AC). For a complete list of PPPoE tags and their structure, see RFC 2516.

- **Frame Check Sequence (FCS)** - A 4-byte field that provides bit-level integrity verification on the bits in the Ethernet II frame. The FCS is also called a cyclical redundancy check (CRC). The source node calculates the FCS and places the result in this field. When the destination receives the FCS, it runs the same CRC algorithm and compares its own value with the one placed in the FCS field by the source node. If the two values match, the frame is considered valid and the destination node processes it. If the two values do not match, the frame is silently discarded.

For more information about the PPPoE connection process, see "Dial-up Remote Access Processes and Interactions" later in this section.

**LCP**

LCP (Link Control Protocol) negotiates link and PPP parameters to dynamically configure the data link layer of a PPP connection. Common LCP options include the PPP MRU, the authentication protocol, compression of PPP header fields, callback, and multilink options. For more information about LCP, see RFC 1661.

**LCP Packet Structure**

LCP uses the PPP Protocol ID of 0xC0-21. The packet structure of LCP is illustrated in the following figure. Each LCP packet is a single LCP message that consists of an LCP Code field identifying the type of LCP packet; an Identifier field so that requests and replies can be matched; a Length field indicating the size of the LCP packet; and LCP packet type-specific data.

**LCP Packet Structure**

The following table lists the LCP packet types.

**LCP Packet Types**

| LCP Code | LCP Packet Type | Description |
|---|---|---|

| | | |
|---|---|---|
| 1 | Configure-Request | Sent to open or reset a PPP connection. Configure-Request contains a list of LCP options with changes to default option values. |
| 2 | Configure-Ack | Sent when all of the values of all of the LCP options in the last Configure-Request received are recognized and acceptable. When both PPP peers send and receive Configure-Acks, the LCP negotiation is complete. |
| 3 | Configure-Nack | Sent when all the LCP options are recognized, but the values of some options are not acceptable. Configure-Nack includes the offending options and their acceptable values. |
| 4 | Configure-Reject | Sent when LCP options are not recognized or not acceptable for negotiation. Configure-Reject includes the unrecognized or non-negotiable options. |
| 5 | Terminate-Request | Optionally sent to close the PPP connection. |
| 6 | Terminate-Ack | Sent in response to the Terminate-Request. |
| 7 | Code-Reject | Sent when the LCP code is unknown. The Code-Reject message includes the offending LCP packet. |
| 8 | Protocol-Reject | Sent when the PPP frame contains an unknown Protocol ID. The Protocol-Reject message includes the offending LCP packet. Protocol-Reject is typically sent by a PPP peer in response to a PPP NCP for a local area network (LAN) protocol not enabled on the PPP peer. |
| 9 | Echo-Request | Optionally sent to test the PPP connection. |
| 10 | Echo-Reply | Sent in response to an Echo-Request. The PPP Echo-Request and Echo-Reply are not related to the Internet Control Message Protocol (ICMP) Echo Request and Echo Reply messages. |
| 11 | Discard-Request | Optionally sent to exercise the link in the outbound direction. |

**LCP Options**

When using the Configure-Request, Configure-Ack, Configure-Nack, and Configure-Reject LCP packet types, the LCP data portion of the LCP packet consists of one or more LCP options, as illustrated in the following figure. Each LCP option consists of an option Type field; a Length field indicating the total length, in bytes, of the option; and the data associated with the option.

**LCP Options**

The following table lists common LCP options negotiated by Microsoft PPP peers.

**LCP Options**

| Option Name | Option Type | Option Length | Description |
|---|---|---|---|
| Maximum Receive Unit (MRU) | 1 | 4 | The maximum size (up to 65,535) of the PPP frame. The default MRU is 1,500. If neither peer is changing the default, this option is not negotiated. |

| | | | |
|---|---|---|---|
| Asynchronous Control Character Map (ACCM) | 2 | 6 | A bit map that enables (bit set to 1) or disables (bit set to 0) the use of character escapes for asynchronous links for the 32 ASCII control characters from 0x00 to 0x20. By default, character escapes are used. The ACCM bit map is set to 0x00-00-00-00 for links with XON/XOFF software flow control. |
| Authentication Protocol | 3 | 5 or 6 | Indicates the authentication protocol used during the authentication phase of the connection. Values for this field for Microsoft PPP peers are 0xC2-27 for Extensible Authentication Protocol (EAP); 0xC2-23-80 for Microsoft Challenge Handshake Authentication Protocol version 1 (MS-CHAP); 0xC2-23-81 for MS-CHAP version 2; 0xC2-23-05 for Message Digest 5 Challenge Handshake Authentication Protocol (MD5-CHAP); 0xC0-27 for Shiva Password Authentication Protocol (SPAP); and 0xC0-23 for PAP. |
| Magic Number | 5 | 6 | A random number chosen to distinguish a peer and detect looped back lines. |
| Protocol Compression | 7 | 2 | A flag indicating that the PPP Protocol ID be compressed to a single octet when the 2-byte Protocol ID is in the range of 0x00-00 to 0x00-FF. |
| Address and Control Field Compression | 8 | 2 | A flag indicating that the PPP Address field (always set to 0xFF) and the PPP Control field (always set to 0x03) must be removed from the PPP header. |
| Callback | 13 or 0x0D | 3 | A 1-octet indicator of how callback is to be determined. For remote access clients and servers running Microsoft Windows 32-bit operating systems, the callback option octet is set to 0x06, indicating that the callback is determined during Callback Control Protocol (CBCP) negotiation. |

**NCP**

After the link and PPP parameters have been negotiated with LCP, the PPP peers then use a series of NCPs (Network Control Protocols) to negotiate the parameters of individual LAN protocols. Microsoft PPP supports the NCPs listed in the following table.

### Network Control Protocols

| Protocol | Description |
|---|---|
| IPCP | IPCP negotiates the use of IP. |
| ATCP | ATCP negotiates the use of AppleTalk. |
| Compression Control Protocol (CCP) | CCP packets are exchanged to configure MPPC (Microsoft Point-to-Point Compression Protocol) and MPPE (Microsoft Point-to-Point Encryption Protocol). |
| BACP (Bandwidth Allocation Control Protocol) | Working with MP (Multilink Protocol) and BAP (Bandwidth Allocation Protocol), BACP elects a favored peer in case both PPP peers request to add or remove a connection at the same time. |

**IPCP**

IPCP (Internet Protocol Control Protocol) as used by Microsoft PPP peers is documented in RFC 1332 and RFC 1877. IPCP negotiates IP-based parameters to dynamically configure a TCP/IP-based PPP peer across a point-to-point link. Common IPCP options include an IP address and the IP addresses of Domain Name System (DNS) servers.

**Packet Structure**

IPCP uses the PPP Protocol ID of 0x80-21. The packet structure of IPCP is exactly the same as LCP, except only packet types 1 through 7 are defined. For Configure-Request, Configure-Ack, Configure-Nack, and Configure-Reject IPCP packet types, the IPCP data portion of the IPCP packet consists of one or more IPCP options. Each IPCP option consists of an Option Type field; an Option Length field indicating the total length, in bytes, of the option; and the data associated with the option.

**Negotiated Options**

The following table lists the IPCP options negotiated by Microsoft PPP peers.

### IPCP Options

| Option Name | Option Type | Option Length | Description |
|---|---|---|---|

| | | | |
|---|---|---|---|
| IP compression protocol | 2 | 4 | The Van Jacobsen TCP compression protocol. |
| IP address | 3 | 6 | The IP address to be allocated to the remote access client. |
| Primary DNS server address | 129 or 0x81 | 6 | The primary DNS server for the remote access client. |
| Primary NBNS server address | 130 or 0x82 | 6 | The primary NBNS (WINS) server for the remote access client. |
| Secondary DNS server address | 131 or 0x83 | 6 | The secondary DNS server for the remote access client. |
| Secondary NBNS server address | 132 or 0x84 | 6 | The secondary NBNS (WINS) server for the remote access client. |

There are no IPCP options for these common TCP/IP configuration items:

- Subnet mask

  The subnet mask is assumed by the remote access client to be the class-based subnet mask of the IP address that is allocated to the remote access client.

- Default gateway

  The default gateway IP address is not allocated by the remote access server. However, a default route is created on the remote access client, which points to the remote access connection. If a default route already exists in the routing table, then the metric of the existing default route is increased and a new default route is added with a lower metric. This is the default behavior for remote access clients running Windows 32-bit operating systems. This behavior can be modified by disabling the **UseDefault Gateway on Remote Network** setting on the TCP/IP properties of a remote access client's phone book entry or dial-up connection object.

- DNS domain name

  The DNS domain name configured from the TCP/IP protocol properties on the remote access server is not negotiated during IPCP. For Windows Server 2003 remote access clients, the DNS domain name can be obtained through a DHCPInform message. For more information, see "TCP/IP Configuration for Remote Access Clients" later in this section.

**ATCP**

ATCP (AppleTalk Control Protocol) as used by Microsoft PPP peers is documented in RFC 1378. ATCP negotiates AppleTalk-based parameters to dynamically configure an AppleTalk-based PPP peer across a point-to-point link. Common ATCP options include AppleTalk address and server information.

**Packet Structure**

ATCP uses the PPP Protocol ID of 0x80-29. The packet structure of ATCP is exactly the same as the packet structure for LCP, except that only packet types 1 through 7 are defined. For Configure-Request, Configure-Ack, Configure-Nack, and Configure-Reject ATCP packet types, the ATCP data portion of the ATCP packet consists of one or more ATCP options. Each ATCP option consists of an option Type field; an option Length field indicating the total length, in bytes, of the option; and the data associated with the option.

**Negotiated Options**

The following table lists the ATCP options negotiated by Microsoft PPP peers.

### ATCP Options

| Option Name | Option Type | Option Length | Description |
|---|---|---|---|
| AppleTalk Address | 1 | 6 | Negotiates the AppleTalk network and node numbers. |
| Server Information | 3 | 16 | Used to convey information about the remote access server. |

**CCP**

CCP (Compression Control Protocol) is documented in RFC 1962. CCP negotiates parameters to dynamically configure, enable, and disable data compression algorithms between PPP peers across a point-to-point link. Common CCP options include an organization identifier and the use of MPPC.

**Packet Structure**
CCP uses the PPP Protocol ID of 0x80-FD. The packet structure of CCP is exactly the same as the packet structure for LCP, except only packet types 1 through 7 are defined. For Configure-Request, Configure-Ack, Configure-Nack, and Configure-Reject CCP packet types, the CCP data portion of the CCP packet consists of one or more CCP options. Each CCP option consists of an option Type field; an option Length field indicating the total length, in bytes, of the option; and the data associated with the option.

**Negotiated Options**
The following table lists the CCP options negotiated by Microsoft PPP peers.

### CCP Options

| Option Name | Option Type | Option Length | Description |
|---|---|---|---|
| Organization Unique Identifier | 0 | 6 or larger | Used to negotiate an organization's proprietary compression protocol. |
| MPPC | 18 or 0x12 | 6 | Used to indicate the use of MPPC, MPPE, and the encryption strength. |

**MPPE and MPPC**
With CCP option 18, Microsoft PPP peers negotiate both MPPC and MPPE at the same time. The option data field for CCP option 18 is 4 bytes (32 bits) long. Bits within this data field are used as flags to indicate:

- Whether compression is enabled (0x00-00-00-01).
- Whether 40-bit session keys are derived from the LAN Manager version of the user's password (0x00-00-00-10).
- Whether 40-bit session keys are derived from the Windows NT version of the user's password (0x00-00-02-00).
- Whether 56-bit session keys are derived from the Windows NT version of the user's password (0x00-00-00-80).
- Whether 128-bit session keys are derived from the Windows NT version of the user's password (0x00-00-00-40).
- Whether the encryption keys are refreshed with each PPP frame (0x01-00-00-00).

For multiple choices, the flag values are added together. For example, for compression (0x00-00-00-01) and 128-bit encryption keys (0x00-00-00-40), the resulting 32-bit option data field is set to 0x00-00-00-41.

### Note

- The Encryption Control Protocol (ECP) is used to negotiate a specific encryption method and is documented in RFC 1968. However, for Microsoft PPP peers, the only supported encryption is MPPE, which is negotiated during CCP with the negotiation of MPPC. Therefore, Microsoft PPP peers do not use ECP.

**MP, BAP, and BACP**
Windows Server 2003 remote access supports the Multilink protocols listed in the following table.

### Multilink Protocols

| Protocol | Description |
|---|---|
| MP | Allows multiple physical links to appear as a single logical link over which data can be sent and received. |
| BAP | Used to dynamically add or remove additional links to an MP connection. |
| BACP | Elects a favored peer in case both PPP peers request to add or remove a connection at the same time. |

**MP**
MP is defined in RFC 1990 and used to aggregate multiple physical links into a single logical link. A good example is the aggregation of both B-channels of an ISDN Basic Rate Interface (BRI) connection. MP fragments, sequences, and re-orders

alternating packets sent across multiple physical connections so that the end result is a single logical link with the combined bandwidth of all of the aggregated physical links. MP is the recommended method of combining multiple B-channels of a BRI connection because the support for bonding, the combining of ISDN B-channels through hardware support, can be specific to the ISDN adapter. MP can be used for any ISDN adapter. MP must be supported on both sides of the connection.

The following figure illustrates the structure of an MP frame. The payload of a Multilink PPP packet is either a fragment of a PPP frame or the entire PPP frame. Multilink PPP fragmentation need not occur if the Multilink PPP packet fits within the MRU of the link. To prevent incorrect ordering of the datagrams or fragments across multiple links, additional fields are used between the PPP Protocol field and the IP datagram. Multilink PPP uses the PPP Protocol ID of 0x00-3D.

**Multilink PPP**

RFC 1717 defines two different packet formats for short sequence numbers and long sequence numbers. The sequence number is used to prevent the misordering of frames that are sent across multiple links, not to sequence fragments.

For short sequence numbers, a two-byte Delimitation/Sequence # field consists of four bits used for delimitation and 12 bits used for the sequence number. Within the delimitation field are two flags. The first bit (the Beginning bit) is an indicator that this fragment begins a sequence of fragments corresponding to a packet. The second bit (the Ending bit) is an indicator that this fragment ends a sequence of fragments corresponding to a packet. The other bits in the first four bits of the short sequence number header are set to 0.

For a PPP frame that is sent without fragmentation, both the Beginning and Ending bits are set. For a PPP frame that is larger than the MRU of the physical link, the PPP frame is fragmented, and each fragment is sent as a separate PPP packet. MP performs a data-link layer fragmentation that is not related to IP fragmentation.

For long sequence numbers, a four-byte Delimitation/Sequence # field consists of eight bits (one byte) used for delimitation, and 24 bits (3 bytes) used for the sequence number. Within the delimitation field, the same bits as the short sequence number header define the Beginning bit and the Ending bit. The other bits in the first byte of the long sequence number header are set to 0. The long sequence number header is used by default, unless the short sequence number is chosen during LCP negotiation.

The following table lists Multilink LCP options negotiated by Microsoft PPP peers. For information about other Multilink options, see RFC 1990.

**Multilink LCP Options**

| Option Name | Option Type | Option Length | Description |
|---|---|---|---|
| Multilink Maximum Receive Reconstructed Unit | 17 or 0x11 | 4 | Specifies the number of octets that a peer can reconstruct when performing reassembly of fragmented MP frames. |
| Short Sequence Number Header Format | 18 or 0x12 | 2 | Specifies the use of the short sequence number in the MP header. |
| Multilink Endpoint Discriminator | 19 or 0x13 | 9 | A unique system identifier to differentiate links from two PPP peers with the same authenticated name. |

**BAP**

Although MP allows for multiple physical links to be aggregated, MP does not provide a mechanism to adapt to changing conditions by adding extra links when needed or terminating extra links when unneeded. This additional capability is provided by BAP and BACP, as defined in RFC 2125. BAP is a PPP control protocol that is used on an MP connection to dynamically manage links. BAP uses the PPP Protocol of ID 0xC0-2D.

For example, an MP and BAP-enabled remote access client and remote access server create an MP connection consisting of a single physical link. As the use of the single link rises to a configured level, the remote access client uses a BAP Call-Request

message to request an additional link. The BAP Call-Request message specifies the type of link desired, such as analog phone, ISDN, or X.25. The remote access server then sends a BAP Call-Response message that contains the phone number of an available port on the remote access server of the same type specified by the remote access client in the BAP Call-Request.

When use on the second link drops to a specified level, either the remote access client or the remote access server can send a BAP Link-Drop-Query-Request message to drop the link.

BAP also supports a Callback-Request message in which the requesting peer specifies the link type and the number to call back. For more information about BAP messages, see RFC 2125.

The following table lists the BAP LCP option negotiated by Microsoft PPP peers.

**BAP LCP Option**

| Option Name | Option Type | Option Length | Description |
|---|---|---|---|
| BAP Link Discriminator | 23 or 0x17 | 4 | A unique number used to identify a link in a Multilink PPP connection. |

**BACP**

BACP is a PPP NCP that negotiates a single option: the election of a favored peer. If both peers of an MP and BAP-enabled connection send BAP Call-Request or BAP Link-Drop-Query-Request messages at the same time, the favored peer is the peer whose requests are implemented.

BACP uses the PPP Protocol ID of 0xC0-2B. The packet structure of BACP is exactly the same as the packet structure for LCP, except that only packet types 1 through 7 are defined. For Configure-Request, Configure-Ack, Configure-Nack, and Configure-Reject BACP packet types, the BACP data portion of the BACP packet consists of the single BACP Favored-Peer option listed in the following table.

**BACP Favored Peer Option**

| Option Name | Option Type | Option Length | Description |
|---|---|---|---|
| Favored-Peer | 1 | 6 | A randomly allocated 4-byte magic number used to elect a favored BAP peer. The favored peer is the peer with the lowest magic number. |

**PPP Authentication Protocols**

After both PPP peers agree on a single, specific PPP authentication protocol, authentication for PPP is accomplished through that protocol.

Windows Server 2003 remote access supports the PPP authentication protocols listed in the following table.

**PPP Authentication Protocols**

| Protocol | Description | Security Level |
|---|---|---|
| PAP ( Password Authentication Protocol) | Uses plaintext passwords. It is typically negotiated if the remote access client and remote access server cannot negotiate a more secure form of validation. | The least secure authentication protocol.<br><br>Does not protect against replay attacks, remote client impersonation, or remote server impersonation. |
| SPAP (Shiva Password Authentication Protocol) | A reversible encryption mechanism employed by Shiva remote access servers. | More secure than PAP, but less secure than CHAP or MS-CHAP.<br><br>Does not protect against remote server impersonation. |

| | | |
|---|---|---|
| CHAP (Challenge Handshake Authentication Protocol) | A challenge-response authentication protocol that uses the industry-standard Message Digest 5 (MD5) hashing scheme to encrypt the response. | An improvement over PAP and SPAP in that the password is not sent over the PPP link.<br><br>Requires a plaintext version of the password to validate the challenge response.<br><br>Does not protect against remote server impersonation. |
| MS-CHAP (Microsoft Challenge Handshake Authentication Protocol version 1) | A nonreversible, encrypted password authentication protocol that is similar to CHAP. | More secure than CHAP.<br><br>Requires an MD4 hash of the password to validate the challenge response.<br><br>Does not protect against remote server impersonation |
| MS-CHAP v2 (Microsoft Challenge Handshake Authentication Protocol version 2) | An upgrade of MS-CHAP. | Provides stronger security than MS-CHAP.<br><br>A comparison of MS-CHAP and MS-CHAP v2 features appears later in this section. |
| EAP (Extensible Authentication Protocol) | Allows for arbitrary authentication of a remote access connection through the use of authentication schemes known as EAP types. | Offers the strongest security by providing the most flexibility in authentication variations. |

For information about authentication processes for PPP authentication protocols, see "Dial-up and Remote Access Processes and Interactions" later in this section.

**PAP**

PAP is included in Windows Server 2003 so that:

- Remote access clients running Windows 32-bit operating systems can connect to older remote access servers that do not support a secure authentication protocol
- Remote access clients running Microsoft operating systems that do not support a secure remote access protocol can connect to remote access servers running Windows 32-bit operating systems.

**Note**

- To make your remote access server more secure, ensure that PAP is disabled. As a consequence, however, older remote access clients not running Microsoft operating systems that do not support secure authentication protocols will be unable to connect.

**SPAP**

A Windows Server 2003 remote access client can use SPAP to authenticate itself to a Shiva remote access server. A remote access client running Windows 32-bit operating systems can use SPAP to authenticate itself to a Windows Server 2003 remote access server.

**CHAP**

CHAP is used by vendors of dial-in servers and clients. CHAP is supported by both the Windows Server 2003 remote access server and remote access client.

CHAP protects against replay attacks by using an arbitrary challenge string per authentication attempt. Instead of sending the password over the link, the password is used to create a one-way hash from a challenge string. The server, knowing the client's password, can duplicate the operation and compare the result with that sent in the client's response.

CHAP requires that local or domain passwords are stored in a reversibly encrypted form.

**MS-CHAP**
As in CHAP, the remote access server sends a challenge that consists of a session ID and an arbitrary challenge string to the remote client. The remote client must return the user name and an MD4 hash of the challenge string, the session ID, and the MD4-hashed password.

One difference between CHAP and MS-CHAP is that, in CHAP, the plaintext version of the password must be available to validate the challenge response. With MS-CHAP, the remote access server requires only the MD4 hash of the password to validate the challenge response. In Windows Server 2003, the user's password is stored as an MD4 hash and in a reversibly encrypted form. When CHAP is used, the remote access server decrypts the reversibly encrypted password to validate the remote access client's response.

MS-CHAP also allows for error codes including a "password expired" code and password changes. MS-CHAP protects against replay attacks by using an arbitrary challenge string per authentication attempt.

If MS-CHAP is used as the authentication protocol and MPPE is negotiated, then shared secret encryption keys are generated by each PPP peer. MS-CHAP also provides a set of messages that allows a user to change the password during the user authentication process.

**MS-CHAP v2**
Windows Server 2003 includes support for MS-CHAP v2, which provides stronger security for remote access connections. The following table compares the security features of MS-CHAP to those of MS-CHAP v2.

**MS-CHAP and MS-CHAP v2 Security Feature Comparison**

| MS-CHAP | MS-CHAP v2 |
|---|---|
| LAN Manager encoding of the response used for backward compatibility with older Microsoft remote access clients is cryptographically weak. | LAN Manager-encoded responses are not allowed. |
| LAN Manager encoding of password changes is cryptographically weak. | LAN Manager-encoded password changes are not allowed. |
| Only one-way authentication is possible. The remote access client cannot verify that it is dialing in to its organization's remote access server or a masquerading remote access server. | Two-way authentication, also known as mutual authentication, is provided. The remote access client receives verification that the remote access server that it is dialing in to has access to the user's password. |
| With 40-bit encryption, the cryptographic key is based on the user's password. Each time the user connects with the same password, the same cryptographic key is generated. | The cryptographic key is always based on the user's password and an arbitrary challenge string. Each time the user connects with the same password, a different cryptographic key is used. |
| A single cryptographic key is used for data sent in both directions on the connection. | Separate cryptographic keys are generated for transmitted and received data. |

**EAP**
EAP is an extension to PPP that allows for arbitrary authentication mechanisms to be employed for the validation of a PPP connection. With PPP authentication protocols such as MS-CHAP and SPAP, a specific authentication mechanism is chosen during the link establishment phase. Then, during the connection authentication phase, the negotiated authentication protocol is used to validate the connection. The authentication protocol itself is a fixed series of messages sent in a specific order.

With EAP, the authentication mechanism is not chosen during the link establishment phase. Instead, each PPP peer negotiates to perform EAP during the connection authentication phase. After the connection authentication phase is reached, the PPP peers must first negotiate the use of a specific EAP authentication scheme known as an EAP type. After the EAP type is agreed on, EAP allows for an open-ended conversation between the remote access client and the remote access server that can vary based on the parameters of the connection. The conversation consists of requests for authentication information and the responses. The length and detail of the authentication conversation depends on the EAP type.

For example, when EAP is used with security token cards, the remote access server can separately query the remote access client for a name, PIN, and card token value. As each query is asked and answered, the user passes through another level of authentication. When all questions have been answered satisfactorily, the user is authenticated and permitted access to the network.

The use of EAP is negotiated during LCP negotiation by specifying the authentication protocol LCP option (type 3) and the authentication protocol 0xC2-27. After LCP negotiation is complete, EAP messages use the PPP Protocol ID of 0xC2-27.

Windows Server 2003 includes support for the MD5-Challenge and Extensible Authentication Protocol-Transport Level Security (EAP-TLS) EAP types.

EAP is designed to allow authentication plug-in modules at both the client and server ends of a connection. By installing an EAP type library file on both the remote access client and the remote access server, a new EAP type can be supported. This presents vendors with the opportunity to supply a new authentication scheme at any time. EAP provides the most flexibility in authentication uniqueness and variations.

**Note**

- Protected Extensible Authentication Protocol (PEAP) is used as an authentication method for 802.11 wireless client computers, but is not supported for other remote access clients. For more information, see the "IAS Technical Reference" and "802.11 Wireless Technical Reference."

**EAP Infrastructure**

EAP is a set of internal components that provide architectural support for EAP types. For successful authentication, both the remote access client and authenticator must have the same EAP authentication module installed. Windows Server 2003 provides two EAP types: MD5-Challenge and EAP-TLS. EAP-TLS is available only for members of a domain. In addition, EAP contains EAP-RADIUS, which is not an EAP type, but is used to send EAP messages to a RADIUS server for authentication.

You can also install additional EAP types. The components for an EAP type must be installed on every remote access client and every authenticator.

**MD5-Challenge**

MD5-Challenge is the CHAP authentication mechanism used within the EAP framework. Rather than negotiating to perform MD5-Challenge authentication during the link establishment phase, the authenticator and peer negotiate to use EAP during the connection authentication phase.

MD5-Challenge is a required EAP type and can be used to test EAP interoperability. Like CHAP, MD5-Challenge requires that local or domain passwords are stored in a reversibly encrypted form.

**EAP-TLS**

The Transport Layer Security (TLS) protocol, based on Secure Sockets Layer (SSL), allows applications to communicate securely. TLS provides authentication (user and data), data integrity, and data confidentiality services. To achieve these services, TLS specifies a framework that allows the following:

- Client and two-way authentication using symmetric or asymmetric encryption.
- Negotiation of the specific encryption algorithm (the cipher-suite).
- Secured exchange of encryption keys to be used for encrypting messages.
- Message integrity and user authentication using a message authentication code.

For more information about TLS, see RFC 2246. For more information about EAP-TLS, see RFC 2716.

EAP-TLS uses the TLS protocol for authentication during the establishment of a PPP connection. With EAP-TLS, mutual authentication between the PPP client and the authenticator is performed through the exchange and verification of certificates. The client attempting the connection sends a user certificate, and the authenticator sends a machine certificate. If smart cards are used for remote access authentication, EAP-TLS is the required authentication method. For more information about smart card authentication, see "IAS Technical Reference."

EAP-TLS is supported only on Windows Server 2003 remote access server computers that are members of a Windows Server 2003 mixed or native domain. Stand-alone Windows Server 2003 remote access servers do not support EAP-TLS.

**EAP-RADIUS**

EAP-RADIUS passes EAP messages of any EAP type by the remote access server to a RADIUS server for authentication. The EAP messages sent between the remote access client and remote access server are encapsulated and formatted as RADIUS messages between the remote access server and the RADIUS server. The remote access server becomes a pass-through device passing EAP messages between the remote access client and the RADIUS server. All processing of EAP messages occurs at the remote access client and the RADIUS server.

EAP-RADIUS is used in environments in which Remote Authentication Dial-In User Service (RADIUS) is used as the

authentication provider. An advantage of using EAP-RADIUS is that EAP types do not need to be installed at each remote access server, only at the RADIUS server.

In a typical use of EAP-RADIUS, the remote access server is configured to use EAP and to use RADIUS as its authentication provider. When a connection attempt is made, the remote access client negotiates the use of EAP with the remote access server. When the client sends an EAP message to the remote access server, the remote access server encapsulates the EAP message as a RADIUS message and sends it to its configured RADIUS server. The RADIUS server processes the EAP message and sends a RADIUS-encapsulated EAP message back to the remote access server. The remote access server then forwards the EAP message to the remote access client.

For more information about RADIUS support for EAP, see RFC 2869.

**CBCP**
The Microsoft implementation of PPP includes the optional use of CBCP (Callback Control Protocol) immediately after authentication.

CBCP negotiates the use of callback in those cases in which the remote access server, after authenticating the remote access client, terminates the physical connection, waits a specified amount of time, and then calls the remote access client back at either a static or dynamically configured phone number. Common CBCP options include the phone number that will be used by the remote access server to call back the remote access client.

**Packet Structure**
CBCP uses the PPP Protocol ID of 0xC0-29. The packet structure of CBCP is exactly the same as the packet structure for LCP; however, only the Callback-Request (type 1), Callback-Response (type 2), and Callback-Ack (type 3) types are used. For all CBCP packet types, the CBCP data portion of the CBCP packet consists of one or more CBCP options. Each CBCP option consists of an option Type field; an option Length field indicating the total length, in bytes, of the option; and the data associated with the option.

**Negotiated Options**
The following table lists the CBCP options negotiated by Microsoft PPP peers.

**CBCP Options**

| Option Name | Option Type | Option Length | Description |
|---|---|---|---|
| No callback | 1 | 2 | No callback is used for the connection. |
| Callback to a user-specified number | 2 | variable | The user of the remote access client computer determines the callback number. |
| Callback to an administrator-defined number | 3 | variable | Settings on the remote access server determine the callback number. |
| Callback to any of a list of numbers | 4 | variable | The remote access server calls back to one of a list of phone numbers. |

**Dial-up Remote Access Processes and Interactions**
This section describes the following processes that take place when establishing a dial-up remote access connection.

- Remote access connection
- TCP/IP configuration for Remote Access clients
- PPP connection
- Connection attempt processing with Remote Access policies
- Broadcast Name Resolution

**Remote Access Connection**
Connections are established by remote access clients that call the remote access programming interface, which, in turn, uses TAPI to pass call connection information to the dial-up equipment. After the physical connection is made, TAPI is no longer

used; other remote access components negotiate the connection with link, authentication, and network control protocols by communicating directly with NDISWAN.

After a remote access connection is established, protocol drivers can communicate over that connection using standard NDIS calls such as NdisSend(). NdisSend() calls for dial-up connections are forwarded to NDISWAN, which then determines the appropriate device and port, performs compression and encryption, provides PPP framing, and then forwards the completed frame to the WAN miniport driver. The WAN miniport driver then forwards the frame to the dial-up adapter.

All inbound remote access client connections, initiated by remote access clients to the remote access server, are represented as a single adapter called the remote access server interface. For each outbound remote access client connection, initiated by the remote access server, a separate interface is created.

To accept calls, the remote access server instructs each WAN miniport driver to indicate when it goes into a line-up state. When the call is placed, the WAN miniport driver passes the line-up state indicator through NDISWAN to the TAPI components. TAPI returns a call handle to NDISWAN to be used to refer to the physical connection, and then NDISWAN and the remote access components negotiate the rest of the remote access connection.

**IP and AppleTalk Routing with Remote Access Server**

After the remote access connection is established, the remote access client can begin sending LAN protocol traffic to the remote access server or to locations beyond the remote access server. When the remote access client sends LAN protocol traffic that is not destined for the remote access server, the remote access server must forward the LAN traffic to its appropriate destination. To accomplish this, the remote access server must have forwarding capabilities enabled on its routable protocols and act as an IP and AppleTalk router.

When Routing and Remote Access is installed and enabled to provide point-to-LAN remote access connectivity, it enables forwarding between the installed LAN adapters and the WAN miniport interface.

The following figure illustrates the remote access server architecture as it appears when routing IP packets. For simplicity, only IP routing is shown. However, AppleTalk routing operates in a similar way.

**IP Routing on the Remote Access Server**

**Packet Processing from Remote Access Clients**

The following process describes how IP packets sent by the remote access client are forwarded by the remote access server.

1. Depending on the dial-up technology, either the entire PPP frame is received by the WAN hardware and passed as a single frame to the appropriate WAN miniport driver, or individual bits of the PPP frame are passed to the appropriate WAN miniport driver.

2. The WAN miniport driver passes the PPP frame to Ndiswan.sys.

3. Ndiswan.sys verifies the PPP checksum and uses the PPP protocol ID to determine that it is an IP datagram.

4. The IP datagram is passed to the TCP/IP protocol driver.

5. The TCP/IP protocol driver, which is enabled for IP forwarding, determines a forwarding interface and an IP address based on the destination IP address in the IP datagram and the contents of its routing table.

6. To forward the IP datagram using the LAN adapter, the TCP/IP protocol calls NDIS with an NdisSend(), along with instructions to send it using the LAN adapter.

7. NDIS forwards the IP datagram to the appropriate LAN miniport driver.

8. The LAN miniport forwards the IP datagram to the LAN adapter through NDIS.

The end result is that packets from the remote access client are forwarded using the same IP routing process used for all IP routing. The success of the IP forwarding process depends on whether the remote access server can find a suitable entry in the IP routing table. Therefore, either the remote access server is configured with a default gateway, or the remote access server has specific routes to all the locations on the intranet to which the remote access server is attached. Specific routes can be added through static routes, or by enabling a routing protocol on the remote access server.

**Packet Forwarding to Remote Access Clients**
The following process describes how IP packets sent by intranet hosts to the remote access client are forwarded by the remote access server.

1. The LAN adapter passes a frame to its appropriate LAN miniport driver through NDIS. For information about how an IP datagram is forwarded to the MAC address of the remote access server, see "TCP/IP On-Subnet and Off-Subnet Addressing" in the next section.

2. The LAN miniport driver passes the IP datagram to the TCP/IP protocol driver through NDIS.

3. The TCP/IP protocol driver, which is enabled for IP forwarding, determines a forwarding interface and IP address based on the destination IP address in the IP datagram and the contents of its routing table. When the remote access client connects, a host route is created in the IP routing table for the IP address allocated to the remote access client that points to the remote access server interface.

4. To forward the IP datagram using the WAN adapter, the TCP/IP protocol calls NDIS with an NdisSend() with instructions to send it using NDISWAN and a specific connection handle.

5. NDISWAN resolves the connection handle to a specific device and port, adds a PPP header and trailer, and forwards the IP datagram to the appropriate WAN miniport driver through NDIS.

6. The WAN miniport driver forwards the IP datagram to the WAN adapter through NDIS.

The end result is that packets from intranet hosts are forwarded using the same IP routing process used for all IP routing. The success of the IP forwarding process depends on whether the IP addresses of remote access clients can be reached from the hosts on the intranet.

**TCP/IP On-Subnet and Off-Subnet Addressing**
The remote access server can be configured for on-subnet or off-subnet addressing. This addressing configuration determines how an IP node on a subnet to which the remote access server is attached resolves the MAC address of the remote access server.

- On-subnet addressing is the allocation of IP addresses to remote access clients that are in a range defined by a subnet to which the remote access server is attached. On-subnet addressing uses a subset of addresses of an attached subnet.

- Off-subnet addressing is the allocation of IP addresses to remote access clients that are not in a range defined by a subnet to which the remote access server is attached. Off-subnet addressing uses a separate subnet address space that is unique to the intranet.

**On-Subnet Addressing and Proxy ARP**
With on-subnet addressing, remote access clients are logically on the same subnet as a subnet attached to the remote access server. Proxy Address Resolution Protocol (ARP) is used by the remote access server to receive IP datagrams that are forwarded to remote access clients.

There are two cases in which Proxy ARP is used:

- When the remote access server is configured to use Dynamic Host Configuration Protocol (DHCP) to obtain addresses for IP-based remote access clients.

- When the remote access server is configured with a static IP address pool that consists of address ranges that are a subset of the addresses for a subnet to which the remote access server is attached.

In either case, the remote access clients are logically on the same subnet as the remote access server. Therefore, IP nodes on that subnet forwarding IP datagrams to a remote access client perform a direct delivery by sending a broadcast ARP Request frame for the remote access client's IP address.

The remote access client cannot respond to the ARP Request because the remote access server does not forward the ARP Request frame to the remote access client, and the remote access client does not have a MAC address corresponding to the remote access connection.

Therefore, the remote access server responds with an ARP Reply frame with its own MAC address. The node forwarding the packet then sends the IP datagram to the remote access server's MAC address. The remote access server then uses the IP routing process to forward the IP datagram across the dial-up connection to the remote access client.

**Off-Subnet Addressing and IP Routing**
With off-subnet addressing, remote access clients are logically on a separate subnet that can be reached across the remote access server. In this case, Proxy ARP is not used. The remote access server is acting as a router between the subnet of the remote access clients and the subnets to which the remote access server is attached. IP nodes on the LAN-based subnets attached to the remote access server that forward IP datagrams to a remote access client perform an indirect delivery by sending a broadcast ARP Request frame for the remote access server's IP address.

To reach remote access clients from IP nodes on the intranet, routes that represent the address ranges of the IP address pool and point to the LAN interface of the remote access server must be present in intranet routers.

When the first TCP/IP-based remote access client connects, routes corresponding to the off-subnet address ranges that point to the remote access server interface are added to the IP routing table of the remote access server. If the remote access server is configured with an IP routing protocol, the new routes are advertised to neighboring routers by using the advertising process of the configured routing protocol. If the remote access server is not configured with an IP routing protocol, routes corresponding to the off-subnet address ranges that point to the remote access server's LAN interface must be added to the routers of the intranet.

**TCP/IP Configuration for Remote Access Clients**
This section describes how the remote access server for Windows Server 2003 allocates network configuration parameters for TCP/IP-based remote access clients.

**IPCP Configuration**
To configure a TCP/IP-based remote access client with IPCP, the remote access server allocates an IP address and assigns the IP addresses of DNS and WINS servers.

**IP Address Allocation**
To allocate an IP address to a remote access client, the remote access server is either configured to use DHCP to obtain IP addresses, or with a static IP address pool.

**DHCP and Automatic Private IP Addressing**
When the remote access server is configured to use DHCP to obtain IP addresses, Routing and Remote Access instructs the DHCP client component to obtain 10 IP addresses from a DHCP server. The remote access server uses the first IP address obtained from DHCP for the remote access server interface, and subsequent addresses are allocated to TCP/IP-based remote access clients as they connect. IP addresses freed due to disconnected remote access clients are reused.

When all 10 IP addresses are used, the remote access server uses the DHCP client component to obtain 10 more. You can modify the number of IP addresses obtained at a time by changing a registry entry. For more information about registry entries for dial-up remote access, see "Dial-up Remote Access Tools and Settings."

With the Windows NT 4.0 remote access server, the DHCP-allocated addresses are recorded and reused when remote access is restarted. The Windows Server 2003 and Windows 2000 Server remote access servers now release all DHCP-allocated IP addresses using DHCPRELEASE messages each time the service is stopped.

If the remote access server initially starts using DHCP-allocated addresses and the DHCP server becomes unavailable, then an IP address cannot be allocated to additional TCP/IP-based remote access clients.

If a DHCP server is not available when Routing and Remote Access is started, then the DHCP client returns 10 addresses in the range of 169.254.0.1 to 169.254.255.254 to allocate to remote access clients. The address range 169.254.0.0/16 is used for Automatic Private IP Addressing (APIPA). APIPA addresses for point-to-LAN remote access connectivity work only if the network to which the remote access server computer is attached is also using APIPA addresses. If the local network is not using APIPA addresses, remote access clients are only able to obtain point-to-point remote access connectivity. For more information about APIPA, see "DHCP Technical Reference."

If a DHCP server becomes available, then the next time Routing and Remote Access needs IP addresses, DHCP addresses are

obtained. These DHCP addresses are allocated to remote access clients that connected after the addresses were obtained.

The remote access server uses a specific LAN interface to obtain DHCP-allocated IP addresses for remote access clients. You can select which LAN interface to use from the **IP** tab on the properties of a remote access router in the Routing and Remote Access snap-in. By default, **Allow RAS to select adapter** is selected, which means that Routing and Remote Access randomly picks a LAN interface to use.

**Static IP Address Pool**
When a static IP address pool is configured, the remote access server uses the first IP address in the first address range for the remote access server interface, and subsequent addresses are allocated to TCP/IP-based remote access clients as they connect. IP addresses freed due to disconnected remote access clients are reused.

If an address range in the static IP address pool is for off-subnet addresses, either enable an appropriate routing protocol on the remote access server or add the routes corresponding to the IP address ranges to the routers of your intranet. For more information, see "TCP/IP On-Subnet and Off-Subnet Addressing" earlier in this section.

**DNS and WINS Address Assignment**
As part of the IPCP negotiation, the remote access server assigns the IP addresses of DNS and WINS servers. The set of DNS and WINS server IP addresses that are assigned to the remote access client depends on the following factors:

- Whether DNS and WINS server IP address assignment is prohibited.
- Whether DNS and WINS server IP addresses for remote access clients are globally configured by using data stored in the registry.
- Whether the remote access server has more than one LAN interface.
- Whether the DNS and WINS server IP addresses for the remote access server are configured statically or are obtained through DHCP.

**Prohibiting DNS and WINS IP Address Assignment**
You can prevent the remote access server from assigning DNS and WINS IP addresses by changing a registry entry.

**Configuring Global DNS and WINS IP Address Assignment**
You can globally configure DNS and WINS server IP addresses for remote access clients by entering the IP addresses in the registry.

For more information about registry entries for dial-up remote access, see "Dial-up Remote Access Tools and Settings."

**Multiple LAN Interfaces**
If the DNS and WINS server IP address assignment is not prohibited or globally configured, then the remote access server allocates the DNS and WINS server IP addresses of a LAN interface on the remote access server to remote access clients. If there is only one LAN interface, which is the typical configuration of a dial-up remote access server, the remote access server allocates the DNS and WINS server IP addresses of the single LAN interface to remote access clients. If there is more than one LAN interface, the DNS and WINS server IP addresses of a specific LAN interface must be determined.

With multiple LAN interfaces, which is the typical configuration of a VPN remote access server, the remote access server, by default, picks one LAN interface randomly during startup and uses the DNS and WINS server IP addresses of the chosen LAN interface to allocate to remote access clients. To override this behavior, you can select the desired LAN interface through the **IP** tab on the properties of a remote access router in the Routing and Remote Access snap-in. By default, **Allow RAS to select adapter** is selected.

**Static Configuration or DHCP**
After the LAN adapter for DNS and WINS server IP address assignment has been determined:

- If the LAN adapter has a static IP configuration, then the IP addresses of the statically-configured DNS and WINS servers are allocated to remote access clients.
- If the LAN adapter obtained its IP configuration using DHCP, then the IP addresses of the DHCP-obtained DNS and WINS servers are allocated to remote access clients.

The following figure illustrates the way in which the remote access server determines the set of DNS and WINS server IP addresses to assign to remote access clients during IPCP negotiation.

**Determining DNS and WINS Server IP Address**

**Overriding IPCP-Allocated DNS and WINS Server IP Addresses with DHCPInform**

After IPCP is completed, Windows Server 2003 remote access clients send their remote access servers a DHCPInform message. DHCPInform is a DHCP message used by DHCP clients to obtain DHCP options. While PPP remote access clients do not use DHCP to obtain IP addresses for the remote access connection, Windows Server 2003 remote access client's use the DHCPInform message to obtain DNS server IP addresses, WINS server IP addresses, and a DNS domain name. The DHCPInform message is sent after the IPCP negotiation is concluded.

The DHCPInform message received by the remote access server is then forwarded to a DHCP server. The remote access server forwards DHCPInform messages only if it has been configured with the DHCP Relay Agent, as discussed in the following section. The response to the DHCPInform message is forwarded back to the requesting remote access client.

If the DHCPInform response contains DNS and WINS server IP address options, then these new values override what was allocated during IPCP. When the remote access client is a Windows Server 2003 remote access client and the DHCPInform response contains a DNS domain name, the DNS domain name is used as the per-adapter DNS suffix for the remote access connection of the remote access client. For more information on per-adapter DNS suffixes, see the "DNS Technical Reference."

**Remote Access Server and the DHCP Relay Agent**

To facilitate the forwarding of DHCPInform messages between remote access clients and DHCP servers, the remote access server uses the DHCP Relay Agent, a component of the Windows Server 2003 remote access router. To configure the remote access server to use the DHCP Relay Agent, add the **Internal** interface to the DHCP Relay Agent IP routing protocol with the Routing and Remote Access snap-in.

If the remote access server is using DHCP to obtain IP addresses for remote access clients, then the remote access server uses the DHCP Relay Agent to forward DHCPInform messages to the DHCP server of the selected LAN interface, which is found on the **IP** tab on the properties of a remote access router in the Routing and Remote Access snap-in.

If the remote access server is using a static IP address pool to obtain IP addresses for remote access clients, then the DHCP Relay Agent must be configured with the IP address of at least one DHCP server. Otherwise, DHCPInform messages sent by remote access clients are silently discarded by the remote access server.

**PPP Connection**

The following four phases must be completed successfully before the PPP connection is ready to transfer user data:

1. PPP configuration
2. Authentication
3. Callback
4. Protocol configuration

**Phase 1: PPP Configuration**

PPP configures PPP protocol parameters using LCP. During the initial LCP phase, each peer negotiates communication options that are used to send data and include:

- PPP parameters, such as MRU, Address and Control field compression, and Protocol ID compression.

- Which authentication protocols are used to authenticate the remote access client. An authentication protocol is selected but not implemented until the authentication phase.

- Multilink options.

**Preventing the Flag Character from Occurring in the Middle of a PPP Frame**
PPP employs two different methods to prevent the occurrence of the Flag character from appearing in the middle of a frame.

**PPP on Asynchronous Links**
On asynchronous links, such as analog phone lines, PPP uses a technique called character stuffing to prevent the occurrence of the Flag character within the PPP frame. If the Flag character (0x7E) occurs elsewhere in the PPP frame, the sender replaces it with the sequence 0x7D-5E. The 0x7D character is known as the PPP Escape character. If the PPP Escape character occurs, the sender replaces it with the sequence 0x7D-5D. The receiver translates 0x7D-5E sequences back to 0x7E and 0x7D-5D sequences back to 0x7D.

In addition, character values less than 0x20 can be modified to prevent the serial drivers from interpreting them as control characters. If negotiated by LCP, characters below 0x20 are modified by sending the sequence: 0x7D-[Original character with the 6th bit complemented]. For example, the byte 0x01 would be transmitted as 0x7D-0x21.

**PPP on Synchronous Links**
With synchronous links, such as T-Carrier, ISDN, or other digital links, a technique called bit stuffing is used to prevent the occurrence of the Flag character within the PPP frame. The Flag character is the bit sequence 01111110. Bit stuffing ensures that six 1 bits in a row occur only when the Flag character is sent. To accomplish this, bit stuffing sends the Flag character unmodified and elsewhere inserts a 0 bit whenever a sequence of five 1 bits occurs. Therefore, the bit sequence 111111 is encoded on the medium as 1111101 and the bit sequence 111110 is encoded as 1111100. Bit stuffing means that a byte can be encoded on the medium as more than eight bits, but the stuffed bits are added and removed by the synchronous link hardware.

**PPPoE Connection**
The PPPoE connection process has the following two phases:

1. A discovery phase, in which a client computer uses PPPoE frames to discover the presence of an AC, a device that terminates the cable modem or DSL connection and provides access to the Internet, and to determine a PPPoE session ID.

2. A PPP session phase, in which a PPP connection is established and used for data transfer in the same way as a dial-up or VPN-based PPP connection.

**Phase 1: PPPoE Discovery**
The PPPoE discovery phase consists of the following four PPPoE frames:

1. The PPPoE Active Discovery Initiation (PADI) frame is sent by the PPPoE client to the Ethernet broadcast address (0xFF-FF-FF-FF-FF-FF). Within the Ethernet payload, the Code field is set to 9; the Session ID is set to 0; and there is a single Service-Name PPPoE tag, as well as other tags as needed. If the network connection in the Network Connections folder corresponding to the broadband Internet adapter has been configured with a service name, that service name is sent. Otherwise, the PADI frame is sent with a null service name.

2. The PPPoE Active Discovery Offer (PADO) frame is sent by the AC to the unicast MAC address of the PPPoE client. Within the Ethernet payload, the Code field is set to 7; the Session ID is set to 0; and there are the AC-Name and Service-Name tags, as well as other tags as needed. If the network connection in the Network Connections folder corresponding to the broadband Internet adapter has not been configured with a service name, it is automatically set to the value of the Service-Name tag in the PADO frame.

3. The PPPoE Active Discovery Request (PADR) frame is sent by the PPPoE client to the unicast MAC address of the AC. Within the Ethernet payload, the Code field is set to 25; the Session ID is set to 0; and there is a Service-Name tag and other tags as needed.

4. The PPPoE Active Discovery Session (PADS) frame is sent by the AC to the unicast MAC address of the PPPoE client. Within the Ethernet payload, the Code field is set to 101; the Session ID field is set to the session ID for the PPP session of the PPPoE client; and there is a Service-Name tag, as well as other tags as needed.

To terminate the PPPoE session, either the PPPoE client or the AC can send a PPPoE Active Discovery Terminate (PADT) frame, which contains the Code field set to 167 and the session ID set to the session being terminated.

**Phase 2: PPP Session**

After the PPPoE discovery process is complete, a PPP connection is negotiated and network protocol data, such as IP datagrams, are sent over the PPPoE connection. The following figure shows a PPPoE frame that contains a PPP frame.

### Structure of a PPPoE Frame Containing a PPP Frame

Because of the additional PPPoE overhead, the maximum size of PPP frames that can be sent over a PPPoE connection is 1494 bytes.

**LCP Negotiation**

During the LCP negotiation, LCP packets are exchanged between PPP peers to negotiate a set of options and option values when sending data. The LCP negotiation is actually two separate dialogues between two PPP peers (Peer 1 and Peer 2):

1. Peer 1 asks, negotiates, and then receives confirmation of the LCP options that are used when sending data to Peer 2. This dialogue starts with Peer 1 sending a Configure-Request message and ends when Peer 2 sends a Configure-Ack message.

2. Peer 2 asks, negotiates, and then receives confirmation of the LCP options that are used when sending data to Peer 1. This dialogue starts with Peer 2 sending a Configure-Request message and ends when Peer 1 sends a Configure-Ack message.

Peer 1 and Peer 2 do not have to use the same set of LCP options.

When a PPP peer sends its initial Configure-Request, the response can be any of the following:

- A Configure-Nack message because one or more options have unacceptable values.

- A Configure-Reject message because one or more of the options are unknown or not negotiable.

- A Configure-Ack message because all of the options have acceptable values.

When a PPP peer receives a Configure-Nack message or Configure-Reject message, it sends a new Configure-Request message with modified options or option values. When a Configure-Ack message is received, the PPP peer is ready to send data.

The following figure shows a LCP negotiation process for Peer 1 using the options W, X, Y, and Z.

### Sample LCP Negotiation

The following sequence describes the LCP negotiation show in the figure:

1. Peer 1 sends a Configure-Request message requesting option W; option X set to 100; option Y set to 0; and option Z. Options W and Z are flag options.

2. Peer 2 does not understand option Z, so it sends a Configure-Reject message containing option Z.

3. Peer 1 sends a new Configure-Request message requesting option W; option X set to 100; and option Y set to 0.

4. Peer 2 prefers that option X be set to 200, so it sends a Configure-Nack message containing option X and its preferred value.

5. Peer 1 sends a new Configure-Request message requesting option W; option X set to 200; and option Y set to 0.

6. Peer 2 sends a Configure-Ack message.

Each time Peer 1 sends a new Configure-Request message, it changes the Identifier value in the LCP header so that Configure-Request messages can be matched with their responses.

This process describes only how Peer 1 sends data to Peer 2. A separate LCP negotiation must be performed so that Peer 2 can be configured to send data to Peer 1. Very often, the LCP packets for the two dialogues are intermixed during the connection process. Peer 1 is configuring the way it sends data at the same time as Peer 2.

**Phase 2: Authentication**
After LCP is complete, the authentication protocol agreed upon by the remote access server and the remote access client is implemented. The nature of this traffic is specific to the PPP authentication protocol.

**PAP Negotiation**
The use of PAP is negotiated during LCP negotiation by specifying the authentication protocol LCP option (type 3) and the authentication protocol 0xC0-23. After LCP negotiation is complete, PAP messages use the PPP protocol ID of 0xC0-23.

PAP is a simple exchange of messages:

1. The remote access client sends a PAP Authenticate-Request message to the remote access server containing the remote access clients user name and clear text.

2. The remote access server checks the user name and password and sends back either a PAP Authenticate-Ack message when the user's credentials are correct, or a PAP Authenticate-Nak message when the user's credentials are not correct.

**SPAP Negotiation**
The use of SPAP is negotiated during LCP negotiation by specifying the authentication protocol LCP option (type 3) and the authentication protocol 0xC0-27. After LCP negotiation is complete, SPAP messages use the PPP protocol ID of 0xC0-27.

Like PAP, SPAP is a simple exchange of messages:

1. The remote access client sends an SPAP Authenticate-Request message to the remote access server containing the remote access client's user name and encrypted password.

2. The remote access server decrypts the password, checks the user name and password, and sends back either an SPAP Authenticate-Ack message when the user's credentials are correct, or an SPAP Authenticate-Nak message with a reason why the user's credentials are not correct.

**CHAP Negotiation**
The use of CHAP is negotiated during Phase 1 by specifying the authentication protocol LCP option (type 3), the authentication protocol 0xC2-23, and the algorithm 0x05. After LCP negotiation is complete, CHAP messages use the PPP Protocol ID of 0xC2-23.

The challenge handshake authentication process for CHAP is an exchange of three messages:

1. The remote access server sends a CHAP Challenge message containing a session ID and an arbitrary challenge string.

2. The remote access client returns a CHAP Response message containing the user name in clear text and a hash of the challenge string, session ID, and the client's password using the MD5 one-way hashing algorithm.

3. The remote access server duplicates the hash and compares it to the hash in the CHAP Response. If the hashes are the same, the remote access server sends back a CHAP Success message. If the hashes are different, a CHAP Failure message is sent.

**MS-CHAP Negotiation**
The use of MS-CHAP is negotiated during LCP negotiation by specifying the authentication protocol LCP option (type 3), the authentication protocol 0xC2-23, and the algorithm 0x80. After LCP negotiation is complete, MS-CHAP messages use the PPP protocol ID of 0xC2-23.

The challenge handshake authentication process for MS-CHAP is an exchange of three messages:

1. The remote access server sends an MS-CHAP Challenge message containing a session ID and an arbitrary challenge string.

2. The remote access client returns an MS-CHAP Response message containing the user name in clear text and a hash of the challenge string, session ID, and the MD4 hash of the client’s password using the MD4 one-way hashing algorithm.

3. The remote access server duplicates the hash and compares it to the hash in the MS-CHAP Response. If the hashes are the same, the remote access server sends back an MS-CHAP Success message. If the hashes are different, an MS-CHAP Failure message is sent.

**MS-CHAP v2 Negotiation**
The use of MS-CHAP v2 is negotiated during LCP negotiation by specifying the authentication protocol LCP option (type 3), the authentication protocol 0xC2-23, and the algorithm 0x81. After LCP negotiation is complete, MS-CHAP messages use the PPP protocol ID of 0xC2-23.

The challenge handshake authentication process for MS-CHAP v2 is an exchange of three messages:

1. The remote access server sends an MS-CHAP v2 Challenge message to the remote access client that consists of a session identifier and an arbitrary challenge string.

2. The remote access client sends an MS-CHAP v2 Response message that contains:

    - The user name.

    - An arbitrary peer challenge string.

    - A one-way encryption of the received challenge string, the peer challenge string, the session identifier, and the user’s password.

3. The remote access server checks the MS-CHAP v2 Response message from the client and sends back an MS-CHAP v2 Response message containing:

    - An indication of the success or failure of the connection attempt.

- An authenticated response based on the sent challenge string, the peer challenge string, the client's encrypted response, and the user's password.

4. The remote access client verifies the authentication response and if it is correct, uses the connection. If the authentication response is not correct, the remote access client terminates the connection.

**Client Verification with EAP-MD5**
After the connection authentication phase is reached, the following process verifies the client:

1. The authenticator sends an EAP-Request message requesting the identity of the client.

2. The client sends its user ID to the authenticator as an EAP-Response message.

3. The authenticator sends an EAP-Request message containing the MD5 challenge string.

4. The client sends the MD5 hash of its user ID and password to the authenticator as an EAP-Response message.

5. On validation of the user ID and password, the authenticator sends a Success message to the client.

**Phase 3: Callback**
The Microsoft implementation of PPP includes an optional callback phase using CBCP immediately after authentication. The dial-in properties of the user account must be enabled for callback; otherwise, the remote access client cannot receive a call. Either the remote access client or the remote access server must specify the callback number.

If a connection is implementing callback, both PPP peers hang up and the remote access server calls the remote access client at the negotiated number.

**Phase 4: Protocol Configuration**
After the PPP is configured and callback is complete (optional), network layer protocols can be configured. With remote access on Windows 32-bit operating systems, the remote access server sends the remote access client Configuration-Request messages for all of the LAN protocols enabled for remote access on the remote access server. The remote access client either continues the negotiation of the LAN protocols enabled at the remote access client or sends an LCP Protocol-Reject message containing the Configuration-Request message.

IPCP and ATCP each go through a negotiation process very similar to LCP negotiation to configure their corresponding network layer protocol. CCP packets are exchanged to configure MPPC and MPPE.

**Connection Attempt Processing with Remote Access Policies**
To process a connection attempt, the parameters of the connection attempt are compared to the user name, password, and dial-in properties of the user account and the configured remote access policies.

Some general characteristics of remote access connection attempt processing are:

- If a connection attempt does not use a valid user name and password, then the connection attempt is denied.

- If there are no configured policies, then all connection attempts are denied.

- If the connection attempt does not match any of the remote access policies, then the connection attempt is denied.

- If the remote access permission of the user account for the remote access user is set to **Deny Access**, the connection attempt is always denied for that remote access user.

- The only time that a connection attempt is allowed is when it matches the conditions of a remote access policy; remote access permission is enabled either through the dial-in properties of the user account or through the remote access permission of the remote access policy (assuming the user's remote access permission is set to control access through remote access policies); and the parameters of the connection attempt match or conform to the parameters and conditions of the dial-in properties of the user account and the remote access policy profile properties.

The following figure illustrates the processing of remote access connection attempts using the dial-in properties of the user account and remote access policies. The figure assumes that the user name and password sent during the authentication process match a valid user account.

**Connection Attempt Processing**

For more information about remote access policies and IAS, see "IAS Technical Reference."

**Broadcast Name Resolution**

Enabling broadcast name resolution on a remote access server allows a remote access client to resolve full computer names and NetBIOS names of computers and other resources on a remote network that does not have either a DNS or a WINS server configured. This feature requires no configuration of the remote access clients; it is enabled by default on the remote access server.

When broadcast name resolution is enabled, the remote access server uses a NetBIOS over TCP/IP (NetBT) proxy to resolve names as follows:

1. A remote access client that must resolve a name to an IP address broadcasts a NetBIOS Name Query packet across all interfaces.

2. The remote access server receives the NetBIOS Name Query packet and checks its cache for the appropriate mapping of name to IP address.

   - If the remote access server has the appropriate mapping, it sends a NetBIOS Name Query Response packet to the remote access client.

   - If the remote access server does not have the appropriate mapping, it broadcasts the NetBIOS Name Query packet on all of its LAN interfaces. The resource whose name is being resolved sends a NetBIOS Name Query Response packet to the remote access client.

   After the remote access server routes the NetBIOS Name Query Response packet from the resource to the remote access client, the mappings remain in the cache of the server for a limited period of time. The default period of time is 10 minutes.

3. After this point, the remote access client uses the IP address of the resource to send packets to that resource.

As a result, a remote access client can resolve names of resources on a remote network as if the remote access client were on the same LAN as the resources.

**Note**

- By default, broadcast name resolution allows remote access clients to resolve names on a remote network, but it does not allow resources on a LAN to resolve the names of remote access clients. Remote access servers with broadcast name resolution enabled do not, by default, broadcast NetBIOS Name Query packets to interfaces that connect to the Internet. Unless you change this behavior, a remote access client cannot resolve the name of another remote access client. If you have a network that averages 10 connections or fewer, you might want to change this behavior.

# Dial-up Remote Access Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dial-up Remote Access Tools and Settings**

**In this section**

- Dial-up Remote Access Tools
- Dial-up Remote Access Registry Entries

The "Dial-up Remote Access Tools" section describes tools that are useful for auditing, customizing, and troubleshooting dial-up remote access connections.

The "Dial-up Remote Access Registry Entries" section describes the registry entries that enable the configuration of Internet Protocol (IP) addresses and the storage of Point-to-Point Protocol (PPP) settings.

**Dial-up Remote Access Tools**

The following tools are associated with dial-up remote access.

**Connection Manager**

**Category**

Connection Manager is client connection software that is available as part of the operating system.

**Version compatibility**

Connection Manager is available in Windows Server 2003 and Windows Server 2000 and is compatible with Windows XP, Windows Millennium Edition, Windows 98 and Windows NT 4.0.

Connection Manager is client connection software that administrators can customize and distribute to users. The customized and distributed Connection Manager software includes a service profile, which contains all of the files required to install Connection Manager.

Connection Manager also contains the Connection Manager Administration Kit (CMAK) component and Connection Point Services (CPS).

**Connection Manager Administration Kit**

CMAK is a wizard that creates the Connection Manager service profile and then builds the service profile as a compressed, self-installing executable file that administrators can distribute to users.

**Connection Point Services**

CPS enables you to automatically distribute and update custom phone books. These phone books contain one or more point of presence (POP) entries, with each POP supplying a telephone number that provides dial-up access to an Internet access point. The phone books give users complete POP information, so when they travel they can connect to different Internet access points rather than being restricted to a single POP.

Without the ability to update phone books (a task CPS handles automatically), users would have to contact technical support to be informed of changes in POP information and to reconfigure their client dialer software.

CPS contains two major components:

- Phone Book Administrator (PBA)
- Phone Book Services (PBS)

**Phone Book Administrator**

PBA creates and maintains phone book files for use with Connection Managerservice profiles. Each phone book is a collection of POPs provided by either the administrator or one or more Internet service providers (ISPs) that the organization uses to provide Internet access. Each POP provides a local access number and connection settings for a specific region within a country/region or dependency.

**Phone Book Services**

PBS is an Internet Information Services (IIS) extension. When a service profile that is configured to check for phone book updates establishes a connection, Connection Manager queries the PBS server for a phone book update. PBS compares the version of the phone book that the service profile is using with the most recent files in the phone book database and then sends any updates to the service profile.

For more information about Connection Manager, see the "Connection Manager Technical Reference."

**Netdiag**
**Category**
Netdiag is a diagnostic tool available as part of the operating system as Netdiag.exe.

**Version compatibility**
Netdiag is available in Windows Server 2003, Windows XP, and Windows Server 2000.

Netdiag helps isolate networking and connectivity problems by performing a series of tests to determine the state of your network client. These tests and the network status information they expose give network administrators and support personnel a more direct means of identifying and isolating network problems. In addition, because this tool does not require parameters or switches to be specified, support personnel and network administrators can focus on analyzing the output rather than on training users about how to use the tool.

For more information about Netdiag, see "Windows Support Tools" in the Tools and Settings Collection.

**Netsh**
**Category**
Netsh is a command-line scripting tool available as part of the operating system.

**Version compatibility**
Netsh is available in Windows Server 2003, Windows 2000 Server, and all versions of Windows that include TCP/IP.

Netsh enables you to display or modify the network configuration of a local or remote computer. You can also use Netsh to enable the components in Windows Server 2003 to log tracing information to files. You can enable and disable tracing for specific components or for all components.

For more information about Netsh, see "Command-Line References" in the Tools and Settings Collection.

**Network Monitor**
**Category**
Network Monitor is a tool for monitoring, recording, and analyzing network traffic. Network Monitor is part of Microsoft Systems Management Server (SMS). A limited version, which can capture frames that are sent to or from the network adapter of the computer on which Network Monitor is installed, is included with Windows Server 2003 and can be installed as an optional networking component.

**Version compatibility**
Network Monitoris available in Windows Server 2003 and Windows Server 2000.

Network Monitor, a packet capture and analysis tool, can capture and view the traffic sent between a remote access server and a remote access client during the remote access connection process and during data transfer. Network Monitor captures all PPP packets sent over a serial link, including connection establishment and PPP-encapsulated user data.

### Note

- If compression or encryption are used, then the PPP payload is not interpreted by Network Monitor. Compressed or encrypted payloads are indicated by the PPP protocol ID of 3D (assuming protocol ID compression). To see the structure of user data within PPP payloads, disable compression and encryption.

To use Network Monitor to interpret unencrypted remote access traffic, you must be familiar with PPP. For more information about PPP and Network Monitor, see "Dial-up Remote Access Protocols" and "Dial-up Remote Access Processes and Interactions" in How Dial-up Remote Access Works. Network Monitor captures can be saved as files and sent to Microsoft Product Support Services for analysis.

To capture PPP packets with Network Monitor, you set the capture network to the network corresponding to the dial-up connection. You can use Network Monitor to:

- Troubleshoot the PPP connection establishment process.

- Ensure that PPP payloads are being encrypted.

- Ensure that PPP payloads are being compressed.

When using Network Monitor, keep the following in mind:

- Captured PPP frames do not contain a Flag character but do contain an Ethernet-like source address and destination address. This behavior is due to Network Monitor's receipt of packets from Ndiswan.sys, an intermediate NDIS driver that provides an IEEE 802.3 miniport interface to protocol drivers. Ndiswan.sys looks like an Ethernet adapter to protocols.

  For each PPP frame, the Ethernet-like source and destination addresses are both set to either **SEND** or **RECV** to indicate that the PPP frame was either sent or received by the computer on which the capture was taken. The **SEND** and **RECV** addresses do not necessarily identify the traffic of a remote access server or remote access client. If the capture was taken on the remote access server, then **SEND** frames were sent by the remote access server and **RECV** frames were sent by the remote access client. If the capture was taken on the remote access client, then **SEND** frames were sent by the remote access client and **RECV** frames were sent by the remote access server.

- Captured PPP frames contain an Address or Control field regardless of whether address and control field compression are negotiated.

- Protocol ID compression is usually negotiated with Microsoft PPP peers, making the PPP Protocol ID a single byte when possible.

- Use Network Monitor display to view only the traffic of desired protocols. For example, to view the Internet Protocol Control Protocol (IPCP) negotiation only, set the display filters to disable the display of all protocols except IPCP.

**Sample PPP Connection Captured with Network Monitor**
The following printout is an example of a PPP connection establishment process captured with Network Monitor showing only the frame summaries. The entries are indented to improve readability.

```
1 8.726 SEND SEND LCP
        Config Req Packet, Ident = 0x00, Length = 36
2 8.796 RECV RECV LCP
        Config Req Packet, Ident = 0x00, Length = 25
3 8.796 SEND SEND LCP
        Config Ack Packet, Ident = 0x00, Length = 25
4 8.816 RECV RECV LCP
        Config Reject Packet, Ident = 0x00, Length = 17
5 8.816 SEND SEND LCP
        Config Req Packet, Ident = 0x01, Length = 23
6 8.886 RECV RECV LCP
        Config Ack Packet, Ident = 0x01, Length = 23
7 8.886 SEND SEND LCP
        Ident Packet, Ident = 0x02, Length = 18
8 8.886 SEND SEND LCP
        Ident Packet, Ident = 0x03, Length = 23
9 8.886 RECV RECV PPPCHAP
        Challenge, ID = 0x 1: Challenge
10 8.886 SEND SEND PPPCHAP
        Challenge, ID = 0x 1: Response, administrator
11 8.976 RECV RECV PPPCHAP
        Challenge, ID = 0x 1: Success

        Callback Request, Ident = 0x01
13 8.976 SEND SEND CBCP
        Callback Response, Ident = 0x01
14 8.996 RECV RECV CBCP
        Callback Acknowledgement, Ident = 0x01
15 8.996 SEND SEND CCP
        Configuration Request, Ident = 0x04
16 8.997 SEND SEND IPCP
        Configuration Request, Ident = 0x05
17 8.997 RECV RECV CCP
        Configuration Request, Ident = 0x01
```

```
18 9.017 RECV RECV IPCP
        Configuration Request, Ident = 0x02
19 9.037 RECV RECV NBFCP
        Configuration Request, Ident = 0x04
20 9.147 SEND SEND CCP
        Configuration Acknowledgement, Ident = 0x01
21 9.147 SEND SEND IPCP
        Configuration Acknowledgement, Ident = 0x02
22 9.167 SEND SEND LCP
        Protocol Reject Packet, Ident = 0x07, Length = 32
23 9.237 RECV RECV CCP
        Configuration Reject, Ident = 0x04
24 9.237 RECV RECV IPCP
        Configuration Reject, Ident = 0x05
25 9.237 SEND SEND IPCP
        Configuration Request, Ident = 0x08
26 9.287 RECV RECV IPCP
        Configuration No Acknowledgement, Ident = 0x08
27 9.287 SEND SEND IPCP
        Configuration Request, Ident = 0x0A
28 9.327 RECV RECV IPCP
        Configuration Acknowledgement, Ident = 0x0A
29 10.729 SEND SEND CCP
        Configuration Request, Ident = 0x04
30 10.960 RECV RECV CCP
        Configuration Reject, Ident = 0x04
31 10.960 SEND SEND CCP
        Configuration Request, Ident = 0x0B
32 10.960 RECV RECV CCP
        Configuration Acknowledgement, Ident = 0x0B
```

The trace was captured on the remote access client. Therefore, the **SEND** frames were sent from the remote access client and the **RECV** frames were sent from the remote access server. In this trace, you can see the four phases of the establishment of the PPP connection:

- Phase 1: PPP configuration is performed in frames 1 through 8 by using the exchange of Link Control Protocol (LCP) configuration packets.
- Phase 2: Authentication, in which the user's credentials are verified, is performed in frames 9 through 11.
- Phase 3: Callback is performed in frames 12 through 14.
- Phase 4: Protocol configuration, in which compression, encryption, and IP are configured, is performed in frames 15 through 38.

In addition to the summary view, Network Monitor can also expand frames for detailed analysis. For example, frame 1 from this trace is displayed as:

```
FRAME: Base frame properties
FRAME: Time of capture = Nov 18, 1998 15:23:6.967
FRAME: Time delta from previous physical frame: 0 milliseconds
FRAME: Frame number: 1
FRAME: Total frame length: 50 bytes
FRAME: Capture frame length: 50 bytes
FRAME: Frame data: Number of data bytes remaining = 50 (0x0032)
PPP: Link Control Protocol Frame (0xC021)
PPP: Destination Address = SEND_
PPP: Source Address = SEND_
PPP: Protocol = Link Control Protocol
LCP: Config Req Packet, Ident = 0x00, Length = 36
LCP: Code = Configuration Request
LCP: Identifier = 0 (0x0)
LCP: Length = 36 (0x24)
LCP: Options: ASYNC.MAP:00 00 00 00-MAGIC#:0x0C05-PROT.COMP- ADR/CF.COMP-
CALL.BACK:Unkn---
LCP: ASYNC.MAP:00 00 00 00
LCP: Option Type = Async Control Character Map
LCP: Option Length = 6 (0x6)
```

```
LCP: Async Control Character Map = 00 00 00 00
LCP: MAGIC#:0x0C05
LCP: Option Type = Majic Number
LCP: Option Length = 6 (0x6)
LCP: Magic Number = 3077 (0xC05)
LCP: PROT.COMP
LCP: Option Type = Protocol Field Compression
LCP: Option Length = 2 (0x2)
LCP: ADR/CF.COMP
LCP: Option Type = Address and Control Field Compression
LCP: Option Length = 2 (0x2)
LCP: CALL.BACK:Unkn
LCP: Option Type = Callback
LCP: Option Length = 3 (0x3)
LCP: CallBack = 0x06
LCP: Multilink Maximum Receive Reconstructed Unit
LCP: Option Type = 0x11
LCP: Option Length = 4 (0x4)
LCP: Multilink Endpoint Discriminator
LCP: Option Type = 0x13
LCP: Option Length = 9 (0x9)
```

**PPP Tracing**

**Category**

PPP tracing is an operating system tool available in Routing and Remote Access.

**Version compatibility**

PPP tracing is supported in Windows Server 2003 and Windows 2000 Server. PPP tracing is the same as the PPP logging feature in Windows NT 4.0 and earlier.

To use PPP tracing to troubleshoot PPP connection failures, you must be familiar with PPP. For more information about PPP and PPP tracing, see "Dial-up Remote Access Protocols" and "Dial-up Remote Access Processes and Interactions" in How Dial-up Remote Access Works.

Tracing is a facility of Windows Server 2003 remote access and routing components that allows you to optionally enable and disable the recording of programming code and network events to a file. PPP tracing logs the PPP packets exchanged during the PPP connection establishment process and is valuable for troubleshooting the failure of a PPP connection.

By default, the PPP log is stored in the Ppp.log file in the *systemroot*\Tracing folder. The PPP log generated by PPP tracing contains the programming calls and contents of PPP packets for PPP control protocols. PPP tracing cannot be used to view PPP user data sent across the connection.

**Sample PPP Trace**

The following printout is an excerpt from a PPP trace of a PPP connection establishment process. The entries are indented to improve readability.

```
[1472] 15:57:50:094: Line up event occurred on port 5
[1472] 15:57:50:104: Starting PPP on link with IfType=0x0,IPIf=0x0
[1472] 15:57:50:104: RasGetBuffer returned ae70054 for SendBuf
[1472] 15:57:50:104: FsmInit called for protocol = c021, port = 5
[1472] 15:57:50:104: ConfigInfo = 273e
[1472] 15:57:50:104: APs available = 1
[1472] 15:57:50:104: FsmReset called for protocol = c021, port = 5
[1472] 15:57:50:104: Inserting port in bucket # 5
[1472] 15:57:50:104: Inserting bundle in bucket # 6
[1472] 15:57:50:104: FsmOpen event received for protocol c021 on port 5
[1472] 15:57:50:104: FsmThisLayerStarted called for protocol = c021,
            port = 5
[1472] 15:57:50:104: FsmUp event received for protocol c021 on port 5
[1472] 15:57:50:104: <PPP packet sent at 11/04/1998 23:57:50:104
[1472] 15:57:50:104: <Protocol = LCP, Type = Configure-Req, Length =
            0x2f, Id = 0x0, Port = 5

            |.`.R............|
```

The last three lines are a hexadecimal display of the same LCP packet in frame 1 of the preceding Network Monitor trace. To understand this frame, you must manually parse this frame according to the PPP and LCP packet structure. An example of the parsing of this PPP frame is listed in the following table.

**Parsing of the LCP Configure-Request**

| Bytes | Meaning |
|---|---|
| C0 21 | PPP Protocol ID for LCP. |
| 01 | LCP code for a Configure-Request. |
| 00 | LCP identifier for this Configure-Request. |
| 00 24 | Length, in bytes, of the LCP packet (36 bytes long). |
| 02 | LCP option for Asynchronous Control Character Map (ACCM). |
| 06 | Length, in bytes, of the ACCM option. |
| 00 00 00 00 | Data for the ACCM option. |
| 05 | LCP option for the magic number. |
| 06 | Length, in bytes, of the magic number option. |
| 00 00 C0 05 | Data for the magic number option. |
| 07 | LCP option for protocol compression. |
| 02 | Length, in bytes, of the protocol compression option. |
| 08 | LCP option for address and control field compression. |
| 02 | Length, in bytes, of the address and control field compression option. |
| 0D | LCP option for callback. |
| 03 | Length, in bytes, of the callback option. |
| 06 | Callback option data. |
| 11 | LCP option for the Multilink Maximum Receive Reconstructed Unit. |
| 04 | Length, in bytes, of the Multilink Maximum Receive Reconstructed Unit option. |
| 06 4E | Multilink Maximum Receive Reconstructed Unit option data. |
| 13 | LCP option for the Multilink Endpoint Discriminator option. |
| 09 | Length, in bytes, of the Multilink Endpoint Discriminator option. |
| 03 00 60 08 52 F9 D8 | Multilink Endpoint Discriminator option data. |

**Rasdiag Category**

Rasdiag is a diagnostic tool for remote access clients that is available as part of the Windows XP operating system as Rasdiag.exe.

**Version Compatibility**
Rasdiag is available in Windows XP.

Rasdiag collects diagnostic information about remote services and places that information in a file. You can use this tool to work with Microsoft Product Support Services to troubleshoot remote connection issues by taking a snapshot of the configuration data and capturing an attempted remote connection.

Rasdiag is not described in the Support Tools section of Windows XP Help. For more information about Rasdiag, see "Windows Support Tools" in the Tools and Settings Collection.

**Rasdial**
**Category**
Rasdial is a command-line tool that automates the process of dialing up a network connection and is available as part of the operating system.

**Version Compatibility**
Rasdial is available in Windows Server 2003, Windows XP, and Windows Server 2000.

Rasdial creates a simple batch file that connects to a dial-up network connection by specifying an entry in the current rasphone.pbk file, located in the ../Documents and Settings/*username*/ folder for an individual user connection, and the ../Documents and Settings/All Users/ folder for all user connections. You can also use Rasdial to connect to or disconnect from a network connection.

Rasdial is different from Autodial:

- Rasdial does not automatically detect your network connection status before dialing a connection and does not depend on the Remote Access Auto Connection Manager service. Rasdial requires that there is an existing phone book entry that can be used or modified.

Rasdial is different from Rasphone:

- Rasdial provides unattended dialing. It does not support the following features available in Rasphone: prefix/suffix, auto-redial, change password, retry authentication, statistics, operator-assisted dialing, and connections requiring Terminal mode input.

For more information about Rasdial, see "Windows Support Tools" in the Tools and Settings Collection.

**Dial-up Remote Access Registry Entries**
The following registry entries are associated with dial-up remote access.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_LOCAL_MACHINE\SYSTEM**
The following registry key is located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services \RemoteAccess\Parameters\Ip

**Ip**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services \RemoteAccess\Parameters\

**Version**
The Ip registry setting is available in Windows Server 2003 and Windows 2000 Server.

When the remote access server is configured to use Dynamic Host Configuration Protocol (DHCP) to obtain IP addresses, Routing and Remote Access instructs the DHCP client component to obtain 10 IP addresses from a DHCP server. When all 10 IP addresses are used, the remote access server uses the DHCP client component to obtain 10 more. You can modify the number of IP addresses obtained at a time by changing the value of **InitialAddressPoolSize**.

If you do not want the remote access server to assign Domain Name System (DNS) and Windows Internet Name Service (WINS) IP addresses, set the values of **SuppressDNSNameServers** and **SuppressWINSNameServers** to **1**.

To globally configure DNS and WINS server IP addresses for remote access clients, enter the IP addresses in the values of **DNSNameServers** and **WINSNameServer**.

**HKEY_LOCAL_MACHINE\SYSTEM**
The following registry key is located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RasMan\PPP

**PPP**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RasMan\

**Version**
The PPP registry setting is available in Windows Server 2003 and Windows 2000 Server.

Routing and Remote Access stores PPP settings at this location.

# Telnet Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

All versions of Microsoft Windows Server 2003 operating systems include Telnet Client and Telnet Server components. Using Telnet Client and Server, you can create a remote command console session on a host. You can run command line programs, shell commands, and scripts in a remote command console session just as though you were locally logged on to the host and using a local command prompt window.

This subject describes how you can use Telnet for remote administration, the functions that Telnet performs, and how Telnet servers and clients interact.

**In this subject**

- What Is Telnet?
- How Telnet Works
- Telnet Tools and Settings

# What Is Telnet?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 and Windows XP Professional include Telnet Client and Telnet Server, which allow users to make remote connections based on the Telnet protocol. Using Telnet Client and Server, you can create a remote command console session on a host. Using a local command prompt window, you can run command line programs, shell commands, and scripts in a remote command console session just as though you were locally logged on to the host. Thus, having Telnet client and server software solves two networking problems. It allows for interoperability between disparate operating systems, and it facilitates administration of remote systems, saving administrative time and network resources.

**Interoperability**
Telnet Client and Server are well suited for troubleshooting and configuring remote computers, especially in mixed environments that require interoperability between different operating systems. For example, you can use Windows Server 2003 Telnet Client to connect to a Telnet server that is running on another operating system such as UNIX. Likewise, you can use a Telnet client that is running on UNIX to connect to a computer running Windows Server 2003 Telnet Server. Telnet Client and Server are also ideal in situations where memory and processor resources are minimal on a client or host or where network bandwidth is limited. This is because computers running Telnet clients and servers use less memory and processor time than other remote management tools, and Telnet clients and servers transmit only plaintext (unencrypted characters) across the network.

**Remote Administration**
Remote administration is a method of managing one or more remote computers from a single location. In a large organization, you can use remote administration to centrally manage hundreds or even thousands of computers located in other buildings or even in other cities. In a small organization, you can use remote administration to manage a single server located in an adjacent office.

By its nature, remote administration lowers the total cost of ownership (TCO) by making system management easier and more efficient. Using remote administration, server operators and technicians can manage and troubleshoot servers without having to locally log on to the server, thereby lowering the cost of on-site support. Remote administration also assists help desk technicians in solving problems more quickly by letting them take control of a user's computer.

**Telnet and Other Technologies**
Telnet is closely related to two other technologies that provide an alternative for remote command console sessions, depending on your needs for distributed computing, security, configuration requirements, and so on.

**Windows Server 2003 Terminal Services**
Telnet and Terminal Services are similar in that they are both used for remote sessions. However, Terminal Services extends the model of distributed computing by allowing client computers to operate in a server-based computing environment. Whereas Telnet only allows terminal emulation between a Telnet server and client, Terminal Services running on Windows Server 2003-based computers allows clients to run applications, while data processing, and data storage occur on the server. Applications and user sessions are transmitted over the network and displayed via terminal emulation software. Similarly, print streams, keyboard input, and mouse clicks are also transmitted over the network between the server and the terminal emulation software. Each user logs on and sees only their individual session, which is managed transparently by the server operating system and is independent of any other client session. You might want to consider using Windows Server 2003 Terminal Services if you require more extensive distributed computing.

**Windows Services for UNIX 3.5**
Windows Services for UNIX 3.5 includes a Telnet character-mode client that provides functionality not included in Windows Server 2003. The Windows Services for UNIX character-mode client supports both stream mode and console mode. It also provides for logging and additional configuration settings.

Windows Services for UNIX 3.5 includes two Telnet servers:

- The default, Windows-based Telnet server, which is functionally similar to the one included with all versions of Microsoft Windows since Windows 2000

- The Interix telnetd

Only one of these Telnet servers can be enabled at a time. By default, neither Telnet server is enabled for security reasons.

The Windows Services for UNIX 3.5 Telnet server accepts logons from a variety of clients, including the Telnet clients shipped with Windows 2000, Windows NT, Windows 95, and Windows 98, as well as a variety of character-mode terminal clients from virtually any operating system. Additionally, it can be configured to meet specific site requirements to improve security, simplify logons, support stream or console mode, and so forth.

The Windows Services for UNIX 3.5 Telnet server should be familiar to users of Windows 2000, Windows XP, and Windows Server 2003. It is essentially the same as the server included in Windows XP Professional and Windows Server 2003, and it is very similar to the one included in Windows 2000 editions. It uses the Windows command shell (Cmd.exe) as the default shell. You can start and stop this server from either the Services MMC (Services.msc) or from the Windows Services for UNIX Administration MMC (Sfumgmt.msc). If you are using Windows and UNIX in a mixed networking environment, you might want to consider installing Windows Services for UNIX 3.5 to extend the capabilities of Telnet.

# How Telnet Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Understanding Telnet
- Telnet Architecture
- Telnet Limitations
- Related Information

All Windows versions include Telnet Client and Telnet Server components. Using Telnet Client and Server, you can create a remote command console session on a host. You can run command line programs, shell commands, and scripts in a remote command console session just as though you were locally logged on to the host and using a local command prompt window.

Windows Server 2003 Telnet Client and Server are well suited for troubleshooting and configuring remote computers, especially in mixed environments that require interoperability between different operating systems. For example, you can use Telnet Client to connect to a Telnet server that is running on another operating system such as UNIX. Likewise, you can use a Telnet client that is running on UNIX to connect to a computer running Telnet Server. Windows Server 2003 Telnet Client and Server are also ideal in situations where memory and processor resources are minimal on a client or host or where network bandwidth is limited. This is because computers running Telnet clients and servers use less memory and processor time than other remote management tools, and Telnet clients and servers transmit only plaintext (unencrypted characters) across the network.

**Understanding Telnet**

Before using the Windows Server 2003 Telnet tools, you should consider the following:

- Windows Server 2003 Telnet Client and Server are based on the Telnet protocol, which specifies a method for transmitting and receiving unencrypted ASCII characters (plaintext) across a network. Understanding how the protocol works, and how Telnet clients and servers use the Telnet protocol, helps you manage Telnet connections.

- The Windows Server 2003 Telnet tools have several inherent limitations that affect the types of remote management tasks you can perform and the level of security that is in effect when you perform those tasks. Understanding these limitations helps you determine when and when not to use the Telnet tools.

- You can configure Telnet Server settings by using the Windows Server 2003 Telnet administration tool (Tlntadmn.exe) and the registry editor (Regedit.exe). Although the default Telnet Server settings are sufficient for most Telnet client connections, you might need to change the default settings to better suit your organization. Examples of Telnet Server settings include: authentication type, default port assignment for Telnet connections, maximum number of client connections, and maximum number of failed logon attempts.

- By default, members of the local administrators group can log on to a Telnet server. However, you might not want all Telnet users to have full administrative control of the host they log on to. In this case, you can use a Telnet clients group to grant users Telnet logon rights without granting them any administrative rights on the host. To configure these user rights from the graphical user interface, you must use the Active Directory Users and Groups snap-in or the Local Users and Groups snap-in. You can also use the **Net User** and **Net Group** commands to configure user rights from the command line.

- You can configure several optional settings when you use Telnet Client to establish a Telnet session on a host. Depending on the type of Telnet server you are logging on to, and how the Telnet server is configured, you might need to enable or change some of these optional settings. Examples of Windows Server 2003 Telnet Client settings include: client-side logging, terminal type, port assignment, and alternate user name for logon.

- You can manage active Telnet sessions on a host by using the Windows Server 2003 Telnet administration tool. Some of the administrative tasks you can perform include: terminating Telnet sessions, sending console messages to users with active Telnet sessions, and listing Telnet session information (for example, user name, logon time, idle time, and client IP address).

### Note

- The information in this document refers to the Telnet Client and Telnet Server components that are installed by default with Windows Server 2003 and Windows XP Professional operating systems.

**Telnet Architecture**

Most network operating systems provide a Telnet client and a Telnet server. Telnet clients and servers are small executable programs that allow a local computer (a client) to access services and programs on a remote computer (a host). Telnet clients and servers, including Windows Server 2003 Telnet Client and Telnet Server, are based on the Telnet protocol, which is a subset of the TCP/IP suite and is described in RFC 854. The Telnet protocol specifies two general mechanisms: how Telnet clients and servers establish a connection across a network and how they transmit and receive information across a network.

You usually run a Telnet client program on a local computer: for example, a workstation that you are logged on to. You usually run a Telnet server program on a remote computer: for example, a host you want to administer. Telnet client programs initiate connections with Telnet servers. Telnet servers run in the background on a host, listening for Telnet clients to request a connection.

**Common Telnet Features**

Because Telnet clients and servers are based on the same standard protocol, all Telnet clients and servers have several features in common. These common features are what make Telnet clients and servers well suited for performing remote administration tasks in environments that require interoperability among disparate operating systems. In short, the Telnet protocol makes it possible for you to connect a computer running Windows Server 2003 Telnet Client to a UNIX Telnet server. The key features that make this interoperability possible include the following:

**Common communication protocols**

All Telnet clients and servers use TCP/IP as the underlying communication protocol. This makes Telnet clients and servers particularly useful for remotely administering computers across the Internet or within wide area networks (WANs) that are connected to the Internet. If your network does not support TCP/IP, you will not be able to use a Telnet client or server.

**Common communication ports**

TCP port 23 is reserved for Telnet client and server communication. By default, most Telnet clients initiate communication on port 23, and most Telnet servers listen on port 23 for connection requests. You can change the default port assignments with some Telnet client and server software, such as Windows Server 2003 Telnet Client and Server, but port 23 is the universally accepted port for Telnet communication.

**Common character set for communication**

All Telnet clients and servers are capable of transmitting and receiving a predefined character set consisting of standard ASCII character codes and ASCII control codes. All Telnet clients and servers transmit the ASCII codes across a network in unencrypted form (plaintext).

**Common implementation of the Network Virtual Terminal**

All Telnet clients and servers implement a network virtual terminal (NVT). The NVT is responsible for translating operating system-specific instructions (keyboard codes or display codes) into a consistent set of codes that all Telnet clients and servers can transmit and receive. The NVT is what makes Telnet clients and servers capable of communicating with each other regardless of which operating system they are using.

**Creating a Telnet Connection**

To create a Telnet connection between a Telnet client and a Telnet server, you must do the following:

- **Start the Telnet Server program on the host.** On Windows Server 2003, Telnet Server (Tlntsvr.exe) runs as a service. You can start the service manually every time you want to connect to a host, or you can configure the service so that it starts every time your computer starts. Telnet clients cannot connect to a host unless a Telnet server program (or service) is running and listening for connection requests.

- **Run the Telnet Client program on the local computer.** When you run Windows Server 2003 Telnet Client (Telnet.exe), you must specify the host to which you want to connect. You can also configure several optional connection

settings and features.

When you run a Telnet client, it makes a connection request to the host. If a Telnet server responds to the request, the Telnet client and server negotiate the details of the connection, such as flow control settings, window size, and terminal type. After the connection details are successfully negotiated, and logon credentials are validated, the Telnet server program creates a Telnet command console session.

On Windows Server 2003, each Telnet command console session consists of two processes: Tlntsess.exe and Cmd.exe. Tlntsess.exe is responsible for managing the Telnet session. Cmd.exe is the command interpreter, or shell program, that runs commands, programs, or scripts on the host.

**Note**

- Cmd.exe is the default command interpreter for a Windows Server 2003 Telnet command console session. However, you can configure the Windows Server 2003 Telnet Server program to use as a default any command interpreter or shell program that is installed on the host.

**Running Programs Remotely Using a Telnet Connection**

After you establish a Telnet connection with Telnet Server, the following message appears in the command prompt window on the client:

```
*= = = =
```

# Telnet Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Telnet Tools
- Telnet Registry Entries

Telnet Server tools and settings determine how Telnet Server handles auditing, authentication, idle session time-out, and other remote command console session options. Usually, you do not need to configure Telnet Server options to connect a Telnet client to Windows Server 2003-based Telnet Server: the default Telnet Server options are compatible with most Telnet clients. However, you must configure Telnet Server options if you want to do any of the following:

- Audit logon and logoff information.
- Disable NTLM or password authentication, or change the default domain for authenticating unqualified user names (by default, the domain in which the machine account resides is used to authenticate unqualified user names).
- Prohibit authentication of user accounts in trusted domains, which restricts Telnet access to users whose user accounts are stored only in the local Security Accounts Manager (SAM) database (by default, Telnet Server authenticates user accounts in trusted domains and the local SAM database).
- Change the default shell, or command interpreter, that is used for Telnet sessions (Cmd.exe is the default shell).
- Specify an IP address on which you want the Telnet Server program to listen for connection requests.
- Change the mode of operation from console mode to stream mode.
- Ensure that all programs started in a Telnet session terminate when you disconnect a Telnet session.
- Change the TCP port on which Telnet Server listens for a connection (by default, Telnet servers listen on TCP port 23).
- Change the maximum number of Telnet sessions that Telnet Server will accept (the default is 2).
- Change the maximum number of logon attempts before a user is disconnected (the default is 3).
- Disable idle session time-out, or change the idle session time-out value (the default is 1 hour).
- Disable Alt key mapping (by default, pressing Ctrl-A simulates the Alt key).

**Telnet Tools**
The following tools are associated with Telnet Server.

**Telnet.exe: Telnet Command Prompt**
**Category**
The Telnet command prompt tool is included with the Windows Server 2003 and Windows XP operating systems.

**Version compatibility**
Use this command on computers running Windows Server 2003 or Windows XP.

Once all of the settings and options are configured, you can use Telnet.exe to initiate and conduct a Telnet session. You can create a Telnet connection, configure Telnet.exe options, and use all Telnet.exe features by using the Telnet command prompt.

The Telnet command prompt is useful if you are performing quick maintenance tasks on several different hosts or you need to use advanced Telnet options and features.

You can access the Telnet command prompt by running the **Telnet** command without any command-line parameters. You can also access the Telnet command prompt by typing the Telnet escape character during an active Telnet session. The default escape character is Ctrl+].

After you start the Telnet command prompt, the following message appears:

```
Welcome to Microsoft Telnet Client
Escape Character is 'Ctrl+]'
Microsoft Telnet >
```

You can close the Telnet command prompt by using the **Quit** command.

**Telnet.exe with command-line parameters**

You can create a Telnet connection and configure some Telnet.exe options by using the **Telnet** command in conjunction with various command-line parameters. Using the **Telnet** command with command-line parameters is helpful if you are creating Telnet connections within a script or batch file or you do not need to use advanced Telnet client options and features. When you use **Telnet** with command-line parameters, you can use a single command to create a connection with a host. The command-line syntax for Telnet.exe is:

```
telnet [-a][-eescape_char][-flog_file][-luser_name][-tterm]host [port]
```

The command-line parameters are described in the following table.

**Telnet.exe Command-Line Parameters**

| Parameter | Description |
|---|---|
| **-a** | Instructs Telnet.exe to log on to the host using the credentials of the user who is currently logged on to the client. |
| **-e** *escape_char* | Specifies an escape character, which displays the Telnet command prompt. The default escape character is Ctrl+]. |
| **-f** *log_file* | Creates a client-side log file and turns on client-side logging for the current session. The *log_file* parameter must consist of a path and file name. |
| **-l** *user_name* | Instructs Telnet.exe to log on to the host using the user account that is specified in *user_name*. The user account specified in *user_name* must have Telnet logon rights on the host. |
| **-t** *term* | Specifies the terminal type. The default terminal type is ANSI. Other valid terminal types include VT52, VT100, and VTNT. |
| *host* | Specifies the host with which you want to create a Telnet connection. The *host* parameter can be a NetBIOS name, a fully qualified domain name, or an IP address. |
| *port* | Specifies the TCP port on which you want to create a Telnet connection. The default Telnet port is 23. |

For example, the following command uses the credentials of the user who is currently logged on to the client to create a Telnet connection on port 23 with a host named server01:

```
Telnet Server01
```

Likewise, the following example creates the same Telnet connection and enables client-side logging to a log file named c:\telnet_logfile:

```
telnet -f c:\telnet_logfile server01
```

The connection with the host remains active until you exit the Telnet session (by using the **Exit** command), or you use the Telnet Server administration tool to terminate the Telnet session on the host.

**TIntadmn.exe: Telnet Administration**

**Category**
The Telnet administration command-line tool is included with the Windows Server 2003 and Windows XP operating systems.

**Version compatibility**
Run this command on computers running Windows Server 2003 or Windows XP.

Tlntadmn.exe is a command-line tool, and is installed by default when you install Windows Server 2003. Unlike the Telnet Server administration tool in Windows 2000, Tlntadmn.exe is a noninteractive tool that must be run with various command-line parameters. Because Tlntadmn.exe is noninteractive, and uses command-line parameters to configure Telnet Server options, you can use Tlntadmn.exe in scripts or batch files to automate Telnet Server configuration tasks. You must be a member of the Administrators local group to use the Telnet Server administration tool.

For more information about **Tlntadmn.exe**, see "Telnet commands" in the Command Line References in the Tools and Settings Collection.

**Telnet Registry Entries**
The following registry entries are associated with Telnet.

You can configure most Windows Server 2003 Telnet Server options by using the Telnet Server administration tool (Tlntadmn.exe). However, you can only configure some options by using the registry editor (Regedit.exe). You should use the registry editor to configure only the Telnet Server options that cannot be configured with the Telnet Server administration tool.

You must be a member of one of the following groups to use Regedit.exe: Administrators, Server Operators, and Power Users. You can use Regedit.exe to change registry settings on a local or a remote computer. However, only members of the Administrators group can use Regedit.exe to configure registry settings on a remote computer.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft**
The following registry entries are located under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\TelnetServer\1.0\.

**AllowTrustedDomain**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\TelnetServer\1.0.\

**Version**
The AllowTrustedDomain entry is included in Windows Server 2003 and Windows XP.

You can prevent the Telnet Server program from authenticating users on trusted domains by configuring this registry entry.

By default, the Telnet Server program authenticates user accounts in trusted domains and in the local SAM database. Preventing the Telnet Server program from authenticating user accounts in trusted domains restricts Telnet access to only those users whose user accounts are in the local SAM database. By default, the AllowTrustedDomain registry entry has a value of 1. To prevent Telnet Server from authenticating user accounts in trusted domains, you must set this registry entry to 0.

**DefaultShell**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\TelnetServer\1.0.\

**Version**
The DefaultShell entry is included in Windows Server 2003 and Windows XP.

You can change the default shell, or command interpreter, that the Telnet Server program uses for a Telnet session by configuring this registry entry.

By default, Telnet Server runs all commands in the Windows Server 2003-based command interpreter (Cmd.exe). You can change this to any command interpreter that is installed on the host. You must provide a path and file name for the command interpreter.

**ListenToSpecificIpAddr**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\TelnetServer\1.0.\

**Version**
The ListenToSpecificIpAddr entry is included in Windows Server 2003 and Windows XP.

You can configure the Telnet Server program so it listens for connection requests that are sent to a specific IP address. This is useful if a host has several network adapters, and you want to limit Telnet connections to only one of the network adapters. It is also useful if you have a firewall, and you want to filter Telnet traffic through the firewall to only a few IP addresses.

By default, this registry entry has the value INADDR_ANY, which instructs Telnet Server to listen for Telnet connection requests that are sent to all IP addresses assigned to the host. You can change the value of this registry entry to any IP address that is assigned to the host.

# Terminal Services in Windows Server 2003 Technical Reference

Updated: November 14, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Terminal Services component of the Microsoft Windows Server 2003 operating system delivers the Windows Server 2003 desktop and the latest Windows-based applications to a wide variety of desktops, including those that normally would not be able to run Windows. Through terminal emulation, Terminal Services allows the same set of applications to run on diverse types of desktop hardware. For organizations wanting to more flexibly deploy applications and control desktop management costs, a Terminal Services architecture offers an important enhancement to the traditional two or three tier client-server architecture based on servers and full-scale personal computers.

Terminal Services extends the model of distributed computing by allowing PCs to operate in a server-based computing environment. With Terminal Services running on a Windows Server 2003-based computer, all client application execution, data processing, and data storage occur on the server. Applications and user desktops are transmitted over the network and displayed via terminal emulation software. Similarly, print streams, keyboard input, and mouse clicks are also transmitted over the network between the server and the terminal emulation software. Each user logs on and sees only their individual session, which is managed transparently by the server operating system and is independent of any other client session.

| **Note** |
| --- |
| In Windows Server 2008 R2, Terminal Services was renamed Remote Desktop Services. To find out what's new in this version and to find the most up-to-date resources, visit the Remote Desktop Services page on the Windows Server TechCenter. |

# What Is Terminal Services?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Terminal Services?**

**In this section**

- Reducing the Total Cost of Ownership
- Common Terminal Services Scenarios
- Interactions with Other Technologies
- Related Information

Terminal Services provides the ability to host multiple, simultaneous client sessions on Windows Server 2003. Terminal Services is capable of directly hosting compatible multi-user client desktops running on a variety of Windows-based and non Windows-based computers. Standard Windows-based applications do not need modification to run on the terminal server, and all standard Windows Server 2003-?based management infrastructure and technologies can be used to manage the client desktops. In this way, corporations can take advantage of the rich choice of applications and tools offered by today's Windows operating system environment.

**Reducing the Total Cost of Ownership**

Organizations are always searching for ways to reduce the costs of ownership and this is one of the major goals of Terminal Services. Terminal Services lets enterprises more easily and cost-efficiently accomplish this goal by allowing organizations to:

- Centrally deploy and manage Windows-based applications.
- Remotely administer Windows Server 2003-based computers.

**Centrally deploy and manage Windows-based applications.**

Terminal Services provides centralized deployment and management of 32-bit Windows-based applications to Windows-based terminals, remote users, or local PC desktops. Using Terminal Services, companies can ensure that all clients are using the current version of an application because the software is installed once on a server computer, rather than on every desktop throughout the company. This model reduces the costs and challenge of updating desktop machines, especially for remotely located desktops or branch office environments. In addition, Terminal Services features such as Remote Control can simplify application support.

Organizations can use Terminal Server mode to deliver Windows-based applications to heterogeneous desktop environments, over local area network (LAN), wide area network (WAN) and dial-up connections. This is a cost-effective way to deploy line-of-business applications that are frequently updated, hard to install, or need to be accessed over low-bandwidth connections.

Terminal Services acts as a convenient bridging tool for earlier desktops migrating to Windows XP Professional. It allows the Windows XP desktop experience to be delivered "virtually" to non-PC desktops and PCs that need hardware upgrades before they can run a full Windows XP operating system locally. Terminal Services clients are available for many different desktop platforms including Microsoft MS-DOS, Windows-based PCs, Macintosh, UNIX and others. By letting users access current applications on hardware that might otherwise be of little use, Terminal Services can help companies that are gradually replacing older machines. (Connectivity to MS-DOS, Macintosh, and UNIX-based machines requires a third party add-on such as Citrix MetaFrame).

**Remotely administer Windows Server 2003-based computers**

Remote Desktop for Administration can greatly reduce the overhead associated with remote administration. Enabled by Terminal Services technology, Remote Desktop for Administration is specifically designed for server management. Therefore, it does not install the application-sharing and multi-user capabilities or the process scheduling of the full Terminal Server component (formerly called Terminal Services in Application Server mode). As a result, Remote Desktop for Administration can be used on an already busy server without noticeably affecting performance and CPU utilization, which makes it a convenient and efficient service for remote management.

Remote Desktop for Administration is used to remotely manage Windows Server 2003 servers. This mode is designed to provide operators and administrators with remote access to typical back-end servers and domain controllers. The administrator has access to the graphical user interface-based tools that are available in the Windows environment, even if he or she is not using a Windows-based computer to administer the server. Administrators can securely manage their Windows Server 2003-based computers over any network connection from any device using the Terminal Services Client software. This lets an administrator perform tasks such as directory maintenance, virus scans, backups, reboots and even promote a server to be a domain controller—all from a remote location.

Remote Desktop for Administration allows for the management of servers from any location without affecting server performance or application compatibility. In addition to the console session, up to two remote administration sessions are supported; since this is meant as a single-user remote access solution, no Terminal Server Client Access License (CAL) is required to use Remote Desktop for Administration.

Administrators can also fully administer computers running Windows Server 2003 family operating systems from computers running earlier versions of Windows by installing Remote Desktop Connection.

**Note**

- Remote Desktop for Administration is disabled by default in Windows Server 2003 family operating systems.

#### Common Terminal Services Scenarios

The way in which you plan to use Terminal Server has an effect on how you deploy it. The following scenarios outline the various ways in which you might use Terminal Server in your organization. Use the information in these scenarios to clarify how you are going to use Terminal Server in your organization.

#### Hosting Line-of-Business Applications

If your organization or certain groups within your organization use specialized applications to do their work, it might be beneficial to host the applications with Terminal Server. For example, you might decide to use Terminal Server in the following situations:

- **Custom applications.** If your line-of-business application is developed in-house or especially for your organization, and it tends to require frequent updating or repair, deploying the application once on a terminal server can simplify administration of the application. This is especially useful if your environment is geographically dispersed or if you are deploying Terminal Server to centrally serve your organization's branch offices.

- **Large central data pool.** Applications that rely on access to a single data source often run better on a terminal server because large amounts of data do not have to travel across the network to users. Instead, the data processing takes place on the server. Only the keystrokes and display information travel across the network, so you can use lower bandwidth connections. This is especially useful if the users of the data pool are located remotely, for example in a branch office with a slow connection to the database server.

- **Task workers.** In environments where you want workers to access only the application that they need to perform their jobs, you can centralize the administration of these users by using Terminal Server.

- **IT Admin tools.** System administrators can perform tasks that require Enterprise Administrator or Domain Administrator permissions on a terminal server that has the necessary tools installed on it. They can also run their desktop applications on their local computer without these permissions.

- **Upgrading operating systems.** If your organization uses a line-of-business application that is not optimized for your desktop operating system, you can host the application with Terminal Server rather than change operating systems.

#### Hosting the Desktop

You can use Terminal Server to host user's entire desktop environments, so that when users log on, they see their usual desktop environments or desktop environments especially designed for their remote use. In this situation, users can open and close the applications they choose in the same way that they access applications from the Windows desktop on the local computer. You can host the desktop in the situations discussed in the following sections.

#### Remote users

Hosting the desktop with Terminal Server can provide consistency and better performance for users in remote locations because large amounts of application data are not being transmitted over the connection. For example, you might use Terminal Server in the following situations:

- **Bandwidth-constrained locations.** In areas where high bandwidth is not available or cost-effective, deploying applications on a terminal server can improve performance for users who are connecting to the network from a remote location.

- **Mobile users.** For users who are traveling and tend to access the corporate network over connections of varying bandwidth, Terminal Server can provide a more consistent experience.

#### Client heterogeneity

If your organization is in the process of converting all users to the same platform or upgrading desktop hardware, you can use Terminal Server to quickly deliver the most up-to-date version of the operating system and applications to the user while enabling you to spread the desktop platform or hardware conversion over a longer period of time. You can also deliver a highly controlled standard desktop to users by using Terminal Server, as illustrated in more detail in the following list:

- **Mixed-platform environment.** If you have users who require applications based on operating systems other than Windows to perform their jobs, but your organization is transitioning to or requires a Windows-based desktop, you can host the desktop with Terminal Server. This requires the use of third-party software in conjunction with Terminal Server.

- **Upgrading hardware.** If your organization is planning to upgrade to Windows XP on the desktop, but not all of the desktop hardware is compatible, you can use Terminal Server to host the desktops of users who have older hardware while you are in the process of upgrading the hardware. All users can have the same desktop environment and run the latest versions of the applications designed for Windows XP regardless of their desktop hardware.

- **Highly controlled environments.** In situations where you want to deliver a standardized and controlled environment to users, you can host the desktop with Terminal Server to centralize management.

#### Hardware Considerations

You can reduce hardware costs by hosting applications with Terminal Server and using thin client devices or older hardware on your user's desktops.

- **Use of thin clients.** Windows Powered thin clients (sometimes called Windows-based terminals) offer an alternative to personal computers and traditional "green screen" terminals by enabling easy remote access to productivity and line-of-business applications that are hosted on Windows-based terminal servers.

- **Extending the life of older hardware.** Rather than replacing older hardware that is no longer capable of running new Windows-based applications, you can use that older hardware much like a thin client to access the desktop and applications on the server rather than on the local computer.

#### Using the Remote Desktop Web Connection

The Remote Desktop Web Connection is an ActiveX control that provides virtually the same functionality as the executable version of Remote Desktop Connection, but it delivers this functionality over the Web even if the executable version is not installed on the client computer. When hosted in a Web page, the ActiveX Client Control allows a user to log on to a terminal server through a TCP/IP Internet or intranet connection and view a Windows desktop inside Internet Explorer.

The Remote Desktop Web Connection provides an easy way to offer Terminal Server through a URL. Consider using the Remote Desktop Web Connection in the following situations:

- **Roaming users.** Users who are away from their computers can use Remote Desktop Web Connection to gain secure access to their primary workstations from any computer running Windows and Internet Explorer, provided they can reach the target computers.

- **Delivery of extranet applications.** You can use Remote Desktop Web Connection to allow business partners or customers access to internal applications over the Internet. Users who gain access in this manner do not need to reconfigure their computers, and they do not gain access to your internal network.

- **Deployment transition.** You can deploy the Remote Desktop Web Connection quickly and use it while you are deploying your full Remote Desktop Connection infrastructure.

#### Interactions with Other Technologies

Terminal Services depends on, or interacts with, the following technologies:

- RDP Protocol - On the server, RDP uses its own video driver to render display output by constructing the rendering information into network packets using RDP protocol and sending them over the network to the client. On the client, RDP receives rendering data and interprets the packets into corresponding Microsoft Win32 graphics device interface API calls. For the input path, client mouse and keyboard events are redirected from the client to the server. On the server, RDP uses its own virtual keyboard and mouse driver to receive these keyboard and mouse events.

- Terminal Server Interactions with RDP

# How Terminal Services Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Terminal Services Works**

**In this section**

- Terminal Services Architecture
- Terminal Services Physical Structure
- Terminal Services Processes and Interactions
- Network Ports Used by Terminal Services
- Related Information

Terminal Services provides the ability to host multiple, simultaneous client sessions on Microsoft Windows Server 2003. Terminal Server is capable of directly hosting compatible multi-user client desktops running on a variety of Windows-based and non Windows-based hardware. Standard Windows-based applications do not need modification to run on the Terminal Server, and all standard Windows Server 2003-based management infrastructure and technologies can be used to manage the client desktops.

**Terminal Services Architecture**

Terminal Services consists of four components: the Windows Server 2003 multi-user kernel, the Remote Desktop client, the Terminal Services Licensing service, and Session Directory Services. Specifically:

Multi-user kernel. The multi-user kernel extensions, originally developed for Windows NT 4.0 Server, Terminal Server Edition, have been enhanced and fully integrated as a standard part of the Windows Server 2003 family kernel. These are resident on the server at all times, regardless of whether Terminal Services is enabled or not.

Remote Desktop client: The client software is an application that establishes and maintains the connection between a client and a server computer running Terminal Services.

Terminal Services Licensing service: This system allows terminal servers to obtain and manage terminal server client access license (TS CAL) tokens for devices and users connecting to a terminal server.

Session Directory Services: The session directory (SD) keeps a list of sessions indexed by user name, and allows a user to reconnect to the terminal server where the user's disconnected session resides and resume that session.

**Terminal Services Architecture**

The following table describes the Terminal Services architecture components.

**Terminal Services Components**

| Component | Description |
|---|---|
| CSRSS.exe | The Client-Server Runtime Subsystem is the process and thread manager for all logon sessions. |
| RdpDD.sys | Captures the Windows user interface and translates it into a form that is readily converted by RDPWD into the RDP protocol |
| RdpWD.sys | Unwraps the multi-channel data and then transfers it to the appropriate session. |
| SMSS.exe | Session Manager creates and manages all sessions. |
| Termsrv.exe | Manages client connections and initiates creation and shutdown of connection contexts. |
| Termdd.sys | The RDP protocol, which listens for RDP client connections on a TCP port. |
| Tdtcp.sys | Packages the RDP protocol onto the underlying network protocol, TCP/IP. |
| Wlnotify.dll | Runs in the session's WinLogon process to create processes in the user session. |
| Win32k.sys | Manages the Windows GUI environment by taking the mouse and keyboard inputs and sending them to the appropriate application. |
| WinLogon.exe | This system service handles user logons and logoffs and processes the special Windows key combination Ctrl-Alt-Delete. WinLogon is responsible for starting the Windows shell (which is usually Windows Explorer). |

**Terminal Services Architecture**

As the Windows Server 2003 Terminal Server boots and loads the core operating system, the Terminal Server service (termsrv.exe) is started and begins waiting for session connections. Each connection is given a unique session identifier or "SessionID" to represent an individual session to the Terminal Server, and each process created within a session is "tagged" with the associated SessionID to differentiate its namespace from any other session namespaces.

The console session (Terminal Server keyboard, mouse, and video) is always the first to load, is treated as a special-case client connection, and is assigned SessionID0. The console session starts as a normal Windows Server 2003 session, with the configured Windows display, mouse, and keyboard drivers loaded.

After creating the console session, the Terminal Server service then calls the Windows Session Manager (SMSS.EXE) to create two idle client sessions, which then await client connections. To create the idle sessions, the Session Manager starts the Client-Server Run-time Subsystem (CSRSS.EXE), and a new SessionID is assigned to that process. The CSRSS process also invokes the WinLogon process (WINLOGON.EXE) and the Windows Manager and GDI kernel module (Win32k.sys) under the newly associated SessionID.

The Windows image loader recognizes this Win32k.sys as a SessionSpace loadable image by a predefined bit set in the image header. It then relocates the code portion of the image into physical memory with pointers from the virtual kernel address space for that session if Win32k.sys has not already been loaded. By design, it always attaches to a previously loaded image's code (Win32k.sys) if one already exists in memory (that is, from any active application or session). The data (or non-shared) section of this image is then allocated to the new session from a newly created SessionSpace pageable kernel memory section.

Unlike the console session, Terminal Server client sessions are configured to load separate drivers for the display, keyboard, and mouse. The display driver is the Remote Desktop Protocol (RDP) display device driver (rdpdd.dll), and the mouse and keyboard drivers are replaced with the RDP driver Rdpwd.sys. These drivers allow the RDP client session to be both available and interactive, remotely. Finally, Terminal Server also invokes a connection listener thread for the RDP protocol (Termdd.sys), which listens for RDP client connections on a TCP port.

At this point, the CSRSS process exists under its own SessionID namespace, with its data instantiated per process as necessary. Any processes created from within this SessionID will execute within the SessionSpace of the CSRSS process automatically. This prevents processes with different SessionIDs from accessing another sessions data.

**Terminal Services Physical Structure**

Terminal Services provides remote access to a Windows desktop through "thin client" software, allowing the client computer to serve as a terminal emulator. It provides an effective and reliable way to distribute Windows-based programs, providing a single point of installation with multiple users having access to the Windows Server 2003 operating system desktop, where they can run programs, save files, and use network resources as if they were sitting at that computer.

For computers running Windows Server 2003 operating systems, the Terminal Services client program (Remote Desktop Connection) is already installed. Windows Server 2003 operating systems also include Terminal Services Client software for computers running 16- and 32-bit operating systems.

A Terminal Services client can exist in a variety of forms. Thin-client hardware devices that run an embedded Windows-based operating system can run the Terminal Services client software to connect to a server computer running Terminal Services. Windows, Macintosh, or UNIX computers can run Terminal Services client software to connect to a Terminal Services server to display Windows-based applications. This combination of Terminal Services clients provides access to Windows-based applications from virtually any operating system.

**Terminal Server Licensing**

The Windows Server 2003 operating system family provides a client license management system known as Terminal Server Licensing. This system allows terminal servers to obtain and manage terminal server client access license (TS CAL) tokens for devices and users connecting to a terminal server. Terminal Server Licensing is a component service of Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition. It can manage unlicensed, temporarily licensed, and client-access licensed clients, and supports terminal servers that run Windows Server 2003 as well as the Windows 2000 Server operating system. This greatly simplifies the task of license management for the system administrator, while minimizing under- or over-purchasing of licenses for an organization. Terminal Server Licensing is used only with Terminal Server and not with Remote Desktop for Administration.

**Session Directory**

Terminal Services is a technology that lets users run Microsoft Windows-based applications on a remote Windows Server 2003-based computer. In a Terminal Server-based computing environment, all application execution and data processing occur on the server. In a load balanced environment, a farm of terminal servers have incoming session connections distributed in a balanced manner across the servers in the farm. The session directory (SD) keeps a list of sessions indexed by user name, and allows a user to reconnect to the terminal server where the user's disconnected session resides and resume that session.

### Terminal Services Physical Structure

### Terminal Services Components

| Component | Description |
|---|---|
| Terminal Server | Hosts applications for client computers. |
| Terminal Server Licensing Service | Issues TS Device CAL token to a requesting terminal server. |
| Session Directory | Maintains a list of the user names associated with the session IDs connected to the servers in a load balanced Terminal Server cluster. |

| | |
|---|---|
| Remote Desktop Connection | Client software that allows a connection to one remote computer. |
| Remote Desktops MMC Snap-in | Client software used by administrators to connect to multiple remote computers simultaneously. |
| Remote Desktop Web Connection | ActiveX RDP Web browser client. |

**Terminal Services Processes and Interactions**
Terminal Services transmits only the user interface of the program to the client, with the client computer connecting through the network, sending keystroke and mouse-movement information over the Remote Desktop Protocol to the Terminal Server. It then sends the client screen information in the form of simple (and bandwidth-friendly) GDI events, backed with bitmap information if required to properly display the desktop state.

Each user logs on and sees only their individual session, which is managed transparently by the server operating system and is independent of any other client session. The Terminal Server provides virtual Windows session management, so users can essentially treat that session as their own personal computer.

**Remote Desktop Clients**
There are three clients for Terminal Services: Remote Desktop Connection, Remote Desktops Snap-In, and Remote Desktop Web Connection. The client software is a very small software application that establishes and maintains the connection between a client and a server computer running Terminal Services. Each client transmits all input from the user to the server, such as keystrokes and mouse movements, and all output from the server such as application display information and print streams. Remote Desktop Web Connection provides most of the same functionality as the Remote Desktop Connection software; but it does not require a private network, or virtual private network connection. Remote Desktop Web Connection is covered in the next section.

### Connection using Remote Desktop Connection

**Remote Desktop Connection and Remote Desktops Snap-In**
The Terminal Services client has a new name, Remote Desktop Connection. Remote Desktop Connection can be installed and run on any Windows 95, Windows 98, Windows Millennium Edition, or Win32 platform (non-Windows-based clients are supported by the Citrix Metaframe add-on).

The client initiates a connection to the Terminal Server through TCP port 3389. The Terminal Server RDP listener thread detects the session request and creates a new RDP stack instance to handle the new session request. The listener thread hands over the incoming session to the new RDP stack instance and continues listening on the TCP port for further connection attempts. Each RDP stack is created as the client sessions are connected to handle negotiation of session configuration details.

First, an encryption level is established for the session. The Terminal Server initially supports three encryption levels: low, medium, and high.

Low encryption encrypts only packets being sent from the client to the Terminal Server. This “input only” encryption is to protect the input of sensitive data like a user’s password. Medium encryption encrypts outgoing packets from the client the same as low-level encryption, but also encrypts all display packets being returned to the client from the Terminal Server. This method of encryption secures sensitive data as it travels over the network to be displayed on a remote screen. Both low and medium encryption use the RC4 algorithm with a 40-bit key. High encryption encrypts packets in both directions, to and from the client, but uses the industry standard, non-exportable 128-bit high-level encryption.

At this point, prior to any logon being presented to the end user, the licensing details are negotiated. First, the client secures a Windows Server 2003 Client access license. Second, a Windows Server 2003 desktop license is verified on the machine that is connecting, and if no license can be validated, a connectivity license is provided to a non-Windows client to allow connection to the Terminal Server.

After session details have been negotiated, the server RDP stack instance, for this connection, is mapped to an existing idle Win32k user session, and the user is prompted with the Windows Server 2003 logon screen. If autologon is configured, the encrypted user name and password is passed to the Terminal Server and logon proceeds. If no idle Win32k sessions currently

exist, the Terminal Server service calls the Session Manager (SMSS) to create a new user space for the new session. Much of the Win32k user session is using shared code and does load noticeably faster after one instance has previously loaded.

After the user types her or his user name and password, encrypted packets are sent to the Terminal Server. The Winlogon process performs the necessary account authentication to ensure that the user has sufficient credentials to log on and then passes the user's domain and user name to the Terminal Server service, which maintains a domain/user name, SessionID list. If a SessionID is already associated with this user, they are remapped into the existing namespace, and the previous session stack is reloaded. Otherwise, the connection proceeds as normal and the Terminal Server service creates a new domain/user name, SessionID mapping. If for some reason more than one session is active for this user, the list of sessions is displayed and the user decides which one to make the reconnection.

The Remote Desktops snap-in is ideal for administrators who are remotely administering multiple servers or terminal servers. You can create Remote Desktop connections to multiple terminal servers or to computers running Windows 2000 Server or Windows Server 2003 family operating systems with the Remote Desktops MMC snap-in. A navigable tree display provides easy switching between connections.

**Remote Desktop Web Connection**

Remote Desktop Web Connection provides virtually the same functionality as Remote Desktop Connection, but delivers this functionality over the Web. When embedded in a Web page, Remote Desktop Web Connection can establish a Remote Desktop session with a remote computer, even if Remote Desktop Connection is not installed on the client computer. Remote Desktop Web Connection must be installed on a Web server with Internet Information Services (IIS) and Active Server Pages (ASP) enabled.

The Remote Desktop Web Connection is an ActiveX control that offers full feature parity with the standard Remote Desktop Connection client software offered in Windows XP and the Windows Server 2003 family of operating systems. The Remote Desktop Web Connection, like the Remote Desktop Connection which is installed by default, allows for connectivity to a Terminal Server. When installing the Remote Desktop Web connection on a specified computer the ActiveX control and sample ASP pages are installed. Internet Information Services is the delivery mechanism for the Remote Desktop Web Connection ActiveX control. This ActiveX control launches a Remote Desktop session to a Terminal Server computer from within Internet Explorer.

**How Remote Desktop Web Connection works**

Remote Desktop Web Connection connects to the Terminal Server as follows:

1. The user opens a Web browser and requests the initial Remote Desktop Web Connection (DHTML) login page.

2. The IIS server sends the page, and if this if the first time the client has connected, the user is also prompted to download the Remote Desktop ActiveX Control.

3. The user populates the connection information which includes the Terminal Server name.

4. The client computer creates a connection directly to the Terminal Server computer by using port 3389.

**Connection Process**

Remote Desktop Web Connection is a Web application that consists of an ActiveX control and DHTML pages. The DHTML pages provided only serve as a way to pass parameters to the Remote Desktop ActiveX control. Once the information is passed from the DHTML page to the ActiveX control, the Web page and the Web server no longer has a role in the process. Internet Information Services only serves as a mechanism for delivering the ActiveX control. When the user clicks **Connect**, the parameters from the DHTML page are passed to the control and a Remote Desktop connection to the Terminal Server is initiated.

When you connect to the IIS computer that is serving up the Remote Desktop Web Connection page, you are connecting over port 80. Upon connection to the Web page, the ActiveX control is downloaded to your client computer and stored in the default location for downloaded controls in Internet Explorer - %systemroot\Downloaded Program Files. From the supplied sample

Web page, the name of the Terminal Server and the display resolution are passed as parameters to the ActiveX control. After these parameters are passed, the connect method on the control is called, and then a session is launched to the Terminal Server computer. The Active X control on the client computer then creates a connection directly to the Terminal Server computer over TCP port 3389.

### Note

- The Web client is the same as the full Remote Desktop Connection client without the entire configuration interface. It obtains these properties from the Remote Desktop Web Connection page, and not by any communication with the IIS computer itself.

**Session Disconnect**
If a user decides to disconnect the session, the processes and all virtual memory space remain and are paged off to the physical disk if memory is required for other processes. Because the Terminal Server keeps a mapping of domain/user names and SessionIDs, when the same user reconnects, the existing session is loaded and made available again. An additional benefit of RDP is that of being able to change session screen resolutions, depending on what the user requests for the session. For example, let's say a user had previously connected to a Terminal Server session at 800 x 600 resolution and disconnected. If the user then moves to a different computer that only supports 640 x 480 resolution and reconnects to the existing session, the desktop is redrawn to support the new resolution.

**Automatic Reconnection**
Automatic Reconnection adds resilience to the Remote Desktop Connection client is Windows Server 2003. It is designed to recover from temporary connection losses due to network problems. Automatic Reconnection enables disconnected Terminal Services sessions to automatically re-authenticate to a Terminal Server without prompting the user for credentials.

Mobile users can greatly benefit from this feature. For example, with the previous versions of Terminal Server client, a user working with a wireless laptop which momentarily loses connectivity would be disconnected from the session and greeted with the message "The connection was ended because of a network error. Please try connecting to the remote computer again." Now with Automatic Reconnection, the user resumes the original session without needing to re-enter a password.

**Reconnection Process:**
The Automatic Reconnection process is managed using a cookie that is sent to the client. When reconnection is initiated on the client, it sends this cookie to the server as a token for validating the connection. The auto reconnection cookie is generated at the server, and is flushed and regenerated any time a user logs in to a session or when a session is reset. This ensures that after the user connects to the session from a different computer, the original computer cannot reconnect. The server also invalidates and updates the cookie at hourly intervals, sending an updated cookie to the client as long as the session is active.

**User Logoff**
Once a user logs off from the session, all processes associated with the SessionID are terminated and any memory allocated to the session is released. Of course, if the user was running a 32-bit application like Microsoft Word and logged off from the session, the application would remain in memory until the very last user exited from the application.

**Terminal Services Licensing service**
The Windows Server 2003 operating system family provides a client license management system known as Terminal Server Licensing. This system allows terminal servers to obtain and manage terminal server client access license (TS CAL) tokens for devices and users connecting to a terminal server. Terminal Server Licensing is a component service of Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition. It can manage unlicensed, temporarily licensed, and client-access licensed clients, and supports terminal servers that run Windows Server 2003 as well as the Windows 2000 Server operating system. This greatly simplifies the task of license management for the system administrator, while minimizing under- or over-purchasing of licenses for an organization. Terminal Server Licensing is used only with Terminal Server and not with Remote Desktop for Administration.

**Terminal Server Licensing**

Terminal Server for Windows Server 2003 (known as Application Server mode in Windows 2000 Server) provides application deployment and management for users on a variety of devices through its application server mode. Each device or user who initiates a session on a terminal server running Windows Server 2003 must be licensed with one of the following:

1. Windows Server 2003 Terminal Server Device Client Access License.

2. Windows Server 2003 Terminal Server User Client Access License.

3. Windows Server 2003 Terminal Server External Connector.

Note that additional licenses might be needed, such as Microsoft or other application, operating system, and Client Access licenses. The licenses in the preceding list are required even if other add-on products are used on top of Windows Server 2003.

The Terminal Services Licensing service is only associated with licensing for a terminal server client. It is not used to license any other application or service, and does not replace or interoperate with the licensing service for any other component, or alter your rights and obligations under any End User License Agreement (EULA). The Terminal Server Licensing service is not a replacement for purchasing a TS CAL.

TS CAL tokens are electronic representations of real licenses, but they are not actual licenses themselves. Therefore if a license token is lost, it does not mean that you have lost an actual license. If you have the documentation to prove that you have bought an actual license, the license token can be re-issued. Conversely, just because you have a license token does not mean that it necessarily maps to an actual legal license.

Terminal Services Licensing is designed to manage these license tokens to allow an administrator to more accurately assess an organization's licensing requirements. However, there are a few situations in which a license token will not map to an actual license. The administrator should determine if this is the case, and if necessary, purchase extra licenses (but not install the corresponding license tokens) to account for this discrepancy.

**How Terminal Services Licensing Works**

All communication during the licensing process occurs between the client and the terminal server, and between the terminal server and the license server. The terminal server client never communicates directly with the license server.

When a client device attempts to connect to a terminal server in Per Device mode, the terminal server determines if the client has a license token. Terminal server clients store license tokens in the following registry key:

HKEY_LOCAL_MACHINE\Software\Microsoft\MSLicensing

If a client has no license token, the terminal server attempts to contact a license server from its list of discovered license servers. If no contact is made, the terminal server restarts the discovery process. If no license server responds, the device can not connect to the terminal server unless it is operating within the terminal server grace period.

When a license server responds, the terminal server requests a temporary token for the device because this is the first time the device has connected to a terminal server. The terminal server then pushes this temporary token to the device. After a user has provided valid credentials resulting in a successful logon, the terminal server instructs the license server to mark the issued temporary token as validated.

The next time a user attempts to connect to a terminal server in Per Device mode from this device, the terminal server requests a Windows Server 2003 TS Device CAL token for this device. If the license server has available TS Device CAL tokens, the

license server removes one token from the available pool, marks it as issued to the device, logs the device name, the user name of the device, and the date issued, and then pushes this TS Device CAL token to the device.

If the license server has no TS Device CAL tokens, it will first look to any other license server in its domain, workgroup, or site. License servers maintain information about where other accessible license servers exist, and if they have license tokens. If another license server is accessible that does have inventory, the first license server will request a license token from the second license server and deliver it to the terminal server, which then passes the token to the client device. If there are no available TS Device CAL tokens, the device will continue to connect with the temporary token.

Temporary tokens allow devices to connect for 90 days, and will then expire. TS Device CALs, while representing perpetual licenses, are set to expire 52-89 days from the date they are issued. The terminal server always attempts to renew these tokens 7 days prior to their expiration. The purpose of this system is to recover TS Device CAL tokens that are lost due to events such as hardware failure or operating system reinstallation.

**Client License Distribution Per User**
When a terminal server is configured in Per User mode, the terminal server must be able to locate a license server after the grace period has expired. While it is possible to install TS Per User CAL tokens on a license server, there is currently no method of assigning a TS Per User CAL token to a particular user account.

**Client License Distribution for External Connector**
There is currently no support in Terminal Server Licensing or the Microsoft Clearinghouse for the External Connector. In order to use an External Connector license, you will need to configure your terminal server in Per User mode.

**Terminal Server Licensing Model**
Terminal Server Licensing operates between several components as shown in the previous figure, including the Terminal Server Licensing-enabled license server, the Microsoft Certificate Authority and License Clearinghouse, one or more terminal servers, and terminal server clients. A single license server can support multiple terminal servers. There can be one or more license servers in a domain, or throughout a site.

**Microsoft Certificate Authority and License Clearinghouse**
The Microsoft Clearinghouse is the facility Microsoft maintains to activate license servers and to issue client license key packs to license servers. A client license key pack is a digital representation of a group of client access license tokens. The Microsoft Clearinghouse is accessed through the Terminal Services Licensing administrative tool. It can be reached directly over the Internet, through a Web page, or by phone.

**License Server**
A license server is a computer on which Terminal Server Licensing is installed. A license server stores all TS CALs license tokens that have been installed for a group of terminal servers and tracks the license tokens that have been issued. One license server can serve many terminal servers simultaneously. A terminal server must be able to connect to an activated license server in order for permanent license tokens to be issued to client devices. A license server that has been installed but not activated will only issue temporary license tokens.

**Terminal Server**
A terminal server is a computer on which the Terminal Server service is installed. It provides clients access to Windows-based applications running entirely on the server and supports multiple client sessions on the server. As clients connect to a terminal server, the terminal server determines if the client needs a license token, requests a license token from a license server, and then delivers that license token to the client.

**Terminal Services Session Directory Service**
In a Terminal Server-based computing environment, all application execution and data processing occur on the server computer. In a load balanced environment, terminal servers are grouped into farms, with each farm being represented to client machines as a single computer name with one IP address. The device performing the load balancing redirects incoming session connections to each machine in the farm according to its load balancing algorithm. Using a load-balancing solution with Terminal Server distributes sessions across the servers in the farm for improved performance. Terminal Services Session Directory, which is available with Windows Server 2003, Enterprise Edition, works with your load-balancing solution.

Session Directory is a load balancing feature that enables users to easily reconnect to a disconnected session on a server farm running Terminal Services. The Session Directory is a database that tracks user session's that are running on load-balanced terminal servers. It provides information when a user reconnects (after disconnecting intentionally or because of a network failure) to ensure that the user reconnects to the same session rather than starting a new session. Session Directory, which can support several thousand sessions, is also cluster-aware. Session Directory is compatible with the Windows Server 2003 load balancing service and is supported by third-party external load balancer products.

Terminal Services Session Directory management works with a load balancing service to ensure that users are transparently reconnected to the original server hosting their disconnected Terminal Server session.

The components of Terminal Services Session Directory are:

- A network load-balancing solution
- Two or more Terminal Servers logically grouped into a Terminal Server cluster
- A Session Directory server

Network Load Balancing, a clustering technology included in the Windows Server 2003, Enterprise Edition, and Windows Server 2003, Data Center Edition, enables servers to deliver high performance and failover protection. Network Load Balancing distributes IP traffic to multiple copies (or instances) of a TCP/IP service, such as Terminal Server or IIS, each running on an individual host within the cluster. The clients access the cluster using one or more virtual IP addresses; from there the NLB cluster evenly partitions the client requests among the hosts. From the clients point of view, the cluster appears to be a single server. As enterprise traffic needs increase, network administrators can simply add an additional server and incorporate it into the cluster.

In a load balanced environment, each Terminal Services cluster is represented to client machines as a single computer name with one IP address. The device or service performing its load balancing redirects connections to individual servers (nodes) in the cluster according to its load balancing algorithm.

Load balancing pools the processing resources of several servers using the TCP/IP networking protocol whereas Session Directory keeps track of the disconnected sessions on the cluster and ensures that users are reconnected to those same sessions.

Session Directory members can only be comprised of Enterprise and Datacenter Terminal Servers. Computers running Windows Server 2003, Standard Edition, are unable to join a Session Directory because they lack the required clustering technology; however a computer running Windows Server 2003, Standard Edition, can operate as the Session Directory server.

**How Session Directory Works**

1. An incoming connection to the cluster is load balanced to one node, which provides the logon prompt.
2. When the user logs on to the Terminal Server cluster, the Terminal Server receiving the initial client logon request sends the user name to the Session Directory server.
3. The Session Directory server checks the user name against its database and sends the result to the requesting server. The Session Directory database is a jet database containing a list of sessions indexed by user name.
4. If the user has no disconnected sessions, the log on process continues at the server hosting the initial connection.
5. If the user has a disconnected session on another serer, the initial hosting server sends the client information necessary for the client to continue authentication against the server hosting the disconnected session. The transition from one server to the other is transparent to the user.
6. When the user logs on to the disconnected session, the Session Directory is updated.

The Terminal Server Session Directory database is updated and queried by the Terminal Servers whenever users log on, log off, or disconnect from a session.

**Note**

- The Session Directory redirection feature is dependent on the version of the Remote Desktop Connection client used. The Remote Desktop client released with Windows XP is the minimum level necessary to function properly with Session Directory. Windows 2000 and Windows NT 4.0 Terminal Server clients are not Session Directory-aware, so client sessions will not be redirected to a disconnected session when that session is on an alternate node.

**Network Load Balancing**

Session Directory exists to solve a problem for Terminal Server clusters. These clusters can be load balanced using various solutions. This section discusses some general practices for any solution in use for load balancing. Here are some general considerations for Terminal Server clusters:

Consider splitting network traffic between two network adapters: one for Terminal Services connections and the other for access to other network resources and infrastructure. This allows for network access to the server in case the adapter bound to the cluster becomes unavailable.

For easier administration, place all load-balanced Terminal Servers into an Organizational Unit (OU) and apply Group Policy settings to that OU.

Home directories and other user data storage will need to be configured in such a way that the users can easily access their data no matter which server they are logged into.

Network Load Balancing (NLB) was previously installed by adding it as a service to a network connection and then configuring that network component on each node individually. NLB Manager in Windows Server 2003 is a new centralized snap-in added to provide easier configuration and maintenance for NLB configurations.

Although it is still possible to configure an NLB cluster by modifying network connection properties directly, the best practice is to use NLB Manager. In addition, the use of both NLB Manager and modifying network properties to configure an NLB cluster is not recommended.

**Remote Desktop for Administration**

You can use Remote Desktop for Administration to manage a network remotely using a configuration similar to the one shown in the following illustration.

Remote Desktop for Administration provides remote access to the server desktop by using the Terminal Services Remote Desktop Protocol (RDP) on port 3389. RDP transmits the user interface to the client session, and also transmits keyboard and mouse clicks from the client to the server. You can create up to two simultaneous remote connections. Each session you log on to is independent of other client sessions as well as the server console session. In essence, you can use Remote Desktop for Administration to log on to the server remotely as though you were logged on locally.

If you need to connect to the server console session remotely (for example, to access applications that direct only their user interface to the console), either use the Remote Desktops snap-in or use Remote Desktop Connection from the command line. When you attempt to connect to the console session, whether remotely or locally, you will be notified if there is already another user connected to the console session. The notification message will be shown after your logon credentials are validated, and will include information about the user who is logged on to the console session, including user name, location of logon (local or remote), and the state of the session (in use, locked, or idle).

**Note**

- Be aware of the security implications of remote logons. Users who log on remotely can perform tasks as though they were sitting at the console. For this reason, you should ensure that the server is behind a firewall. You should require all users who make remote connections to use a strong password.

The connection to Remote Desktop for Administration uses TCP/IP, either over an existing network connection or by remote access. A remote access server running one of the Windows Server 2003 family of operating systems provides two different types of remote access connectivity:

Network and Dial-up Connections

Virtual private networking

The following illustration shows how you can connect to a computer running one of the Windows Server 2003 family of operating systems from a remote location using remote access.

**Administering Windows Server 2003 family operating systems remotely**
After you are connected to a computer running a Windows Server 2003 family operating system, you can use Remote Desktop for Administration to remotely administer the server and its local computers. Remote Desktop for Administration gives you access to a variety of administrative tools used to configure and manage computers. Through a Terminal Services session, you can access Microsoft Management Console (MMC), Active Directory, Systems Management Server, network configuration tools, and most other administrative tools.

Remote Desktop for Administration is extremely useful because it provides remote access to most configuration settings, including Control Panel, which usually cannot be configured remotely. Also, using Remote Desktop for Administration can be particularly convenient for diagnosing a problem and testing multiple solutions quickly.

You can access the servers from anywhere in the world by using a wide-area network (WAN), a virtual private network (VPN), or a dial-up connection. You can start time-consuming batch administrative jobs (for example, tape backups), disconnect, and later reconnect to the corporate network to check progress.

Server application and operating system upgrades can be completed remotely as well as tasks that are not usually possible unless you are sitting at the console, such as domain controller promotion/demotion and disk defragmentation. Server file system tasks such as copying large files and virus scanning are much more efficient when performed within a Remote Desktop for Administration session, rather than using utilities that are executed from a client computer.

Administrative tasks are quicker and more intuitive than using command line utilities, although it is still possible to open a command shell.

### Note

- For some third-party applications, pop-up messages cannot be seen in a Terminal Services session. This is because there is a different security context or desktop for the connected session that does not display the application's pop-up messages. The pop-up messages in these instances will go directly to the console. If you need to see these messages, connect to the console session using Remote Desktop Connection from the command line or the Remote Desktops snap-in.

**Network Ports Used by Terminal Services**
Terminal Server uses RDP to communicate between client and server. RDP works only across a TCP/IP connection, such as a local area network (LAN), wide area network (WAN), dial-up, Integrated Services Digital Network (ISDN), digital subscriber line (DSL), or virtual private network (VPN) connection. You can still use other protocols, such as Internetwork Packet Exchange (IPX) or NetBIOS Extended User Interface (NetBEUI), as the transport protocol for non–Terminal Server traffic, such as network file or printer sharing, or between the client portion of a client-server application and its server.

### Port Assignments for Terminal Services

| Service Name | UDP | TCP |
|---|---|---|
| Remote Desktop Protocol (RDP) | | 3389 |

**Related Information**

The following resources contain additional information that is relevant to this section.

# Terminal Services Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Terminal Services Tools and Settings**

**In this section:**

- Terminal Services Tools
- Terminal Services Group Policy Settings
- Terminal Services WMI Classes
- Network Ports Used by Terminal Services
- Related Information

This section summarizes the tools and settings associated with Terminal Services.

**Terminal Services Tools**

The following tools are associated with Terminal Services.

**Change.exe: Change logon**

**Category**

This tool is included in all Microsoft Windows Server 2003 operating systems except the Web edition.

**Version compatibility**

This tool will run on all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

Enables or disables session logons to a server that has Terminal Server enabled. The change logon command disables logons from client sessions other than the system console. Users that are currently logged on are not affected. Client sessions are always re-enabled when you restart the system. If you are connected to the terminal server from a remote location and disable client sessions, and if you log off before re-enabling client sessions, you will not be able to reconnect. You need to logon at the system console in order to re-enable sessions.

**Change.exe: Change port**

**Category**

This tool is included in all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

**Version compatibility**

This tool will run on all Windows Server 2003 operating systems except Windows Server 2003, Web edition..

Changes the COM port mappings for MS-DOS application compatibility. Most MS-DOS applications support only COM1 though COM4 serial ports. Change port maps a serial port to a different port number, allowing applications that cannot access high-numbered COM ports to access the serial port. For example, to map COM12 to COM1 for use by a MS-DOS application, type change port com12=com1. Remapping works only for the current session.

You can run Change port without any parameters to display the available COM ports and the current COM port mappings.

**Change.exe: Change user**

**Category**

This tool is included in all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

**Version compatibility**

This tool will run on all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

Changes the .ini file mapping for the current user. Use change user /install before installing an application to create .ini files for the application in the Terminal Server system directory. These files are used as master copies for the user-specific .ini files.

After installing the application, use change user /execute to revert to normal .ini file mapping.

**Cprofile.exe: Clean profile**

**Category**
This tool is included in all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

Cleans the specified profiles of wasted space and removes user-specific file associations from the registry when disabled.

A terminal server uses file associations to determine which application to use to access files of various types. File types are registered using Windows Explorer.

Per-user file associations allow each user to have a different application associated with a specific file type. For example, one user could have .doc files associated with Microsoft Word and another user could have .doc files associated with Windows WordPad.

If user-specific file associations are enabled, Clean profile only removes the unused space from the user profile. If user-specific file associations are disabled, Clean profile also removes the corresponding registry entries.

**Flattemp.exe: Flat Temp**

**Category**
This tool is included in all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

Enables or disables flat temporary folders. After each user has a unique temporary directory, use flattemp /enable to enable flat temporary directories.

The default method for creating temporary folders for multiple users (usually pointed to by the TEMP and TMP environment variables) is to create subfolders in the \Temp folder, using the logonID as the subfolder name. For example, if the TEMP environment variable points to C:\Temp, the temporary folder assigned to the user logonID DonHall is C:\Temp\DonHall. Using flattemp, you can point directly to the \Temp folder and prevent subfolders from forming. This is useful when you want the user temporary folders to be contained in home directories, whether on a terminal server local drive or on a shared network drive. You should use this command only when each user has a separate temporary folder.

**Logoff.exe: Logoff**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Logs off a user from a session and deletes the session from the server. You can always log off from the session to which you are currently logged on. You must, however, have Full Control permission to log off users from other sessions.

Logging off a user from a session without warning can result in loss of data at the user's session. You should send a message to the user using the msg command to warn the user before taking this action.

If no ID or name for the session is specified, logoff logs off the user from the current session. If you specify a session name, it must be an active one.

When you log off a user, all processes end and the session is deleted from the server.

You cannot log off a user from the console session.

**Msg.exe: Msg**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Sends a message to a user. If you do not specify a name for the user or session, msg displays an error message. When specifying the name of a session, it must be an active one.

The user must have send message access permission to send a message.

**Mstsc.exe: Remote Desktop Connection**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Mstsc.exe is the command-line tool that launches Remote Desktop Connection. Remote Desktop Connection (formerly known as the Terminal Services client) is installed by default on all Windows Server 2003 family operating systems. You can use Remote Desktop Connection to connect to terminal servers, or to the desktop of a computer running one of the Windows Server 2003 family operating systems or Windows XP for remote administration.

Remote Desktop Connection allows you to create and configure your connection, save your connection settings to a file, and open and edit your saved connection files, all in the same program.

**Query.exe: Query process**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Query process displays information about processes running on a terminal server. You can use this command to find out which programs a specific user is running, and also which users are running a specific program.

If you do not specify the user name, session name, or program name, query process displays only the processes belonging to the current user.

If a session is specified, it must identify an active session. You can use wildcards to identify the process.

Query process returns the following information:

- The user who owns the process
- The session that owns the process
- The ID of the session
- The name of the process
- The state of the process
- The ID of the process

**Query.exe: Query session**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Query session displays information about sessions on a terminal server. The list includes information not only about active sessions but about other sessions that the server runs..

A user can always query the session to which the user is currently logged on. To query other sessions, the user must have Query Information access permission.

If you do not specify a session using session name, user name, or session id, query session displays information about all active sessions in the system.

**Query.exe: Query termserver**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Query termserver displays a list of all terminal servers on the network.

Query termserver searches the network for all attached terminal servers and returns the following information:

- The name of the server.
- The network (and node address if the /address option is used).

**Query.exe: Query user**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Query user displays information about user sessions on a terminal server. You can use this command to find out if a specific user is logged on to a specific terminal server. Query user returns the following information:

- The name of the user
- The name of the session on the terminal server
- The session ID
- The state of the session (active or disconnected)
- The idle time (the number of minutes since the last keystroke or mouse movement at the session)
- The date and time the user logged on

If you use query user without specifying a user name, session name, or session ID, a list of all users who are logged on to the server is returned. Alternatively, you can also use query session to display a list of all sessions on a server.

**Reset.exe: Reset session**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Enables you to reset (delete) a session from the terminal server. You can always reset your own sessions, but you must have Full Control access permission to reset another user's session.

Be aware that resetting a user's session without warning can result in loss of data at the session.

You should reset a session only when it malfunctions or appears to have stopped responding.

**Shadow.exe: Shadow**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Shadow enables you to remotely control an active session of another user. You can either view or actively control the session. If you choose to actively control a user's session, you will be able to input keyboard and mouse actions to the session.

You can always remotely control your own sessions (except the current session), but you must have Full Control access permission to remotely control another session. You can also initiate remote control using Terminal Services Manager.

Before monitoring begins, the server warns the user that the session is about to be remotely controlled, unless this warning is disabled. Your session might appear to be frozen for a few seconds while it waits for a response from the user.

Your session must be capable of supporting the video resolution used at the session you are remotely controlling or the operation fails.

The console session can neither remotely control another session nor can it be remotely controlled by another session.

**Tscc.msc: Terminal Services Configuration snap-in**

**Category**
This tool is included in all Windows Server 2003 operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

A Terminal Services connection provides the link clients use to log on to a session on the server. A TCP/IP connection is configured when Terminal Services is installed. Using Terminal Services Configuration, you can change the default properties of the connection or add new connections.

When you open Terminal Services Configuration you will see that a connection has already been configured. This is called the RDP-TCP connection. Typically, this is the only connection that needs to be configured for clients to connect to the server for Remote Desktop for Administration or application sharing with Terminal Server. Only one RDP (Remote Desktop Protocol) connection can be configured for each network adapter. If you want to configure additional RDP connections, you must install additional network adapters.

With Terminal Services Configuration, you can reconfigure the properties of the RDP-TCP connection, which includes limiting the amount of time client sessions can remain active on the server, setting protection levels for encryption, and selecting which permissions you want users and groups to have. Some connection properties can also be configured on a per-user basis using Terminal Services Group Policies or the Terminal Services extension to Local Users and Groups. For example, you can set different session time limits for each user when you use the Terminal Services extension to Local Users and Groups. Using Terminal Services Configuration, you can only set session time limits on a per-connection basis, which means the same time limit applies to all users who log on to the server using the connection.

**Tscon.exe: Tscon**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 family operating systems and on all Windows XP operating systems.

Tscon allows you to connect to another session. You must have Full Control access permission or Connect special access permission to connect to another session. You cannot connect to the console session

If you do not specify a password in the password parameter, and the target session belongs to a user other than the current one, tscon fails.

**Tsdiscon.exe: Tscon**

**Category**
This tool is included in all Windows Server 2003 family operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Tsdiscon disconnects a session from a terminal server. You must have Full Control permission to disconnect another user from a session.

If no session ID or session name is specified, tsdiscon disconnects the current session. The console session cannot be disconnected.

Any applications that were running when you disconnected the session are automatically running when you reconnect to that session with no loss of data.

**Tskill.exe: Tskill**

**Category**
This tool is included in all Windows Server 2003 operating systems and in all Windows XP operating systems.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems and on all Windows XP operating systems.

Tskill ends a process. You can use tskill to end only those processes belonging to you, unless you are an administrator. Administrators have full access to all tskill functions and can end processes running in other user sessions.

When all processes running in a session end, the session also ends.

**Tsmmc.msc: Remote Desktops snap-in**

**Category**
This tool is included in all Windows Server 2003 operating systems. For Windows XP, this tool is available in the Windows Server 2003 Administration Tools Pack.

**Version compatibility**
This tool will run on all Windows Server 2003 and Windows XP operating systems.

Windows Server 2003 provides the ability to connect to the console (session 0) of a computer by using a Remote Desktops connection. Because of this, a Connect to Console check box is available in the user interface, but this feature only works when you connect to a Windows Server 2003-based computer.

It is still possible to use the Remote Desktops tool to connect to a computer that is running Microsoft Windows NT 4.0, Terminal Server Edition, or Windows 2000 Server with Terminal Services enabled, but this creates a regular Remote Desktop Protocol (RDP) session. The option to connect to the console session is ignored.

The Remote Desktops snap-in is ideal for administrators who are remotely administering multiple servers or terminal servers. You can create Remote Desktop connections to multiple terminal servers or to computers running Windows 2000 Server or Windows Server 2003 family operating systems with the Remote Desktops snap-in. A navigable tree display provides easy switching between connections.

By default, the Remote Desktops snap-in connects you to the console session of the computer you specify in the connection. To run a specific program on connection, create a new connection that specifies the program name, and ensure that the default behavior is not selected.

**Tsprof.exe: Terminal Services profile**

**Category**
This tool is included in all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems except Windows Server 2003, Web edition.

Copies the user configuration information, which is displayed in the Terminal Services extensions to Local Users and Groups and Active Directory Users and Computers, from one user to another. Terminal Services profile can also set the profile path for a user.

**Tsadmin.exe: Terminal Server administration**

**Category**
This tool is included in all Windows Server 2003 operating systems except Windows Server 2003, Web Edition.

**Version compatibility**
This tool will run on all Windows Server 2003 operating systems except Windows Server 2003, Web Edition.

Use Terminal Services Manager to view information about terminal servers that reside in trusted domains. Use this tool to monitor users, sessions, and applications on each terminal server, and to carry out assorted actions to manage the server.

When a user creates a session by connecting to a terminal server from a client computer, the session appears in the Session list in Terminal Services Manager. In addition, the name of the user who logs on by using the session appears in the Users list. Any applications run in the user's session can be monitored on the Processes list. Therefore, you can oversee all users, sessions, and processes on a terminal server from one location.

**Terminal Services Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with Terminal Services.

**Group Policy Settings Associated with Terminal Services**

| Group Policy Setting | Description |
|---|---|
| Keep-Alive Connections | Specifies whether persistent connections are allowed. |
| Automatic reconnection | Specifies whether to allow Remote Desktop Connection clients to automatically reconnect to Terminal Services sessions if their network link is temporarily lost. |
| Restrict Terminal Services users to a single remote session | Specifies whether to restrict users to a single remote Terminal Services session. |
| Enforce Removal of Remote Desktop Wallpaper | Specifies whether desktop wallpaper is displayed to remote clients connecting via Terminal Services. |
| Deny log off of an administrator logged in to the console session | Specifies whether to allow an administrator attempting to connect to the console of a server to log off an administrator currently logged on to the console. |
| Allow Time Zone Redirection | Specifies whether to allow the client computer to redirect its time zone settings to the Terminal Services session. |
| Do not allow clipboard redirection | Specifies whether to prevent the sharing of clipboard contents (clipboard redirection) between a remote computer and a client computer during a Terminal Services session. |
| Do not allow smart card device redirection | Specifies whether to prevent the mapping of smart card devices in a Terminal Services session. |
| Allow audio redirection | Specifies whether users can choose where to play the remote computer's audio output during a Terminal Services session. |
| Do not allow COM port redirection | Specifies whether to prevent the redirection of data to client COM ports from the remote computer in a Terminal Services session. |
| Do not allow client printer redirection | Specifies whether to prevent the mapping of client printers in Terminal Services sessions. |
| Do not allow LPT port redirection | Specifies whether to prevent the redirection of data to client LPT ports during a Terminal Services session. |
| Do not allow drive redirection | Specifies whether to prevent the mapping of client drives in a Terminal Services session. |
| Do not set default client printer to be default printer in a session | Specifies whether the client default printer is automatically set as the default printer in a Terminal Services session. |
| Always prompt client for password upon connection | Specifies whether Terminal Services always prompts the client for a password upon connection. |
| Set client connection encryption level | Specifies whether to enforce an encryption level for all data sent between the client and the remote computer during a Terminal Services session. |
| Secure Server (Require Security) | Specifies whether a Terminal Server requires secure RPC communication with all clients or allows unsecured communication. |
| Limit number of connections | Specifies whether Terminal Services limits the number of simultaneous connections to the server. |

| | |
|---|---|
| Limit maximum color depth | Specifies the maximum color resolution (color depth) for Terminal Services connections. |
| Allow users to connect remotely using Terminal Services | Specifies whether to allow users to connect remotely using Terminal Services. |
| Do not allow local administrators to customize permissions | Specifies whether to disable the administrator rights to customize security permissions in the Terminal Services Configuration tool (tscc.msc). |
| Remove Windows Security item from Start menu | Specifies whether to remove the Windows Security item from the Settings menu on Terminal Services clients. |
| Remove Disconnect option from Shut Down dialog | Specifies whether to remove the Disconnect option from the Shut Down Windows dialog box on Terminal Services clients. |
| License Server Security Group | Specifies the terminal servers and license servers to which a Terminal Server License Server offers licenses. |
| Prevent License Upgrade | Specifies how a License Server distributes license upgrades to terminal servers running Windows 2000. |
| Do not delete temp folder upon exit | Specifies whether Terminal Services retains a user's per-session temporary folders at logoff. |
| Do not use temp folders per session | Specifies whether to prevent Terminal Services from creating session-specific temporary folders. |
| Terminal Server IP Address Redirection | Specifies how client devices are directed when reconnecting to an existing terminal server session. |
| Join Session Directory | Specifies whether Terminal Services uses a Session Directory for tracking user sessions, allowing a group of terminal servers to locate and connect a user back to an existing session. |
| Session Directory Server | Specifies whether to configure a server as a Session Directory Server for Terminal Services sessions on your network. |
| Session Directory Cluster Name | Specifies the Cluster Name for the terminal server, associating it with other servers in the same logical group. |
| Set time limit for disconnected sessions | Specifies a time limit for disconnected Terminal Services sessions. |
| Sets a time limit for active Terminal Services sessions | Specifies a time limit for active Terminal Services sessions. |
| Sets a time limit for active but idle Terminal Services sessions | Specifies a time limit for active but idle Terminal Services sessions. |
| Allow reconnection from original client only | Specifies whether to allow users to reconnect to a disconnected Terminal Services session using a computer other than the original client computer. |
| Terminate session when time limits are reached | Specifies whether to terminate a timed-out Terminal Services session instead of disconnecting it. |
| Set path for TS Roaming Profiles | Specifies whether Terminal Services uses the specified network path for roaming user profiles. |
| TS User Home Directory | Specifies whether Terminal Services uses the specified network share or local directory path as the root of the user's home directory for a Terminal Services session. |
| Sets rules for remote control of Terminal Services user sessions | Specifies the level of remote control permitted in a Terminal Services session. |
| Start a program on connection | Configures Terminal Services to run a specified program automatically upon connection. |

For more information about Group Policy settings, see the Group Policy Settings Reference for Windows Server 2003.

**Terminal Services WMI Classes**

The following table lists and describes the WMI classes that are associated with Terminal Services.

### WMI Classes Associated with Terminal Services

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_TerminalService | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSSessionDirectory | \\root\Cimv2 | Windows Server 2003 |
| Win32_TerminalServiceSetting | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSGeneralSetting | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSLogonSetting | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSSessionSetting | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSEnvironmentSetting | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSRemoteControlSetting | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSClientSetting | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSNetworkAdapterSetting | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSPermissionsSetting | \\root\Cimv2 | Windows Server 2003 |
| Win32_TSAccount | \\root\Cimv2 | Windows Server 2003 |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by Terminal Services**

Terminal Server uses RDP to communicate between client and server computers. RDP works only across a TCP/IP connection, such as a local area network (LAN), wide area network (WAN), dial-up, Integrated Services Digital Network (ISDN), digital subscriber line (DSL), or virtual private network (VPN) connection. You can still use other protocols, such as Internetwork Packet Exchange (IPX) or NetBIOS Extended User Interface (NetBEUI), as the transport protocol for non-Terminal Server traffic, such as network file or printer sharing, or between the client portion of a client-server application and its server.

### Port Assignments for Terminal Services

| Service Name | UDP | TCP |

# Data Streaming and E-mail Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Data Streaming and E-mail Technologies**

The use of streaming video and audio media is becoming an increasingly desirable feature in network technologies. As networks become more saturated with traffic, the timely delivery of latency-sensitive data, such as the data generated by video conferencing and Internet Protocol (IP) telephony programs, becomes more problematic. ATM and QoS are two technologies that you can use to facilitate the timely delivery of latency-sensitive data.

POP3 is an e-mail protocol that can be used facilitate mail delivery to computers that are not part of a network or computers that do not have an e-mail server on the local network.

**ATM**

Most network technologies use variable-length packet mechanisms to transfer data, and the available network bandwidth is divided into fixed channels or slots synchronized by a timing mechanism. This method is inefficient, and as the quantity of latency-sensitive data places increasing demands on the finite network bandwidth, the inefficiency becomes more problematic.

Asynchronous transfer mode (ATM) is a recent innovation in broadband networking technology that can be used to build high-speed networks. ATM differs from other existing LAN and WAN technologies because it is specifically designed to use bandwidth resources at maximum efficiency and support high-speed communications. To do this, ATM uses small, fixed-length cells to efficiently structure and parcel data for transfer. Because devices that communicate on an asynchronous network negotiate the rate at which they will communicate, based on physical hardware limitations and the ability to maintain a reliable flow of information within the network, they do not have the same types of restrictions as most existing network technologies.

ATM has been demonstrated at data rates up to 9.6 gigabits per second (Gbps) over Synchronous Optical NETwork (SONET), an international specification for fiber-optic communication. ATM is a scalable solution that can simultaneously accommodate data, voice, audio, fax, and video information types.

ATM provides versatility by means a set of features, including ATM-LAN emulation, address resolution protocol (ARP) address resolution service (MARS), and Encapsulated Ethernet over a permanent virtual connection (PVC):

- The ATM LAN emulation client enables existing programs and protocols designed for use on Ethernet and Token Ring networks to run without modification over an ATM network.
- In ATM, the LAN emulation (LANE) client module conforms to the ATM Forum LANE 1.0 specification. The ARP/MARS service enables the Microsoft TCP/IP stack to resolve ATM addresses to hardware addresses for more direct and efficient use of ATM media.
- Encapsulated Ethernet over PVC enables the transmission of Ethernet packets across PVC on an ATM network adapter.

**POP3**

Post Office Protocol version 3 (POP3) service enables a server to host e-mail accounts for subscribers of Internet service providers (ISP) or for small businesses. The most common use is for home ISP clients or small businesses that cannot locally implement and support a mail server, Simple Mail Transfer Protocol (SMTP) service, and related mail handling infrastructure. The POP3 protocol is used to retrieve mail that is being held by a mail server that offers SMTP service. The POP3 service performs the tasks of downloading messages, moving the messages from a folder in the file system of a mail server to clients on small networks, or to stand-alone home computers. Typically, after mail is downloaded from the mail server, the mail server deletes the mail from its folder.

**QoS**

As the finite bandwidth of a network becomes more congested with traffic, it becomes increasingly problematic to deliver latency-sensitive data in a timely manner. Quality of Service (QoS) is a set of service requirements that a network must meet to ensure an adequate service level for data transmission. The goal of QoS is a guaranteed delivery system for network traffic, such as Internet Protocol (IP) packets. A QoS guarantee indicates a service level that a program requires to transmit data at a specified rate and to deliver it within a specified time. Because QoS provides some guarantee of sufficient network resources, it gives a shared network a level of service similar to that of a dedicated network.

QoS facilitates the deployment of media-rich applications, such as video conferencing and Internet Protocol (IP) telephony, without adversely affecting network throughput. QoS achieves more efficient use of network resources by differentiating

between subsets of data such as fax data and latency-sensitive streaming media. QoS can also improve the performance of mission-critical software such as Enterprise Resource Planning (ERP) applications.

# ATM Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ATM Technical Reference**
Asynchronous transfer mode (ATM) refers to a number of related technologies, including software, hardware, and connection media. ATM is specifically designed to support high-speed communication. ATM differs from other existing LAN and WAN technologies by allowing networks to use bandwidth resources at maximum efficiency while maintaining Quality of Service (QoS) for users and programs.

The basic components of ATM are the computers that are connected to the ATM network and the devices that both connect these computers and ensure that data is transferred successfully. The computers that are connected to the ATM network are called endstations. Routers, Digital Subscriber Line Access Multiplexers (DSLAM) and ATM switches are examples of devices that connect end stations and ensure that data is transferred successfully.

**What Is ATM?**

**In this section**

- ATM Overview
- Connection Types: LAN vs. ATM

The cost of maintaining separate, specialized networks for computer, voice, and video is high. To reduce networking costs, ATM enables integration of all of these services on a single network and the combination of existing networks into a single infrastructure. In particular, Windows operating systems provide rich connectivity using Asynchronous Transfer Mode (ATM) while maintaining support for legacy systems.

To support ATM, Network Driver Interface Specification (NDIS) has been updated with ATM commands. Because many applications do not yet use ATM services, Windows Server 2003 includes support for LAN Emulation (LANE) for LAN applications, such as Ethernet. Similarly, IP over ATM support has been added, eliminating the additional header cost of LAN packets. Winsock 2.0 native ATM has also been added to support the many applications that use Windows Sockets (Winsock).

**ATM Overview**

ATM is a connection-oriented, unreliable (does not acknowledge the receipt of cells sent), virtual circuit packet switching technology. Unlike most connectionless networking protocols, ATM is a deterministic networking system — it provides predictable, guaranteed quality of service. From end to end, every component in an ATM network provides a high level of control. ATM technology includes:

- **Scalable performance.** ATM can send data across a network quickly and accurately, regardless of the size of the network. ATM works well on both very low and very high-speed media.
- **Flexible, guaranteed Quality of Service (QoS).** ATM allows the accuracy and speed of data transfer to be specified by the client. This feature distinguishes ATM from other high-speed LAN technologies such as gigabit Ethernet. The QoS feature of ATM also supports time dependent (or isochronous) traffic. Traffic management at the hardware level ensures that quality service exists end-to-end. Each virtual circuit in an ATM network is unaffected by traffic on other virtual circuits. Small packet size and a simple header structure ensure that switching is done quickly and that delays due to high traffic are minimized.
- **Unobstructed speed.** ATM imposes no architectural speed limitations. Its pre-negotiated virtual circuits, fixed-length cells, message segmentation and re-assembly in hardware, and hardware-level switching all help support extremely fast forwarding of data.
- **Integration of different traffic types.** ATM supports integration of voice, video, and data services on a single network. ATM over Asymmetric Digital Subscriber Line (ADSL) enables residential access to these services.

**Connection Types: LAN vs. ATM**

Traditional LANs, such as Ethernet and Token Ring, use a connectionless, unreliable approach, that cannot guarantee successful transmission when sending information across the network. Likewise, TCP/IP data transfers between networks are connectionless and unreliable. ATM, which is a connection-oriented, circuit-based technology, differs from the traditional approaches to networking.

**Traditional LAN**

In a traditional LAN, each client uses a network adapter card, which has a software driver. Above that driver is a protocol driver, such as TCP/IP. The protocol driver bundles information into frames of varying size and gives each bundle an appropriate header. As a result, when the adapter gains access to the media, the data packets are sent on the media to a destination hardware address. Traditional LAN technologies do not guarantee that data arrives on time or in the proper order. While Ethernet and Token Ring can detect errors, they provide no service guarantees and are not responsible for the recovery of missing or corrupted data packets.

Because the end stations are joined by a common medium, each end station on the traditional LAN recognizes the frames, or packets, of data put on the wire by each of the others, regardless of whether the frame is passed sequentially from one station to the next (as in a ring topology) or broadcast to all stations simultaneously (as with Ethernet). Each station has an adapter card, which processes the frame and examines the destination address. If the address applies to that computer, the frame is checked for errors. If there are no errors, the adapter initiates a hardware interrupt and passes the frame to the network adapter driver. The following figure, Traditional LAN: Connectionless Data Transmittal of a Packet, shows an example of a traditional LAN.

**Traditional LAN: Connectionless Data Transmittal of a Packet**

Because a traditional LAN is connectionless, it cannot provide mechanisms that can guarantee successful transmission. For example, it cannot determine the status of the destination adapter to ensure that it can receive a frame. It cannot ensure that bandwidth is available throughout the transmission. Unanticipated blockage, due to the media access control scheme of shared access technologies, can hinder a traditional LAN technology from supporting time-sensitive applications such as video or voice traffic. Traditional LANs can use upper-level protocol drivers to verify packet transmission (retransmitting, if necessary), partition big messages into smaller ones, and use time stamps for synchronization. However, these services add time to the transmission, and none of them provides end-to-end QoS guarantees.

**Traditional Internetworking**

If the destination address is remote rather than local, the chances of transmission failure increase. If a router on an Ethernet network detects a broadcast meant for another network, the router accepts the packet and passes it on using TCP/IP. A TCP/IP datagram is packet-switched to its destination individually. The header of each contains a globally significant switching address. This address allows a routing decision to be made each time the packet is forwarded, and packets to the same destination might follow completely different paths to get there, jumping over networks that use different underlying technology. No connection is required, but no delivery is guaranteed. The following figure, Two Packets Taking Different Routes Through a Traditional LAN, shows an example of two packets taking different routes through a traditional LAN.

**Two Packets Taking Different Routes Through a Traditional LAN**

Like an Ethernet data transfer, a routed data transfer cannot offer guarantees because bandwidth is never reserved ahead of time. The packets being sent over TCP/IP are simply transmitted on the wire and routed. While this allows flexibility in routing around obstructions, network performance can vary a great deal depending on conditions at the routers and on the amount of network traffic.

**ATM Networks**

In contrast to connectionless transmission protocols, ATM is connection-oriented. An ATM endpoint establishes a defined path known as a virtual channel (VC), also called virtual circuit, to the destination endpoint prior to sending any data on the network. It then sends a series of same-size frames, called cells, along the virtual channel towards the destination.

While establishing the connection, the ATM endpoint also negotiates a QoS contract for the virtual channel. The QoS contract spells out the bandwidth, maximum transit delay, acceptable variance in the transit delay, and so forth, that the VC provides, and this contract extends from one endpoint to the other through all of the intermediate ATM switches.

The path of ATM traffic is established at the outset, and the switching hardware merely needs to examine a simple header to identify the proper path. Beyond specifying a path, ATM allows a location to establish a full duplex connection (traffic travels in both directions) with multiple locations at the same time. Note, however, that ATM is an unreliable transmission protocol because it does not acknowledge the receipt of cells sent. As with LANs, missing or corrupted information must be detected and corrected by upper-layer protocols.

The following figure, "ATM Virtual Channel and Packet Transmission," illustrates ATM virtual channel and packet transmission.

**ATM Virtual Channel and Packet Transmission**

**Network Speed**

Unlike Ethernet networks, ATM has no inherent speed limit, and its efficiency is not affected by the distance that the data has to travel. In addition, ATM establishes the pathway for a particular series of packets at the outset and ATM switches make minimal switching decisions thereafter. To travel across the ATM network, data is segmented into same-size cells, and encapsulated with a header that contains information about switching, congestion, and error-checking.

Cells are transmitted in order, and the ATM network uses Virtual Path Identifier and Virtual Channel Identifier (VPI/VCI) numbers in the ATM header to forward them efficiently. A switch reads the header, compares the VPI/VCI to its switching table to determine the correct output port and new VPI/VCI, and then forwards the cell. All the addressing information that the ATM switch needs is contained in the header and is always found in the same place. This makes the forwarding task simple to implement in hardware by, reducing latency. Moreover, with ATM from end to end, there is no data translation required if a packet must travel from a LAN through a WAN to reach a destination LAN. The following figure, "ATM Fixed-Length Cells," shows two ATM end stations sending fixed-length cells from A to B (although ATM traffic is bi-directional).

**ATM Fixed-Length Cells**

Because ATM uses small (53-byte), fixed-length cells that require less logic to process, the network spends no time determining where a particular cell begins and ends. The small cell size ensures that delays in forwarding cells are minimized. Because the cell size is so predictable, buffer usage and analysis algorithms can be simplified and optimized.

Traditional LAN technologies, such as Ethernet, have inherent speed limitations Either the underlying infrastructure (the cable) or the segment length must be changed to support fast traffic. However, unlike Ethernet and Token Ring, ATM has no such imposed limitations. If you can invent a faster physical layer — if you can design a quicker method of transmitting data from one place to another over one wire or many wires — ATM can work over that physical layer and at those new speeds. In addition, ATM allows information with different requirements and from different nodes to be transmitted nearly simultaneously without conflict.

ATM places fixed-length cells on the media when the data is produced according to the parameters of a negotiated connection. ATM can simultaneously handle the needs of isochronous (time-dependent) traffic, such as voice and video, and non-isochronous traffic, such as LAN data.

# How ATM Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How ATM Works**

**In this section**

- ATM Architecture
- ATM Components
- ATM Cell Structure
- Virtual Paths and Virtual Channels
- Quality of Service
- ATM Addresses
- ATM Connection Types
- LAN Emulation
- TCP/IP Over ATM
- Additional Resources

Asynchronous transfer mode (ATM) is one of many network transmission protocols included in Windows Server 2003. The most commonly used transmission protocol included in Windows Server 20003 is TCP/IP, which is a connectionless protocol. As such, TCP/IP cannot offer some of the advantages that a connection-oriented, virtual circuit, packet-switching technology, such as ATM, can. Unlike most connectionless networking protocols, ATM is a deterministic networking system — it provides predictable, guaranteed quality of service.

The ideal environment in which to use ATM is one that combines computer, voice, and video networking into a single network, and the combination of existing networks into a single infrastructure.

**ATM Architecture**

ATM is a combination of hardware and software that can provide either an end-to-end network or form a high-speed backbone. The structure of ATM and its software components comprise the ATM architecture, as the following illustration shows. The primary layers of ATM are the physical layer, the ATM layer, and the ATM Adaptation layer.

**ATM Architectural Diagram**

Each layer and sublayer is described briefly in the following table, “ATM Layers.”

**ATM Layers**

| Layer | Function |
|---|---|

| | |
|---|---|
| ATM Adaptation | The ATM Adaptation layer facilitates the use of packets larger than a cell. Packets are segmented by the ATM interface, transmitted individually, and then reassembled on the receiving end. The ATM Adaptation Layer includes the Segmentation and Reassembly and Convergence sublayers. |
| ATM | The ATM layer regulates cells and cell transport and establishes and releases Virtual Circuits. The ATM layer has no sublayers |
| Physical | The Physical layer represents the physical medium and regulates Physical layer functions such as voltages and bit timing. The Physical layer consists of the Transmission Convergence and the Physical Medium Dependent sublayers |

**Physical Layer**

The physical layer provides for the transmission and reception of ATM cells across a physical medium between two ATM devices. This can be a transmission between an ATM endpoint and an ATM switch, or it can be between two ATM switches. The physical layer is subdivided into a Physical Medium Dependent sublayer and Transmission Convergence sublayer.

**PMD Sublayer**

The Physical Medium Dependent (PMD) sublayer is responsible for the transmission and reception of individual bits on a physical medium. These responsibilities encompass bit timing, signal encoding, interacting with the physical medium, and the cable or wire itself.

ATM does not rely on any specific bit rate, encoding scheme or medium and various specifications for ATM exist for coaxial cable, shielded and unshielded twisted pair wire, and optical fiber at speeds ranging from 64 kilobits per second to 9.6 gigabits per second. In addition, the ATM physical medium can extend up to 60 kilometers or more by using single-mode fiber and long-reach lasers. Thus it can readily support wide-range connectivity, including a private metropolitan area network. The independence of ATM from a particular set of hardware constraints has allowed it to be implemented over radio and satellite links.

**Transmission Convergence Sublayer**

The Transmission Convergence (TC) sublayer functions as a converter between the bit stream of ATM cells and the PMD sublayer. When transmitting, the TC sublayer maps ATM cells onto the format of the PDM sublayer, such as the DS-3 interface or Synchronous Optical Network (SONET) frames. Because a continuous stream of bytes is required, unused portions of the ATM cell stream are filled by idle cells. These idle cells are identified in the ATM header and are silently discarded by the receiver. They are never passed to the ATM layer for processing.

The TC sublayer also generates and verifies the Header Error Control (HEC) field for each cell. On the transmitting side, it calculates the HEC and places it in the header. On the receiving side, the TC sublayer checks the HEC for verification. If a single bit error can be corrected, the bit is corrected, and the results are passed to the ATM layer. If the error cannot be corrected (as in the case of a multibit error) the cell is silently discarded.

Finally, the TC sublayer delineates the ATM cells, marking where ATM cells begin and where they end. The boundaries of the ATM cells can be determined from the PMD layer formatting or from the incoming byte stream using the HEC field. The PMD performs the HEC validation per byte on the preceding 4 bytes. If it finds a match, the next ATM cell boundary is 48 bytes away (corresponding to the ATM payload). The PMD performs this verification several times to ensure that the cell boundaries have been determined correctly.

**ATM Layer**

The ATM layer provides cell multiplexing, demultiplexing, and VPI/VCI routing functions. The ATM layer also supervises the cell flow to ensure that all connections remain within their negotiated cell throughput limits. If connections operate outside their negotiated parameters, the ATM layer can take corrective action so the misbehaving connections do not affect connections that are obeying their negotiated connection contract. The ATM layer also maintains the cell sequence from any source.

The ATM layer multiplexes and demultiplexes and routes ATM cells, and ensures their sequence from end to end. However, if a cell is dropped by a switch due to congestion or corruption, it is not the responsibility of the ATM layer to correct the dropped cell by means of retransmission or to notify other layers of the dropped cell. Layers above the ATM layer must detect the lost cell and decide whether to correct it or disregard it.

In the case of interactive voice or video, a lost cell is typically disregarded because it takes too long to resend the cell and place it in the proper sequence to reconstruct the audio or video signal. A significant number of dropped cells in time-dependent services, such as voice or video, results in a choppy audio or video playback, but the ATM layer cannot correct the problem unless a higher Quality of Service is specified for the connection.

In the case of data (such as a file transfer), the upper layer application must sense the absence of the cell and retransmit it. A file with randomly missing 48-bytes chunks is a corrupted file that is unacceptable to the receiver. Because operations, such as file transfers, are not time dependent, the contents of the cell can be recovered by incurring a delay in the transmission of the

file corresponding to the recovery of the lost cell.

**ATM Layer Multiplexing and Demultiplexing**
ATM layer multiplexing blends all the different input types so that the connection parameters of each input are preserved. This process is known as traffic shaping.

ATM layer demultiplexing takes each cell from the ATM cell stream and, based on the VPI/VCI, either routes it (for an ATM switch) or passes the cell to the ATM Adaptation Layer (AAL) process that corresponds to the cell (for an ATM endpoint).

**ATM Adaptation Layer**
The ATM Adaptation Layer (AAL) creates and receives 48-byte payloads through the lower layers of ATM on behalf of different types of applications. Although there are five different types of AALs, each providing a distinct class of service, Windows Server 2003 supports only AAL5. ATM Adaptation is necessary to link the cell-based technology at the ATM Layer to the bit-stream technology of digital devices (such as telephones and video cameras) and the packet-stream technology of modern data networks (such as frame relay, X.25 or LAN protocols such as TCP/IP or Ethernet).

**AAL5**
AAL5 provides a way for non-isochronous (time-dependent), variable bit rate, connectionless applications to send and receive data. AAL5 was developed as a way to provide a more efficient transfer of network traffic than AAL3/4. AAL5 merely adds a trailer to the payload to indicate size and provide error detection. AAL5 is the preferred AAL when sending connection-oriented or connectionless LAN protocol traffic over an ATM network. Windows Server 2003 supports AAL5.

AAL5 provides a straightforward framing at the Common Part Convergence Sublayer (CPCS) that behaves more like LAN technologies, such as Ethernet. The following figure, "Breakdown of an AAL5 Cell Header and Payload," shows a detailed breakdown of an AAL5 Cell Header and Payload, followed by a detailed description of each of the components.

### Breakdown of an AAL5 Cell Header and Payload

With AAL5, there is no longer a dual encapsulation. The service class frames cells at the CPCS, but not at the Segmentation and Reassembly sublayer to minimize overhead. It also uses a bit in the Payload Type (PT) field of the ATM header rather than a separate SAR framing.

AAL5 is the AAL of choice when sending connection-oriented (X.25 or Frame Relay) or connectionless (IP or IPX) LAN protocol traffic over an ATM network.

**AAL5 CPCS Sublayer**
The preceding figure, "Breakdown of an AAL5 Cell Header and Payload," shows the framing that occurs at the AAL5 CPCS sublayer. (Note that only a trailer is added.).

**CPCS PDU Payload**
The block of data that an application sends. The size can vary from 1 byte to 65,535 bytes. The packet assembler/disassembler (PAD) consists of padding bytes of variable length (0-47 bytes), which create a whole number of cells by making the CPCS PDU payload length a multiple of 48 bytes.

**User-to-User Indication**
Transfers information between AAL users.

**Common Part Indicator**
Currently used only for alignment processes so that the AAL5 trailer falls on a 64-bit boundary.

**Length of CPCS PDU Payload Field**
Indicates the length of the CPCS PDU payload in bytes. The length does not include the PAD.

**Cyclic Redundancy Check (CRC)**
A 32-bit portion of the trailer that performs error checking on the bits in the CPCS PDU. The AAL5 CRC uses the same CRC-32 algorithm used in 802.*x*-based networks such as Ethernet and Token Ring.

**AAL5 SAR sublayer**
Byte-by-byte, the preceding figure, "Breakdown of an AAL5 Cell Header and Payload," shows the framing that occurs at the AAL5 SAR sublayer. There is no SAR header or trailer added. On the transmitting side, the AAL5 SAR sublayer merely segments the CPCS PDU into 48-byte units and passes them to the ATM layer for the final ATM header.

On the receiving side, the sublayer reassembles a series of 48-byte units and passes the result to the CPCS. The AAL5 SAR uses the third bit in the PT field to indicate when the last 48-byte unit in a CPCS PDU is being sent. When the ATM cell is received with the third bit of the PT field set, the ATM layer indicates this fact to the AAL; the AAL then begins a CRC and length-checking analysis of the full CPCS PDU.

**ATM Components**
To support native Asynchronous Transfer Mode (ATM), NDIS has been updated with native ATM commands. Because many applications do not yet use native ATM services, LANE support was added for LAN applications, such as Ethernet. Similarly, Microsoft has added IP over ATM support, thereby eliminating the additional header cost of LAN packets. Microsoft also added Winsock 2.0 native ATM to support the many applications that use Windows Sockets (Winsock).

Furthermore, circuit connectivity has been added to theTelephony Application Programming Interface TAPI (connection management protocol) to provide complete ATM support. TAPI can now make and receive calls and can redirect them to ATM circuits or from circuits into devices or other network types. Examples include Microsoft DirectShow, as well as Point to Point Protocol (PPP) over ATM as the dial-up remote access protocol on ATM. Using the raw channel access (RCA) kernel streaming filter, TAPI can be used to connect a data stream to the RCA filter containing video, and send it over an ATM circuit, as shown in the following figure, "Windows ATM Services."

**Windows ATM Services**

These enhancements allow applications to exploit ATM services, such as Quality of Service (QoS), and with the use of TAPI, achieve a high level of integration between established multimedia features and network protocols.

**ATM Call Manager**
The ATM signaling component, also known as the UNI call manager, handles virtual channel creation and management. This section describes how the ATM call manager does its job, specifically the handling of both permanent and switched virtual connections.

**How the Call Manager Differentiates PVCs and SVCs**
Permanent virtual connections (PVCs) are almost identical to switched virtual connections (SVCs), but each PVC must be manually configured, device by device, by an administrator. In contrast, SVCs are dynamically configured when they are established. Each device — from a starting end station through switches to another end station — independently determines its role in supporting a virtual connection It also determines what device to forward the request to, and whether or not it can guarantee the requested Quality of Service at that time. PVC resource allocations are set aside the moment they are first configured, whether or not they are used immediately. SVC resource allocations are allocated dynamically.

The SVC and PVC values are both stored in the internal tables of the ATM call manager, the ATM adapter, and the ATM switch, and the kind of values stored in those tables are identical. The difference between the two kinds of connections lies in how the connection values are handled at initialization. At that time, the ATM call manager checks the registry for any PVCs. If it finds one, it stores its VC number, along with other VC information such as Quality of Service, the process ID (or more generically, the service access point), and the source and destination addresses. It uses a single bit to designate that it is a PVC and not an SVC.

During initialization, the ATM adapter does not know about PVCs. Until someone (typically an administrator) configures an application to use a PVC, applications are not aware of PVCs either. When an application wants to use a PVC, it issues an ATM command through its provided interfaces. The request specifies the destination address, the Quality of Service, and the virtual

connection number (among other information). Up to this point, the PVC is handled exactly as if it were a request for an SVC. The call manager receives the request and checks the information received against the entries in its internal table of VCs. If it finds a match, and the match is designated as a PVC in the PVC field in its table, the call manager then handles the rest of the process differently from how it handles an SVC request.

A typical SVC request initiates two commands; the first determines whether the adapter can handle another VC, and the second activates the VC along the path of network components. A PVC request, however, works a little differently. When the call manager receives a request specifying a PVC, it behaves as if the PVC has already been established from end to end. It sends the two initiating calls in rapid succession to the ATM adapter. The ATM adapter never detects that it is working with a PVC. It obtains the Quality of Service and other information from the setup commands and determines how to shape the traffic. From that point, the PVC functions identically to an SVC.

**Data Encapsulation over PVC**

Support for Ethernet and IP data encapsulation over ATM using VC Multiplexing or LLC/SNAP AAL5 PVCs is new to Windows Server 2003. This support extends to the encapsulation and transport of IP or Ethernet packets over ATM between clients that are connected to a supporting infrastructure using a permanent virtual connection. ATM supports Ethernet and IP data encapsulation by acting as a bridging Ethernet or routing adapter for the TCP/IP protocol.

ATM AAL5 PVC support is similar in concept to ATM LANE, except where LANE uses SVCs instead of PVCs.
Windows Server 2003 supports the two encapsulation methods, LLC Encapsulation and VC Multiplexing as described in RFC 2684. Both Ethernet and IP protocols are supported by using either encapsulation method for bridged and routed protocol data units (PDUs). For example PPP over Ethernet, (PPPoE), Layer 2 Tunneling Protocol (L2TP ), Ethernet, or Ethernet encapsulated in IP are some of the protocols supported by using ATM AAL5 PVC support in Windows Server 2003.

ATM AAL5 is implemented as an NDIS intermediate driver, as shown in the following figure, "(NGFD_ATM90) ATM AAL5 NDIS Intermediate Driver."

**(NGFD_ATM90) ATM AAL5 NDIS Intermediate Driver**

There are several common scenarios for using ATM AAL5 PVCs. One example is using ATM AAL5 PVC support for remote connectivity from a home or small office that uses an internal ADSL mode. In Windows Server 2003 you configure the ADSL mode as an ATM AAL5 PVC connection, listed as Microsoft Ethernet PVC - RFC 2684 in Windows Server 2003. As shown in the following figure, "(NGFD_ATM91) ADSL Connectivity with ATM AAL5 PVC ,"the ADSL modem connects by using the Public Switched Telephone Network (PSTN) to a Digital Subscriber Line Access Multiplexer (DSLAM) located at your service provider, most likely the central office of your local telephony carrier. The DSLAM either bridges the encapsulated data directly to a network or connects to an external bridge, router, or ATM switch located at your service provider. A connection can then be made to the targeted network, such as your corporate office or the Internet.

**(NGFD_ATM91) ADSL Connectivity with ATM AAL5 PVC**

**ATM LAN Emulation Module**

LAN emulation client services are included in the Windows Server 2003 operating system. When Plug and Play detects an ATM adapter and installs the appropriate driver, the LANE client is also installed by default. This permits full LANE connectivity without the need for configuration, provided that the following conditions exist:

- The switch has LANE services available and turned on.
- The LANE services configuration has an enabled default, Emulated Local Area Network (ELAN).

For centralized administration and ease of configuration, this LANE client implementation allows configuration of only the ELAN name. All other ELAN configuration information — such as the Maximum Transmissible Unit (MTU), ELAN type, and LAN Emulation Server (LES) — is obtained from the LAN Emulation Configuration Server (LECS). If a default ELAN is enabled in the LECS, no configuration is required.

**ATMARP and ARP MARS**
IP over ATM support is included with Windows Server 2003. IP over ATM exposes many features of ATM so that TCP/IP can make use of them directly. With this support, applications written to use TCP/IP can also make use of ATM.

In addition, the client that runs ATMARP (IP over ATM) in Windows Server 2003 supports multicast address resolution by using Multicast Address Resolution Service (MARS). This client contains an ATM ARP/MARS service that enables Windows to act as both an ATMARP server and a MARS with integrated Multicast Server (MCS). The MARS setup allows configuration of a ranges of addresses; the service acts as an MCS for all those addresses.

**API Support: Winsock 2.0, TAPI, and NDIS 5.0**
All Windows Server 2003 enhancements to SNMP are possible due to extensions to the operating system. The chief extension is a connection-oriented service added to NDIS version 5.0. NDIS 5.0 includes Connection-Oriented NDIS (CoNDIS), a new NDIS API extension for the support of connection-oriented media. These new APIs enable applications and protocols to create VCs and specify Quality of Service for those VCs. CoNDIS supports multiple call managers to enable various media-specific signaling needs, including an ATM-specific call manager. In addition, CoNDIS supports point-to-multipoint connections for efficient multicast services, as shown in the following figure "Supported CoNDIS Multicast Services."

**Supported CoNDIS Multicast Services**

Two components operate on top of NDIS, integrating ATM services with the rest of the operating system and exposing ATM services through well-known APIs. Winsock 2.0 now has direct ATM support by using the Winsock ATM Service Provider. Winsock support provides direct access to ATM services from user-mode applications. With the addition of IP over ATM support, Windows Sockets applications that use TCP/IP as a transport protocol can be run over ATM networks and inter-operate with standard LAN-based IP clients.

**NDIS 5.0 ATM Miniport Drivers**
Although NDIS 5.0 supports both connectionless and connection-oriented network adapter drivers, only the connection-oriented drivers are of use in an ATM network.

Connection-oriented miniport drivers are always deserialized; that is, they serialize the operation of their own miniport functions and queue all incoming packets internally rather than relying on NDIS to perform the same functions. This improves full-duplex performance if the critical sections of the driver are kept small.

While NDIS library continues to support legacy NDIS 3.0 network adapter drivers, only NDIS 4.0 and 5.0 miniport drivers can take advantage of the enhanced functionality and performance characteristics of the NDIS library support for network adapter drivers.

NDIS has several connection-oriented features. It also contains additional features such as binary compatibility, improved

power management by means of Wake On LAN support (which enables a network adapter to turn on a client from a low power state based on packet receipt), and checksum performance in hardware rather than in software. As a result, driver performance is improved over all network types.

**TAPI**

Telephony Application Programming Interface (TAPI) is responsible for connection setup and other operating system functions related to telephony. In Windows Server 2003, TAPI has been expanded to support telephony over connection-oriented media such as ATM. While TAPI does not handle data directly, it can create a circuit and connect that circuit to another device.

By redirecting calls, TAPI provides more than just high bandwidth and good connectivity. The TAPI component of CoNDIS maps (or proxies) the TAPI call management functions to NDIS 5.0 call management functions, allowing a connection from another medium to be redirected to or from ATM. For example, TAPI can redirect calls to a data handler such as the raw channel access filter, or DirectShow components.

### Note

- DirectShow allows hardware and software vendors to create individual multimedia modules called filters. Multiple filters can be connected by the use of pins and a filter graph. TAPI connects different components, and DirectShow uses the same approach to enable filters and devices to connect to each other.

**PPP over ATM**

With the advent of Digital Subscriber Line (DSL) technologies, high-speed network access from the home and small office environment is becoming more of a reality. Several standards are being developed in these areas, including Asymmetric DSL (ADSL) and Universal ADSL (UADSL or DSL Lite). These technologies operate over a local loop, typically copper wire running between the public telephone network and the home. In most areas, this local loop connects directly to an ATM core network run by a telephone company.

Without changing protocols, ATM over the DSL service preserves the high-speed characteristics and QoS guarantees, which are available in the core. These guarantees create the potential for an end-to-end ATM network to the residence or small office. This network model provides several advantages, including:

- Protocol transparency
- Support for multiple classes of QoS with service guarantees
- Bandwidth scalability
- An evolution path to newer DSL technologies

Adding the Point-to-Point Protocol (PPP) over this end-to-end architecture adds functionality and usefulness. PPP provides the following additional advantages:

- Authentication
- Open System Interconnection (OSI) Layer 3 address assignment
- Multiple concurrent sessions to different destinations
- OSI Layer 3 protocol transparency
- Encryption and compression

These enhancements provide high bandwidth, even over a telephone line with an ATM adapter and this new level of integrated ATM support. In addition, with the adoption of PPP over ATM, little change is required at the ISP level, as telephone companies and ISPs typically use PPP.

Finally, if each VC carrying a PPP session carries only one session, each destination has its own authenticated PPP session, providing per-VC authentication. This provides an extra measure of security. Using Null Encapsulation over AAL5 can further reduce overhead because the protocol multiplexing is provided in PPP.

**PPP over ATM and NDISWAN**
In earlier versions of Windows operating systems, the Network Driver Interface Specification Wide Area Network (NDISWAN) component both supported operation of standard protocol stacks over WAN media and acted as the PPP engine. As explained earlier, in Windows Server 2003 the NDISWAN component has been extended and the TAPI proxy component added to provide this same support over NDIS 5.0 connection-oriented media, such as ATM.

At initialization, the NDISWAN component, acting as a client to the TAPI proxy, registers itself as the stream handler for PPP data. When the user starts dial-up networking to connect to a network, the dial-up networking module communicates with TAPI to make the phone call. When the request is made on an ATM device, TAPI does two things:

- Using the TAPI proxy and NDIS 5.0, it uses a call manager to make the telephone call by way of the ATM adapter.
- When the call connects, it redirects the connection from the adapter by using NDIS 5.0 to NDISWAN.

NDISWAN then handles further network (PPP) negotiation, and ultimately, by means of the LAN and TCP/IP stacks, it connects the user's computer to the remote network. The important thing to note here is that TAPI makes the call and then gives the resulting connection to another process, in this case NDISWAN.

This connectability enables several new types of applications, such as DVD-quality streaming video, real-time process control, a common standard for both LAN and WAN, and integrated software that pulls together aspects of TV, telephony, and data streams. Many of these applications make use of the raw channel access filter and DirectShow technology.

**Support for Raw Channel Access Filtering: DirectShow**
DirectShow technology was developed to better integrate multimedia services and to help multimedia developers more easily customize the operating system to their needs. DirectShow allows hardware and software vendors to create individual multimedia modules called filters. Multiple filters can be connected by the use of pins and a filter graph. TAPI connects different components, and DirectShow uses the same approach to enable filters and devices to connect to each other.

The following figure, "Windows COM-Based DirectStreaming," shows Windows COM-based DirectStreaming by which a Windows Server 2003-based application can handle many categories of real-time inputs.

**Windows COM-Based DirectStreaming**

DirectShow has an RCA filter — a simple module that exposes the raw data, whether it is voice, video, or other, to any device that wants to handle it. With NDIS 5.0, the RCA filter can be connected to TAPI. NDIS 5.0 can export ATM VCs as DirectShow pins.

**Raw Channel Access Filtering**
The Windows Server 2003 support for raw channel access filtering comes by means of the CoNDIS 5.0 driver. The NDIS proxy sets up a call at the ATM layer, running from the proxy to the call manager and on to the client. Unlike many voice or video feeds, this connection is made by using AAL5 rather than AAL1. The analog data transferred through the filter becomes digital data, which is packaged and handled as any other data over an AAL5 connection.

**DirectShow Application**
An example of using DirectShow and raw channel access support in Windows ATM services is a video-streaming application that delivers current weather information over the telephone. Customers can simply dial a number for the recorded information.

The following steps outline this process:

1. At initialization, the raw channel access filter registers as the stream handler for voice data.

2. A user calls a number to get the current weather information.

3. TAPI receives the call. TAPI redirects the incoming call to the raw channel access filter because it is a voice call.

4. NDIS 5.0 maps the DirectShow pin to the VC number.

5. DirectShow searches the filter graph, and the stream starts.

The following figure, "Weather Report Application Using DirectShow RCA Filter," shows how a weather report application uses the DirectShow raw channel access filter. The path shows how the data is routed through the various protocols from telephony data to the application layer.

**Weather Report Application Using DirectShow RCA Filter**

**IP Phone Access**

Similarly, a user can make a telephone call that is routed across a traditional LAN. This can enable such things as IP-based telephones. Again, TAPI handles the incoming call and uses NDIS 5.0 to connect it to a pin. DirectShow then reformats the data using a real-time protocol filter that goes through UDP/IP to reach an Ethernet card. The resulting connection allows a telephone user to talk to a computer user. This ATM-based network integration crosses previous boundaries between telephone and computer networks.

**ATM Cell Structure**

At either a private or a public User-Network Interface (UNI), an ATM cell always consists of a 5-byte header followed by a 48-byte payload. The header is composed of six elements, each detailed in the following figure, "Cell Header Structure."

**Cell Header Structure**

**Generic Flow Control**

The Generic Flow Control (GFC) field is a 4-bit field that was originally added to support the connection of ATM networks to shared access networks such as a Distributed Queue Dual Bus (DQDB) ring. The GFC field was designed to give the User-Network Interface (UNI) 4 bits in which to negotiate multiplexing and flow control among the cells of various ATM connections. However, the use and exact values of the GFC field have not been standardized, and the field is always set to 0000.

**Virtual Path Identifier**

The Virtual Path Identifier (VPI) defines the virtual path for this particular cell. VPIs for a particular virtual channel connection are discovered during the connection setup process for switched virtual connection (SVC) connections and manually configured for permanent virtual connection (PVC) connections. At the UNI, the VPI length of 8 bits allows up to 256 virtual

paths. VPI 0 exists by default on all ATM equipment and is used for administrative purposes such as signaling to create and delete dynamic ATM connections.

**Virtual Channel Identifier**
The Virtual Channel Identifier (VCI) defines the virtual channel within the specified virtual path for this particular cell. Just as with VPIs, VCIs are also discovered during the connection setup process for switched virtual connection (SVC) connections and manually configured for permanent virtual connection (PVC) connections. The VCI length of 16 bits allows up to 65,536 virtual channels for each virtual path. VCIs from 0 to 15 are reserved by the International Telecommunication Union ITU and VCIs from16 to 32 are reserved by the ATM Forum for each virtual path. These reserved VCIs are used for signaling, operation and maintenance, and resource management.

The combination of VPI and VCI values identifies the virtual channel for a specified ATM cell. The VPI/VCI combination provides the ATM forwarding information that the ATM switch uses to forward the cell to its destination. The VPI/VCI combination is not a network layer address such as an IP or IPX network address.

The VPI/VCI combination acts as a local identifier of a virtual channel and is similar to the Logical Channel Number in X.25 and the Data Link Connection Identifier (DLCI) in Frame Relay. At any particular ATM endpoint or switch, the VPI/VCI uniquely identifies a virtual connection to the next ATM endpoint or switch. The VPI/VCI pair need not match the VCI/VPI used by the final destination ATM endpoint.

The VPI/VCI combination is unique for each transmission path, that is for each cable or connection to the ATM switch. However, two different virtual channels on two different ports on an ATM switch can have the same VPI/VCI without conflict.

**Payload Type Indicator**
The Payload Type Indicator is a 3-bit field. Its bits are used as follows:

- The first bit indicates the type of ATM cell that follows. A first bit set to 0 indicates user data; a bit set to 1 indicates operations, administration and management (OA&M) data.

- The second bit indicates whether the cell experienced congestion in its journey from source to destination. This bit is also called the Explicit Forward Congestion Indication (EFCI) bit. The second bit is set to 0 by the source. If an interim switch experiences congestion while routing the cell, it sets the bit to 1. After it is set to 1, all other switches in the path leave this bit value at 1.

- Destination ATM endpoints can use the EFCI bit to implement flow control mechanisms to throttle back on the transmission rate until cells with an EFCI bit set to 0 are received.

- The third bit indicates the last cell in a block for AAL5 in user ATM cells. For non-user ATM cells, the third bit is used for OA&M functions.

**Cell Loss Priority**
The Cell Loss Priority (CLP) field is a 1-bit field used as a priority indicator. When it is set to 0, the cell is high priority and interim switches must make every effort to forward the cell successfully. When the CLP bit is set to 1, the interim switches sometimes discard the cell in congestion situations. The CLP bit is very similar to the Discard Eligibility bit in Frame Relay.

An ATM endpoint sets the CLP bit to 1 when a cell is created to indicate a lower priority cell. The ATM switch can set the CLP to 1 if the cell exceeds the negotiated parameters of the virtual channel connection. This is similar to bursting above the Committed Information Rate in Frame Relay.

**Header Error Control**
The Header Error Control (HEC) field is an 8-bit field that allows an ATM switch or ATM endpoint to correct a single-bit error or to detect multi-bit errors in the first 4 bytes of the ATM header. Multi-bit error cells are silently discarded. The HEC only checks the ATM header and not the ATM payload. Checking the payload for errors is the responsibility of upper layer protocols.

**Virtual Paths and Virtual Channels**
ATM uses virtual paths and channels to logically divide the bandwidth of the transmission path.

The following figure, “Channels within a Path inside the Transmission Medium,” shows how virtual paths and channels are divided within the transmission medium.

### Channels Within a Path Inside the Transmission Medium

**Transmission Path**
The transmission path consists of the physical cable connected to a particular port of an ATM switch. The cable has a defined bandwidth, such as 155 megabits per second for an Optical Carrier-3 (OC-3) optical fiber link.

**Virtual Path**
The bandwidth of the transmission path is logically divided into separate virtual paths and identified using the VPI in the ATM header. Each virtual path is allocated a fixed amount of bandwidth. Virtual paths do not dynamically vary their bandwidths beyond what has been allocated.

**Virtual Channel**
The bandwidth of a virtual path is logically divided into separate virtual channels using a virtual channel identifier in the ATM header. Unlike virtual paths, virtual channels share the bandwidth dynamically within a virtual path.

**Switching Hierarchy**
The transmission path to virtual path to virtual channel hierarchy is the basis for ATM switching. ATM can switch cells at the transmission path, virtual path and virtual channel level.

**Switching at the transmission path level**
Switching at the transmission path level allows an ATM switch to determine which output port to use to forward the cell.

**Switching at the virtual path level**
Switching at the virtual path level allows entire groups of virtual channels to be switched at the same time. Virtual path switching is similar to the telephone system cross-connect switching of entire groups of telephone calls based on the area code of the phone number. The switching occurs based on the area code, not the 7-digit individual phone number.

When performing virtual path switching, an ATM only takes action on the virtual path identifier in the ATM cell header. This ability to bypass the rest of the header makes virtual path switching faster than virtual channel switching.

ATM virtual path switching most often occurs within the public networks of ATM service providers because this virtual path switching allows ATM service providers to aggregate bundles of virtual channels along high-speed backbone links. These aggregate channels create trunk line structures very similar to those used in telephone networks.

**Switching at the virtual channel level**
Switching at the virtual channel level allows for precise switching and bandwidth allocation. Virtual channel switching resembles switching a phone call to its final 7-digit location; that is, ATM switching is based on the entire VPI/VCI, just as the final phone switching is based on the entire 10-digit phone number (3-digit area code plus 7-digit individual phone number).

ATM virtual channel switching occurs within both private and public networks. A switch must analyze both the virtual path identifier and the virtual channel identifier to make a switching decision.

**Quality of Service**
As part of the negotiated connection, ATM endpoints establish a service contract that guarantees a specific quality of service. These Quality of Service (QoS) guarantees are not offered by traditional LAN technologies.

With a traditional LAN, any notion of service guarantee is based on priority, where one transmission receives delivery preference over others. Because the sending end station does not know the condition of the network or the recipient of the data prior to transmission (traditional LANs are connectionless), traffic is subject to delay at routers and elsewhere. These unforeseen delays make bandwidth availability and delivery times difficult to predict. While higher-priority traffic typically reaches its destination prior to lower-priority traffic, it is possible that the higher priority traffic arrives too late for isochronous traffic.

### Note

- The term "QoS" applies to several forms of quality guarantees, including ATM QoS and generic quality of service. Of the three, only ATM QoS is implemented at the hardware level.

ATM offers precise and explicit service guarantees that are not based on a relative structure (such as priority). With ATM, a data supplier can request a specific bandwidth, maximum delay, and delay variation tolerance. Each ATM switch then determines whether or not it can meet the request after taking current allocations into consideration. If it can accommodate the transmission, it guarantees the service level and allocates the necessary resources. With ATM, the service contract is enforced, and the bandwidth is allocated at the hardware level. All switches between the sender and receiver agree to the service level

before the contract is granted. The source station hardware, also having agreed to the contract, is responsible for shaping the traffic to fit the connection contract before it enters the network.

ATM offers five service categories.

**Constant Bit Rate (CBR)**
Specifies a fixed bit rate. Data is sent in a steady stream with low cell loss. This is an expensive service because the granted bandwidth must be allocated, whether or not it is actually used. CBR is typically used for circuit emulation. This category is supported in Windows Server 2003.

**Variable Bit Rate (VBR)**
Specifies a throughput capacity over time, but data is not sent at a constant rate. This also specifies low cell loss. It is available in two varieties, real-time VBR for isochronous applications and non-real-time VBR for all others.

**Available Bit Rate (ABR)**
Ensures a guaranteed minimum capacity but allows data to be sent at higher capacities when the network is free. ABR adjusts the rate of transmission based on feedback, which specifies low cell loss. ABR provides better throughput than VBR, but is less expensive than CBR. It is important to note that ABR has only recently been fully defined, and not all hardware and software support this service category. It is part of the UNI 4.0 specification.

**Unspecified Bit Rate (UBR)**
Does not guarantee bandwidth or throughput, and cells can be dropped. A UBR connection does not have a contract with the ATM network. This category is supported in Windows Server 2003.

**Weighted Unspecified Bit Rate (WUBR)**
The newest service category put forward by the ATM Forum, and it functions by assigning different processing priorities to different types of traffic, similar to a traditional connectionless LAN. Each such type of traffic is carried across a different connection; cells in connections with lower priority are dropped before those with higher priority.

Guaranteed QoS allows ATM to support time-sensitive (isochronous) applications, such as video and voice, as well as more conventional network traffic. While 100-megabit Ethernet and other high-speed networks can provide comparable bandwidth, only ATM can provide the QoS guarantees required for real-time telephony, VCR-quality video streaming, CD-quality sound, smooth videoconferencing, and other delay-sensitive voice and video applications.

QoS is so vital to the industry that several initiatives are underway to provide QoS support for connectionless TCP/IP–based networks. While these solutions are useful, they require that all nodes on the network participate, which can be difficult to guarantee on heterogeneous networks. Because these solutions shape the traffic in software, latency and variations in delay are sometimes introduced. This is not the case with ATM.

Most importantly, the acceptance of ATM as a common standard for both LANs and WANs enables an enterprise to deploy QoS applications and integrated services. The deployment of ATM/Asymmetric Data Subscriber Line (ADSL) to the home enables residential access to these services. ADSL uses existing copper twisted-pair telephone lines to transmit broadband data to the home, without requiring recabling or a new telephone infrastructure. This extends the reach of ATM networks from the home desktop to the business desktop and everywhere in between.

**ATM Addresses**
ATM addresses are needed to support the use of virtual connections through an ATM network. At the simplest level, ATM addresses are 20 bytes in length and composed of three distinct parts. The following figure, "Simplified View of ATM Addressing," shows the three parts of the 20-byte ATM address.

### Simplified View of ATM Addressing

This ATM address breaks down into the following three basic parts:

**ATM switch identifier**
The first 13 bytes identify a particular switch in the ATM network. The use of this portion of the address can vary considerably depending on which address format is in use. Each of the three major ATM addressing schemes in use provides information about ATM switch location differently. The three formats are the data country/region code (DCC) format, international code designator (ICD) format, and the E.164 format proposed by the ITU Telecommunication Standardization Sector (ITU-T) for international telephone numbering use in broadband Integrated Services Digital Network (ISDN) networks.

**Adapter MAC address**
The next 6 bytes identify a physical endpoint, such as a specific ATM adapter, using a media access control (MAC) layer address that is physically assigned to the ATM hardware by the manufacturer. The use and assignment of MAC addresses for ATM hardware is identical to MAC addressing for other Institute of Electrical and Electronic Engineers (IEEE) 802.*x* technologies, such as Ethernet and Token Ring.

**Selector**
The last byte is used to select a logical connection endpoint on the physical ATM adapter.

Although all ATM addresses fit this basic three-part structure, there are significant differences in the exact format of the first 13 bytes of any given address, depending on the addressing format that is being used or whether the ATM network is for public or private use.

In summary, the 20-byte ATM address is in the hierarchical format starting with the switch at the highest level, down to the adapter, and then down to the logical endpoint.

All of the three ATM address formats that are currently in widespread use (DCC, ICD, and E.164) include the following characteristics:

- Compliance with the Network Service Access Point addressing plan as proposed by the Open Standards Interconnection protocol suite of the International Standards Organization.
- Each can be used to establish and interconnect privately-built ATM networks that support switched virtual connections (SVCs).

**Addressing in Detail**
The type of ATM address used depends on whether the addresses are for a public or private ATM network. ATM addresses are used to establish virtual channels between ATM endpoints. The following figure, "Primary ATM Address Formats," shows the three primary address formats.

**Primary ATM Address Formats**

The most important fields from these address formats are listed in the following table, "Primary ATM Address Format Fields."

**Primary ATM Address Format Fields**

| Address Fields | Function |
|---|---|
| AFI | The single-byte authority and format identifier (AFI) identifies the type of address. |
| DCC | The defined values are 45 for E.164, 47 for ICD and 39 for DCC addresses. |
| AA | This single byte identifies the-specific part (DSP) of the address. |
| Reserve | Reserved for future use. |
| RD | 2 bytes of routing domain information. |
| Area | 2 bytes of area identifier. |
| ESI | 6 bytes of end-system identifier, which is an IEEE 802.x MAC address. |
| SEL | 1 byte of NSAP selector. |

| | |
|---|---|
| ICD | 2 bytes of ICD. |
| E.164 | 8 bytes (16 digits) of the ISDN telephone number. |

**ATM Connection Types**
ATM connections between endpoints are not distinguished only by their various Quality of Service parameters and the formats of their addressing schemes. They also fall into one of two larger categories: point-to-point connections and point-to-multipoint connections. The connection types that any particular ATM connection uses depend on how ATM signaling builds its connection.

**Signaling**
Signaling components exist at the end station and at the ATM switch. The signaling layer of ATM software is responsible for creating, managing, and terminating switched virtual connections (SVCs). There are two signaling standards:

**User Network Interface**
The ATM standard wire protocol implemented by the signaling software

**Network Network Interface**
The way one ATM switch signals another ATM switch

### ATM Signaling

**Point-to-Point Connection**
When process that uses ATM seeks to connect to another process elsewhere on the network, it asks the signaling software to establish an SVC. To do this, the signaling software sends an SVC creation request to the ATM switch using the ATM adapter and the reserved signaling VC. Each ATM switch forwards the request to another switch until the request reaches its destination. An ATM switch determines which switch to send the request to next based on the ATM address for the connection and the internal network database (routing tables) of the switch. Each switch also determines if the need of the request for service category and Quality of Service can be met. At any point in this process, a switch can refuse the request.

If all the switches along the path can support the virtual channel as requested, the destination end station receives a packet that contains the VC number. From that point on, the process that uses ATM can interact with the destination process directly by sending packets to the VPI/VCI that identify the specified VC.

The ATM adapter shapes data traffic for each VC to match the contract made with the ATM network. If too much data is sent for any reason, the ATM switch can ignore — and lose — the data in favor of providing bandwidth to another contract or set of contracts. This is true for the entire breadth of the network; if bandwidth or speed exceeds the limits established by the contract, any device, including the ATM adapter, can simply drop the data. If this happens, the end stations concerned are not notified of the cell loss.

**Point-to-Multipoint Connection**
Unlike a standard LAN environment, ATM is a connection-oriented medium that has no inherent capabilities for broadcasting or multicasting packets. To provide this ability, the sending node can create a virtual channel to all destinations and send a copy of the data on each virtual channel. However, this is highly inefficient. A more efficient way to do this is through point-to-multipoint connections. Point-to-multipoint connects a single source endpoint, known as the root node, to multiple destination endpoints, known as leaves. Wherever the connection splits into two or more branches, the ATM switches copy cells to the multiple destinations.

Point-to-multipoint connections are unidirectional; the root can transmit to the leaves, but the leaves cannot transmit to the root or to each other on the same connection. Leaf-to-node and leaf-to-leaf transmission requires a separate connection. One reason for this limitation is the simplicity of AAL5 and the inability to interleave cells from multiple payloads on a single

connection.

**LAN Emulation**
LAN Emulation (LANE) is a group of software components that allows ATM to work with legacy networks and applications. With LAN emulation, you can run your traditional applications and protocols that use LAN on an ATM network without modification.

LANE makes the ATM protocol layers appear to be an Ethernet or Token Ring LAN to overlying protocols and applications. LAN emulation provides an intermediate step between fully exploiting ATM and not using ATM at all. LANE can increase the speed of data transmission for current applications and protocols when ATM is used over high speed media; unfortunately, LANE does not take advantage of native ATM features such as QoS. However, LANE does allow your current system and software to run on ATM, and it facilitates communication with nodes attached to legacy networks.

**LANE Architecture**
LANE consists of two primary components: the LANE client and the LANE services. The LANE client allows LAN protocols and applications that use LAN to function as if they were communicating with a traditional LAN. It exposes LAN functionality at its top edge (to users) and native ATM functionality at its bottom (to the ATM protocol layers).

The LANE services are a group of native ATM applications that hide the connection-oriented nature of ATM from connectionless legacy protocols. These services maintain the databases necessary to map LAN addresses to ATM addresses, thus allowing the LANE clients to create connections and send data.

The LANE services components can reside anywhere on an ATM network, but most ATM switches are included with LANE services components installed. Therefore, for practical purposes, LANE services reside on an ATM switch or group of switches.

The three primary LANE services are the LAN emulation configuration server (LECS), the LANE server (LES), and the Broadcast and Unknown server (BUS). The LECS distributes configuration information to clients, allowing them to register on the network. The LES manages one or more Emulated LANs (ELANs). It is responsible for adding members to the ELAN, maintaining a list of all the members of ELAN, and handling address resolution requests for the LANE clients. The BUS handles broadcast and multicast services, as shown in the following figure. "LANE Client, LECS, LES, and BUS."

**LANE Client, LECS, LES, and BUS**

**Lane Client Interaction with ATM Network**
When the LANE client seeks to join the network, the first thing it must do is find the LECS because the LECS gives the client the address of the LES managing the ELAN that it seeks to join. Without the LES address, the client cannot communicate with other members of the ELAN. At initialization the client has neither established a connection to any ATM switch nor to the switch or other entity containing the LECS. The client must establish an ATM connection, preferably a connection directly to the configuration server.

If the ATM network only has a single ATM switch, and the switch contains all the LANE services, then finding the LECS is easy. However, if the network has multiple switches, the local switch to which the LANE client has immediate access might not have LANE services running on it. Fortunately, LANE includes several established mechanisms for a LANE client to discovery the LECS.

**LECS Discovery**
The LANE client can use any of the following techniques when attempting to connect to the LECS:

- It can use a well-known ATM address, defined in the ATM protocol.
- It can use a well-known VC.
- It can query using the Integrated Local Management Interface (ILMI).

Both the well-known ATM address and the well-known VC are standardized. Most switches and clients are preconfigured with this information. In most cases, the LANE client can find the LECS using one of these methods. However, if the well-known

values have been changed at the end station or at the switch, either type of discovery becomes unsuccessful.

If this happens, the LANE client can fall back on ILMI, a protocol standard (similar to Simple Network Management Protocol) designed for ATM administrative and configuration purposes. ILMI provides a query function that the LANE client can use to find the LECS address, and then set up a VC to it.

After the client has discovered the LECS and connected to it, the client asks the LECS to provide configuration information to allow it to connect to a particular ELAN. It does this by sending one or more pieces of information about the desired ELAN, such as the LAN type (Ethernet or Token Ring), the maximum packet size, and the name of the LAN.

The LECS takes the information from the LANE client and reads its table of ELANs to find a match. When it locates the correct ELAN, it returns that address to the LANE client.

**LES Address Matching**
With the information provided by the LECS, the LANE client can join the ELAN. To do this, it sends an emulated LAN address and its true ATM address to the LES. The LES registers this information. From then on, the LANE client can send and receive data over the ATM network as if it were using a normal LAN.

When the LANE client receives a request from a protocol (such as TCP/IP, IPX, or NetBEUI) to send information to another point in the ELAN, it sends the destination LAN address to the LES. The LES looks for a match in its database, and then returns the true ATM address to the LANE client. The client then sets up a normal VC between itself and the destination, and subsequent data traffic is sent directly on this VC without any further intervention by the LES or the other LANE services. While this address resolution request is being processed, interim traffic is sent to the BUS and copied from there to all stations in the ELAN.

If the LES does not find a match for the destination address, the data is sent to the Broadcast and Unknown Server (BUS). The BUS attempts to deliver the data to the unknown client.

**BUS Distribution**
The BUS does two things: it handles distribution of data to unknown clients and it emulates LAN broadcast services. If the LES cannot find a particular ELAN client, the data is sent to the BUS for distribution, and the BUS forwards it to all the clients of the ELAN.

The BUS also handles broadcasts. It registers its address with the LES identical to any other client. It registers under the address of F (x16), which is the normal LAN address for a broadcast message. When a LANE client protocol wants to broadcast a message to the entire LAN, it addresses the message to F (x16) and passes it on. The LEC sends this address to the LES for resolution, and the LES returns the ATM address of the BUS. The LEC can then send the message to the BUS. The BUS maintains a list of all clients on the ATM network and sends the message to all clients. The BUS service is typically located in the same piece of equipment with the LES.

**Integrated Local Management Interface**
The ILMI resides on an ATM switch and provides diagnostic, monitoring, and configuration services to the User-Network Interface. The ILMI is defined by the ATM Forum and uses the Simple Network Management Protocol (SNMP) and a Management Information Base (MIB). It runs over AAL3/4 or AAL 5 with a default VPI/VCI of 0/16.

The ILMI MIB contains data describing the physical layer, the local VPCs and VCCs, network prefixes, administrative and configuration addresses, ATM layer statistics, and the ATM layer itself. The most common client-oriented function of the ILMI is to assist a client during LECS discovery.

**TCP/IP over ATM**
The protocol for classical IP over ATM (sometimes abbreviated as CLIP/ATM) is a well-established standard spelled out in RFC 1577 and subsequent documents. Windows Server 2003 provides a full implementation of this standard.

The IP over ATM approach provides several advantages over ELAN solutions. The most obvious advantages are its ability to support QoS interfaces, its lower overhead (as it requires no MAC header), and its lack of a frame size limit.

**IP over ATM Architecture**
IP over ATM is a group of components that do not necessarily reside in one place. When they don't reside in one place, the services are not typically on an ATM switch. For the purposes of this discussion, it is assumed the IP over ATM server services reside on a Windows Server 2003 server.

The core components required for IP over ATM are roughly the same as those required for LANE, as both approaches require the mapping of a connectionless medium to a connection-oriented medium, and vice versa. In IP over ATM, these services are provided by an IP ATMARP server for each IP subnet. This server maintains a database of IP and ATM, and provides configuration and broadcast services.

**IP over ATM Components**
IP over ATM is a very small layer between the ATM protocol and the TCP/IP protocol. As with LANE, the client emulates

standard IP to the TCP/IP protocol at its top edge while simultaneously issuing native ATM commands to the ATM protocol layers underneath.

IP over ATM is often preferred to LANE because it is faster than LANE. A primary reason for this performance advantage is that IP over ATM adds almost no additional header information to packets as they are handed down the stack. After it has established a connection, the IP over ATM client typically can transfer data without modification.

As with LANE, IP over ATM is handled by two main components: the IP over ATM server and the IP over ATM client. The IP over ATM server is composed of an ATMARP server and Multicast Address Resolution Service (MARS). The ATMARP server provides services to map network layer IP unicast addresses to ATM addresses, while MARS provides similar services for broadcast and multicast addresses. Both services maintain IP address databases just as LANE services do.

The IP over ATM server can reside on more than one computer, but the ATMARP and MARS databases cannot be distributed. You can have one IP over ATM server handle ATMARP traffic, and one handle MARS. If, however, you divided the ATMARP Server between servers, it effectively creates two different IP networks. All IP over ATM clients in the same logical IP subnet (LIS) need to be configured to use the same ATMARP server. Traditional routing methods are used to route between logical IP subnets, even if they are on the same physical network.

Windows Server 2003 includes fully integrated ATMARP and MARS servers.

**ATMARP Server**
The IP over ATM client and ATMARP server go through a process similar to the LANE client and the LECS when a client joins the network and discovers other network members. As with LANE, after an address is found, native ATM takes over and TCP/IP packets are sent across a VC from end station to end station. There is, however, a major difference in how the IP over ATM client discovers the ATMARP server.

**ATMARP Server Discovery**
Because the ATMARP server typically resides on a server rather than on an ATM switch, it is not possible to use ILMI or a well-known VC to discover its address. In fact, there is no default IP over ATM mechanism for server discovery. To start using IP over ATM, an administrator must find the ATM address of the appropriate ATMARP server and manually configure each IP over ATM client with this address. In a single ATM switch network, this is not much of a problem, but in larger networks it can become a demanding job. To ease configuration in smaller networks, ATM ARP/MARS servers and ATM ARP/MARS clients running Windows Server 2003 use a default address.

After the ATMARP server has been discovered, the IP over ATM client can use this server to resolve IP to ATM address mappings and communicate with other computers. The ATMARP server supports only unicast traffic. To send packets to a broadcast address or multicast list, the IP over ATM client uses MARS.

**MARS**
Mimicking the role of the BUS in LAN emulation, MARS handles distribution of broadcast and multicast messages to all the members of the network or to all members of a multicast group. Because of the potential for blockage, MARS provides two modes of operation. When an ATMARP client receives a request to send a packet to a multicast or broadcast IP address, it sends a request to the MARS to resolve this address to a list of clients that are members of that group. In one mode of operation, the MARS return a list of all ATM addresses to which the group address resolves. The client then creates a Point-to-Multipoint (PMP) ATM connection to all of these addresses and forwards the packet on that connection.

The other mode of operation involves a multicast server (MCS). The MCS registers interest in one or more multicast groups with the MARS. The MCS receives information describing the membership of that group, as well as updates when clients join or leave that group. When a client requests a group address resolution from the MARS, the MARS simply returns the single address of the MCS. The packet is then sent to the MCS, which creates the PMP connection and distributes the packet to all members of the group.

The following figures are examples of the VCs that are created in each of these modes.

**IP Multicast over ATM Connections Without MCS**

**IP Multicast over ATM Connections with MCS**

The disadvantage of the first method, in which each client sending packets to the group creates its own PMP connection to all other members of the group, is the large number of virtual channels required. The disadvantage of the second method, which uses the MCS, is that the MCS becomes both a central point of failure and a potential blockage because it distributes all multicast packets for all of the groups it serves.

**IP over ATM Operation**

IP over ATM faces the same problems, and relies on the same basic tools and fixes as LANE. In particular, it faces the issues of address resolution and broadcasting.

In normal ATM, SVC connections are established by sending a connection request containing the ATM address of the destination endpoint to the ATM switch. Before an IP endpoint can create an SVC in this manner, the endpoint must resolve the IP address of the destination to an ATM address.

Typically, when an Ethernet host needs to resolve an IP address to an Ethernet MAC address, it uses an ARP broadcast query frame. Hardware broadcasting is not done in ATM. The Address Resolution Protocol (ARP) of the ATMARP server resolves IP addresses to ATM addresses.

An ATM endpoint that needs to resolve an IP address sends an ATMARP request to the ATMARP server for its LIS. The ATMARP request contains the ATM address, IP address, and the requested IP address of the sender. If the ATMARP server accepts the requested IP address, it sends back an ATMARP response containing the requested ATM address. If the requested IP address is not found, the ATMARP servers send back a negative ATMARP reply, unlike the procedure in an ELAN, which sends an unresolved address to the LANE BUS. This behavior allows an ARP requestor to distinguish between an unknown address and non-functioning ATMARP server.

The end result is a three-way mapping from the IP address to an ATM address to a VPI/VCI pair. The IP address and ATM address are required to create a VC. The IP address and VPI/VCI then are required to send the subsequent cells containing data across the VC.

An ATM endpoint creates SVCs to other ATM endpoints within its LIS. For an ATM endpoint to resolve an arbitrary IP address, it must be configured with the ATM address of the ATMARP server in its LIS.

When the server starts, an ATM endpoint establishes a VC with the ATMARP server using ATM signaling. As soon as the VC is opened with the server, the server sends the ATM endpoint an ATMARP request. When the ATM endpoint sends the response, the ATMARP server has the ATM and IP address of the new ATM endpoint. In this way, the ATMARP server builds its table of ATM to IP address mappings.

**IP over ATM Client Initialization**

In Windows Server 2003, IP over ATM does not require the use of an Inverse ARP. Instead, the client goes directly to the server to register itself on the network. Because the process is automatic, no human intervention is required to initialize the client. Depending on whether the client address is mapped to a static address or a dynamic address, the procedure varies between the following two approaches.

**With a static IP address**
The following example details each step in establishing an IP over ATM connection for a single IP over ATM client with a static IP address. First, the client initializes and gets an ATM address from the ATM switch. The client then connects to the ATM ARP/MARS server and joins the broadcast group. The IP-to-ATM address mapping of the client is also added to the ATMARP server database. The client is now ready to contact other hosts and begin data transfer.

**With DHCP**
Establishing an IP over ATM connection for a single IP over ATM client using Dynamic Host Configuration Protocol (DHCP) is similar but not identical. First the client initializes and gets an ATM address from the ATM switch. Then the client connects to the ATM ARP/MARS server and joins the broadcast group. The client connects to the multicast server (MCS) and sends a DHCP request. The MCS broadcasts the DHCP request to all members of the broadcast group.

When the DHCP server receives the request, it sends a DHCP reply to the MCS. The MCS then broadcasts the reply to the broadcast group. The client receives the DHCP reply and then registers its IP and ATM addresses with the ATM ARP/MARS server. The client is now ready to contact other hosts and begin data transfer.

**Logical IP Subnets**
A LAN-based IP internetwork consists of a series of cabling plants separated by IP routers. The cabling plants connect the hosts of an IP network or subnet together and the routers connect the networks and subnets to each other. An IP host on a particular network can send IP packets directly to a host on the same network by addressing the packet to the media access control (MAC) address of the destination host. An IP host can send IP packets to hosts on other networks by addressing the packet to the MAC address of the router. This paradigm can connect hundreds (or thousands) of hosts on the same network to hundreds (or thousands) more on other networks. While this configuration works well for connectionless, broadcast-based technologies such as Ethernet and Token Ring, it is important to use care when attempting to create the same situation with ATM. The following figure, "Two LISs Running on a Single Switch," shows two LISs running on a single switch.

**Two LISs Running on a Single Switch**

Before a single IP packet can be sent, a connection must be created between the source and destination at the ATM layer. On an ATM network using SVC, the path must be negotiated between switches so that the sender has a valid VPI/VCI address to which to send the ATM cells. While possible, it is not very practical to have hundreds (or thousands) of ATM endpoints on the same IP network. A host, such as a network server, cannot send an arbitrarily large number of VCs to other hosts in the network. More VCs mean more overhead and resources for the both the operating systems and the hardware (ATM adapters and switches) of the IP network. If connecting across an ATM service provider, more VCs also mean more cost.

The logical IP subnet (LIS) is a way of constraining the number of ATM endpoints in an IP network or subnet. The LIS is a group of IP hosts that share a common IP network number; these hosts communicate with each other directly using ATM virtual channels. Different logical IP subnets can be created on the same ATM switch to create a virtual IP internetwork.

Note the example in the previous figure, "Two LISs Running on a Single Switch." When hosts in LIS 131.107.56.0/24 are ready to communicate among each other, they establish a VC with each other (direct delivery). When hosts in LIS 131.107.56.0/24 are ready to communicate with hosts in LIS 131.107.68.0/24, they establish a VC with the router and send an IP packet to the router (indirect delivery). The router then establishes its own VC with the destination host and forwards the IP packet.

An IP router belongs to multiple LISs and is configured with multiple IP addresses and subnet masks. If the router has a single ATM interface (and therefore a single ATM address), it can either use the single ATM address (with the unique End System Identifier) or use multiple ATM addresses by varying the last byte in the 20-byte ATM address (the SEL field). To give clients a secondary point of access, a router uses multiple addresses primarily in the case of a server failure, when a route is no longer functional.

**Services at an ATM Switch**
The overall scheme of ATM protocols, hardware, and interconnections comes together as shown in the following figure, "Overview of ATM Architecture from Desktop to WAN." The hardware includes ATM clients, ATM switches, and the blades that function as edge devices between a device or application that uses ATM and another protocol or environment. The connections include SVCs and permanent virtual connections (PVCs), all handled by the local switch shown at the center of the diagram.

In addition, the following figure, "Overview of ATM Architecture from Desktop to WAN," shows LANE clients joining the local switch, as well as a client being redirected from Local Switch 2 by the LECS to the BUS and LES services on Local Switch 1. The bottom layer is the client section, showing all the ARP, ATM, and other clients of the local switch. (With the exception of a remote access client, which is shown dialing into the switch at the top of the diagram). The various forms of edge devices are shown in the central section, and remote connections are shown at the top.

# What Is POP3 Service?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is POP3 Service?**

**In this section**

- Common POP3 Scenarios
- Other E-Mail Retrieval Technologies
- POP3 Dependencies
- Related Information

The POP3 service supplements existing functionality in Windows Server 2003 provided by the SMTP service, which receives e-mail messages. The POP3 service makes e-mail messages available for download from a server, enabling a server to host e-mail accounts and provide basic e-mail access.

The POP3 service performs the tasks of message download and request handling on a Windows-based server, where message download consists of transmitting the messages from a folder in the file system to clients and request handling is performed according to the POP3 protocol, which defines how the server responds to requests sent from an e-mail client.

Basic e-mail access depends on the POP3 protocol implemented by the POP3 service. The POP3 protocol, described in RFC 1939, "Post Office Protocol - Version 3," a standard for retrieving e-mail messages from servers, is stable, widely used, and supports basic e-mail access. The POP3 protocol supports message download to a client after the Simple Mail Transfer Protocol (SMTP) delivers messages received by means of the Internet. SMTP transmits e-mail from the originating server to the destination server using a protocol defined in the proposed standard, RFC 2821, "Simple Mail Transfer Protocol." For more information about the POP3 and SMTP protocols, see RFC 1393 and RFC 2821 in the IETF RFC Database.

The POP3 service is a scaleable e-mail server that meets the basic e-mail access needs of businesses and organizations. Any client that supports RFC 1939 can be configured to use the POP3 service to download e-mail. The POP3 service supports the following client authentication methods: Active Directory integrated authentication, Local Windows accounts authentication, and Encrypted Password file authentication. Because the POP3 service mail store exists in the file system, message storage and retrieval do not require specific database technologies on the server.

**Common POP3 Scenarios**

The POP3 service is designed to meet the needs of businesses and organizations with a small number of users needing basic e-mail access. However, the POP3 service is capable of scaling up to meet the needs of Internet service providers (ISPs) offering basic e-mail access to a large number of users.

**Small Businesses and Organizations**

Many small businesses have an investment in a Windows Server infrastructure that is suitable for an e-mail platform like POP3. POP3 enables organizations to host e-mail services for their Internet domain and support basic e-mail service. E-mail clients receive e-mail from the POP3 server and send e-mail by using the SMTP service. Groupware and scheduling functionality are not available with the POP3 service.

**Internet Service Providers**

ISPs offer e-mail service to customers as an added incentive; therefore the cost of e-mail service must be low enough that it does not impact the bottom line. Because POP3 use is so widespread, system administrators are familiar with existing POP3-compatible technology. The POP3 service in Windows Server 2003 supports a variety of authentication methods and scales up well to meet the demands of the ISP. Additionally, ISPs with large user bases can take advantage of the Active Directory directory service to store account information.

**Other E-Mail Retrieval Technologies**

POP3 is not the only protocol to support message retrieval. Internet Message Application Protocol version 4 (IMAP4) is similar in purpose to POP3. The IMAP4 protocol defines an extensive command set, including message searching, downloading of individual message body parts, and message tagging. IMAP4 implementations are not as common as POP3 because of the complexity of the IMAP4 protocol. Consequently, the use of IMAP4 is not as widespread as POP3 although the use of IMAP4 is growing as users demand more features from ISPs. For more information about IMAP4, see RFC 3501, "Internet Message

Access Protocol -Version 4, Rev 1" in the IETF RFC Database.

Messaging API (MAPI) is a protocol used with Microsoft Exchange Server and various e-mail clients for feature-rich messaging, including groupware and scheduling. One of the capabilities of MAPI is message retrieval for clients, such as Microsoft Outlook 2003. MAPI provides access to messages and folders and the associated properties of messaging objects. Message retrieval occurs in the context of a remote procedure call (RPC) from the client to the Exchange Server store, with the message contents transmitted in the response to the RPC call.

**POP3 Dependencies**

The POP3 service has the following dependencies:

- **Authentication Methods.** Active Directory integrated authentication, Local Windows accounts authentication, or Encrypted Password file authentication are the authentication methods that may be used with the POP3 service. All methods allow plaintext authentication, permitting credentials to be transmitted without encryption. If Active Directory-integrated authentication is chosen, Active Directory must be in place and functioning properly.

- **NTFS or FAT file system.** The POP3 service uses the file system as the mail store and takes advantage of NTFS access control lists (ACLs) to secure the mailboxes. POP3 service supports other file systems but NTFS provides the access control features that secure the mailboxes, and is strongly recommended.

- **Mail delivery from the Internet.** The SMTP service is a component that is installed by the POP3 service and receives incoming mail for the POP3 service.

# How POP3 Service Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How POP3 Service Works**

**In this section**

- POP3 Architecture
- POP3 Protocol
- POP3 Physical Structure
- POP3 Processes and Interactions
- Network Ports Used by POP3
- Related Information

The POP3 service enables a server to host e-mail accounts and includes tools to administer the servers, domains, and mailboxes.

The POP3 service performs the tasks of message download and request handling on a Windows-based server, where message download consists of transmitting the messages from a folder in the file system to clients and request handling is performed according to the POP3 protocol, which defines how the server responds to requests sent from an e-mail client.

The SMTP service receives e-mail from the Internet, saves the e-mail to the Queue folder, and notifies the SMTP delivery service for POP3 of the arrival of e-mail. The delivery service then moves the e-mail to the POP3 mail store, where it is available for download to POP3 e-mail clients.

The ideal environment for the POP3 service consists of the following:

- Windows Server 2003 is installed and functioning properly.
- Server hardware is sized appropriately for the number of users and disk space requirements.
- A suitable authentication configuration for the installation is implemented, using, Active Directory integrated, local Windows accounts or encrypted password file authentication.
- The volume that holds the mail store is formatted with the NTFS file system.
- Quotas are enabled on the volume that will host the mailboxes.
- The Internet domain name is registered with a naming authority.
- The SMTP service is configured as a mail exchange host with the Internet Service Provider.
- Mail Exchanger (MX) records have propagated through the Domain Name System.

**Note**

- Mail Exchanger (MX) records and mail exchange host configurations are not required for all installations. Consult your ISP to determine how your server should be configured.

This section covers how the service works with existing services and components of Windows Server 2003. The POP3 protocol

is presented to explain the command set implemented by the POP3 service. The physical structure of the POP3 e-mail system and the mail store is shown to illustrate the processes and interactions of the POP3 service and the SMTP service.

**POP3 Architecture**

The POP3 service uses the SMTP service, an existing component of Internet Information Services (IIS), to provide inbound message delivery as well as outbound message sending for POP3 clients. The figure POP3 Architecture shows the modularity of the POP3 service and the relationship with IIS and the file system.

**POP3 Architecture**

The POP3 service is the interface between e-mail clients and the mail store. POP3 listens on TCP port 110 for connections from e-mail clients, authenticates the client, and manages the connection with the client.

The authentication store is the repository of user information needed to authenticate the user. The store can be the Active Directory database, the local SAM database, or the encrypted password file for the user. The authentication module accesses the authentication store to verify the credentials submitted by the client to the POP3 service.

The Mail Storage Access API is the common interface to the mail store for all processes. The POP3 service, the SMTP delivery service for POP3, and the POP3 Server Administrator use the API to access the mail store.

The mail store uses the file system for storage. The mail store is typically located on the same server as the POP3 service, but it should be located on a different local or network volume than the operating system to avoid potential disk space problems. For large mail stores, the mail store can be placed on a Network Attached Storage (NAS) device and accessed by one or more servers running the POP3 service. Even though the mail store is contained in the file system, it is accessed by using the Mail Storage Access API.

The SMTP delivery service for POP3 is the component that transfers e-mail from the SMTP service to the user mailboxes. The delivery service is notified by the SMTP service when new e-mail arrives. New e-mail is delivered to the mail store by means of the Mail Storage Access API.

The POP3 Server Administrator is the interface used by the tools to configure the server, domains, and mailboxes. The server administrator accesses the mail store by means of the Mail Storage Access API to create or modify domains and mailboxes. Modifications to the service itself are made through calls to the administration interface within the POP3 service.

With the exception of the authentication store, the installation of the POP3 service installs all of the components shown in the figure POP3 Architecture. The POP3 service installation copies the files to the server and registers the dynamic-link libraries. The file names are listed in the table POP3 Components along with a description of the file. The files are copied to the *systemroot*\system32\pop3server directory, unless noted otherwise, and the installation path is added to the system path variable.

The following table lists the components of the POP3 service.

**POP3 Components**

| Component | Description |
|---|---|

| | |
|---|---|
| P3admin.dll | The interface to the mail store that supports the creation, deletion, verification, and renaming of mailboxes and domains. The POP3 Server Administrator uses this functionality. |
| P3store.dll | The interface to the mail store that supports mailbox locking, message creation and deletion, and creation, modification, and retrieval of the hashed password. The POP3 service, SMTP delivery service for POP3, and POP3 Server Administrator use this functionality. |
| Pop3auth.dll | The interface to the authentication methods. |
| Pop3evt.dll | The interface to the System log. |
| Pop3svc.exe | The Microsoft POP3 Service, which is started by the Service Control Manager. Pop3svc initializes the socket and thread pools, starts the listener, and manages the client connections to the service. |
| Winpop.exe | Command line tool to administer the POP3 service. Installation location is *systemroot*\system32. |
| P3server.msc | POP3 service console file used when the Microsoft Management Console (MMC) console is used. Installation location is *systemroot*\system32. |
| Pop3perf.dll | Contains methods that collect performance counter data from the POP3 service and make it available for display in the System Monitor. |
| Pop3pi.h | Header file that contains the list of performance counter indices used by the POP3 service. |
| Pop3snap.dll | The interface to the MMC. |
| Pop3perf.ini | Initialization files for the performance counters, which are not dynamically initialized. |

**POP3 Protocol**

The POP3 protocol is an application layer protocol, similar to the SMTP in the figure POP3 Protocol Architecture. Since POP3 uses TCP as the transport layer, it belongs on the same side of the figure as SMTP.

**POP3 Protocol Architecture**

RFC 1939, "Post Office Protocol -Version 3" defines a set of commands and responses for accessing a mailbox on a server and retrieving the messages. The POP3 service implements RFC 1939.

The POP3 protocol defines not only the commands and responses between a POP3 client and server but also the state of the session. The state of the session defines whether a POP3 command is valid in that context. The protocol defines commands for authentication, message retrieval, and message management in a series of three states. The three states of a POP3 session are:

- Authorization
- Transaction
- Update

POP3 commands submitted by the POP3 client are valid only in the context of the current state and the state changes as the session progresses. Typically, session state progresses from the authorization state, to the transaction state, and finally to the

update state. However, a session can go from the authorization state to being disconnected if a client sends the QUIT command while in the authorization state.

The authorization state is the state of the session once a connection has been established. The connection between the client and server uses the TCP three-way handshake to establish a network connection. The table Authorization State lists the commands sent by the client to the POP3 server.

**Authorization State**

| Command | Description |
|---|---|
| USER *username* | Requires an argument that specifies the mailbox name. The USER command is used when plaintext authentication is allowed. |
| PASS *password* | Must be preceded by the USER command. Requires the argument that specifies the password for the mailbox account. The response will indicate logon failure if an incorrect password was supplied, another user is already logged on to the mailbox, or the account is otherwise locked. |
| AUTH or AUTH [NTLM\|APOP] | If no argument is passed by the client, the response from the server contains the authentication methods in effect. The POP3 service accepts NTLM or APOP as valid arguments. |

The transaction state is the second state of the POP3 session. The commands valid in the transaction state provide information about the e-mail messages, return the contents of the messages, and mark the messages for deletion. The table Transaction State lists the commands sent by the client to the POP3 server. The commands in the table are valid when the POP3 session is in the transaction state.

**Transaction State**

| Command | Description |
|---|---|
| STAT | Returns a response with the number of messages in the mailbox and the byte count for each message. |
| LIST or LIST *n* | If no argument is supplied, the server returns a listing for each message containing the message length and message marker. If an argument is supplied, the server returns a listing for the specified message, it if exists. |
| RETR *n* | Returns the contents of the specified message, if it exists and has not been previously marked for deletion. Returns an error if no message id is specified. |
| DELE *n* | Returns a success response if the argument is an existing message not previously marked for deletion. This command does not delete the message. |
| NOOP | Returns a positive response but the server performs no action. |
| RSET | Returns a positive response after it removes the deletion mark from messages previously marked for deletion. |
| TOP *n* | Returns the number of specified lines of a message not previously marked for deletion. |
| UIDL or UIDL *n* | Returns a globally-unique identifier (GUID) for each message in the mailbox or a specified message, if the message was not previously marked for deletion. |

The update state is the last state of a POP3 session. The receipt of the QUIT command signals the server to delete any messages marked for deletion. The QUIT command can also be used in the authorization state to end a session before it enters the transaction state. In this situation, the connection to the server is terminated. For more information about the POP3 protocol, see RFC 1939.

**Note**

- Messages were marked for deletion in the transaction state by the DELE command. The actual deletion did not occur when the messages were marked for deletion.

The table Update State lists the single command sent by the client to end the session. The server displays the greeting message in response to this command.

**Update State**

| Command | Description |
|---|---|
| QUIT | Causes the greeting message to be displayed. Any messages previously marked for deletion by the DELE command are deleted when the QUIT is sent. |

**POP3 Physical Structure**

The physical structure of the POP3 mail system is shown in the figure Physical Structure of E-mail Systems. It shows both end systems running the POP3 and SMTP service. A message is shown as it travels from the sender through the Internet to the destination by using the protocols shown.

**Physical Structure of E-mail Systems**

The major components of the physical structure are client systems, mail servers, and the Internet. A client system can be a personal computer, laptop, or personal digital assistant. The client system must have a POP3 client capable of communicating with an SMTP service for sending mail and a POP3 service for receiving mail. The typical client configuration includes a setting for the SMTP server and the POP3 server, either as IP addresses or as resolvable host names.

The servers are shown with an SMTP service to send mail to and receive mail from the Internet. The Internet provides the backbone of networks used to carry the message from the originating system to the destination system. The delivery service, which is not shown, is used to deliver mail to the POP3 mailboxes.

The SMTP service and SMTP delivery service for POP3 work together to deliver a message sent by means of the Internet. As shown in the figure, all message transmission uses the SMTP protocol until the message reaches the destination host. The POP3 protocol is used by the POP3 service to download e-mail messages to the client.

**Various Installations of the POP3 Service**

The most common POP3 server installation is shown in the figure Typical POP3 Server Installation. The POP3 service and the message store are on one server and the mail store is on a volume on the same server.

**Typical POP3 Server Installation**

The clients shown in the figure connect to the single server. The POP3 service and the message store are on the server and the mail store is on a volume on the same server. Ideally, the mail store is located on a separate volume from the operating system. The processes and interactions of the server are contained within the server, with the possible exception of the authentication routines, which might make calls to other servers depending on the authentication method employed by the POP3 service.

The use of a remote store with the POP3 service is shown in the figure POP3 Server with Remote Store. The remote store is a

NAS device that provides large message stores with room to grow.

**POP3 Server with Remote Mail Store**

In this installation, the mail store is accessing a disk that is on a NAS device. This installation also supports one or more domains and all clients access a single server to retrieve e-mail. The advantage of this installation is the ability to grow the store as needed, as long as the hardware is capable of adequately supporting the user's. Any incoming e-mail to the POP3 users from the Internet is delivered to the SMTP service on the POP3 server and written to the mail store on the NAS device.

In the figure Multiple POP3 Servers, three servers access a remote store on a NAS device. The POP3 clients connect to different servers to balance the load across the servers. Adding more servers allows the POP3 service to support more users and provides a level of redundancy.

**Multiple POP3 Servers**

The only notable difference in this installation is that any incoming e-mail to the POP3 servers from the Internet is delivered to the SMTP server designated to receive e-mail for the domain, which then delivers the mail to the POP3 mail store. Any outbound messages are delivered to the Internet by the SMTP server designated for this purpose, although the same server typically receives and sends messages for a domain. Because there is more than one POP3 server, a server should be assigned the task of receiving inbound e-mail.

**Note**

- If you are using encrypted password file authentication, you must use the same globally unique identifier (GUID) on each mail server. To do so, select one mail server, identify its GUID, and then configure all other mail servers to use the same GUID.

**POP3 Processes and Interactions**

The mail delivery process is how e-mail travels from the originating server to the destination server. The process described in the figure POP3 E-mail Delivery shows the steps and the protocol used for each leg of the journey.

**POP3 E-mail Delivery**

In the figure POP3 E-mail Delivery, e-mail is sent to someone@example.com.

1. The e-mail is submitted for the user someone@example.com.

2. The SMTP service resolves the e-mail domain, example.com, to a mail server on the Internet, mailserver1.example.com.

3. E-mail is routed to the example.com domain where it is received by the SMTP service on mailserver1.example.com.

4. The SMTP service places the e-mail in the Queue folder on the destination mail server. The delivery service is notified of new e-mail for the domain example.com.

5. The delivery service moves e-mail to the recipients mailbox, P3_someone.mbx, in the mail store.

6. The user checks for e-mail by connecting to the mailbox for someone@example.com. The POP3 service verifies the credentials for the user and then either accepts or denies the connection.

7. If the user authenticates successfully, the e-mail is downloaded to the user's computer.

**Preparing to Retrieve E-Mail**

The POP3 service initializes its resources when the service is started by the Service Control Manager. Before the service can accept requests, it must do the following:

- Initialize the endpoint for connections and listen for requests

- Create a thread pool

- Create a socket pool

**Listening for Connection Requests**

In order for clients to connect to the service, the server must listen on some communication endpoint for a connection request. The POP3 service listens, by default, on TCP port 110 for incoming connections, unless it is configured to listen on another

port. The service expects clients connecting to the POP3 service to use the POP3 protocol during the session. When a TCP connection is established, the server sends a greeting message that identifies itself as a POP3 server. In the past, attempts have been made to exploit vulnerabilities in software using the version information included in the greeting message. The greeting message can be configured to hide system information.

**Creating a POP3 Service Thread Pool**
The POP3 service creates a pool of threads at initialization that wait on the I/O Completion Port for I/O Completion packets. I/O completion ports are used when thread pools process asynchronous I/O requests for an application. When an I/O Completion packet is posted to the port, the packet is passed to a thread to perform work for the packet. The I/O Completion packet has a handle to a data structure called the I/O Context. The I/O Context contains information about the type of I/O, callback functions, and other information specific to the type of object, such as an inactivity timer.

**Creating a POP3 Service Socket Pool**
The POP3 service creates a pool of sockets to handle incoming connection requests. While the service is running, the service maintains a pool of sockets sufficient to handle the connection requests while not consuming resources needlessly. There are four settings that are specific to the socket pool. The first setting is the minimum number of sockets that the POP3 service creates at startup. The *socketmin* setting is chosen to support a reasonable number of connections and allow the server to start up quickly. The default value of *socketmin* is 10.

The *socketthreshold* value is the number of unused sockets in the pool; the *socketthreshold* value is also the size of the block of sockets to create when new sockets are created. When the number of sockets remaining in the pool reaches the *socketthreshold* value, the server adds more sockets to the pool in anticipation of connection requests. If the threshold value is reached, the POP3 service creates new sockets in increments equal to the threshold setting size. If the *socketthreshold* value is greater than the remaining number of sockets until the maximum value is reached, the service will create only as many sockets as possible. The default value is 5.

The maximum number of sockets, *socketmax*, is the total number of sockets the POP3 service will create. As the POP3 service increase the size of the pool, the number of sockets will approach the maximum value. Once the maximum setting is reached, the POP3 service will not create any additional sockets. At this point, any incoming requests are placed in a queue. The size of the queue is determined by the *socketbacklog* setting. If the number of connections exceeds the number represented by *socketmax +socketbacklog*, any incoming connection requests are refused.

When a connection is closed, the socket is closed and the total number of sockets in use is decremented by 1. If the total number of available sockets is less than *socketthreshold* and *socketmax*, a new block of sockets is created. The server always maintains a sufficient number of sockets for incoming connections.

### Note

- The POP3 service manages connections to the server and automatically disconnects idle connections.

**Storing Messages**
The POP3 mail store maintains an organizational structure of message domains and mailboxes for the POP3 service, using the existing file system on the server. This organizational structure permits the POP3 service to host a single e-mail domain or many e-mail domains on a server. Mail domains are folders in the file system that exist at the same level in the directory and contain any mailboxes created in the domain. Mailboxes contain the e-mail messages for the recipient.

### Mail Store

The mail store is a directory on the local file system or a Universal Naming Convention (UNC) path, or the mail store can exist on a NAS device. In the latter configuration, multiple POP3 servers can access the same mail store. The POP3 service can use the FAT file system but the recommended file system is NTFS. By using NTFS, the mail store offers logging, recovery, and disk quotas. In the event of a server crash, NTFS can recover data by replaying its log files.

Disk quotas are a feature of the NTFS file system that can be helpful for managing the POP3 mail store. The POP3 mail store is

not a single-instance storage system, in which the server keeps only a single copy of a message and a separate table of recipients indexed by a message identifier. When a single-instance storage system stores a message sent to more than one recipient on a server, the recipient's access the same instance of the message in the mail store. When one recipient deletes the message, the message remains in the mail store until all other recipients have deleted the message.

When a message is received by the SMTP service, each recipient of a message receives a separate copy of the message from the delivery service. The use of disk quotas ensures that individual mailboxes and the mail store in general do not use excessive or unanticipated amounts of disk space and adversely affect the performance of the POP3 service or the server. A disk use policy that encourages users to download messages to a local disk and not use the POP3 mail store as a permanent storage location can be implemented through the use of disk quotas.

**Mail Root**
The mail root is the first organizational segment, shown in the figure Mail Store. The POP3 mail root is a directory path that identifies the first part of the path to the mail store. By default, the mail root is defined as *system_drive*\InetPub\Mailroot\Mailbox. All domains will be created under the mail root.

**Mail Domain**
The mail domain is the second segment of the organizational structure. When a domain is created by one of the configuration tools, the directory is created under the mail root. The domain name must be unique within the mail root and as a property of the SMTP service, where the domain is stored as a property in the IIS metabase. The domain name must:

- Have fewer than 255 characters
- Consist of alphabetic and numeric characters in the set {a-z, 0-9, -}
- Be registered with an Internet Naming Authority

**Mailbox**
The mailbox is the third segment of the organizational structure. The mailboxes are shown in the diagram as the folders on the right hand side. The mailboxes for a domain are logically grouped together by the domain because the path to the mailbox includes the domain name. Mailboxes for user accounts are created in a directory in a POP3 domain to hold the e-mail message delivered by the SMTP delivery service for POP3. The organizational structure permits mailbox names to be used more than once in different domains so a new domain can have mailboxes with the same names as those shown in the diagram. The mailbox folder name is P3_*mailbox name*.mbx, where the mailbox name must:

- Have fewer than 64 characters
- Cannot consist of characters in the set {@ ( ) / \ [ ] : ; , " . * = | ? + }
- Be unique in the context of the domain

When a mailbox is created, it has the following contents:

- Lock file
- Quota file

The mailbox lock file prevents simultaneous access to the mailbox by an e-mail client. The lock file is usually an empty file with one notable exception. The lock file contains the hashed password if Encrypted Password file authentication is enabled on the server. The hashed password is compared to the hash value sent by client and the user is granted or denied access based on the comparison.

The mailbox will also contain a quota file if the authentication method is Active Directory integrated or local Windows account authentication. For these two methods, the quota file is created when the mailbox is created. If Encrypted Password file authentication is the authentication method, the quota file must be created by using the command-line tool Winpop. The security identifier (SID) for the account is contained in the quota file and file ownership of all messages is assigned to the SID.

**Message Files**
The message files are the last item of the organizational structure. All e-mail message files are created using a naming convention with an .eml extension appended to identify the file as a message. Because the volume of messages delivered to the POP3 service can be large, a naming convention was implemented that allows for 10,000 messages per millisecond. The

naming convention names each e-mail message by using a timestamp consisting of the year, month, day, hour, minute, second, and millisecond plus a 4-digit counter. Using the message file format, message files appear as P3##..##.eml, where ##..## is a string of 26 digits derived by using the naming convention.

**Authenticating Clients**

The authentication module in the POP3 service is the interface to the authentication methods. The authentication module interacts with an abstraction referred to as an authentication database. The authentication process might refer to a file in the mailbox directory for authentication rather than query a database. The available choices for authentication method are:

- Active Directory integrated authentication
- Local Windows accounts authentication
- Encrypted Password file authentication

**Paths to Authentication**

The three possible paths to authentication are plaintext, NTLM, and authenticated POP (APOP). The plaintext authentication consists of the following sequence:

1. Client sends USER *mailbox*.
2. Server send +OK.
3. Client sends PASS *password*.
4. Server send +OK.

The NTLM sequence consists of the client sending an AUTH command, such as AUTH NTLM or AUTH APOP.

If the client sends the AUTH command with one of the authentication methods as an argument, the response and subsequent data are base-64 encoded to obscure the conversation. The client-server sequence still happens as described in RFC 1939, when AUTH is used but the commands and the responses must be converted to and from base64 encoding.

The ensuing discussion of authentication necessitates some mention of passwords being transmitted in the clear. NTLM requires the use of encrypted conversations during authentication. If NTLM is enabled, the plaintext transmission of passwords is not allowed. If the client sends the AUTH command, the server will respond with a listing of the accepted authentication mechanisms, APOP and NTLM. NTLM authentication is a challenge/response mechanism supported by the POP3 service. When the POP3 client connects to the server with the AUTH NTLM command, the server sends a random string of bytes (challenge) to the client, which the client encrypts with a hash of the user password. The client then sends the encrypted challenge back to the server where the response is decrypted with the password hash stored on the server. If the server is able to derive the original challenge from the client response, then the client is successfully authenticated.

APOP authentication is a challenge/response process used with POP3 and Internet Message Access Protocol 4 (IMAP4) servers. When a client connects to the mail server, the server appends an ASCII character string to the server greeting message. The client uses the string and the user password to create a hash value that is transmitted to the server, where it is compared to the value in the encrypted password file. When APOP is enabled, Encrypted Password file authentication uses the MD5 hashing algorithm in conjunction with CRAM, referred to as MD5-CRAM.

**Authentication Methods**

Active Directory integrated authentication is an option if the POP3 server is installed in an Active Directory domain on a domain controller or member server. Active Directory integrated authentication supports both plaintext authentication and NTLM authentication. The authentication store can be an Active Directory database or a global catalog derived from an Active Directory database.

Local Windows accounts authentication is an option when the POP3 server is not a member of an Active Directory domain and user accounts are created and maintained on the local server. Local Windows authentication supports both plaintext and NTLM authentication. When local accounts are created for POP3 user accounts, the authentication store is the local SAM database.

Encrypted Password file authentication is an option when the POP3 server is not a member of an Active Directory domain and user accounts are not created on the local server. A hash of the password is created using the Message Digest 5 (MD5) hashing algorithm and saved in the lock file in the mailbox when Encrypted Password file authentication is chosen as an authentication method. During authentication, the client sends a hash of the user password which is compared to the hashed password stored

in the lock file. This type of authentication is called a Challenge Response Authentication Mechanism (CRAM). If the hashed passwords match, the authentication of the user is successful. Encrypted Password file authentication supports both plaintext and APOP authentication.

**POP3 Service and Authentication Module**

The authentication process shown in the figure Architecture of POP3 Service and Authentication Module is a conceptual representation of the authentication.

**Note**

- MD5 is a hashing algorithm, based on its predecessors, MD2 and MD4. CRAM is a challenge-response authentication mechanism, based on the hashing of a password known only to the server and the user. When using the MD5-CRAM mechanism, a client transmits a digest of a password in response to a challenge from the server. The hashed password is sent across the network to be used in the authentication of a user.

**Requesting E-mail Delivery**

In the figure POP3 Service and Mail Store, the Mail Storage Access API provides an abstraction to the mail store and is shown as an interface to the mail store.

**POP3 Service and Mail Store**

If the client has successfully authenticated with the server, then the session progresses to the Transaction state. Other than the NOOP command, all of the commands sent by the client in the Transaction state require the POP3 service to access the mail store. The POP3 service reads from and writes to the mail store by means of the Mail Storage Access API.

The Mail Storage Access API creates an abstraction to the storage environment. This abstraction offers a consistent interface to the mail store and allows other storage possibilities in future releases. The Mail Storage Access API is called by other modules in the POP3 service, including the SMTP delivery service for POP3 and the POP3 Server Administrator.

When the client successfully authenticates with the service, the POP3 service modifies the lock file in the users mailbox directory to prevent another session from opening the same mailbox. The mailbox "lock" file is named "lock" and this file is created when the mailbox is created. When the mailbox is locked, the file name is reversed to "kcol." The mailbox lock does not interfere with the mail delivery service as it delivers messages.

**Delivering Messages**

In the figure POP3 Service and Mail Delivery, the delivery of a message from the Internet to the POP3 mail store is illustrated. The message is shown passing through the SMTP delivery service for POP3 to the mail store, where it can be downloaded

using the POP3 service.

**POP3 Service and Mail Delivery Module**

The SMTP delivery service for POP3 delivers messages to the individual mailboxes in the mail store. The delivery service replaces the default SMTP mail delivery module. When new mail arrives, the delivery service is notified by the SMTP service that the SMTP service has put messages in the SMTP Queue folder. The delivery service is an event sink that is triggered by the arrival of new mail. The SMTP delivery service for POP3 uses the same Mail Storage Access API to write the message files as the POP3 service uses to retrieve messages from the message store. If a message is delivered to a mailbox that is currently in use, the message is not available during this session and must be downloaded during a subsequent session.

The mail is delivered to the mailbox after it is retrieved from the Queue folder. A message sent to multiple recipients in a POP3 domain will be retrieved from the Queue folder as multiple messages, one for each recipient. The POP3 mail store does not implement single-instance message store, therefore each mailbox receives a copy of the message. Each message file is named using the naming convention described in the section on the physical structure of the POP3 service.

If quotas are in place and the user has exceeded the disk space quota, the message is returned to the sender if the **Deny disk space once the quota has been met** option is enabled. If the nondelivery report (NDR) cannot be sent to the original sender, the message is left in the Badmail folder.

**Administering the Server, Domain, and Mailbox**

The POP3 Server Administrator provides control over the POP3 service, domains, and mailboxes. Through the POP3 Server Administrator, all settings for the server, domain, and mailbox are available. The POP3 Server Administrator stores settings for the authentication method, socket and thread pool, and port number in the registry of the server. The architecture diagram does not depict the registry but these settings are registry entries.

In the figure POP3 Service and Server Administrator, the interaction with other components of the POP3 service is shown. The Server Administrator uses the Mail Storage Access API to make changes to mail store, such as creating new domains and users. The Server Administrator also creates and modifies settings in the IIS metabase.

**POP3 Service and Server Administrator**

**Creating a Domain**

The POP3 Server Administrator uses the Mail Storage Access API to create, modify, or delete domains in the mail store. When a new domain is created, the server administrator creates a directory entry for the domain under the mail root. There are three steps performed for the domain creation:

- Create a directory for the domain.
- Set the permissions on the directory.
- Add the domain name as an SMTP domain listing in the IIS metabase.

The new domain name is added as an SMTP property for SMTP in the IIS metabase. When a new domain is created to be used by multiple POP3 servers, the server administrator creates a directory entry for the domain and adds the domain name to the IIS metabase on the server. Subsequent installation of other servers accessing the same store will only add the domain name to the IIS metabase on that server.

**Deleting a Domain**

When a domain is deleted, the directory entry is deleted from the directory and the domain name is removed from the metabase. The deletion of a POP3 domain in an environment with multiple servers has some caveats that are worth noting. The first installation of a domain creates the mail store and adds the domain name to the metabase; the first deletion of a domain removes the mail store and deletes the domain name from the metabase. The domain name must be deleted from the metabase on other servers by deleting the domain on those servers.

**Creating a Mailbox**

The POP3 Server Administrator uses the Mail Storage Access API to create, modify, or delete mailboxes in the mail store. When a new mailbox is created, a directory is created under the domain for the mailbox. The following actions occur when the mailbox is created:

- Create the mailbox in a directory in the POP3 domain.
- Set permissions on the mailbox. When the mailbox is created, only local and domain administrators and the local network service have permissions to read from and write to the mailbox.
- Create an associated account. If the service is using Active Directory integrated or local Windows account authentication, an associated account should be created. No associated account is created for encrypted password file authentication.
- Add account to groups, if necessary. If the local Windows account authentication method is chosen, the user created for the associated account will be added to the “POP3 Users” group, which has no rights to log on locally to the server. If Active Directory integrated authentication is chosen, the user created for the associated account will have typical Active Directory domain user rights.

**Deleting a Mailbox**
When an existing mailbox is deleted, the mailbox and its contents are deleted from the server. The POP3 Server Administrator deletes the associated account in Active Directory or the SAM database only if the option to delete the associated account was specified. Otherwise, the administrator will be prompted about the deletion of an associated account. If Encrypted Password authentication is being used, no associated account was created.

**Locking or Unlocking Domain Mailboxes**
The POP3 Server Administrator can lock or unlock individual mailboxes or all mailboxes in a domain. When a mailbox is created, a lock file is created in the mailbox directory. The POP3 Server Administrator locks the mailbox by changing the name of the "lock" file from "lock" to "kcol." The POP3 service uses the same functionality to lock a mailbox when a session is underway to prevent simultaneous access to a mailbox.

The POP3 Server Administrator uses the Mail Storage API to access the mail store. The POP3 Server Administrator configures the IIS and SMTP service components through the IIS metabase.

**Network Ports Used by POP3**
By default, the POP3 service listens on the well-known TCP port 110 for incoming connections from e-mail clients. There is no UDP port for the POP3 service. The administrator of the POP3 service can specify a different TCP port using the administration tools, provided that the new port number is not already reserved for another protocol.

### Port Assignments for POP3

| Service Name | UDP | TCP |
|---|---|---|
| POP3 Service | None | 110 or an unassigned port chosen by the administrator. |

**Related Information**

- RFC 1939, "Post Office Protocol -Version 3" in the IETF RFC Database
- RFC 2821, "Simple Mail Transfer Protocol" in the IETF RFC Database

# POP3 Service Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- POP3 Service Tools
- POP3 Service Registry Entries
- POP3 Service WMI Classes
- Network Ports Used by POP3 Service

The following tools, registry settings, and Windows Management Instrumentation (WMI) classes are associated with the POP3 service.

**POP3 Service Tools**
The following tools are used to administer the POP3 service.

**Winpop.exe: Winpop**
**Category**
Operating system tool

**Version compatibility**
All versions of Winpop in Microsoft Windows Server 2003 are identical.

Winpop is the POP3 service command-line tool that sets or retrieves the service settings for the POP3 service. Winpop can also perform the domain or mailbox activities essential to the operation of the POP3 installation.

For more information about Winpop.exe, see "Command Line References" in the Tools and Settings Collection.

**P3server.msc: POP3 snap-in**
**Category**
Operating system tool

**Version compatibility**
All versions of Microsoft Management Console (MMC) and the POP3 snap-in in Windows Server 2003 are identical.

The Microsoft Management Console POP3 snap-in provides a user interface to perform the same administrative activities as Winpop.exe. The POP3 snap-in lets the administrator see all of the domains and mailboxes graphically and administer POP3 remotely.

**POP3 Service Web Administration**
**Category**
Web interface component

**Version compatibility**
All versions of POP3 Service Web Administration in Windows Server 2003 are identical.

POP3 Service Web Administration provides remote management capabilities by using a Web browser interface as a client. From this interface, the administrator has access to settings for the Server Properties and the Domains and Mailboxes. POP3 Service Web Administration is automatically installed when you install the E-Mail Service from Add/Remove Windows Components, or you can install it manually from Add/Remove Windows Components. However, it is not installed by using Configure Your Server Wizard to configure the Mail server role. In order to use POP3 Service Web Administration, you need to make sure that Web Interface for Remote Administration is also installed on the same server. You can access the interface by entering `https://servername:8098` in a Web browser or in the Run dialog box at a client computer, where `servername` is the name of the server on which you installed POP3 Service Web Administration.

**POP3 Service Registry Entries**
The following registry entries are associated with the POP3 service.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values might be written to the registry. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**POP3 Server**
The following registry entries are located under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Pop3 Service\

**ConsoleFile**
**Registry path**
HKLM\SOFTWARE\Microsoft\Pop3 Service\

**Version**
Windows Server 2003

Stores the path to the MMC file (.msc), installed in the *windir*\system32 directory.

**CreateUser**
**Registry path**
HKLM\SOFTWARE\Microsoft\Pop3 Service\

**Version**
Windows Server 2003

Stores a value that indicates whether an associated user account will be created in Active Directory or the local Security and Accounts Manager (SAM) database when a mailbox is created. The value that is set depends on whether the **Automatically create a user** check box is selected.

**Greeting**
**Registry path**
HKLM\SOFTWARE\Microsoft\Pop3 Service\

**Version**
Windows Server 2003

Stores the greeting message for the POP3 service. The default message, **Microsoft Windows POP3 Server Version 1.0 <FQDN of server> ready,** can be changed to hide the system information. This key does not exist by default and must be created. For more information about creating this registry key, see "Advanced Mail Server Configurations" on the Microsoft Windows Server System Web site.

**InstallDir**
**Registry path**
HKLM\SOFTWARE\Microsoft\Pop3 Service\

**Version**
Windows Server 2003

Stores the path to the executables and DLLs installed by the POP3 server installation, with the exception of winpop.exe and p3server.msc, which are installed in the *windir*\system32 directory. The default installation path is *windir*\system32\pop3server.

**Logging Level**
**Registry path**
HKLM\SOFTWARE\Microsoft\Pop3 Service\

**Version**
Windows Server 2003

Stores the logging level for the POP3 service. The default value is 1 and the range of values is from 0 to 3, as shown in the following table. The events are written to the event log and can be viewed by using the Event Viewer.

| Value | Explanation |
|---|---|
| 0 | No events are logged by the POP3 service. |

| | |
|---|---|
| 1 | Only critical events are logged by the POP3 service. |
| 2 | Critical and warning events are logged by the POP3 service. |
| 3 | Critical, warning, and informational events are logged by the POP3 service. |

**MailRoot**
**Registry path**
HKLM\SOFTWARE\Microsoft\Pop3 Service\

**Version**
Windows Server 2003

Stores the path to the mail root directory, typically *systemdrive*\inetpub\mailroot. The POP3 e-mail domains are created as subdirectories underneath the mail root.

**RequireSPA**
**Registry path**
HKLM\SOFTWARE\Microsoft\Pop3 Service\

**Version**
Windows Server 2003

Stores the setting for Secure Password Authentication (SPA) on the server. The POP3 server checks the value at startup to determine if SPA is required for local Windows account or Active Directory authentication. If SPA is enabled, plain text transmission of passwords is not allowed. This key is not created until SPA is activated; it is disabled by default.

**Pop3Svc**
The following registry entries are located under HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Pop3Svc\

**Description**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the textual description as it appears in the Service Control Manager (SCM). The default value of the string is "Provide POP3 downloading service."

**DisplayName**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the display name of the POP3 service as it appears in the SCM. The default value of the string is "Microsoft POP3 Service."

**ErrorControl**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the default configuration setting for the POP3 service, used by the Service Control Manager (SCM). The default value is 1.

**ImagePath**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the image path value, the path to the POP3 service dynamic link library (DLL). The default value is

*windir*\System32\POP3Server\pop3svc.dll.

**MaxNumberofSockets**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the value of the maximum number of sockets POP3 service can create. The default value is 40.

**MinNumberofSockets**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the value of the minimum number of sockets the POP3 service creates at startup. The default value is 10.

**ObjectName**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the account name in which the POP3 service runs on the server. The default account name is "NT AUTHORITY\NetworkService."

**Pop3Port**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the port number the POP3 service listens on for incoming connection requests. By default, the POP3 service listens on TCP port 110 for incoming connections. If this value is changed, the port number must also be changed on the clients to match the server setting.

**SocketBacklog**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the value of the socket backlog that the POP3 service permits when the maximum number of sockets allowed is in use. The socket backlog is the number of pending connections for the POP3 service. When the number of sockets reaches *maxnumberof sockets+socketbacklog*, new client connections for the POP3 service are rejected. The default value is 5.

**SocketsThreshold**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows 2003 Server

Stores the sockets threshold value the POP3 service uses as a guideline. The sockets threshold setting determines how many sockets the POP3 service creates at a time. If the number of sockets in existence does not exceed the maximum number of sockets (*MaxNumberofSockets*), the server creates new sockets in a block size equal to the sockets threshold value. The threshold value also indicates when the POP3 service needs to create more sockets. If the number of available sockets reaches the threshold value, the POP3 service creates new sockets. The default value is 5.

**Start**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**

Windows Server 2003

Stores the number of attempts the SCM makes to start the POP3 Service. The default value is 3.

**ThreadCountPerCPU**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the thread count value for the POP3 service. By default, the POP3 service creates two threads per CPU to handle client requests. The number of threads per processor multiplied by the number of processors equals the number of simultaneous requests the POP3 service can process.

**Type**
**Registry path**
HKLM\System\CurrentControlSet\Services\Pop3Svc\

**Version**
Windows Server 2003

Stores the default configuration setting for the POP3 service used by the SCM. The default value is 16.

**Application**
The following registry entries are located under
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Eventlog\Application\Pop3Svc

### Note

- There are identical keys located under HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Eventlog\Application\Pop3 Service. These keys, however, are used by the Simple Mail Transfer Protocol (SMTP) service and are not used by the POP3 Service.

**CategoryCount**
**Registry path**
HKLM\System\CurrentControlSet\Services\Eventlog\Application\Pop3Svc

**Version**
Windows Server 2003

Stores the number of event categories supported by the POP3 service. The default value is 2.

**CategoryMessageFile**
**Registry path**
HKLM\System\CurrentControlSet\Services\Eventlog\Application\Pop3Svc

**Version**
Windows Server 2003

Stores language-dependent strings that describe the event categories. The default value for this string is *windir*\System32\POP3Server\pop3evt.dll.

**EventMessageFile**
**Registry path**
HKLM\System\CurrentControlSet\Services\Eventlog\Application\Pop3Svc

**Version**
Windows Server 2003

Stores language-dependent strings that describe the events. The default value for this string is *windir*\System32\POP3Server\pop3evt.dll.

**TypesSupported**
**Registry path**
HKLM\System\CurrentControlSet\Services\Eventlog\Application\Pop3Svc

**Version**

Windows Server 2003

Stores a value used to mask certain bits of an integer to indicate the type of events supported. The default value is 7, indicating that the first 3 bits are set to 1.

**POP3 Service WMI Classes**

The following table lists and describes a WMI class that is associated with the POP3 service. The class is in the *root\cimv2* namespace.

**WMI Classes Associated with POP3**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_PerfFormattedData_Pop3Svc_POP3Service | \root\cimv2 | Windows Server 2003 |

For more information that describes many WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by POP3 Service**

The POP3 service listens on the well-known TCP port 110 for incoming connections from clients. The administrator of the POP3 server might assign other values by using the administration tools, provided that the new port number is not already assigned to another protocol.

**Port Assignments for POP3**

| Service Name | UDP | TCP |
|---|---|---|
| POP3 service | None | 110 or an unassigned port chosen by the administrator. |

# QoS Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**QoS Technical Reference**
The increase in network traffic in recent years has intensified the competition for network resources. New applications, multimedia applications in particular, place high demands on networks and can have a negative impact on mission-critical applications, such as Enterprise Resource Planning (ERP) systems. Traffic bottlenecks and delays can frustrate end users and put network administrators in reaction mode.

Quality of Service (QoS) is an industry-wide group of standards and mechanisms that support preferential treatment for certain traffic flows. Microsoft Windows Server 2003 provides QoS mechanisms for prioritizing traffic as it is generated by an application. The application can be written to apply QoS parameters to the traffic, or traffic management tools can be used to apply the QoS parameters.

# What Is QoS?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is QoS?**

**In this section**

- QoS Concepts
- Uses and Benefits of QoS
- Network Technologies and Support for QoS
- Windows Server 2003 QoS
- Related Information

Quality of Service (QoS) for networks is an industry-wide set of standards and mechanisms for ensuring high-quality performance for critical applications. By using QoS mechanisms, network administrators can use existing resources efficiently and ensure the required level of service without reactively expanding or over-provisioning their networks.

Traditionally, the concept of quality in networks meant that all network traffic was treated equally. The result was that all network traffic received the network's best effort, with no guarantees for reliability, delay, variation in delay, or other performance characteristics. With best-effort delivery service, however, a single bandwidth-intensive application can result in poor or unacceptable performance for all applications. The QoS concept of quality is one in which the requirements of some applications and users are more critical than others, which means that some traffic needs preferential treatment.

**QoS Concepts**

The goal of QoS is to provide preferential delivery service for the applications that need it by ensuring sufficient bandwidth, controlling latency and jitter, and reducing data loss. The following table describes these network characteristics.

**Network Characteristics Managed by QoS**

| Network Characteristic | Description |
|---|---|
| Bandwidth | The rate at which traffic is carried by the network. |
| Latency | The delay in data transmission from source to destination. |
| Jitter | The variation in latency. |
| Reliability | The percentage of packets discarded by a router. |

The Internet Engineering Task Force (IETF) defines two major models for QoS on IP-based networks: Integrated Services (Intserv) and Differentiated Services (Diffserv). These models encompass several categories of mechanisms that provide preferential treatment to specified traffic. The following table describes the three general categories of QoS mechanisms.

**Note**

- Different versions of Windows support different combinations of these mechanisms. Windows XP and Windows Server 2003 do not support resource reservation.

| Category of QoS Mechanisms | Description |
|---|---|
| Admission control | Determine which applications and users are entitled to network resources. These mechanisms specify how, when, and by whom network resources on a network segment (subnet) can be used. |

| | |
|---|---|
| Traffic control | Regulate data flows by classifying, scheduling, and marking packets based on priority and by shaping traffic (smoothing bursts of traffic by limiting the rate of flow). Traffic control mechanisms segregate traffic into service classes and control delivery to the network. The service class assigned to a traffic flow determines the QoS treatment the traffic receives. |

The Intserv model integrates resource reservation and traffic control mechanisms to support special handling of individual traffic flows. The Diffserv model uses traffic control to support special handling of aggregated traffic flows.

**Uses and Benefits of QoS**

Network administrators can use QoS to guarantee throughput for mission-critical applications so that their transactions can be processed in an acceptable amount of time. Network administrators can also use QoS to manage User Data Protocol (UDP) traffic. Unlike Transmission Control Protocol (TCP), UDP is an inherently unreliable protocol that does not receive feedback from the network and, therefore, cannot detect network congestion. Network administrators can use QoS to manage the priority of applications that rely on UDP, such as multimedia applications, so that they have the required bandwidth even in times of network congestion, but do not overwhelm the network.

QoS provides the following benefits:

- Gives administrators control over network resources and allows them to manage the network from a business, rather than a technical, perspective.
- Ensures that time-sensitive and mission-critical applications have the resources they require, while allowing other applications access to the network.
- Improves user experience.
- Reduces costs by using existing resources efficiently, thereby delaying or reducing the need for expansion or upgrades.

**Network Technologies and Support for QoS**

QoS depends on support throughout the network. To achieve QoS from sender to receiver, all of the network elements through which a traffic flow passes — such as network interface cards, switches, routers, and bridges — must support QoS. If a network device along this path does not support QoS, the traffic flow receives the standard first-come, first-served treatment on that network segment.

Network technologies such as Frame Relay, asynchronous transfer mode (ATM), and the more traditional local area network (LAN) technologies (including Ethernet, Token Ring, and 802.11 wireless LAN) support QoS mechanisms. ATM, in particular, offers a high degree of support for QoS. Because ATM is a connection-oriented networking technology, it can establish a service contract that guarantees a specific quality of service and can allocate network resources. ATM enforces the service contract and allocates bandwidth at the hardware level. For more information about ATM QoS, see "How ATM Works."

Service level guarantees and resource allocations such as those provided by ATM are not supported by the more traditional IEEE 802 LAN technologies. These LAN technologies do not support QoS mechanisms at the hardware level, but at higher levels of the Open Systems Interconnection (OSI) reference model only. For these types of technologies, QoS is primarily based on the concept of priority, in which one data transmission receives delivery preference over other transmissions.

Traditional IEEE 802 LAN technologies are connectionless, so a host that sends a transmission cannot detect the state of the network or the state of the destination host prior to the transmission. Traffic on these network technologies, therefore, is subject to delay at points along the way, making bandwidth availability and delivery time difficult to predict. Although high-priority traffic typically arrives at its destination before lower-priority traffic, high-priority traffic cannot be guaranteed to arrive within a specified time.

Although QoS is more difficult to implement on connectionless networks, there is growing interest in developing QoS for IP-based networks.

**Windows Server 2003 QoS**

QoS in Windows XP and Windows Server 2003 is different from QoS in Windows 2000. Windows 2000 supports both the Intserv and Diffserv models and includes resource reservation, admission control, and traffic control mechanisms. Windows XP and Windows Server 2003 support only the Diffserv model and include traffic control mechanisms.

The current industry trend is toward the use of the Diffserv model because those solutions that use the Intserv model have proven to be difficult to scale in large networks as well as difficult to design and develop. The Diffserv model is designed to be scalable; it offers a simple method of providing differentiated services for IP traffic.

QoS support in Windows Server 2003 has changed for the following reasons:

- The Generic QoS (GQoS) application programming interface (API) is complex for developers to use.
- Many applications cannot determine their traffic requirements in advance.
- Resource allocation does not scale well in large networks.

**Windows 2000 QoS versus Windows Server 2003 QoS**
This section briefly describes the QoS mechanisms available in Windows 2000, Windows XP, and Windows Server 2003.

**Resource Reservation**
In Windows 2000, RSVP works with other components of the Intserv architecture to request network resources for traffic that has known characteristics. Windows XP and Windows Server 2003 do not support RSVP.

**Admission Control**
The Windows 2000 implementation of admission control is QoS Admission Control Service (ACS). ACS works with Subnet Bandwidth Manager (SBM) to manage congested subnets on IEEE 802-type networks. SBM is a signaling protocol used by ACS to indicate when a QoS request can be received. ACS then determines whether sufficient bandwidth is available and grants or rejects the request. Windows XP and Windows Server 2003 do not support ACS and SBM.

**Traffic Control**
In Windows 2000, as well as Windows XP and Windows Server 2003, the Generic Packet Classifier (GPC) classifies packets and the QoS Packet Scheduler schedules and marks packets and shapes traffic flows. Windows 2000, Windows XP, and Windows Server 2003 support prioritization at Layer 2 (Data Link layer) and at Layer 3 (Network layer) of the OSI reference model.

**QoS APIs**
The two QoS application programming interfaces (APIs) included with Windows 2000, General Quality of Service (GQoS) and Traffic Control (TC), are also supported in Windows XP and Windows Server 2003. GQoS is an API used by developers to create QoS-aware applications. In Windows XP and Windows 2003, however, function calls to the GQoS API do not generate RSVP messages. The TC API can be used by traffic management applications running with administrative privileges to apply QoS to applications that are not QoS-aware.

The following table summarizes the QoS mechanisms and APIs available in Windows 2000 compared to Windows XP and Windows Server 2003.

### QoS Mechanisms and APIs

| QoS Mechanism | Windows 2000 | Windows XP and Windows Server 2003 |
|---|---|---|
| RSVP | Yes | No |
| ACS | Yes | No |
| SBM | Yes | No |
| Packet Classifier | Yes | Yes |
| Packet Scheduler | Yes | Yes |
| GQoS | Yes | Yes, with limited functionality |
| TC | Yes | Yes |

**How QoS Works**
**In this section**

- Traffic Control Overview
- Windows Server 2003 QoS Architecture
- QoS Protocols
- QoS Interfaces
- QoS Example
- QoS for Slow Links
- Related Information

The recent rapid growth in the number of bandwidth-intensive and time-sensitive applications, such as IP telephony, video conferencing, and other multimedia applications, often puts a strain on networks and keeps network administrators busy balancing capacity and performance. Windows Server 2003 Quality of Service (QoS) is a group of components that can differentiate traffic flows so that higher-priority traffic receives preferential treatment. Network administrators can use QoS to efficiently manage their resources and to ensure that high-priority applications receive preferential treatment without adversely affecting the performance of more typical network traffic. Various network technologies support QoS, but the focus of this document is on QoS for IP-based networks.

Implementing QoS involves combining a set of technologies defined by the Internet Engineering Task Force (IETF) and the Institute of Electrical and Electronic Engineers (IEEE). These technologies are designed to alleviate the problems caused by shared network resources and finite bandwidth. Although the concept of QoS encompasses a variety of standards and mechanisms, QoS for Windows Server 2003 IP-based networks is centered on traffic control, which includes mechanisms for prioritization and traffic shaping (the smoothing of traffic bursts).

QoS can be used in any network environment in which bandwidth, latency, jitter, and data loss must be controlled for mission-critical software, such as Enterprise Resource Planning (ERP) applications, or for latency-sensitive software, such as video conferencing, IP telephony, or other multimedia applications. QoS also can be used to improve the throughput of traffic that crosses a slow link, such as a dial-up connection.

All the network elements along the path that prioritized traffic takes must support QoS. Such network elements include the sending and receiving hosts, Layer 2 (Data Link layer) network devices (bridges and switches), and Layer 3 (Network layer) network devices (routers), including routers used for wide area network (WAN) links. If a network device along this path does not support QoS, the traffic flow receives the standard first-come, first-served treatment on that network segment.

This section describes how traffic control in Windows Server 2003 works. It covers the following:

- Overview of traffic prioritization and shaping.
- Description of Windows Server 2003 traffic control components.
- Description of the protocols used for Layer 2 and Layer 3 packet marking.
- Overview of the application programming interfaces (APIs) that invoke QoS mechanisms.
- Example of how prioritized traffic traverses a network.

- Description of QoS support for slow links.

**Traffic Control Overview**
Applications generate traffic at varying rates and typically require the network to carry traffic at the rate it is generated. Some applications are more tolerant than others of delays, variation in transmission rate, and data loss. Based on characteristics such as these, network traffic can fall into one of the following two types:

**Elastic traffic**
Elastic traffic adapts easily to changing network conditions. Delivery of elastic traffic is slow when bandwidth is limited and faster when bandwidth is abundant. Elastic traffic is usually generated by transaction-oriented applications, such as bulk data transfers.

**Real-time traffic**
Real-time traffic is limited in its ability to adapt to changing network conditions and delays can significantly reduce intelligibility and usefulness. Real-time traffic is generated primarily by real-time applications, such as video conferencing, that require dedicated bandwidth.

These two types of traffic have different delivery requirements. Traffic control provides the means for differentiating these types of traffic so that their delivery requirements can be met.

**Traffic Control Mechanisms**
Traffic control is a collection of mechanisms that segregate traffic into the appropriate service types and regulate its delivery to the network. Traffic control involves classifying, shaping, scheduling, and marking traffic.

**Classifying Traffic**
Duringclassification, packets are separated into distinct data flows and then directed to the appropriate queue on the forwarding interface. Queues are based on service type. The algorithm that services a queue determines the rate at which traffic is forwarded from the queue.

Traffic control in Windows Server 2003 supports the following service types:

**Best effort**
Best-effort is the standard service level in many IP-based networks. It is a connectionless model of delivery that provides no guarantees for reliability, delay, or other performance characteristics.

**Controlled load**
Controlled load data flows are treated similarly to best-effort data flows in unloaded (uncongested) conditions. This means that a very high percentage of transmitted packets will be delivered successfully to the receiving end node and a very high percentage of packets will not exceed the minimum delay in delivery. Controlled load service provides high quality delivery without guaranteeing minimum latency. For more information about controlled load service types, see the IETF-defined Request for Comment (RFC) 2211 in the IETF RFC Database.

**Guaranteed service**
Guaranteed service provides high-quality delivery with guaranteed minimum latency. The impact of guaranteed traffic on the network is heavy, so guaranteed service is typically used only for traffic that does not adapt easily to change. For more information about guaranteed service types, see RFC 2212 in the IETF RFC Database.

**Network control**
Network control, the highest service level, is designed for network management traffic.

**Qualitative service**
Qualitative service is designed for applications that require prioritized traffic handling but cannot quantify their QoS traffic requirements. These applications typically send traffic that is intermittent or burst-like in nature. For this service type, the network determines how the data flow is treated.

**Shaping and Scheduling Traffic**
During traffic shaping, the bursts in traffic are smoothed over time to create an even data flow. Traffic can be shaped only when it is transmitted, not when it is received.

During scheduling, a QoS component, the QoS Packet Scheduler, negotiates simultaneous requests for network access and determines which queue receives priority.

**Marking Traffic**
Markingmeans specifying a priority level in a packet header. Marking can be performed at Layer 2 of the Open Systems Interconnection (OSI) model (in a tag appended to the media access control [MAC] header) by using 802.1p priorities or at Layer 3 (in the IP header) by using Differentiated Services (Diffserv) priorities, as described later in this document. The priority

level maps to the service type a packet is to receive from network devices.

**Invoking Traffic Control**
In Windows 2000, applications use the Generic QoS (GQoS) API to apply QoS parameters to traffic generated by the application. Applications that use the GQoS API are said to be QoS-aware. In Windows Server 2003, applications can still call the GQoS API to prioritize traffic, but resource reservation is no longer supported.

A lower-level API, the Traffic Control (TC) API, provides prioritization and traffic shaping support at the host level rather than at the application level. Network administrators can use traffic management tools that call the TC API to apply QoS parameters on behalf of an application that is not QoS-aware.

**Windows Server 2003 QoS Architecture**
Traffic control in Windows Server 2003 consists of the TC API, the Generic Packet Classifier (GPC), and the QoS Packet Scheduler. The following diagram illustrates how the traffic control components fit together in Windows Server 2003.

### Traffic Control Architecture

In this diagram, the host computer is running a non-QoS-aware application that is generating traffic. The network administrator uses a traffic management program that calls the TC API to apply QoS parameters to the traffic. Traffic control on the sending host classifies, schedules, and marks the packets to accommodate the QoS service type specified by the traffic management program.

The Generic Packet Classifier classifies packets by service type; the QoS Packet Scheduler schedules the packets, marks them with the appropriate priority, and then sends the prioritized traffic to the network media.

**Traffic Control API**
Traffic control uses standardized QoS parameters to segment packets into sequences and to regulate the sequences. The Traffic Control (TC) API (Traffic.dll) applies the QoS parameters to the appropriate packets. Developers and network administrators use the TC API to specify the traffic that is to receive preferential treatment, the traffic that is to be treated alike, and the QoS parameters that define the preferential treatment. Traffic control uses the following specifications to define traffic:

- A flowspec, which is the list of QoS parameters such as service type and token rate (the permitted transmission rate of packets) that applies to a sequence of packets. A flowspec defines the preferential treatment.

- A flow, which is the sequence of packets that is subject to a flowspec. All of the packets in a flow receive the same treatment.

- A filterspec, which is the list of attributes, including source IP address, destination IP address, and port number, that classifies packets into a single flow.

Using the filterspec and flowspec, traffic control filters packets into the appropriate flow and applies the appropriate QoS parameters to the flow. QoS-aware devices, such as switches and routers, use the filterspec to determine how to handle packets.

**Generic Packet Classifier**
The Generic Packet Classifier (Msgpc.sys) classifies packets generated by an application so that the packets can subsequently be prioritized for sending across the network.

When an application or traffic management program invokes QoS, the Generic Packet Classifier on the sending host determines the service type (defined by the flowspec) to which each individual packet belongs and maps each packet to a queue (flow) based on the service type. After packets are assigned to a queue, the QoS Packet Scheduler can manage the queue in accordance with the QoS parameters specified in the flowspec.

### Note

- In Windows Server 2003, unlike Windows 2000, the GQoS API directly calls the Generic Packet Classifier. In Windows 2000, the GQoS API calls the QoS RSVP Service Provider, which is not supported in Windows Server 2003.

**QoS Packet Scheduler**
The QoS Packet Scheduler (Psched.sys) is a kernel-level component that marks and schedules packets that the Generic Packet Classifier has assigned into queues. The QoS Packet Scheduler enforces QoS parameters for a given flow to achieve traffic shaping.

The QoS Packet Scheduler retrieves packets from the queues and marks them with a priority and rate of flow. The rate of flow is used to pace the transmission of packets to the network, thus mitigating the inherent "send it all right now" nature of IP transmissions. The priority is used to determine the order in which packets are submitted to the network during periods of congestion, thus spreading bursts of traffic over time and creating a more uniform traffic flow.

Using the priority and rate of flow, the QoS Packet Scheduler determines the delivery schedule for each queue and negotiates competition between any queued packets that simultaneously request access to the network.

To ensure preferential treatment throughout the network, packets must be marked so that network devices along the path can detect the priority and handle the packets appropriately. Packets are marked with an 802.1p priority for prioritization by Layer 2 devices and with a Diffserv priority for prioritization by Layer 3 devices. The QoS Packet Scheduler provides 802.1p marking. TCP/IP provides Diffserv marking.

The QoS Packet Scheduler is not automatically installed with Windows Server 2003. You install this component on any host on which you want to perform traffic marking or shaping. Use Network Connections to display the properties for the connection where you want to install the QoS Packet Scheduler; install the QoS Packet Scheduler as a new service.

**Note**

- To use the QoS Packet Scheduler for 802.1p (Layer 2) marking, the network adapter must support 802.1p. On the **Advanced** tab for the properties of the network adapter (available through Network Connections or Device Manager), you must select the option to enable 802.1p support.

**QoS Protocols**

Windows Server 2003 supports both 802.1p (Layer 2) and Diffserv (Layer 3) priority marking. Network devices that support these protocols use the markings to provide end-to-end preferential treatment.

**802.1p**

The IEEE 802.1p signaling standard defines traffic prioritization at Layer 2 of the OSI model. Layer 2 network devices, such as switches, that adhere to this standard can group incoming packets into separate traffic classes.

The 802.1p standard is used to prioritize packets as they traverse a network segment (subnet). When a subnet becomes congested, causing a Layer 2 network device to drop packets, the packets marked for higher priority receive preferential treatment and are serviced before packets with lower priorities.

The 802.1p priority markings for a packet are appended to the MAC header. In Windows Server 2003, the QoS Packet Scheduler performs 802.1p marking.

On Ethernet networks, 802.1p priority markings are carried in Virtual Local Area Network (VLAN) tags. The IEEE 802.1q standard defines VLANs and VLAN tags. This standard specifies a 3-bit field for priority in the VLAN tag, but it does not define the values for the field. The 802.1p standard defines the values for the priority field. This standard defines eight priority classes (0 - 7). Network administrators can determine the actual mappings, but the standard makes general recommendations.

The VLAN tag is placed inside the Ethernet header, between the source address and either the Length field (for an IEEE 802.3 frame) or the EtherType field (for an Ethernet II frame) in the MAC header. The 802.1p marking determines the service level that a packet receives when it crosses an 802.1p-enabled network segment.

The following diagram illustrates the location of an 802.1p priority within a VLAN tag.

**Structure of a VLAN Tag**

Layer 2 priority values are defined by Group Policy. Windows Server 2003 provides a default priority value for each service type on a host. Sophisticated switches, however, might direct hosts or routers to use different mappings. The QoS Packet Scheduler in Windows Server 2003 uses the default priority values listed in the following table.

**Default Priority Values for Service Types**

| Service Type | Priority Marking |
|---|---|

| | |
|---|---|
| Non-conforming packets[1] | 0 |
| Best-effort | 0 |
| Controlled load | 4 |
| Guaranteed service | 5 |
| Network control | 7 |
| Qualitative | 0 |

[1] This service type is applied to packets that do not conform to the flowspec.

These default values can be modified by applying a Computer Configuration Group Policy setting for the host at Administrative Templates\Network\QoS Packet Scheduler\Layer-2 priority value. These Group Policy settings create corresponding registry subkeys and values at HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows\Psched\UserPriorityMapping.

Implementing 802.1p marking on a host requires the following:

- The network adapter and device driver support 802.1p.
- The option to enable 802.1p support is selected.
- The service types are enabled with Group Policy.
- For a customized priority value, the default priority value has been changed with a Group Policy setting.

**Differentiated Services**

Diffserv (Differentiated Services) is a protocol that defines traffic prioritization at Layer 3 of the OSI model. Layer 3 network devices, such as routers, that support this protocol use Diffserv markings to identify the forwarding treatment, or per-hop behavior (PHB), that marked traffic is to receive. Diffserv markings for a packet are placed in the IP header. In Windows Server 2003, TCP/IP performs Diffserv marking.

RFC 2475 defines the architecture for Diffserv. RFC 2474 defines the bits in the Diffserv field. The Type of Service (TOS) field in Internet Protocol version 4 (IPv4) headers and the Traffic Class field in Internet Protocol version 6 (IPv6) headers are redefined for Diffserv values.

RFC 2474 redefines the IPv4 TOS octet as 6 bits for the Diffserv value, also known as Diffserv code point or DSCP, followed by 2 unused bits. The following figure illustrates how Diffserv redefines the TOS field.

**Diffserv Redefinition of TOS Field**

The first 3 bits of the TOS field were formerly used for IP precedence, which indicated the importance of a packet. DSCP values are backward-compatible with IP precedence values, which means that legacy routers that support only IP precedence can interpret DSCP values.

As with Layer 2 prioritization, DSCP values are defined by Group Policy. Windows Server 2003 provides a default DSCP value for each service type on a host, but some Layer 3 network devices can direct hosts to use different values. Windows Server 2003 uses the default DSCP values listed in the following table.

**Default DSCP Values for Service Types for Conforming Packets**

| Service Type | Priority Marking |
|---|---|
| Best-effort | 0 |
| Controlled load | 24 |

| | |
|---|---|
| Guaranteed | 40 |
| Network control | 48 |
| Qualitative | 0 |

Packets that do not conform to the flowspec have a default priority of 0.

These defaults can be modified by applying a Computer Configuration Group Policy setting for the host at Administrative Templates\Network\QoS Packet Scheduler\. The **DSCP value of conforming packets** subcategory supports settings for packets that conform to the flowspec. These Group Policy settings create corresponding registry subkeys and values at HKLM\Software\Policies\Microsoft\Windows\Psched\DiffservByteMappingConforming. The **DSCP value of non-conforming packets** subcategory supports settings for packets that do not conform to the flowspec. These Group Policy settings create corresponding registry subkeys and values at HKLM\Software\Policies\Microsoft\Windows\Psched\DiffservByteMappingNonConforming.

Diffserv differs from 802.1p prioritization in that Layer 3 devices can aggregate flows. Routers, therefore, need to distinguish a comparatively small number of aggregated flows instead of the thousands or millions of individual flows that compose them, and can provide better service to the packets that have higher priority.

**QoS Interfaces**

Windows Server 2003 provides two application programming interfaces (APIs) for assigning QoS parameters to traffic. Application developers use the GQoS API to apply QoS parameters at the application level. Network administrators use traffic management tools that call the TC API to apply QoS parameters at the host level.

**Generic QoS API**

In Windows 2000, the GQoS API was the foundation for QoS. It provided access to several QoS mechanisms, including resource reservation mechanisms and traffic control mechanisms. In Windows XP and Windows Server 2003, the GQoS API still provides access to traffic control mechanisms, but it no longer supports resource reservation. Existing calls to invoke resource reservations are still supported, but they are treated differently: a traffic flow is immediately created locally without a reservation request and the traffic from the application is marked and scheduled as though a reservation had been requested successfully.

GQoS is part of Windows Sockets 2.0 (Winsock2). Most applications use the GQoS API to invoke the QoS capabilities in Windows. For more information about the GQoS API, see “QoS API” on MSDN.

**Traffic Control API**

The TC API provides access to traffic control mechanisms that regulate network traffic on the local host. These components regulate traffic within the kernel of the local host and, through prioritization and scheduling, across the network.

QoS-aware applications (those that call the GQoS API) invoke the TC API indirectly. Network administrators can use traffic management programs to invoke this API directly on behalf of applications that are not QoS-aware. A lower-level API than the GQoS API, the TC API requires administrative privileges.

Unlike the GQoS API, the TC API allows traffic from a number of sources (on the same sending host) to be aggregated into a single traffic control flow. For example, all of the traffic to a specific destination IP address can be included in a single flow, regardless of the source port and destination port. The GQoS API, on the other hand, allows only traffic from a single conversation, which is defined by source and destination IP addresses, source and destination ports, and protocol (Transmission Control Protocol [TCP] or User Datagram Protocol [UDP]) to be included in a single flow.

For more information about the TC API, see “Application-Driven QoS Components” on MSDN.

**QoS Example**

The following diagram illustrates what happens when QoS is invoked for traffic generated by an application. In this diagram, an application running on Client A is generating traffic and sending it to Client B. In this example, the application is not QoS-aware, which means it does not use the GQoS API to specify QoS parameters. Instead, the network administrator uses a traffic management tool to define the QoS parameters for the host.

### Invoking QoS on a Host

In this example, the following occurs:

1. Client A on Network A is running an application that is generating traffic. The application is not QoS-aware, so the traffic is destined for best-effort service.

2. The network administrator has used a traffic management tool (Traffic Control Monitor, for example) to define flows (the filterspec) for each interface on Client A and the QoS parameters that apply to each flow (the flowspec) for preferential treatment.

3. As the application generates traffic, the GPC (Generic Packet Classifier) on Client A classifies the traffic into queues by service type.

4. The QoS Packet Scheduler on Client A manages the queues determined by the GPC by providing preferential treatment for higher-priority traffic. The QoS Packet Scheduler takes the following actions:

   - Reduces traffic bursts by smoothing transmission peaks over a period of time (that is, shapes traffic).

   - Schedules packets for transmission.

   - Marks packets for Layer 3 and, if 802.1p is enabled for the network adapter, Layer 2 prioritization, as specified by QoS Packet Scheduler Group Policy.

   - Sends the packets to the network media.

5. When the traffic reaches the Layer 3 router, the router uses the DSCP marking in the IP header to determine how to forward it.

6. When the traffic reaches the Layer 2 switch, the switch uses the 802.1p marking in the MAC header to give the traffic preferential treatment.

**QoS for Slow Links**
When slow links, such as dial-up modems, are used to connect to the Internet or another remote network, the network can suffer significant performance problems. Windows Server 2003 provides QoS support for these slow links.

**QoS for Internet Connection Sharing Clients**
Some home or small office networks use Internet Connection Sharing (ICS) to connect to the Internet or to another network. With ICS, multiple computers on a small network can access Internet resources by using the Internet connection of the ICS host computer. In these ICS networks, typically the computers are connected to a relatively fast internal network (for example, 100 megabits per second [Mbps] Ethernet). The connection to the Internet, however, can be a slow link, such as a dial-up connection.

When an ICS client computer (one that uses the shared Internet connection provided by the ICS host computer) is on a fast network and connects to a computer on a different fast network through a slow link connection, a speed mismatch occurs. This speed mismatch can result in a significant transmission delay on ICS networks. In this situation, the TCP receive window on the ICS client computer is set to a large value based on the high speed of the local small network. The TCP receive window

specifies the number of bytes remaining in a memory buffer that stores incoming data on a connection. The larger the window size, the more packets a sender can send at one time before waiting for acknowledgements and a newly advertised receive window size.

For a slow link, the ICS client sends the large value of the TCP receive window to the Internet server. When the Internet server responds to the ICS client's request for data, it starts sending data at a slow rate. If packets are not lost, the Internet server gradually increases the sending rate until it sends almost a full window of packets at a time. This is normal TCP connection behavior.

However, the disparity between the large amount of data that the ICS client reports it can receive and the smaller amount of data that can be accommodated by the slow link can cause data to back up in a potentially large queue at the slow link. Large queues can have a negative effect on the performance of other traffic across the slow link.

To avoid such problems caused by slow links, the ICS host computer automatically sets the TCP receive window for communications across the slow link to a size that accommodates the slow link, thus overriding the ICS client computer's default TCP receive window size. The smaller window size does not adversely affect traffic performance because it is the same size as the window that the receiving computer would use if it were connected directly to the slow link. The QoS Packet Scheduler on the ICS host computer makes this window adjustment on behalf of the ICS client computers.

**QoS for Modems**

Many home computers still connect to the Internet through slow, dial-up modem links with connection speeds less than 56 kilobits per second (Kbps). In spite of the speed limitation, users sometimes run several programs that access the Internet concurrently. For example, they might be browsing the Internet, downloading files, receiving e-mail, joining a chat session, or running streaming audio or video. Most programs that support these activities use TCP and open their own connections.

If the QoS Packet Scheduler is not installed on the computer, the first program that uses the slow link initially has exclusive use of the link. Exclusive use allows the program's connection to reach a steady state, which can result in the transfer of a full TCP receive window of data. When the next program starts to transfer data, its connection is subject to the TCP slow-start algorithm that limits how much unacknowledged data can be in transit. Because data is already in transit on the first connection, the second connection takes much longer to reach a steady state and the transfer rate is slower than for the first connection.

To resolve these issues, the QoS Packet Scheduler in Windows XP and Windows Server 2003 uses a Deficit Round Robin (DRR) queue-servicing scheme for slow links. The DRR scheme allocates queues and assigns data flows to each queue. The queues are serviced in a round-robin fashion, which improves responsiveness and performance for all network communications.

The DRR scheme was available in Windows 2000 and is used automatically in Windows XP and Windows Server 2003 when the operating system detects a slow link.

**Integrated Services over Slow Links**

Special mechanisms are provided to perform traffic shaping on slow links, such as 28.8-kilobytes per second (KBps) modem links. On such links, large packets can occupy the link long enough to delay small audio packets that must be sent on the same link. This can cause problems with audio quality. To avoid this problem, traffic control fragments large packets at the link layer, sending only one fragment at a time. Latency-sensitive audio packets can then be inserted in between the larger packet's fragments, thus reducing audio latency and improving audio quality.

Integrated Services over Slow Links (ISSLOW) is a queuing mechanism that is used to optimize slow (low-capacity) network interfaces by reducing latency. In particular, it is designed for interfaces that forward traffic to modem links, ISDN bearer (B) channels, and sub-T1 links.

A typical packet occupies a modem link for up to half a second. Other packets queued behind it can experience significant delays. Packets that are long enough in length to exceed the maximum tolerable delay for their QoS flow are fragmented before transmission through the link, so that high-priority packets can be inserted between the fragments of the larger packet, and meet the required QoS parameters for speedy transmission. The following figure illustrates a Point-to-Point Protocol (PPP) link using ISSLOW.

**PPP Link with ISSLOW**

For example, a PPP link is carrying best-effort traffic in addition to guaranteed service level flow "A." The PPP link capacity is 100 KBps and the average latency is 100 milliseconds. The best-effort traffic is consuming the majority of the bandwidth on the link, which is starving flow "A" of the resources it requires to provide guaranteed service levels. In this example, flow "A" cannot tolerate a delay of more than 145 milliseconds. As the best-effort traffic fills the queue, packets from flow "A" arrive. The first best-effort packet (10 kilobits) is fragmented into 2-kilobit packets. The 8-kilobit packet from flow "A" is fragmented into 2-

kilobit packets as well, and the flow "A" fragments are inserted between the best-effort fragments in order to meet the required latency guarantees of flow "A".

# QoS Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**QoS Tools and Settings**

**In this section**

- QoS Tools
- QoS Group Policy Settings and Registry Entries

**QoS Tools**

The following tool is associated with Quality of Service (QoS).

**Tcmon.exe: Traffic Control Monitor**

**Category**

This tool is included in the Resource Kit Tools for Windows 2000, Windows XP, and Windows Server 2003.

**Version compatibility**

Runs on Windows 2000, Windows XP, and Windows Server 2003.

Tcmon.exe is a tool for viewing and setting traffic control information for local or remote network adapters. The Traffic Control Monitor is a graphical user interface (GUI) tool that interacts with the Traffic Control application programming interface (API).

Several components must be installed for the Traffic Control Monitor to run successfully. The Traffic Control Monitor is installed automatically when Windows Resource Kit tools are installed. The following additional components must be installed separately:

- Comctl32.ocx
- Msvbm60.dll
- Tccom.exe

**Note**

- Tccom.exe can be called by applications or scripts in Visual Basic Scripting Edition (VBScript) or other scripting languages to remotely configure traffic control on a host.

For information about how to install these components, see Windows Resource Kit Tools Help for Traffic Control Monitor.

**QoS Group Policy Settings and Registry Entries**

The following Group Policy settings and registry entries are associated with QoS. Each registry setting has a corresponding Group Policy setting. The registry settings appear at four locations in the registry; most of the settings are repeated in three of those locations. The registry structure matches the structure of the Computer Configuration Group Policy settings under Administrative Templates in the Group Policy tool. Each of the tables in this section describes the Group Policy settings and the registry entries in one of those four locations.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The registry entries are associated with Windows 2000, Windows XP, and Windows Server 2003. For more information about these registry entries, see the Group Policy Settings Reference for Windows Server 2003.

The following table describes three of the Group Policy settings that are associated with the QoS Packet Scheduler that do not

set alternative Differentiated Services Code Point (DSCP) values. These Group Policy settings are located in Computer Configuration Group Policy at Administrative Templates\Network\QoS Packet Scheduler; they control registry entries located under HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows\Psched.

**Group Policy Settings Associated with QoS Packet Scheduler**

| Group Policy Setting | Description | Registry Entry |
|---|---|---|
| Limit outstanding packets | Specifies the maximum number of outstanding packets permitted on the system. When the number of outstanding packets reaches this limit, the QoS Packet Scheduler postpones all submissions to network adapters until the number falls below this limit. | MaxOutstandingSends |
| Limit reservable bandwidth | Specifies the maximum, total percentage of link bandwidth that all QoS-aware applications on this computer can reserve. If no QoS-aware application reserves any bandwidth, then this setting has no effect and all bandwidth is available for use by other applications. If a QoS-aware application reserves more bandwidth than it uses, then the unused, reserved bandwidth is available for use by other applications. The reservation does not ensure that the bandwidth will be available to the QoS-aware application because applications that are not QoS-aware might consume too much bandwidth. For example, the default value of the registry entry reserves 80 percent of the bandwidth for QoS-aware applications, but this does not prevent other applications from using more than the remaining 20 percent of the bandwidth. | NonBestEffortLimit |
| Set timer resolution | Determines the smallest unit of time, in microseconds, used by the QoS Packet Scheduler when scheduling packets for transmission. The QoS Packet Scheduler cannot schedule packets for transmission more frequently than permitted by the value of this entry. | TimerResolution |

The following table describes Group Policy settings that are associated with QoS and that set alternative DSCP values for packets that conform to the QoS traffic flow specification. You can use these Group Policy settings to specify alternative Layer-3 DSCP values, which are used by Layer 3 network devices to identify each of five service types. These Group Policy settings are located in Computer Configuration Group Policy at Administrative Templates\Network\QoS Packet Scheduler\DSCP value of conforming packets; they control registry entries located under HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows\Psched\DiffservByteMappingConforming.

**Group Policy Settings Associated with DSCP Values of Conforming Packets**

| Group Policy Setting | Description | Registry Entry |
|---|---|---|
| Best effort service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the best effort service type. | ServiceTypeBest Effort |
| Controlled load service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the controlled load service type. | ServiceTypeControlledLoad |
| Guaranteed service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the guaranteed service type. | ServiceTypeGuaranteed |
| Network control service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the network control service type. | ServiceTypeNetworkControl |
| Qualitative service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the qualitative service type. | ServiceTypeQualitative |

The following table describes Group Policy settings that are associated with QoS and that set alternative DSCP values for packets that do not conform to the QoS traffic flow specification. You can use these Group Policy settings to specify alternative Layer-3 DSCP values, which are used by Layer 3 network devices to identify each of five service types. These Group Policy settings are located in Computer Configuration Group Policy at Administrative Templates\Network\QoS Packet Scheduler\DSCP value of non-conforming packets; they control registry entries located under HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows\Psched\DiffservByteMappingNonConforming.

**Group Policy Settings Associated with DSCP Values of Non-conforming Packets**

| Group Policy Setting | Description | Registry Entry |
|---|---|---|
| Best effort service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the best effort service type. | ServiceTypeBestEffort |
| Controlled load service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the controlled load service type. | ServiceTypeControlledLoad |
| Guaranteed service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the guaranteed service type. | ServiceTypeGuaranteed |
| Network control service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the network control service type. | ServiceTypeNetworkControl |
| Qualitative service type | Defines the DSCP value that the QoS Packet Scheduler inserts into packets to request the qualitative service type. | ServiceTypeQualitative |

The following table describes Group Policy settings that are associated with QoS and that set alternative Layer-2 priority values. You can use these Group Policy settings to specify alternative Layer-2 priority values, which Layer 2 network devices use to identify each of five service types. These Group Policy settings are located in Group Policy at Administrative Templates\Network\QoS Packet Scheduler\Layer-2 priority value; they control registry entries located under HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows\Psched\UserPriorityMapping.

**Group Policy Settings Associated with Layer-2 Priority Values**

| Group Policy Setting | Description | Registry Entry |
|---|---|---|
| Non-conforming packets | Defines the priority value that the QoS Packet Scheduler inserts into the Layer-2 header of packets that do not conform to the flow specification. | ServiceTypeNonConforming |
| Best effort service type | Defines the priority value that the QoS Packet Scheduler inserts into the Layer-2 header of packets to request the best effort service type. | ServiceTypeBestEffort |
| Controlled load service type | Defines the priority value that the QoS Packet Scheduler inserts into the Layer-2 header of packets to request the controlled load service type. | ServiceTypeControlledLoad |
| Guaranteed service type | Defines the priority value that the QoS Packet Scheduler inserts into the Layer-2 header of packets to request the guaranteed service type. | ServiceTypeGuaranteed |
| Network control service type | Defines the priority value that the QoS Packet Scheduler inserts into the Layer-2 header of packets to request the network control service type. | ServiceTypeNetworkControl |
| Qualitative service type | Defines the priority value that the QoS Packet Scheduler inserts into the Layer-2 header of packets to request the qualitative service type. | ServiceTypeQualitative |

# Network Security Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Learn about network security technologies, including Windows Firewall.

**Network Security Technologies**
Windows Server 2003 provides two network security technologies: Windows Firewall, which provides host-based inspection and filtering of Internet Protocol version 4 (IPv4) and Internet Protocol version 6 (IPv6) traffic, and Ipsec, which provides inspection, filtering, encryption, and authentication of IP traffic.

**Windows Firewall**
Windows Firewall provides host-firewall protection on computers running Windows Server 2003 with Service Pack 1 (SP1) and Windows XP with Service Pack 2 (SP2). As a host firewall, Windows Firewall runs on each of your servers and clients, providing protection from network attacks that pass through your perimeter network or originate inside your organization, such as Trojan horse attacks, worms, or any other type of malicious program spread through unsolicited incoming traffic.

# Windows Firewall Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To protect your network from the growing number of malicious attacks, you need to adopt a defense-in-depth strategy. A defense-in-depth strategy incorporates a variety of network security technologies into your security architecture and implements those technologies in a layered structure that extends from your perimeter network (outer layer) to every computer in your organization (inner layer). By providing host firewall protection on the innermost layer of your network, Windows Firewall, a new security component in Microsoft® Windows Server™ 2003 with Service Pack 1 (SP1), can be an effective part of your defense-in-depth security strategy.

**In this section**

- Common Windows Firewall Scenarios
- Technologies Related to Windows Firewall

Windows Firewall provides host-firewall protection on computers running Windows Server 2003 with Service Pack 1 (SP1) and Windows XP with Service Pack 2 (SP2). As a host firewall, Windows Firewall runs on each of your servers and clients, providing protection from network attacks that pass through your perimeter network or originate inside your organization, such as Trojan horse attacks, worms, or any other type of malicious program spread through unsolicited incoming traffic.

The following figure shows how Windows Firewall works in conjunction with perimeter network firewalls.

Windows Firewall inspects and filters all IP version 4 (IPv4) and IP version 6 (IPv6) network traffic. It is a stateful firewall, which means it tracks the state of each network connection and determines whether incoming traffic is allowed or blocked. Windows Firewall blocks incoming traffic unless it is in response to a request by the host (in which case, it is solicited traffic) or has been specifically allowed (in which case, it has been added to the Windows Firewall exceptions list). Aside from a few Internet Control Message Protocol (ICMP) messages, Windows Firewall allows all outgoing traffic.

Windows Firewall is designed to be a supplemental security solution. You cannot use Windows Firewall as a perimeter firewall. Windows Firewall should be part of a comprehensive security architecture that implements a variety of security technologies, such as border routers, perimeter firewalls, intrusion detection systems, virtual private networking (VPN), IEEE 802.1X authentication for wireless and wired connections, and Internet Protocol security (IPsec).

**Common Windows Firewall Scenarios**

With a few exceptions, Windows Firewall can be enabled on all configurations of Windows Server 2003 with SP1. Therefore, it is recommended that you enable Windows Firewall on every server in your organization, including bastion hosts and other servers in your perimeter network, mobile and remote clients that connect to your network and run Windows Server 2003, and all servers in your internal network. In addition, Windows Firewall can be enabled for any network architecture. Therefore, it is also recommended that you enable Windows Firewall regardless of the way in which you have designed and implemented your perimeter network or your internal network.

**Common Configuration Tasks**

When it is enabled in its default configuration, Windows Firewall blocks all unsolicited incoming network traffic on all network connections. Although blocking unsolicited incoming traffic reduces your attack surface and increases your level of security, it can cause programs and system services that are acting as servers, listeners, or peers to stop working properly. On clients, the number of programs and system services that do this is small because clients are typically configured as service consumers, not service providers. On servers, the number of programs and system services that do this can be large because, by their nature, servers are service providers; they must receive unsolicited incoming traffic.

Therefore, you usually need to configure some Windows Firewall settings on servers so that the appropriate unsolicited traffic is not blocked by Windows Firewall. The configuration changes that you need to make vary according to the server role and the programs and system services that are running on the server.

In addition, you need to configure Windows Firewall settings on every server that you intend to manage remotely. If you are managing the server by using the Administration Tools Pack on a client running Windows XP, then you need to configure Windows Firewall settings on the server to ensure that Windows Firewall allows the unsolicited traffic from the client computer to reach the programs and system services that are running on the server. You might also need to configure Windows Firewall settings on the client if the server initiates traffic to the client (for example, when an e-mail server notifies an e-mail client that new messages have arrived).

**Restrictions and Limitations**

You should disable Windows Firewall in the following scenarios.

**Servers Running Routing and Remote Access**

Do not run Windows Firewall if you are running Routing and Remote Access. Routing and Remote Access uses its own firewall and it cannot be used with Windows Firewall.

**Computers Running a Perimeter Firewall**

Do not run Windows Firewall on a server that is running a perimeter firewall, such as Microsoft Internet Security and Acceleration (ISA) Server 2004. The protection that Windows Firewall provides in this situation is redundant and unnecessary. In addition, Windows Firewall can cause perimeter firewalls such as ISA Server to function improperly.

**Computers Running Non-Microsoft Host Firewalls**

Do not use Windows Firewall on a computer that is running a non-Microsoft host firewall. Although it is possible to run two host firewalls on a single computer, it is not recommended that you do so. Host firewall implementations vary widely and there is no guarantee that a non-Microsoft host firewall and Windows Firewall will work well together.

**Computers Acting as Domain Controllers**

Do not permanently run Windows Firewall on a domain controller. You can use Windows Firewall on a temporary basis (for example, to protect a domain controller from attack while you install security updates, virus signatures, or security software).

In addition, you might want to disable Windows Firewall if a server requires you to open numerous ports or allow a large number of applications and system services to receive unsolicited traffic. In this case, it might make sense to disable Windows Firewall because a significant volume of network traffic will be allowed to pass through Windows Firewall anyway. By disabling Windows Firewall, you eliminate the operational overhead associated with Windows Firewall configuration and maintenance. However, you should closely evaluate the design of any client or server that requires you to open numerous ports. Servers that are configured for numerous roles or to provide numerous services can be a critical point of failure in your organization and might indicate poor infrastructure design.

**Technologies Related to Windows Firewall**

Windows Server 2003 provides several network security technologies that are related to and complement Windows Firewall. It is recommended that you use these technologies in conjunction with Windows Firewall to ensure that your security architecture is built on a solid defense-in-depth strategy.

**IPsec**

IPsec helps protect networks from active and passive attacks by securing IP packets through the use of packet filtering, cryptographic security services, and the enforcement of trusted communications. IPsec supports network-level data integrity, data confidentiality, data origin authentication, and replay protection. Because IPsec is integrated at the Internet layer (layer 3), it provides security for all IPv4-based traffic, and because IPsec is applied transparently to applications, there is no need to configure separate security for each application that uses TCP/IP. In addition, IPsec helps provide defense-in-depth against:

- Network-based attacks from untrusted computers, attacks that can result in the denial-of-service of applications, services, or the network.
- Data corruption.
- Data theft.
- User-credential theft.
- Administrative control of servers, other computers, and the network.

IPsec and Windows Firewall are not mutually exclusive security technologies. The use of IPsec in conjunction with Windows Firewall increases the security of the communication on your internal network and reduces the attack surface on each of your clients and servers. For example, on a secured Web server, you can use Windows Firewall to block all unsolicited incoming traffic except Web traffic and you can use IPsec to secure all Web traffic as it travels across the network.

**VPN**

VPN is a network access technology that is part of the Routing and Remote Access service in Windows Server 2003. You can use VPN to securely connect remote clients and remote offices to an organization's private network. VPN technology provides access to private networks at a lower cost than leased-line connections, which create a physical connection to a port on a remote access server on a private network.

A VPN connection uses authentication and data encryption to help preserve the privacy and, in some cases, integrity of data as it traverses a public network. VPN connections use either Point-to-Point Tunneling Protocol (PPTP) or Layer Two Tunneling Protocol/Internet Protocol security (L2TP/IPsec) over an intermediate network, such as the Internet. By using the Internet as a connection medium, VPN saves the cost of long-distance phone service and hardware associated with the use of dial-up or leased line connections. A VPN solution includes advanced security technologies, such as data encryption, user and computer authentication, authorization, and Network Access Quarantine Control.

VPN clients can use standard tools to access resources. For example, clients can use Windows Explorer to access shared files and folders and connect to printers. Connections are persistent; users do not need to reconnect to network resources during their VPN sessions. Because drive letters and universal naming convention (UNC) names are fully supported by VPN, most commercial and custom applications work without modification.

# How Windows Firewall Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

Windows Firewall Terminology

Windows Firewall Architecture

Windows Firewall Interfaces

Windows Firewall Protocols

Windows Firewall Connection Types

Windows Firewall Service Dependencies

Windows Firewall Physical Structures

Windows Firewall Processes and Interactions

Windows Firewall is a stateful host-firewall technology that inspects and filters all IP version 4 (IPv4) and IP version 6 (IPv6) network traffic. As a stateful firewall, Windows Firewall tracks the state of each network connection and determines whether the unsolicited incoming traffic should be allowed or dropped. Windows Firewall blocks incoming traffic unless the traffic is a response to a request by the host (in which case, it is solicited traffic) or it is specifically allowed (in which case, it has been added to the Windows Firewall exceptions list). Exceptions can be specified by program name, UDP or TCP port number, or system service name. Aside from a few Internet Control Message Protocol (ICMP) messages, Windows Firewall allows all outgoing traffic.

| **Note** |
| --- |
| By default, running dcpromo.exe to configure a computer as a Domain Controller turns off Windows Firewall. Use the Security Configuration Wizard to re-enable Windows Firewall with the port exceptions required to support the Domain Controller role. Alternatively, you can use Microsoft Knowledge Base article 555381, "How to Configure Windows Server 2003 Firewall for a Domain Controller" (http://go.microsoft.com/fwlink/?linkid=91224) to manually enable Windows Firewall with the port exceptions required to support the Domain Controller role. |

**Windows Firewall Terminology**

Before you review the components and processes that are associated with Windows Firewall, it is helpful to understand Windows Firewall terminology.

### Domain profile

A set of Windows Firewall settings that are applied when a computer is connected to a network that contains the domain controllers for the domain in which its computer account resides. The domain profile is one of two profiles used by Windows Firewall to apply settings to a computer.

### Exception

A port, program, or system service that is allowed to receive unsolicited traffic.

### Exceptions list

A rules store that specifies which ports, programs, or system services are allowed to receive unsolicited traffic. To allow unsolicited incoming traffic through Windows Firewall, you add ports, programs, and system services to the exceptions list.

### Notification

A **Windows Security Alert** dialog box that appears when a program that is not listed in the exceptions list attempts to listen for unsolicited traffic on a port. If you have administrative rights on a computer, the notification displays the option to add the program to the exceptions list, which will allow the program to receive unsolicited traffic. If you do not have administrative rights on a computer, the notification displays a warning that a program is attempting to listen on a port.

A **Windows Security Alert** dialog box does not appear when a system service attempts to listen for unsolicited incoming

traffic; it appears only when a program attempts to listen for unsolicited incoming traffic.

**Port**

A logical communication endpoint representing a program or a system service that listens for and receives IP packets. Ports are specified by a positive 16-bit decimal number and by the type of traffic (either UDP or TCP) that is expected to pass through the port. Most ports are predefined and well-known for specific services, such as DHCP and DNS. However, some ports are created dynamically by a server and assigned to the programs and system services that need to listen for incoming traffic from clients.

**Program**

A software program that is usually started by a user and runs under the user's account. Programs run only while the user is logged on to a computer and usually consist of one or more executable (.exe) files and one or more dynamic-link library (.dll) files.

| **Note** |
| --- |
| Some system services run within their own .exe file and are started by a user (for example, the Telnet service, which runs in Tlntsvr.exe). Typically, these system services run under a privileged account, such as Local Service. They do not run under the user's account. In Windows Firewall, any system service that runs within its own .exe file is considered a program. |

**Scope**

A Windows Firewall setting that you configure for an exception. The scope setting controls from which addresses unsolicited traffic is allowed to originate. By default, the scope of an exception is any address, which includes any computer on the Internet. You can change the scope of an exception to locally reachable addresses or a list of individual IPv4 addresses or IPv4 address ranges.

**Standard profile**

A set of Windows Firewall settings that are applied when a computer is not connected to a network that contains the domain controllers in which its computer account resides (for example, a public network, such as the Internet). The standard profile is one of two profiles used by Windows Firewall to apply settings to a computer.

**System service**

A software program that is usually not started by a user and runs under a privileged account, such as LocalSystem. System services run even when a user is not logged on to a computer and usually run as a separate process within Svchost.exe.

**Windows Firewall Architecture**

Windows Firewall relies on several networking components, including the Windows Firewall/Internet Connection Sharing service (also known as the SharedAccess service), the network address translation (NAT) driver (Ipnat.sys), the IPv4-based TCP/IP driver (Tcpip.sys) and the IPv6-based TCP/IP driver (Tcpipv6.sys), and the Windows Sockets (Winsock) driver (Winsock.dll). Windows Firewall also relies on several administrative tools that allow you to configure Windows Firewall settings. The following figure shows the relationship among these components.

The following describes each of the architectural components.

**Administrative tools**

There are several administrative tools that interact with the Windows Firewall/Internet Connection Sharing service and allow you to configure Windows Firewall settings. These tools include Windows Firewall in Control Panel (Firewall.cpl), the **netsh firewall** command, and Group Policy with the Group Policy Object Editor.

### NAT driver

The NAT driver (Ipnat.sys) provides a data store for Windows Firewall. Windows Firewall uses the data store, known as the NAT Mapping Table, to store connection state information for dynamically-created exceptions. The connection state information typically consists of a 5-tuple entry, which includes the protocol, the source and destination port numbers, and the source and destination IP addresses. Without a data store, Windows Firewall would not be a stateful firewall.

| **Note** |
| --- |
| Although Windows Firewall uses the NAT driver, Windows Firewall does not provide any network address translation. |

### TCP/IP driver

The TCP/IP driver (Tcpip.sys) controls the flow of information between a network adapter and a program or system service. As incoming traffic flows through the TCP/IP driver, the traffic is inspected by the NAT driver. The NAT driver processes the traffic based on the entries in the Windows Firewall exceptions list. If the traffic matches an exception, the NAT driver determines that the traffic is allowed; the packets continue through the TCP/IP driver. If the traffic does not match an exception, the NAT driver determines that the traffic is unsolicited; the packets are dropped and do not continue through the TCP/IP stack. Neither the NAT driver nor the TCP/IP driver sends a notification to the sender when packets are dropped (this is sometimes referred to as a silent discard).

### Winsock driver

The Winsock driver is responsible for assigning and binding ports to a program or system service. Programs and system services use this driver when they need to listen for incoming traffic.

### Windows Firewall/Internet Connection Sharing service

The Windows Firewall/Internet Connection Sharing service runs in Svchost.exe. The Windows Firewall/Internet Connection Sharing service is responsible for processing the Windows Firewall exceptions that you configure for network traffic. The Windows Firewall/Internet Connection Sharing service then relays the exceptions to the NAT driver, which inspects the traffic that is flowing through the TCP/IP driver.

### Winsock driver

The Windows Firewall/Internet Connection Sharing service provides all of the processing (filtering) that determines whether unsolicited incoming traffic is allowed or dropped.

#### Windows Firewall Interfaces

There are two interfaces related to Windows Firewall: the firewall-hook interface and the Windows Firewall application programming interfaces (APIs). The following figure shows these interfaces and how they relate to Windows Firewall components.

The firewall-hook interface is used by the TCP/IP driver to communicate with Windows Firewall, which instructs the TCP/IP driver about how to process incoming and outgoing packets. There should be only one firewall-hook interface on Windows XP and Windows Server 2003 operating systems because it is not recommended that software developers implement a firewall-hook driver on these operating systems. To provide additional firewall functionality on Windows XP and Windows Server 2003, software developers should create a Network Driver Interface Specification (NDIS) intermediate miniport driver to manage packets sent and received across a firewall. For information about firewall-hook drivers, see MSDN (http://go.microsoft.com/fwlink/?LinkId=45023).

The Windows Firewall APIs provide a public interface for programmatically configuring Windows Firewall settings. Windows

Firewall APIs and Internet Connection Sharing (ICS) APIs are implemented in Hnetcfg.dll. Using the Windows Firewall API, you can:

- Enable and disable Windows Firewall.
- Add and remove programs and system services from the exceptions list.
- Add and remove TCP and UDP ports from the exceptions list.
- Enable and disable preconfigured system service exceptions.
- Configure ICMP settings.
- Configure the log file.

The following table describes the Windows Firewall APIs.

| Interface | Description |
|---|---|
| **INetFwOpenPort** | Provides access to the properties of a port opened in Windows Firewall. |
| **INetFwOpenPorts** | Provides access to a collection of ports opened in Windows Firewall. |
| **INetFwService** | Provides access to the properties of a service that may be authorized to listen through Windows Firewall. |
| **INetFwRemoteAdminSettings** | Provides access to the settings that control remote administration. |
| **INetFwServices** | Provides access to a collection of services that may be authorized to listen through Windows Firewall. |
| **INetFwAuthorizedApplication** | Provides access to the properties of a program that has been authorized to open ports in Windows Firewall. |
| **INetFwAuthorizedApplications** | Provides access to a collection of programs authorized to open ports in Windows Firewall. |
| **INetFwIcmpSettings** | Provides access to the settings that control ICMP packets. |
| **INetFwProfile** | Provides access to a Windows Firewall settings profile. |
| **INetFwPolicy** | Provides access to a Windows Firewall policy. |
| **INetFwMgr** | Provides access to the Windows Firewall settings for a computer. |

For more information about Windows Firewall APIs, see MSDN.

**Windows Firewall Protocols**

Windows Firewall provides the stateful filtering of TCP/IP traffic (IPv4 and IPv6) that uses the TCP transport protocol. It also provides the "pseudo-stateful" filtering of TCP/IP traffic that uses the UDP transport protocol. ICMP traffic is not statefully filtered; rather, ICMP traffic is allowed or blocked based on Windows Firewall settings (for example, you can explicitly allow or deny incoming echo requests or outgoing destination unreachable messages by configuring Windows Firewall settings). Because Windows Firewall is tied directly to the TCP/IP architecture of Windows, it does not provide any filtering of non-TCP/IP protocols, such as IPX/SPX or AppleTalk.

With the exception of some File Transfer Protocol (FTP) traffic, Windows Firewall does not use Application layer information to statefully filter traffic. FTP is a special case because of the way in which an FTP server establishes the data channel for an FTP file transfer. During a typical FTP user session, an FTP client initiates a control channel with an FTP server. When the FTP client transfers a file from the FTP server, the FTP server tries to establish a data channel with the FTP client by initiating communication on a TCP port different from the one used for the control channel. This can cause most firewalls running on the FTP client computer to drop the data channel packets coming from the server because they appear to be unsolicited. To overcome this problem, Windows Firewall uses the Application Layer Gateway Service to provide dynamic port mapping for the FTP data channel, thereby facilitating the stateful filtering of FTP traffic.

| Note |
| --- |
| Passive (PASV) FTP is not treated as a special case and is not handled by the Application Layer Gateway Service. PASV FTP traffic is statefully filtered by Windows Firewall in the same way other TCP/IP traffic is statefully filtered. |

Although Windows Firewall does not use Application layer information to statefully filter traffic, Windows Firewall does use Application layer information to identify and manage some traffic.

**IPv6 Tunneled Traffic**

IPv6 tunneled traffic is an IPv6 packet that has been encapsulated with an IPv4 header so that hosts that support both IPv4 and IPv6 can communicate using IPv6 even when separated by an IPv4 infrastructure, such as the Internet or a private intranet. The tunneled IPv6 packet bypasses the IPv4 processing of Windows Firewall. However, after the IPv4 header of the packet is removed, the decapsulated IPv6 packet is processed by Windows Firewall just like all other IPv6 traffic.

**AH/ESP**

IPsec uses two transforms, the Authentication Header (AH) and the Encapsulating Security Payload (ESP) header and trailer, to encapsulate and secure IP packets or payloads. These transforms wrap the IP payload with header or header and trailer information and provide security properties, such as data origin authentication, data integrity, data confidentiality, and replay protection.

Traffic protected with AH or ESP is processed by the IPsec components of Windows before it is processed by Windows Firewall. The IPsec components validate the security information in the AH or ESP header and trailer, decrypt the payload if needed, and remove the AH or ESP header and trailer. The resulting IP packet is handed back to the TCP/IP driver, which is then handed to Windows Firewall for processing. However, you can change this behavior so that IPsec-secured traffic bypasses Windows Firewall by configuring the **Windows Firewall: Allow authenticated bypass** Group Policy setting. When you enable this setting, you specify groups of IPsec-secured computers whose traffic bypasses all Windows Firewall processing and overrides any existing policies or settings that would otherwise block the traffic.

**GRE**

The Generic Routing Encapsulation (GRE) protocol is used to encapsulate the data channel of Point-to-Point Tunneling Protocol (PPTP) traffic. Any PPTP traffic that uses a GRE header to encapsulate Point-to-Point Protocol (PPP) frames will pass directly through Windows Firewall. Non-PPTP traffic that uses GRE is filtered by Windows Firewall.

**IGMP**

Internet Group Management Protocol (IGMP) is an IP multicast maintenance protocol. IP multicast provides the one-to-many delivery of traffic without the overhead and performance impact that is associated with broadcast delivery and multiple unicast delivery. IP multicast is used primarily for audio and video teleconferencing and gaming. Hosts and routers send IGMP messages so that IP multicast-enabled routers can determine the set of multicast host groups that have members on a subnet. All IGMP traffic passes directly through Windows Firewall.

**PGM**

The Pragmatic General Multicast (PGM) protocol is a scalable multicast protocol that enables receivers to detect loss, request retransmission of lost data, or notify a program of unrecoverable loss. PGM is often referred to as reliable multicast; it is a receiver-reliable protocol, which means the receiver is responsible for ensuring all data is received, absolving the sender of reception responsibility. Any traffic that uses the PGM protocol passes directly through Windows Firewall.

**Windows Firewall Connection Types**

Windows Firewall can be bound to any network connection that is listed in Network Connections in Control Panel. This includes the following connection types.

**Local area connections**

This includes wired and wireless network connections that use Ethernet, Token Ring, cable modem, 1394, Digital Subscriber Line (DSL) modem, Fiber Distributed Data Interface (FDDI), IP over Asynchronous Transfer Mode (ATM), and WAN technologies such as T1 and Frame Relay.

**Dial-up connections**

This includes network connections that use X.25, modem, and Integrated Services Digital Network (ISDN) technologies.

**VPN connections**

This includes virtual private networking (VPN) connections that use PPTP or Layer Two Tunneling Protocol (L2TP).

### Incoming connections

This includes incoming connections that use dial-up (modem, ISDN, X.25) and VPN (PPTP, L2TP). However, Windows Firewall settings for incoming connections can only be configured globally. You cannot configure Windows Firewall settings on a per-connection basis for incoming connections.

| **Note** |
| --- |
| Windows Firewall cannot be enabled on direct connections, such as serial cable connections, infrared link, and DirectParallel cable connections. |

#### Windows Firewall Service Dependencies

Windows Firewall runs in the Windows Firewall/Internet Connection Sharing service and is dependent on several subsidiary services. If any of the subsidiary services are not running or cannot be started, Windows Firewall might not start or run properly. Windows Firewall depends on the following services.

### Application Layer Gateway Service

The Application Layer Gateway Service (sometimes known as the ALG service) is required if you enable Windows Firewall on a computer that is an FTP client or FTP server that does not use PASV FTP. The Application Layer Gateway Service listens for outgoing FTP traffic from an FTP client. It then extracts the port from which the FTP client is expecting to receive data and creates an appropriate dynamic port mapping for the FTP data channel.

The Application Layer Gateway Service and Windows Firewall interact as follows:

- If the Application Layer Gateway Service is disabled and you try to enable Windows Firewall, Windows Firewall will start, but FTP traffic that does not use PASV FTP might fail.
- If you stop the Application Layer Gateway Service while Windows Firewall is running, Windows Firewall will continue to run, but FTP traffic that does not use PASV FTP might fail.
- If the Application Layer Gateway Service is stopped and its startup type is set to Manual, then the Application Layer Gateway Service will attempt to start when you enable Windows Firewall.

### DCOM Server Process Launcher

The DCOM Server Process Launcher service (sometimes known as the Dcomlaunch service) is new in Windows Server 2003 with Service Pack 1 (SP1); it is responsible for starting all DCOM-related services. Because Windows Firewall relies on DCOM, the DCOM Server Process Launcher service must be running when you start Windows Firewall.

The DCOM Server Process Launcher service and Windows Firewall interact as follows:

- If the DCOM Server Process Launcher is disabled and you try to enable Windows Firewall, Windows Firewall will not start because the Windows Firewall/Internet Connection Sharing service cannot start.
- You cannot stop the DCOM Server Process Launcher service, so it is not possible to configure the DCOM Server Process Launcher service if it is started and Windows Firewall is enabled.
- If the startup type for the DCOM Server Process Launcher service is set to Manual, and the DCOM Server Process Launcher is not started, you will not be able to enable Windows Firewall. If you attempt to enable Windows Firewall, a Windows Firewall dialog box will be displayed to indicate that another process that requires the network address translation driver (Ipnat.sys) is running.

### Network Connections

The Network Connections service (sometimes known as the Netman service) manages all network connections that are created and configured in Network Connections in Control Panel. This service is also responsible for displaying network status in the notification area on the desktop (the area on the taskbar to the right of the taskbar buttons). Windows Firewall uses this service to identify and manage network connections.

The Network Connections service and Windows Firewall interact as follows:

- You cannot enable Windows Firewall if the Network Connections service is disabled.
- If you stop the Network Connections service while Windows Firewall is enabled, Windows Firewall will stop running and become disabled.
- If the Network Connections service is stopped and its startup type is set to Manual, the Network Connections service will attempt to start when you enable Windows Firewall. If the Network Connections service cannot start, Windows Firewall cannot be enabled.

**Network Location Awareness**

The Network Location Awareness service (sometimes known as the Nla service) collects and stores network configuration information, such as changes to the names and locations of IP addresses and domain names. The Network Location Awareness service component supports the Network Location Service, which provides the infrastructure that informs programs and the operating system of the network connections on a computer. Windows Firewall uses the Network Location Awareness service to determine which Windows Firewall profile to use.

The Network Location Awareness service and Windows Firewall interact as follows:

- If the Network Location Awareness service is disabled and you try to enable Windows Firewall, Windows Firewall will start but cannot determine which profile to use. In this case, Windows Firewall uses the settings for the standard profile.
- If you stop the Network Location Awareness service while Windows Firewall is running, Windows Firewall continues to run and use the settings for the profile that it is currently using.
- If the Network Location Awareness service is stopped and its startup type is set to Manual, then the service will attempt to start when you enable Windows Firewall.

**Remote Procedure Call**

The Remote Procedure Call service (sometimes known as the RpcSs service) is a secure interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality that resides in a different process. That different process can be on the same computer, on the local area network (LAN), or across the Internet. The Remote Procedure Call service serves as the RPC Endpoint Mapper (EPM) and Service Control Manager (SCM).

The Remote Procedure Call service and Windows Firewall interact as follows:

- You cannot enable Windows Firewall if the Remote Procedure Call service is disabled.
- If you stop the Remote Procedure Call service while Windows Firewall is enabled, Windows Firewall will stop running and become disabled.
- If the Remote Procedure Call service is stopped and its startup type is set to Manual, then the service will attempt to start when you enable Windows Firewall. If the Remote Procedure Call service cannot start, Windows Firewall cannot be enabled.

**Windows Management Instrumentation**

Windows Management Instrumentation (WMI) is an infrastructure for building management programs and instrumentation released as part of the current generation of Microsoft operating systems. The Windows Management Instrumentation service (sometimes known as the Winmgmt service) provides a common interface and object model to access management information about operating system, devices, programs, and system services. Windows Firewall uses the Windows Management Instrumentation service to store per-connection settings and legacy (ICF) settings.

- You cannot enable Windows Firewall if the Windows Management Instrumentation service is disabled.
- If you stop the service while Windows Firewall is enabled, Windows Firewall will stop running and become disabled.

- If the service is stopped and its startup type is set to Manual, then the service will attempt to start when you enable Windows Firewall. If the Windows Management Instrumentation service cannot start, Windows Firewall cannot be enabled.

**Windows Firewall Physical Structures**
Windows Firewall relies on two physical structures: the NAT Mapping Table, which contains information about the traffic passing through a network connection, and a rules store, which contains the configuration settings (rules) that are used to filter traffic. The state table allows Windows Firewall to track the activity of a given network connection; it is the mechanism that makes Windows Firewall a stateful firewall. The rules store provides a persistent data store for Windows Firewall configuration settings; it is the mechanism that Windows Firewall uses to apply consistent filtering rules to a network connection.

**NAT Mapping Table**
Windows Firewall uses the NAT Mapping Table to store the state of network connections. The NAT Mapping Table is managed by the NAT driver (Ipnat.sys) and is used by both Windows Firewall and Routing and Remote Access to store connection information.

**TCP Connections**
TCP connections are stored in a standard 5-tuple entry format in the NAT Mapping Table. The 5-tuple entry consists of the following data:

- Protocol. This is either TCP or UDP.
- Source address. This is the IP address of the host that initiated the communication session.
- Source port. This is the TCP or UDP port number that the host used to initiate the communication session.
- Destination address. This is the IP address of the computer with which the host initiated traffic.
- Destination port. This is the TCP or UDP port number to which the host sent traffic.

A 5-tuple entry is created in the NAT Mapping Table for every incoming communication session that uses TCP. A separate mapping table is maintained for each network connection (for example, if you have two network adapters in a computer, there is a mapping table for each network adapter). The timeout for established but inactive TCP connections is 24 hours. In other words, the state table entry for an inactive TCP connection remains in the NAT Mapping Table for 24 hours unless the connection is terminated and closed using the standard TCP close sequence.

**UDP Connections**
UDP connections that use ports 1 through 1024 are also stored in the standard 5-tuple entry format in the NAT Mapping Table. The 5-tuple entry is the same as the entry used for TCP connections. The 5-tuple entry is used to track UDP connections on ports 1 through 1024 because these ports are usually designated for use by specific operating system services. Using a 5-tuple entry to store the state of all connections to these ports decreases the likelihood of an attack on these critical system services.

UDP connections that use ports higher than 1024 are stored in a 3-tuple entry format in the NAT Mapping Table. The 3-tuple format, sometimes known as loose source mapping, consists of the following data:

- Protocol. This is always UDP.
- Source address. This is the IP address of the host that initiated the communication session.
- Source port. This is the UDP port number that the host used to initiate the communication session.

A 3-tuple entry is created in the NAT Mapping Table for every incoming communication session that uses a UDP port greater than 1024. A separate mapping table is maintained for each network connection (for example, if you have two network adapters in a computer, there is a mapping table for each network adapter).

Because UDP is a connectionless protocol and has no sequence numbers or flags, it has no mechanism for terminating and closing a connection. Therefore, the timeout for UDP connections is much shorter than that for TCP connections. The timeout for established but inactive UDP connections is 60 seconds. In other words, if an established UDP connection is inactive for 60 seconds, the state table entry for that connection is removed from the NAT Mapping Table. This behavior applies to UDP connections on all ports.

There are some exceptions to the 60-second timeout for UDP connections. When a computer sends a multicast or broadcast message, Windows Firewall waits for up to 3 seconds for a unicast response. In essence, the state table entry for multicast or broadcast connections is maintained for up to 3 seconds; if the multicast or broadcast connection is inactive for 3 seconds (that is, there is no response), then the state table entry is deleted from the NAT Mapping Table. Dynamic Host Configuration Protocol (DHCP) multicast messages are a special case and are exempt from the 3-second timeout.

**ICMP Traffic**

The Windows Firewall state table does not store any information about ICMP traffic. Incoming ICMP traffic is accepted or rejected according to the configured Windows Firewall ICMP settings.

**Rules Store**

A rules store contains the list of rules used by a firewall to determine whether unsolicited incoming traffic is allowed or blocked. A typical rules store is created around the notion of "implicit deny," which means that all unsolicited incoming traffic is blocked (denied) unless there is an explicit rule allowing the traffic through the firewall. Furthermore, a typical rules store is processed sequentially from top to bottom: that is, the firewall compares the characteristics of unsolicited incoming traffic against each rule, one at a time, until a rule is found that allows the traffic (in which case, the traffic passes through the firewall) or the end of the rules list is reached (in which case, the traffic is blocked). Creating and maintaining this type of rules store can be difficult because the order of the rules is important and it is relatively easy to create a rule that inadvertently allows all traffic through the firewall.

Windows Firewall uses the notion of implicit deny, but it does not use a strictly sequential or ordered rules store. When you turn on Windows Firewall in its default configuration, all unsolicited incoming TCP and UDP traffic is blocked. In other words, you must create explicit rules to allow unsolicited incoming traffic to pass through Windows Firewall. However, you do not need to create the rules in any particular order because the rules are not processed sequentially.

| **Note** |
| --- |
| With the exception of some ICMP messages, outgoing traffic is not blocked by Windows Firewall. |

In most cases, the rules used by Windows Firewall to filter unsolicited incoming traffic are a union of the Windows Firewall settings you configure using Windows Firewall in Control Panel, the **netsh firewall** command, local Group Policy settings, and domain-based Group Policy settings. You cannot configure ordered rules or rules that specify a precedence for specific protocols, ports, programs, or IP addresses. The only time the resultant rules are not determined by a union of all settings is when Group Policy settings conflict with settings that you configured locally through Windows Firewall in Control Panel or the **netsh firewall** command. In this case, the resultant rules are still determined by a union, but the domain-based Group Policy settings take precedence over any locally-configured settings (including local Group Policy settings) and the local Group Policy settings take precedence over settings configured through Windows Firewall in Control Panel and the **netsh firewall** command.

| **Note** |
| --- |
| Exceptions that are created programmatically using the Windows Firewall API behave in the same manner as exceptions that are created through Windows Firewall in Control Panel or the **netsh firewall** command. If there is a conflict between an exception that is created programmatically and an exception that is created with Group Policy, the Group Policy settings will take precedence. |

Windows Firewall stores its rules in two locations in the registry:

```
HKLM\Software\Policies\Microsoft\WindowsFirewall
```

This subkey contains the settings you configure through Group Policy (both local Group Policy and domain-based Group Policy).

```
HKLM\System\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy
```

This subkey contains the settings you configure through Windows Firewall in Control Panel, the **netsh firewall** command, and scripts.

**Windows Firewall Processes and Interactions**

This section describes how Windows Firewall processes network traffic and the way in which Windows Firewall interacts with other operating system components.

**Windows Firewall and Post-Setup Security Updates**

By default, Windows Firewall and the Windows Firewall/Internet Connection Sharing service are turned off in Windows Server 2003 with SP1. However, there are instances when Windows Firewall and the Windows Firewall/Internet Connection

Sharing server are turned on automatically on a temporary basis. This occurs when the Post-Setup Security Updates feature runs. The Post-Setup Security Updates feature is designed to reduce the risk of a new server being attacked from the time it is first connected to the network until the most recent security updates are installed from Windows Update. The new feature appears in the graphical user interface as a single dialog box the first time a member of the Administrators group logs on to a new server. The dialog box provides links for installing current security updates and configuring automatic updates. In addition, the Post-Setup Security Updates feature temporarily turns on Windows Firewall, which blocks all inbound connections other than those that are specifically opened during setup or by policy. When you close the Post-Setup Security Updates dialog box, Windows Firewall is turned off.

Post-Setup Security Updates is available only when you perform a clean installation of Windows Server 2003 with SP1, including slip-stream installations. You cannot run Post-Setup Security Updates from the **Start** menu or from the command line (it starts automatically), and it is not available when:

- Windows Firewall is enabled or disabled during setup by using an unattended installation answer file or a Netfw.inf file.
- Windows Firewall is enabled or disabled through Group Policy before the Post-Setup Security Updates dialog box appears.

In addition, Post-Setup Security Updates is not available when you upgrade an existing Windows Server 2003 operating system by adding a service pack or if you upgrade a Windows 2000 Server operating system to Windows Server 2003 with SP1.

**What Happens When Post-Setup Security Updates Is Closed?**
If Windows Update or any other configuration change causes your computer to restart before you click the **Finish** button on the **Post-Setup Security Updates** dialog box, it reopens the next time an administrator logs on to the server.

If you close the **Post-Setup Security Updates** dialog box using ALT+F4 or Task Manager, no change is made to the configuration of Windows Firewall. The tests the server uses to determine whether the **Post-Setup Security Updates** dialog box should be displayed run again the next time a user logs on.

If you close Post-Setup Security Updates by clicking the **Finish** button on the **Post-Setup Security Updates** dialog box, the following occurs:

- If you did not change any Windows Firewall settings while the **Post-Setup Security Updates** dialog box was displayed, a confirmation dialog box appears explaining that inbound connections will now be opened and giving you the opportunity to confirm that you are done with any post-setup security updates. When the action is confirmed, Post-Setup Security Updates attempts to disable Windows Firewall and stop and disable the Windows Firewall/Internet Connection Sharing service.
- If Windows Firewall is disabled successfully, a registry value is set to suppress Post-Setup Security Updates in the future. It is possible that Windows Firewall is disabled successfully, but the attempt to stop the Windows Firewall/Internet Connection Sharing service fails.
- If Windows Firewall settings cannot be changed, a dialog box appears explaining that no changes will be made to inbound connection settings. Post-Setup Security Updates is not suppressed and the tests to determine whether Post-Setup Security Updates should be displayed will be run again the next time a user logs on.
- If Windows Firewall was explicitly enabled or disabled while the Post-Setup Security Updates was displayed, a dialog box appears indicating that no changes will be made to inbound connection settings. These changes could have been made by Group Policy settings or by opening Windows Firewall in Control Panel and clicking **OK** to confirm the firewall settings. A registry value is set to suppress Post-Setup Security Updates in the future.
- If the Windows Firewall/Internet Connection Sharing service was stopped or disabled while the **Post-Setup Security Updates** dialog box was displayed, a dialog box appears indicating that no changes will be made to inbound connection settings. A registry value is set to suppress Post-Setup Security Updates in the future.
- If Internet Connection Sharing was enabled while the **Post-Setup Security Updates** dialog box was displayed, a confirmation dialog box appears indicating that inbound connections will now be opened and giving you the opportunity to confirm that you are done with any post-setup security updates. When the action is confirmed, Post-Setup Security Updates attempts to disable Windows Firewall and stop the Windows Firewall/Internet Connection Sharing service.

- If the state of the firewall cannot be determined, a dialog box appears indicating that no changes will be made to inbound connection settings. Post-Setup Security Updates is not suppressed and the tests to determine whether the **Post-Setup Security Updates** dialog box should be displayed will be run again the next time a user logs on.

| **Note** |
| --- |
| The text that appears in the **Post-Setup Security Updates** dialog box is not refreshed if Windows Firewall status changes after the dialog box is first displayed. If the status of Windows Firewall changes after it appears and before the **Finish** button is clicked, the text may state that all inbound connections are blocked when, in fact, they are not. When you click **Finish**, Post-Setup Security Updates checks the status of Windows Firewall again before displaying a dialog box indicating any changes to be made on closure. |

**When Is the Post-Setup Security Updates Dialog Box Displayed?**

Because the Post-Setup Security Updates feature runs automatically and cannot be started manually, you can use the following information to determine whether Post-Setup Security Updates will run on your server:

| Test Question | Answer=Yes | Answer=No |
| --- | --- | --- |
| Is the logged-on user an administrator? | Continue to the next test. | Skip the remaining tests and do not display the **Post-Setup Security Updates** dialog box. These tests run again the next time a user logs on. |
| Is this is a new installation of a version of Windows Server 2003 that includes Service Pack 1 (not an upgrade)? | Continue to the next test. | Skip the remaining tests and do not display the **Post-Setup Security Updates** dialog box. The registry value is set to suppress Post-Setup Security Updates in the future. |
| Has Post-Setup Security Updates been suppressed in the registry? | Skip the remaining tests and do not display the **Post-Setup Security Updates** dialog box. | Continue to the next test. |
| Is the Windows Firewall/Internet Connection Sharing service running? | Continue to the next test. | Repeat this test for two minutes. If the service has still not started, do not display the **Post-Setup Security Updates** dialog box. These tests are run again the next time a user logs on. |
| Has Windows Firewall been explicitly enabled or disabled for the current Windows Firewall profile?<br><br>(Windows Firewall may have been enabled or disabled using an unattended-setup script at the time of installation or through the application of Group Policy settings or by opening Windows Firewall in Control Panel and clicking **OK** to confirm the settings.) | Skip the remaining tests and do not display the **Post-Setup Security Updates** dialog box. A registry value is set to suppress Post-Setup Security Updates in the future. | If Windows Firewall is enabled and the user did not enable it, display the **Post-Setup Security Updates** dialog box.<br><br>If the status of Windows Firewall cannot be determined, do not display the **Post-Setup Security Updates** dialog box. These tests are run again the next time a user logs on. |

**Startup Protection**

Because there is a brief period of time during startup when a computer is connected to a network but Windows Firewall is not yet running, Windows Firewall uses a special startup policy that allows it to perform stateful packet filtering while your computer is starting. The startup policy, which you cannot configure, allows your computer to perform basic networking startup tasks using DHCP and the DNS service to communicate with a domain controller to obtain Group Policy updates. The startup policy is in effect only until the Windows Firewall/Internet Connection Sharing service starts, at which time Windows Firewall uses its user-configured settings and discards the special startup policy settings.

**Windows Firewall Filtering**

When an incoming packet reaches your computer, Windows Firewall inspects the packet and determines whether it meets

criteria specified in the Windows Firewall exceptions list (the combination of the NAT Mapping Table and the Windows Firewall rules store). If the packet matches an entry in the list, Windows Firewall passes the packet to the TCP/IP protocol for further processing. If the packet does not match an entry in the list, Windows Firewall silently discards the packet and creates an entry in the Windows Firewall log file (if the log file is enabled on the **Log Settings** dialog box in Windows Firewall). The entries in the exceptions list can consist of program names, system service names, TCP ports, and UDP ports. There is no way to create an entry in the exceptions list based on the IP Protocol field in the IP header.

There are only two conditions under which traffic can pass through Windows Firewall:

- When the incoming traffic corresponds to a recent outgoing request, in which case the response traffic is then considered incoming solicited traffic.

An example of this occurs when a DNS Name Query Request message is sent to a DNS server. Windows Firewall adds an entry to the NAT Mapping Table so that the corresponding DNS Name Query Response message sent by the DNS server can be passed to the TCP/IP protocol for further processing.

- When you configure Windows Firewall for exceptions, in which case you allow a computer using Windows Firewall to accept unsolicited incoming traffic when acting as a server, a listener, or a peer.

An example of this occurs when your computer is acting as a Web server. In this case, you must configure Windows Firewall to allow Web traffic so that the computer can respond to requests from Web clients. To do this, you configure an exception, which becomes a rule in the Windows Firewall rules store. You can configure exceptions based on specific programs, in which case the ports required by the program are opened and closed dynamically according to the program's needs, or on TCP or UDP ports, in which case the ports are opened even if the programs or system services are not using them.

**Windows Firewall Profile Determination**

Windows Firewall filters traffic according to the settings that are stored in one of two profiles: the domain profile or the standard profile. Windows Firewall uses a network determination algorithm to determine which profile to use.

The network determination algorithm uses connection-specific DNS suffix information to determine whether a computer is connected to a managed network containing the domain in which the computer is a member. To do this, the algorithm compares the following DNS suffix information:

- The last-received Group Policy update DNS name. This is stored in the HKEY_Local_Machine\Software\Microsoft\Windows\CurrentVersion\Group Policy\History\NetworkName registry entry and represents the connection-specific DNS suffix of the connection over which the last Group Policy update was received.

- The connection-specific DNS suffixes of the currently connected connections (those that are assigned an IP address) that are not Point-to-Point Protocol (PPP) or Serial Line Internet Protocol (SLIP)-based, such as dial-up or VPN network connections.

Using this DNS suffix information, the algorithm performs the following analysis:

- If the computer is not a member of a domain, then the computer is always attached to another network.

- If the last-received Group Policy update DNS name matches any of the connection-specific DNS suffixes of the currently connected connections on the computer that are not PPP or SLIP-based, then the computer is attached to a managed network.

- If the last-received Group Policy update DNS name does not match any of the connection-specific DNS suffixes of the currently connected connections on the computer that are not PPP or SLIP-based, then the computer is attached to another network.

Windows Server 2003 uses this network determination process during startup and when it is informed by the Network Location Awareness service that network settings on the computer have changed. To determine which profile to use, Windows Firewall applies this network determination process as follows:

- If the connection-specific DNS suffix of a currently connected connection on the computer that is not PPP or SLIP-based

(such as an Ethernet or 802.11 wireless network adapter) matches the value of the HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion\Group Policy\History\NetworkName registry entry, Windows Firewall uses the domain profile.

- If the connection-specific DNS suffix of a currently connected connection on the computer that is not PPP or SLIP-based does not match the value of the HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion\Group Policy\History\NetworkName registry entry, Windows Firewall uses the standard profile.

Although this network determination algorithm works well in most situations, configuration variations can cause Windows Server 2003 to determine that it is always attached to the managed network or create temporary configuration problems when roaming between different portions of the same managed network that assign different DNS suffixes with DHCP.

**Always Attached to the Managed Network**
The connection-specific DNS suffix of the connection over which the last set of Group Policy updates were received is determined from its TCP/IP configuration, which is typically configured using DHCP and the DNS Domain Name DHCP option (DHCP option number 15). You can also manually configure connection-specific DNS suffixes.

If the connection-specific DNS suffixes for the computer's connections are manually configured, then the manually-specified value overrides the value from the DNS Domain Name DHCP option. If the manually-configured DNS suffix matches the last-received Group Policy update DNS name, then Windows will always determine that the computer is attached to the managed network.

This can create a problem for Windows Firewall Group Policy settings if an administrator configures Group Policy settings so that Windows Firewall is disabled when the computer is attached to the managed network (this practice is highly discouraged unless another host-based firewall is being used) and Windows Firewall is enabled when the computer is attached to another network. If Windows Server 2003 always determines that the computer is attached to the managed network, Windows Firewall will be disabled when the computer is attached to the Internet, thereby making the computer accessible to network attacks.

**Roaming Between Different Portions of the Same Managed Network**
Temporary network determination problems can also occur when computers roam between portions of a managed network that assign different DNS domain names using DHCP.

For example, a laptop computer with only a wireless LAN connection is a member of the noam.corp.example.com Active Directory domain. DHCP servers in all of the offices of the organization in North America assign the DNS name noam.corp.example.com. However, in Europe, the Active Directory domain is europe.corp.example.com and the DNS servers assign the DNS name europe.corp.example.com. When the user connects a laptop computer to the wireless network in an office in Europe, the computer's last-received Group Policy update DNS name no longer matches the DNS suffix of the computer's wireless connection and Windows determines that the laptop computer is on another network, even though the laptop computer is connected to a portion of the managed network.

However, this condition lasts only as long as it takes for Group Policy settings to be updated. When the computer updates Group Policy settings, the last-received Group Policy update DNS name is reset to the new connection-specific DNS suffix and the computer is then determined to be on the managed network.

Continuing our example, the laptop computer updates Group Policy settings from a domain controller in the noam.corp.example.com domain and the last-received Group Policy update DNS name is set to europe.corp.example.com, which now matches the connection-specific DNS suffix of the wireless connection. When the network determination algorithm is run again, it determines that the computer is connected to a managed network.

The workaround for this issue is to have all of the DHCP servers in an organization assign a common DNS domain name, rather than a region-specific DNS domain name. For our example, the workaround is to have all the DNS servers assign the name "example.com." Therefore, the last-received Group Policy update DNS name will always match the connection-specific DNS suffix of a LAN connection that is attached to the organization network.

The problem of temporarily determining that the computer is on another network when it is actually on the managed network can also occur with the following configurations:

- The DNS Domain Name DHCP option is changed, assigning a domain suffix that does not match the last-received Group Policy update DNS name.

- The DNS Domain Name DHCP option is removed, resulting in a blank connection-specific DNS suffix for the computer's LAN connection.

- The connection-specific DNS suffix for the computer's LAN connection is manually configured and does not match the last-received Group Policy update DNS name.

**Scope Resolution**

Scope settings define from which addresses incoming traffic is allowed to originate for a specific exception. By default, exceptions have unrestricted scope, which means that exceptions apply to all unsolicited incoming IPv4 and IPv6 traffic no matter from where the traffic originates. You can change this default behavior and restrict the scope of an exception by using the **My network (subnet) only** scope option or by using the **Custom list** scope option. The **My network (subnet) only** scope option changes the default behavior so that an exception applies only to unsolicited incoming traffic that originates from an IPv4 or IPv6 address that is directly reachable from your computer. The **Custom list** scope option changes the default behavior so that an exception applies only to specific IPv4 addresses or a range of IPv4 addresses. You cannot use the **Custom list** scope option to specify an IPv6 address or a range of IPv6 addresses.

**Resolving Directly Reachable Computers**

When you use the **My network (subnet) only** scope option to restrict the scope of an exception, Windows Firewall does not perform any IP configuration testing or subnet mask interpretation to determine whether the traffic is coming from a computer that is a neighbor on a locally attached subnet. Instead, Windows Firewall queries the IPv4 and IPv6 routing tables to determine whether the source IPv4 or IPv6 address of the incoming packet can be reached directly. You can see all destinations that are considered directly reachable by typing the **route print** command at a command prompt. For the IPv4 routing table, all IPv4 addresses that match the routes in which the IPv4 address of the **Gateway** column equals the IPv4 address of the **Interface** column are considered directly reachable. For the IPv6 routing table, all IPv6 addresses that match routes in which the **Gateway** column is set to **On-link** are considered directly reachable. Therefore, the set of directly reachable addresses depends on your networking configuration, as specified by the IPv4 and IPv6 configuration of LAN-based connections (such as Ethernet and 802.11 wireless), dial-up connections, and broadband Internet connections. In some Internet configurations, all destinations are considered directly reachable.

For example, for a computer that is directly connected to a private home network only, the set of directly reachable unicast addresses is confined to those that match the IPv4 network ID of the private subnet. If the network connection is configured with an IPv4 address of 192.168.0.99 with a subnet mask of 255.255.0.0, only traffic from IPv4 addresses in the range 192.168.0.0 to 192.168.255.255 is allowed.

In another example, for a computer that is directly connected to both a private home network and the Internet through a cable modem, the set of directly reachable unicast addresses are those that match either the network ID of the private subnet or the subnet of the cable modem provider. For example, if the private network connection is configured with an IPv4 address of 192.168.0.1 and a subnet mask of 255.255.0.0 and the cable modem connection is configured with an IPv4 address of 131.107.17.211 and a subnet mask of 255.255.255.0, traffic received by either network connection is allowed from IPv4 addresses in the ranges from 192.168.0.0 to 192.168.255.255 and from 131.107.17.0 to 131.107.17.255.

**Resolving Specific IP Addresses and Address Ranges**

When you use the **Custom list** scope option to restrict the scope of a exception, you must provide a list of specific IPv4 addresses or a list of IPv4 address ranges (which usually correspond to subnets).

The IPv4 addresses are specified in dotted decimal notation; each address is separated by a comma. IPv4 address ranges are specified using a dotted decimal subnet mask or a prefix length; each address range is separated by a comma. A dotted decimal subnet mask is typically specified as an IPv4 network ID (such as 10.47.81.0/255.255.255.0) or by an IPv4 address within a range (such as 10.47.81.231/255.255.255.0). A network prefix length is typically specified as an IPv4 network ID (such as 10.47.81.0/24) or an IPv4 address within the range (such as 10.47.81.231/24).

Windows Firewall will ignore any IPv6 addresses or IPv6 address ranges that you add to the **Custom list** scope option.

# Windows Firewall Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Windows Firewall Tools
- Windows Firewall Group Policy Settings
- Windows Firewall Automated Installation Tools and Settings
- Windows Firewall Scripting Reference
- Netsh Commands for Windows Firewall
- Windows Firewall Log File and Security Log Settings

**Windows Firewall Tools**
The following tools are associated with Windows Firewall.

**Firewall.cpl: Windows Firewall Control Panel Tool**
**Category**
Control Panel tool included in the operating system.

**Version compatibility**
Available on Windows XP with Service Pack 2 (SP2) and Windows Server 2003 with Service Pack 1 (SP1).

You can use Windows Firewall in Control Panel to configure Windows Firewall settings on a local computer. This includes enabling and disabling Windows Firewall, specifying the type of information that is written to the Windows Firewall log file, and configuring the way Windows Firewall handles network traffic to and from specific programs, services, and ports.

**Gpedit.msc: Group Policy Object Editor**
**Category**
Microsoft Management Console (MMC) snap-in included in the operating system.

**Version compatibility**
Available on Windows 2000, Windows XP, and Windows Server 2003.

You can use the Group Policy Object Editor to configure Windows Firewall Group Policy settings. Windows Firewall Group Policy settings are configured on a per-computer basis and are stored in Administrative Templates (.adm files). You can configure Windows Firewall Group Policy settings on a local Group Policy object (GPO) or an Active Directory GPO. Group Policy settings that are configured on a local GPO are applied to the local computer only. Group Policy settings that are configured on an Active Directory GPO can be linked to an Active Directory container, such as a domain, organizational unit, or site.

**Gpmc.msc: Group Policy Management Console**
**Category**
MMC snap-in included in the operating system.

**Version compatibility**
Available on Windows XP with SP2 and Windows Server 2003 with SP1. Also available for download for Windows XP with SP1 and Windows Server 2003.

You can use the Group Policy Management Console (GPMC) to manage GPOs that contain Group Policy settings for Windows Firewall. This includes managing GPOs for multiple domains and sites within one or more forests. This snap-in uses a simplified user interface (UI) with drag-and-drop support. It can be used to perform many other administrative tasks, such as backup, restore, import, copy, and reporting of GPOs.

**Netsh.exe: Netsh**
**Category**

Command-line tool included in the operating system.

**Version compatibility**
Runs on Windows XP and the Windows Server 2003 family.

You can use the Netsh Firewall context to monitor and configure Windows Firewall settings. Several new commands have been added to the Netsh Firewall context for Windows Server 2003 with SP1. The new commands correspond to new Windows Firewall configuration settings.

You can also use Netsh to apply Windows Firewall settings that are stored in a Netfw.inf file. For more information, see "*Windows Firewall Netfw.inf Settings*" later in this section.

**Windows Firewall Group Policy Settings**
If your organization uses Group Policy, use the Windows Firewall Group Policy settings to configure Windows Firewall. The Group Policy Object Editor (Gpedit.msc) provides access to the Windows Firewall settings. The settings are stored within the Group Policy Object Editor at Computer Configuration/Administrative Templates/Network/Network Connections/Windows Firewall.

The following table lists the Windows Firewall Group Policy settings:

| Setting | Description |
|---|---|
| **Windows Firewall: Allow authenticated IPSec bypass** | Allows unsolicited incoming messages from specified systems that authenticate using the IPsec transport. |
| **Windows Firewall: Protect all network connections** | Turns on Windows Firewall, which replaces Internet Connection Firewall on all computers that are running Windows Server 2003 with SP1. |
| **Windows Firewall: Do not allow exceptions** | Specifies that Windows Firewall blocks all unsolicited incoming messages. This Group Policy setting overrides all other Windows Firewall settings that allow such messages. |
| **Windows Firewall: Define program exceptions** | Allows you to view and change the program exceptions list defined by Group Policy. Windows Firewall uses two program exception lists: one is defined by Group Policy settings and the other is defined by the Windows Firewall component in Control Panel. |
| **Windows Firewall: Allow local program exceptions** | Allows administrators to use the Windows Firewall component in Control Panel to define a local program exceptions list. |
| **Windows Firewall: Allow remote administration exception** | Allows remote administration of this computer using administrative tools such as MMC and Windows Management Instrumentation (WMI). To do this, Windows Firewall opens TCP ports 135 and 445. Services typically use these ports to communicate using remote procedure calls (RPC) and Distributed Component Object Model (DCOM). This policy setting also allows SVCHOST.EXE and LSASS.EXE to receive unsolicited incoming messages and allows hosted services to open additional dynamically-assigned ports, typically in the range of 1024 to 1034. |
| **Windows Firewall: Allow file and printer sharing exception** | Allows file and printer sharing. To do this, Windows Firewall opens UDP ports 137 and 138, and TCP ports 139 and 445. |

| | |
|---|---|
| **Windows Firewall: Allow ICMP exceptions** | Defines the set of Internet Control Message Protocol (ICMP) message types allowed by Windows Firewall. Utilities can use ICMP messages to determine the status of other computers. For example, Ping uses the echo request message. If you do not enable the "Allow inbound echo request" message type, Windows Firewall blocks echo request messages sent by Ping running on other computers, but it does not block outbound echo request messages sent by Ping running on this computer. |
| **Windows Firewall: Allow Remote Desktop exception** | Allows this computer to receive Remote Desktop requests. To do this, Windows Firewall opens TCP port 3389. |
| **Windows Firewall: Allow UPnP framework exception** | Allows this computer to receive unsolicited UPnP messages sent by network devices, such as routers with built-in firewalls. To do this, Windows Firewall opens TCP port 2869 and UDP port 1900. |
| **Windows Firewall: Prohibit notifications** | Prevents Windows Firewall from displaying notifications to the user when a program requests that Windows Firewall add the program to the program exceptions list. |
| **Windows Firewall: Allow logging** | Allows Windows Firewall to record information about the unsolicited incoming messages that it receives. |
| **Windows Firewall: Prohibit unicast response to multicast or broadcast requests** | Prevents this computer from receiving unicast responses to its outgoing multicast or broadcast messages. |
| **Windows Firewall: Define port exceptions** | Allows you to view and change the port exceptions list defined by Group Policy. Windows Firewall uses two port exception lists: one is defined by Group Policy settings and the other is defined by the Windows Firewall component in Control Panel. |
| **Windows Firewall: Allow local port exceptions** | Allows administrators to use the Windows Firewall component in Control Panel to define a local port exceptions list. |

**Windows Firewall Automated Installation Tools and Settings**

There are two automated installation technologies that you can use to deploy or configure Windows Firewall. One technology uses an information file known as Netfw.inf to automate the configuration of Windows Firewall settings. The other technology uses an unattended installation answer file to automate the configuration of Windows Firewall settings.

**Windows Firewall Netfw.inf Settings**

You can use the Windows Firewall information file (Netfw.inf) to deploy Windows Firewall in a corporate environment; however, this automated installation technology is typically used by OEMs to configure new computers in a manufacturing environment.

The Netfw.inf file configures Windows Firewall by modifying registry settings. To configure a Netfw.inf file, you must use standard .inf file structure and syntax.

The Netfw.inf file is found in the following location: %windir%\Inf\Netfw.inf.

**Note**

When you restore Windows Firewall default settings, the settings that are specified in Netfw.inf are reapplied to your computer and all existing settings are deleted.

The following is an example of a Netfw.inf file:

```
[version]
Signature = "$Windows NT$"
DriverVer = MM/DD/YYYY,1.2.3456.7890

[DefaultInstall]
AddReg=ICF.AddReg.DomainProfile
AddReg=ICF.AddReg.StandardProfile

[ICF.AddReg.DomainProfile]

[ICF.AddReg.StandardProfile]
```

**Note**

The first two sections contain version and configuration information and do not need to be modified. The sections that require modification are [ICF.AddReg.DomainProfile] and [ICF.AddReg.StandardProfile].

**[ICF.AddReg.DomainProfile]**
This section is used for defining changes to Windows Firewall's default configuration when a computer is connected to a network that contains its domain.

**[ICF.AddReg.StandardProfile]**
This section is used for defining changes to Windows Firewall's default configuration when a computer is not connected to a network that contains its domain. If a computer is not a member of a domain, then Windows Firewall will always enforce the configuration stored in the standard profile.

**Configuration Options**
The following settings can be defined in the Windows Firewall Netfw.inf file:

- Operational mode
- Disable notifications
- Block unicast responses to multicast and broadcast packets
- Enable remote administration
- Allow ICMP messages
- Open ports
- Allow programs

**Note**

All of the settings defined in the Windows Firewall Netfw.inf file will be applied to all of the computer's network interfaces; you cannot use the Netfw.inf file to open ports or allow ICMP messages for individual interfaces. In addition, you cannot use the Netfw.inf file to define logging settings.

**Operational Mode**
Windows Firewall can be placed in one of the three operational modes by adding the following entries to the Netfw.inf file:

| Mode | Section | Entry |
|---|---|---|

| | | |
|---|---|---|
| **On** | [ICF.AddReg.DomainProfile] | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile", "DoNotAllowExceptions",0x00010001,0 |
| | | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile", "EnableFirewall",0x00010001,1 |
| | [ICF.AddReg.StandardProfile] | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile", "DoNotAllowExceptions",0x00010001,0 |
| | | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile", "EnableFirewall", 0x00010001,0x00000001 |
| **Off** | [ICF.AddReg.DomainProfile] | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile", "DoNotAllowExceptions",0x00010001,1 |
| | | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile", "EnableFirewall",0x00010001,1 |
| | [ICF.AddReg.StandardProfile] | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile", "DoNotAllowExceptions",0x00010001,1 |
| | | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile", "EnableFirewall",0x00010001,1 |
| **Off with no excep-tions** | [ICF.AddReg.DomainProfile] | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile", "DoNotAllowExceptions", 0x00010001,0 |
| | | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile", "EnableFirewall",0x00010001,0 |
| | [ICF.AddReg.StandardProfile] | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile", "DoNotAllowExceptions",0x00010001,0 |
| | | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile", "EnableFirewall",0x00010001,0 |

**Disable Notifications**

Add the following entries to the Windows Firewall Netfw.inf file to disable notifications:

| Section | Entry |
|---|---|
| [ICF.AddReg.DomainProfile] | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile","DisableNotifications", 0x00010001,1 |
| [ICF.AddReg.StandardProfile] | HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile","DisableNotifications", 0x00010001,1 |

**Block Unicast Responses to Multicast and Broadcast Packets**

Add the following entries to the Windows Firewall Netfw.inf file to disable unicast responses to multicast and broadcast packets:

| Section | Entry |
|---|---|

| | |
|---|---|
| [ICF.AddReg.DomainProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile", "DisableUnicastResponsesToMulticastBroadcast", 0x00010001,1` |
| [ICF.AddReg.StandardProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile", "DisableUnicastResponsesToMulticastBroadcast", 0x00010001,1` |

**Enable Remote Administration**

Add the following entries to the Windows Firewall Netfw.inf file to enable remote administration:

| Section | Entry |
|---|---|
| [ICF.AddReg.DomainProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile\RemoteAdminSettings", "Enabled",0x00010001,1` |
| [ICF.AddReg.StandardProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile\RemoteAdminSettings", "Enabled",0x00010001,1` |

Add the following entries to the Windows Firewall Netfw.inf file to define the default scope for remote administration:

| Section | Entry |
|---|---|
| [ICF.AddReg.DomainProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile\RemoteAdminSettings", "RemoteAddresses",0x00000000,scope` |
| [ICF.AddReg.StandardProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile\RemoteAdminSettings", "RemoteAddresses",0x00000000,scope` |

**Scope Definition**

You can define the set of IP addresses from which unsolicited incoming traffic is allowed when you enable remote administration, open a port, or allow a program. This set of IP addresses from which unsolicited incoming traffic is allowed is referred to as the scope of the exception. There are three options when defining the scope for a Windows Firewall exception:

- **All IP Addresses** – This is the default scope for a Windows Firewall exception and it allows unsolicited incoming traffic that matches the exception from any computer. In the Windows Firewall Netfw.inf file, making an entry's scope element an asterisk ("*") will result in a scope of all IP addresses for the entry.

- **Local Subnet Only** – This scope allows unsolicited incoming traffic that matches the exception from any computer on the same subnet as the network connection on which the traffic was received through Windows Firewall, while dropping unsolicited incoming traffic from all other computers. When a computer's subnet changes, the set of allowed IP addresses dynamically changes to match the new subnet. In the Windows Firewall Netfw.inf file, making an entry's scope element **LocalSubnet** will result in a local subnet only scope for the entry.

- **Custom** – This scope is a list of IPv4 addresses and address ranges that typically correspond to subnets. Unsolicited incoming traffic that matches the exception and originates from a computer with an IPv4 address in the defined list is allowed through Windows Firewall. Unsolicited incoming traffic from computers with IPv4 addresses that are not in the list is dropped. A custom scope can include the local subnet (using the **LocalSubnet** string), IPv4 addresses, and IPv4 address ranges, but cannot include IPv6 addresses or IPv6 address ranges. For IPv4 address ranges, you can specify the range using a dotted decimal subnet mask or a prefix length (w.x.y.z/n). When you use a dotted decimal subnet mask, you can specify the range as an IPv4 network ID (such as 10.47.81.0/255.255.255.0) or by using an IPv4 address within the range (such as 10.47.81.231/255.255.255.0). When you use a network prefix length, you can specify the range as an IPv4 network ID (such as 10.47.81.0/24) or by using an IPv4 address within the range (such as 10.47.81.231/24).

| **Note** |
|---|

| |
|---|
| Do not use spaces between the entries in the list of sources or the entire list will be ignored and Windows Firewall will use the default scope of any source IPv4 address. |

**Allow ICMP Messages**

Add the following entries to the Windows Firewall Netfw.inf file to allow certain ICMP messages:

| Section | Entry |
|---|---|
| [ICF.AddReg.DomainProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile\IcmpSettings", "ICMP Message Type",0x00010001,1` |
| [ICF.AddReg.StandardProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile\IcmpSettings", "ICMP Message Type",0x00010001,1` |

The following table lists the permitted values for certain ICMP message types:

| ICMP Message Type | Number | Description |
|---|---|---|
| **AllowOutboundPacketTooBig** | 2 | When an IPv6 packet is too large to be forwarded, data will be dropped and a computer will reply to the sender with a “Packet Too Big” message. |
| **AllowOutboundDestinationUnreachable** | 3 | Data that fails to reach this computer due to an error will be discarded and reported with a “Destination Unreachable” message that explains the failure. |
| **AllowOutboundSourceQuench** | 4 | When the rate of a transmission exceeds a computer’s ability to process incoming data, data will be dropped and the sender will be asked to transmit more slowly. |
| **AllowRedirect** | 5 | Data sent from a computer will be rerouted. |
| **AllowInboundEchoRequest** | 8 | Messages sent to a computer will be repeated back to the sender. This is commonly used for troubleshooting (for example, to ping a computer). |
| **AllowInboundRouterRequest** | 10 | A computer will respond to router discovery messages. |
| **AllowOutboundTimeExceeded** | 11 | When a computer discards a packet because its hop count was exceeded or it ran out of time to assemble fragments of a packet, it will reply to the sender with a “Time Exceeded” message. |
| **AllowOutboundParameterProblem** | 12 | When a computer discards data it has received due to a problematic header, it will reply to the sender with a “Parameter Problem” error message. |
| **AllowInboundTimestampRequest** | 13 | Data sent to a computer can be responded to with a confirmation message indicating the time that the data was received. |
| **AllowInboundMaskRequest** | 17 | A computer will listen for and respond to requests for a network subnet mask. |

**Open Ports**

Add the following entries to the Windows Firewall Netfw.inf file to add static ports to the exceptions list:

| Section | Entry |
|---|---|

| | |
|---|---|
| [ICF.AddReg.DomainProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile\GloballyOpenPorts\List", "port number:protocol",0x00000000, "port number:protocol:scope:mode:port's friendly name"` |
| [ICF.AddReg.StandardProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile\GloballyOpenPorts\List", "port number:protocol",0x00000000,"port number:protocol:scope:mode:port's friendly name"` |

In the two preceding entries, the following elements must be defined:

- **Port Number** – A port is specified by the combination of a protocol and a port number. The port number must be between 1 and 65535, inclusively.
- **Protocol** – A protocol is specified by the combination of a protocol and a port number. The protocol must be either TCP or UDP.
- **Scope** – See "*Scope Definition*" earlier in this section.
- **Mode** – The two permitted values for this element are enabled and disabled. If a port's entry is enabled, the port is statically opened in Windows Firewall. If a port's entry is disabled, the port is not statically opened in Windows Firewall.
- **Port's Friendly Name** – This is the description that will be used to represent the entry in Windows Firewall in Control Panel. It should provide an indication of why the port is statically opened, such as "Web Server (TCP 80)" or "Telnet Server (TCP 23)."

**Allow Programs**

Add the following entries to the Windows Firewall Netfw.inf file to add programs to the exceptions list:

| Section | Entry |
|---|---|
| [ICF.AddReg.DomainProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\DomainProfile\AuthorizedApplications\List", "program's image path",0x00000000, "program's image path:scope:mode:program's friendly name"` |
| [ICF.AddReg.StandardProfile] | `HKLM,"SYSTEM\CurrentControlSet\Services\SharedAccess\Parameters\FirewallPolicy\StandardProfile\AuthorizedApplications\List", "program's image path",0x00000000, "program's image path:scope:mode:program's friendly name"` |

In the two preceding entries, the following elements must be defined:

**Program's Image Path** – This is the fully qualified path for the file to be added to Windows Firewall's default exception list. It may include environmental variables, such as %ProgramFiles%.

**Scope** – See "*Scope Definition*" earlier in this section.

**Mode** –The two permitted values for this element are enabled and disabled. If a program's entry is enabled, ports for the program are dynamically opened in Windows Firewall. If a program's entry is disabled, ports for the program are not dynamically opened in Windows Firewall.

**Program's Friendly Name** – This is the name that will be used to represent the entry in the Windows Firewall user interface. It should include the product name and publisher, such as MSN Messenger version 6.1.

**Windows Firewall Unattended Installation**

You can use an unattended installation answer file, such as Unattend.txt, to automate the configuration of Windows Firewall settings during an unattended installation. Unattended installation is typically used in a corporate environment when you are configuring new computers or deploying a new operating system.

To configure Windows Firewall settings during an unattended installation, you must include the [WindowsFirewall] section along with one or more of the following user-defined sections in your answer file:

- [WindowsFirewall.profile_name]
- [WindowsFirewall.program_name]
- [WindowsFirewall.service_name]
- [WindowsFirewall.portopening_name]
- [WindowsFirewall.icmpsetting_name]

| **Important** |
| --- |
| Applications that are not already installed cannot be added using unattended setup. You must use Netfw.inf to add applications. |

| **Note** |
| --- |
| When you restore Windows Firewall default settings, any settings that you specified in an answer file are deleted and are not restored. To restore the Windows Firewall settings that you configured during installation with an answer file, you must configure the settings manually. |

**[WindowsFirewall]**

The [WindowsFirewall] section contains entries for specifying the log file settings and which user-defined profiles to use.

The [WindowsFirewall] section contains the following entries:

| Entry | Description |
| --- | --- |
| **Profiles** | Specifies the names of the user-defined profiles to use for configuring Windows Firewall (domain, standard, or both domain and standard). |
| **LogFile** | Specifies the location and file name of the Windows Firewall log file. By default, the log file is named Pfirewall.log. |
| **LogSize** | Specifies the maximum size of the Windows Firewall log file. |
| **LogDroppedPackets** | Specifies whether to log dropped packets to the Windows Firewall log file. |
| **LogConnections** | Specifies whether to log connections to the Windows Firewall log file. |

**[WindowsFirewall.profile_name]**

The [WindowsFirewall.profile_name] section is a user-defined section that is referenced by the [WindowsFirewall] section to make changes to Windows Firewall's default configuration.

The [WindowsFirewall.profile_name] section contains the following entries:

| Entry | Description |
| --- | --- |
| **Type** | Specifies the type of profile to use for changing the default configuration of Windows Firewall. |
| **Mode** | Specifies whether to enable or disable Windows Firewall. |
| **Exceptions** | Specifies whether to enable or disable the Windows Firewall exceptions list. |
| **Notifications** | Specifies whether to enable or disable notifications. |
| **MulticastBroadcastResponse** | Specifies whether to enable or disable multicast and broadcast packets. |

| | |
|---|---|
| **AllowedPrograms** | Specifies a list of programs that will not be blocked by Windows Firewall. |
| **Services** | Specifies a list of services that will not be blocked by Windows Firewall. |
| **PortOpenings** | Specifies a list of open ports that will not be blocked by Windows Firewall. |
| **IcmpSettings** | Specifies a list of ICMP message types that will not be blocked by Windows Firewall. |

**[WindowsFirewall.program_name]**

The [WindowsFirewall.program_name] section is a user-defined section that can be used to add programs to the Windows Firewall exceptions list.

The [WindowsFirewall.program_name] section contains the following entries:

| Entry | Description |
|---|---|
| **Program** | Specifies the path of a program to be added to the exceptions list. This is a required entry. |
| **Name** | Specifies the name of a program to be added to the exceptions list. This is a required entry. |
| **Mode** | Specifies whether to enable or disable an entry in the exceptions list. |
| **Scope** | Defines the set of limits on which computers (IP addresses) are allowed to send traffic through the specified exception (program, service). Mode must be set to **1** (on). |
| **Addresses** | Specifies the addresses for an entry in the exceptions list. |

**[WindowsFirewall.service_name]**

Windows Firewall opens static ports used by services in the exceptions list of the current profile. Only services that actually require unsolicited, incoming traffic should be added to the exceptions list. You must add the [WindowsFirewall.service_name] section in the [WindowsFirewall.profile_name] section.

The [WindowsFirewall.service_name] section contains the following entries:

| Entry | Description |
|---|---|
| **Type** | Specifies the type of service to use for changing the default configuration of Windows Firewall. |
| **Mode** | Specifies whether to enable or disable an entry in the exceptions lists. |
| **Scope** | Defines the set of limits on which computers (IP addresses) are allowed to send traffic through the specified exception. The value of the Mode entry must equal **1** (on). |
| **Addresses** | Specifies the addresses for an entry in the exceptions list. |

**[WindowsFirewall.portopening_name]**

A static port may need to be opened for a Windows service to receive unsolicited, incoming traffic. To support these scenarios, you can add static ports to the Windows Firewall exceptions list by using the [WindowsFirewall.portopening_name] section. You must add this section to the [WindowsFirewall.profile_name] section.

The [WindowsFirewall.portopening_name] section contains the following entries:

| Entry | Description |
|---|---|
| **Protocol** | Specifies the protocol of a port. The protocol must be either TCP or UDP. |
| **Port** | Specifies the port number. The port number must be between 1 and 65535, inclusive. |
| **Name** | Specifies the friendly name of a port to be added to the exceptions list. This descriptive name is used to represent the entry for Windows Firewall in Control Panel. |
| **Mode** | Specifies whether to enable or disable an entry in the exceptions list. |
| **Scope** | Defines the set of limits on which computers (IP addresses) are allowed to send traffic through the specified exception. The value of the Mode entry must equal **1** (on). |

| | |
|---|---|
| **Addresses** | Specifies the addresses for an entry in the exceptions list. |

**[WindowsFirewall.icmpsetting_name]**
The default configuration for Windows Firewall blocks all ICMP message types; however, you can modify this behavior by adding entries to the Windows Firewall exceptions list that enable certain ICMP message types. You must include the [WindowsFirewall.icmpsetting_name] section in the [WindowsFirewall.profile_name] section.

The [WindowsFirewall.icmpsetting_name] section contains the following entries:

| Entry | Description |
|---|---|
| **Type** | Specifies the type of ICMP message to enable. |
| **Mode** | Specifies whether to enable or disable the ICMP message type. |

**Windows Firewall Scripting Reference**
This section describes the methods and properties associated with Windows Firewall scripting. You can use them in a script, such as Microsoft Visual Basic Scripting Edition (VBScript) or JScript, to configure Windows Firewall settings. All of these methods and properties are implemented in the Hnetcfg.dll. They are grouped in this section according to the following categories:

- Policy
- Profile
- Remote administration
- ICMP
- Port
- Application
- Service

**Policy**
The following table lists the scripting properties used to access a Windows Firewall policy:

| Property | Description |
|---|---|
| **LocalPolicy** | A read-only element that accesses the local firewall policy. This property is retrieved through the HNetCfg.FwMgr COM Object. |

**Profile**
The following table lists the scripting methods and properties used to access and configure a Windows Firewall profile:

| Method or Property | Description |
|---|---|
| **AuthorizedApplications** | A read-only element that accesses the collection of authorized applications in a profile. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **CurrentProfile** | A read-only element that accesses the current Windows Firewall profile. This property is retrieved through the HNetCfg.FwMgr COM Object (**LocalPolicy** property). |
| **CurrentProfileType** | A read-only element that accesses the type of Windows Firewall profile currently in effect. This property is retrieved through the HNetCfg.FwMgr COM Object. |

| | |
|---|---|
| **ExceptionsNotAllowed** | A read-write element that accesses a Boolean value which is TRUE if Windows Firewall should not allow exceptions. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **FirewallEnabled** | A read-write element that accesses a Boolean value which is TRUE if Windows Firewall is enabled. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **GetProfileByType** | Gets the Windows Firewall profile of the requested type. This method is retrieved through the HNetCfg.FwMgr COM Object (**LocalPolicy** property). |
| **GloballyOpenPorts** | A read-only element that accesses the collection of globally-opened ports in a profile. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **IcmpSettings** | A read-only element that accesses the ICMP settings in a profile. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **NotificationsDisabled** | A read-write element that accesses a Boolean value which is TRUE if interactive notifications are disabled. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **RemoteAdminSettings** | Accesses the object that contains the remote administration settings. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **Services** | A read-only element that accesses the collection of services in a profile. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **Type** | A read-only element that accesses the type of a profile. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **UnicastResponsesToMulticastBroadcastDisabled** | A read-write element that accesses a Boolean value which is TRUE if Windows Firewall should not allow unicast responses to multicast and broadcast traffic. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |

**Remote Administration**

The following table lists the scripting properties used to access the settings that control remote administration:

| Property | Description |
|---|---|
| **Enabled** | A read-write element that accesses a Boolean value which is TRUE if the settings controlling remote administration are currently enabled. This property is retrieved through the HNetCfg.FwMgr COM Object (**RemoteAdminSettings** property). |
| **IpVersion** | A read-write element that accesses the IP version for which remote administration is authorized. This property is retrieved through the HNetCfg.FwMgr COM Object (**RemoteAdminSettings** property). |
| **RemoteAddresses** | Accesses the set of remote addresses from which remote administration is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**RemoteAdminSettings** property). |
| **Scope** | A read-write element that controls the network scope from which remote administration is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**RemoteAdminSettings** property). |

**ICMP**

The following table lists the scripting methods and properties used to access and configure the settings controlling ICMP packets:

| Method or Property | Description |
|---|---|
| **AllowInboundEchoRequest** | A read-write element that accesses a Boolean value which is TRUE if InboundEchoRequest is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **AllowInboundMaskRequest** | A read-write element that accesses a Boolean value which is TRUE if InboundMaskRequest is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **AllowInboundRouterRequest** | A read-write element that accesses a Boolean value which is TRUE if InboundRouterRequest is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **AllowInboundTimestampRequest** | A read-write element that accesses a Boolean value which is TRUE if InboundTimestampRequest is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **AllowOutboundDestinationUnreachable** | A read-write element that accesses a Boolean value which is TRUE if OutboundDestinationUnreachable is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **AllowOutboundPacketTooBig** | A read-write element that accesses a Boolean value which is TRUE if OutboundPacketTooBig is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **AllowOutboundParameterProblem** | A read-write element that accesses a Boolean value which is TRUE if OutboundParameterProblem is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **AllowOutboundSourceQuench** | A read-write element that accesses a Boolean value which is TRUE if OutboundSourceQuench is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **AllowOutboundTimeExceeded** | A read-write element that accesses a Boolean value which is TRUE if OutboundTimeExceeded is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **AllowRedirect** | A read-write element that accesses a Boolean value which is TRUE if Redirect is allowed. This property is retrieved through the HNetCfg.FwMgr COM Object (**IcmpSettings** property). |
| **IsIcmpTypeAllowed** | Determines whether the specified ICMP type is allowed. This method is retrieved through the HNetCfg.FwMgr COM Object. |

| **Note** |
|---|
| All of the methods and properties associated with ICMP are common to both IPv4 and IPv6. |

**Port**

The following table lists the scripting methods and properties used to access and configure a port that has been opened in Windows Firewall:

| Method or Property | Description |
|---|---|
| **_NewEnum** | Returns an object supporting IEnumVARIANT that can be used to iterate through all the ports in a collection. This property is retrieved through the HNetCfg.FwMgr COM Object [**GloballyOpenPorts (Profile)** property]. |

| | |
|---|---|
| **Add** | Adds a new port to a collection. This method is retrieved through the HNetCfg.FwMgr COM Object [**GloballyOpenPorts (Profile)** property]. |
| **BuiltIn** | A read-only element that accesses a Boolean value which is TRUE if a port is defined by the system. This property is retrieved through the HNetCfg.FWOpenPort COM Object. |
| **Count** | A read-only element yielding the number of items in a collection of ports. This property is retrieved through the HNetCfg.FwMgr COM Object [**GloballyOpenPorts (Profile)** property]. |
| **Enabled** | A read-write element that accesses a Boolean value which is TRUE if the settings for a port are currently enabled. This property is retrieved through the HNetCfg.FWOpenPort COM Object. |
| **IpVersion** | A read-write element that accesses the IP version of a port. This property is retrieved through the HNetCfg.FWOpenPort COM Object. |
| **IsPortAllowed** | Determines whether an application can listen for inbound traffic on a specified port. This method is retrieved through the HNetCfg.FwMgr COM Object. |
| **Item** | Returns a specified port if it is within a collection. This method is retrieved through the HNetCfg.FwMgr COM Object [**GloballyOpenPorts (Profile)** property]. |
| **Name** | A read-write element that accesses the friendly name of a port. This property is retrieved through the HNetCfg.FWOpenPort COM Object. |
| **Port** | A read-write element that accesses the port number of a port. This property is retrieved through the HNetCfg.FWOpenPort COM Object. |
| **Protocol** | A read-write element that accesses the protocol type setting of a port. This property is retrieved through the HNetCfg.FWOpenPort COM Object. |
| **RemoteAddresses** | Accesses a set of remote addresses from which a port can listen for traffic. This property is retrieved through the HNetCfg.FWOpenPort COM Object. |
| **Remove** | Removes a port from a collection. This method is retrieved through the HNetCfg.FwMgr COM Object [**GloballyOpenPorts (Profile)** property]. |
| **Scope** | A read-write element that controls the network scope from which a port can listen for traffic. This property is retrieved through the HNetCfg.FWOpenPort COM Object. |

**Application**

The following table lists and gives a short description of the scripting methods and properties used to access and configure an application that has been added to the Windows Firewall exceptions list.

| Method or Property | Description |
|---|---|
| **_NewEnum** | Returns an object supporting IEnumVARIANT that can be used to iterate through all the applications in a collection. This property is retrieved through the HNetCfg.FwMgr COM Object (**AuthorizedApplications** property). |
| **Add** | Adds a new application to a collection. This method is retrieved through the HNetCfg.FwMgr COM Object (**AuthorizedApplications** property). |
| **Count** | A read-only element yielding the number of items in a collection of applications. This property is retrieved through the HNetCfg.FwMgr COM Object (**AuthorizedApplications** property). |
| **Enabled** | A read-write element that accesses a Boolean value which is TRUE if the settings for an application are currently enabled. This property is retrieved through the HNetCfg.FwAuthorizedApplication COM Object. |
| **IpVersion** | A read-write element that accesses the IP version for an application. This property is retrieved through the HNetCfg.FwAuthorizedApplication COM Object. |
| **IsPortAllowed** | Determines whether an application can listen for inbound traffic on a specified port. This method is retrieved through the HNetCfg.FwMgr COM Object. |

| | |
|---|---|
| **Item** | Returns a specified application if it is within a collection. This method is retrieved through the HNetCfg.FwMgr COM Object (**AuthorizedApplications** property). |
| **Name** | A read-write element that accesses the friendly name of an application. This property is retrieved through the HNetCfg.FwAuthorizedApplication COM Object. |
| **ProcessImageFileName** | A read-write element that accesses the process image file name of an application. This property is retrieved through the HNetCfg.FwAuthorizedApplication COM Object. |
| **RemoteAddresses** | Accesses the set of remote addresses from which an application can listen for traffic. This property is retrieved through the HNetCfg.FwAuthorizedApplication COM Object. |
| **Remove** | Removes an application from a collection. This method is retrieved through the HNetCfg.FwMgr COM Object (**AuthorizedApplications** property). |
| **Scope** | A read-write element that controls the network scope from which an application can listen for traffic. This property is retrieved through the HNetCfg.FwAuthorizedApplication COM Object. |

**Service**

The following table lists the scripting methods and properties used to access and configure a service that has been authorized to listen through Windows Firewall:

| Method or Property | Description |
|---|---|
| **_NewEnum** | Returns an object supporting IEnumVARIANT that can be used to iterate through all the services in a collection. This property is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |
| **Count** | A read-only element yielding the number of items in a collection of services. This property is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |
| **Customized** | A read-only element that indicates whether at least one of the ports associated with a service has been customized. This property is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |
| **Enabled** | A read-write element that accesses a Boolean value which is TRUE if all ports associated with the service are enabled. This property is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |
| **GloballyOpenPorts** | A read-only element that accesses the collection of globally-opened ports associated with a service. This property is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |
| **Item** | Returns a specified service if it is within a collection. This method is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |
| **Name** | A read-only element that accesses the friendly name of a service. This property is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |
| **RemoteAddresses** | Accesses the set of remote addresses from which a service can listen for traffic. This property is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |
| **Scope** | A read-write element that controls the network scope from which a service can listen. This property is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |
| **Services** | A read-only element that accesses the collection of services in a profile. This property is retrieved through the HNetCfg.FwMgr COM Object (**CurrentProfile** property or the **GetProfileByType** method). |
| **Type** | A read-only element that accesses the type of a service. This property is retrieved through the HNetCfg.FwMgr COM Object (**Services** property). |

For more information about Windows Firewall interfaces, see MSDN.

**Netsh Commands for Windows Firewall**

You can run these commands from the Windows Server 2003 family command prompt or from the command prompt for the **netsh firewall** context. For these commands to work at the Windows Server 2003 family command prompt, you must type **netsh firewall** before typing commands and parameters as they appear in the following syntax. There might be functional differences between **netsh** context commands on Windows 2000 and the Windows Server 2003 family.

You cannot use the **netsh firewall** commands to remotely configure Windows Firewall settings, and you cannot use the **dump** command to create a script based on the current Windows Firewall configuration.

To view help for a command at the command prompt, type the following:

*CommandName* **/?**

where *CommandName* is the name of the command.

- add allowedprogram
- add portopening
- delete allowedprogram
- delete portopening
- set allowedprogram
- set icmpsetting
- set logging
- set multicastbroadcastresponse
- set notifications
- set opmode
- set portopening
- set service
- show (all commands)

**add allowedprogram**

The **add allowedprogram** command is used to add a program-based exception.

**Syntax**

**add allowedprogram** [[**program** =] *path*] [[**name** =] *name*] [[**mode** =] {**ENABLE**|**DISABLE**}] [[**scope** =] {**ALL**|**SUBNET**|**CUSTOM**}] [[**addresses** =] *addresses*] [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}]

**Parameters**

**[[program =] *path*]**

Specifies the path and file name of a program to be added to the exceptions list. This is a required entry.

**[[name =] *name*]**

Specifies the name of a program to be added to the exceptions list. This is a required entry.

**[[mode =] {ENABLE|DISABLE}]**

Specifies whether to enable or disable a program. This is an optional entry.

- **ENABLE** - Allow through Windows Firewall (default).
- **DISABLE** - Do not allow through Windows Firewall.

**[[scope =] {ALL|SUBNET|CUSTOM}]**

Defines the set of limits on which computers (IP addresses) are allowed to send traffic through the specified program. This is an optional entry.

- **ALL** - Allow all traffic through Windows Firewall (default).
- **SUBNET** - Allow only local network (subnet) traffic through Windows Firewall.
- **CUSTOM** - Allow only specified traffic through Windows Firewall.

**[[addresses =] *addresses*]**
Specifies the custom scope addresses in the exceptions list. This is an optional entry.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**
Specifies the names of the profiles used to configure Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

**Remarks**
**scope** must be **CUSTOM** to specify **addresses**.

**Examples**
The following examples show how the **add allowedprogram** command and preceding parameters can be used to add a program-based exception:

**add allowedprogram** *C:\MyApp\MyApp.exe MyApp* **ENABLE**

**add allowedprogram** *C:\MyApp\MyApp.exe MyApp* **DISABLE**

**add allowedprogram** *C:\MyApp\MyApp.exe MyApp* **ENABLE CUSTOM** *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**add allowedprogram program** = *C:\MyApp\MyApp.exe* **name** = *MyApp* **mode** = **ENABLED**

**add allowedprogram program** = *C:\MyApp\MyApp.exe* **name** = *MyApp* **mode** = **DISABLE**

**add allowedprogram program** = *C:\MyApp\MyApp.exe* **name** = *MyApp* **mode** = **ENABLE scope** = **CUSTOM** *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**add portopening**
The **add portopening** command is used to create a port-based exception.

**Syntax**
**add portopening** [[**protocol** =] {**TCP**|**UDP**|**ALL**}] [[**port** =] **1**-**65535**] [[**name** =] *name*] [[**mode** =] {**ENABLE**|**DISABLE**}] [[**scope** =] {**ALL**|**SUBNET**|**CUSTOM**}] [[**addresses** =] *addresses*] [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}] [[**interface** =] *name*]

**Parameters**
**[[protocol =] {TCP|UDP|ALL}]**
Specifies the protocol of a port. The protocol must be TCP, UDP, or all. This is a required entry.

- **TCP** - Transmission Control Protocol (TCP).
- **UDP** - User Datagram Protocol (UDP).
- **ALL** - All protocols.

**[[port =] 1-65535]**
Specifies the port number. The port number must be between 1 and 65535, inclusive. This is a required entry.

**[[name =] *name*]**
Specifies the friendly name of a port to be added to the exceptions list. This descriptive name is used to represent the entry for Windows Firewall in Control Panel. This is a required entry.

**[[mode =] {ENABLE|DISABLE}]**
Specifies whether to enable or disable a port in the exceptions lists. This is an optional entry.

- **ENABLE** - Allow through Windows Firewall (default).
- **DISABLE** - Do not allow through Windows Firewall.

**[[scope =] {ALL|SUBNET|CUSTOM}]**
Defines the set of limits on which computers (IP addresses) are allowed to send traffic through the specified port. This is an optional entry.

- **ALL** - Allow all traffic through Windows Firewall (default).
- **SUBNET** - Allow only local network (subnet) traffic through Windows Firewall.
- **CUSTOM** - Allow only specified traffic through Windows Firewall.

**[[addresses =] *addresses*]**
Specifies the custom scope addresses in the exceptions list. This is an optional entry.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**
Specifies the names of the profiles used to configure Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

**[[interface =] *name*]**
Specifies the interface name. This is an optional entry.

**Remarks**
**profile** and **interface** cannot be specified together; **scope** and **interface** cannot be specified together. **scope** must be **CUSTOM** to specify **addresses**.

**Examples**
The following examples show how the **add portopening** command and preceding parameters can be used to create a port-based exception:

**add portopening TCP 80** *MyWebPort*

**add portopening UDP 500** *IKE* **ENABLE ALL**

**add portopening ALL 53** *DNS* **ENABLE CUSTOM** *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**add portopening protocol** = **TCP port** = **80name** = *MyWebPort*

**add portopening protocol** = **UDP port** = **500name** = *IKE* **mode** = **ENABLE scope** = **ALL**

**add portopening protocol** = **ALL port** = **53name** = *DNS* **mode** = **ENABLE scope** = **CUSTOM addresses** = *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**delete allowedprogram**
The **delete allowedprogram** command is used to delete an existing program-based exception.

#### Syntax

**delete allowedprogram** [[**program** =] *path* [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}]

#### Parameters

**[[program =] *path***

Specifies the path and file name of the program to be deleted from the exceptions list. This is a required entry.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**

Specifies the names of the profiles used for configuring Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

#### Examples

The following examples show how the **delete allowedprogram** command and preceding parameters can be used to delete an existing program-based exception:

**delete allowedprogram** *C:\MyApp\MyApp.exe*

**delete allowedprogram program** = *C:\MyApp\MyApp.exe*

#### delete portopening

The **delete portopening** command is used to delete a port-based exception.

#### Syntax

**delete portopening** [[**protocol** =] {**TCP**|**UDP**|**ALL**}] [[**port** =] **1**-**65535**] [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}] [[**interface** =] *name*]

#### Parameters

**[[protocol =] {TCP|UDP|ALL}]**

Specifies the protocol of the port to be deleted from the exceptions list. The protocol must be TCP, UDP, or all. This is a required entry.

- **TCP** - Transmission Control Protocol (TCP).
- **UDP** - User Datagram Protocol (UDP).
- **ALL** - All protocols.

**[[port =] 1-65535]**

Specifies the number of the port to be deleted from the exceptions list. The port number must be between 1 and 65535, inclusive. This is a required entry.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**

Specifies the names of the profiles used for configuring Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

**[[interface =] *name*]**

Specifies the interface name. This is an optional entry.

**Remarks**
**profile** and **interface** cannot be specified together.

**Examples**
The following examples show how the **delete portopening** command and preceding parameters can be used to delete a port-based exception:

**delete portopening TCP 80**

**delete portopening UDP 500**

**delete portopening protocol** = **TCP port** = **80**

**delete portopening protocol** = **UDP port** = **500**

**set allowedprogram**
The **set allowedprogram** command is used to modify the settings of a program-based exception.

**Syntax**
**set allowedprogram** [[**program** =] *path*] [[**name** =] *name*] [[**mode** =] {**ENABLE**|**DISABLE**}] [[**scope** =] {**ALL**|**SUBNET**|**CUSTOM**}] [[**addresses** =] *addresses* [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}]

**Parameters**
**[[program =] *path*]**
Specifies the path and file name of a program to be added to the exceptions list. This is a required entry.

**[[name =] *name*]**
Specifies the name of a program to be added to the exceptions list. This is a required entry.

**[[mode =] {ENABLE|DISABLE}]**
Specifies whether to enable or disable a program. This is an optional entry.

- **ENABLE** - Allow through Windows Firewall (default).
- **DISABLE** - Do not allow through Windows Firewall.

**[[scope =] {ALL|SUBNET|CUSTOM}]**
Defines the set of limits on which computers (IP addresses) are allowed to send traffic through the specified program. This is an optional entry.

- **ALL** - Allow all traffic through Windows Firewall (default).
- **SUBNET** - Allow only local network (subnet) traffic through Windows Firewall.
- **CUSTOM** - Allow only specified traffic through Windows Firewall.

**[[addresses =] *addresses*]**
Specifies the custom scope addresses in the exceptions list. This is an optional entry.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**
Specifies the names of the profiles used to configure Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

**Remarks**
**scope** must be **CUSTOM** to specify **addresses**.

**Examples**

The following examples show how the **set allowedprogram** command and preceding parameters can be used to modify the settings of a program-based exception:

**set allowedprogram** *C:\MyApp\MyApp.exe MyApp* **ENABLE**

**set allowedprogram** *C:\MyApp\MyApp.exe MyApp* **DISABLE**

**set allowedprogram** *C:\MyApp\MyApp.exe MyApp* **ENABLE CUSTOM** *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**set allowedprogram program** = *C:\MyApp\MyApp.exe* **name** = *MyApp* **mode** = **ENABLED**

**set allowedprogram program** = *C:\MyApp\MyApp.exe* **name** = *MyApp* **mode** = **DISABLE**

**set allowedprogram program** = *C:\MyApp\MyApp.exe* **name** = *MyApp* **mode** = **ENABLE scope** = **CUSTOM** *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**set icmpsetting**

The **set icmpsetting** command is used to specify Internet Control Message Protocol (ICMP) traffic that has been added to the exceptions list.

**Syntax**

**set icmpsetting** [[**type** =] {**2**|**3**|**4**|**5**|**8**|**9**|**11**|**12**|**13**|**17**|**ALL**}] [[**mode** =] {**ENABLE**|**DISABLE**}] [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}] [[**interface** =] *name*]

**Parameters**

**[[type =] {2|3|4|5|8|9|11|12|13|17|ALL}]**

Specifies the type of ICMP message to enable. This is a required entry.

- **2** - Allow outbound packet too big.
- **3** - Allow outbound destination unreachable.
- **4** - Allow outbound source quench.
- **5** - Allow redirect.
- **8** - Allow inbound echo request.
- **9** - Allow inbound router request.
- **11** - Allow outbound time exceeded.
- **12** - Allow outbound parameter problem.
- **13** - Allow inbound timestamp request.
- **17** - Allow inbound mask request.
- **ALL** - All types.

**[[mode =] {ENABLE|DISABLE}]**

Specifies whether to enable or disable the ICMP message type. This is an optional entry.

- **ENABLE** - Allow through Windows Firewall (default).
- **DISABLE** - Do not allow through Windows Firewall.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**

Specifies the names of the profiles used to configure Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

**[[interface =] *name*]**
Specifies the interface name. This is an optional entry.

**Remarks**
**profile** and **interface** cannot be specified together; **type 2** and **interface** cannot be specified together.

**Examples**
The following examples show how the **set icmpsetting** command and preceding parameters can be used to specify ICMP traffic that has been added to the exceptions list:

**set icmpsetting 8**

**set icmpsetting 8 ENABLE**

**set icmpsetting ALL DISABLE**

**set icmpsetting type** = **8**

**set icmpsetting type** = **8mode** = **ENABLE**

**set icmpsetting type** = **ALL mode** = **DISABLE**

**set logging**
The **set logging** command is used to specify Windows Firewall logging options.

**Syntax**
**set logging** [[**filelocation** =] *path*] [[**maxfilesize** =] **1**-**32767**] [[**droppedpackets** =] {**ENABLE**|**DISABLE**}] [[**connections** =] {**ENABLE**|**DISABLE**}]

**Parameters**
**[[filelocation =] *path*]**
Specifies the location and file name of the Windows Firewall log file. By default, the log file is named Pfirewall.log. This is a required entry.

**[[maxfilesize =] 1-32767]**
Specifies the maximum size (in kilobytes) of the Pfirewall.log file. This is an optional entry.

**[[droppedpackets =] {ENABLE|DISABLE}]**
Specifies whether to log dropped packets to the Pfirewall.log file. This is an optional entry.

- **ENABLE** - Log.
- **DISABLE** - Do not log.

**[[connections =] {ENABLE|DISABLE}]**
Specifies whether to log connections to the Pfirewall.log file. This is an optional entry.

- **ENABLE** - Log.
- **DISABLE** - Do not log.

**Remarks**
At least one parameter must be specified.

**Examples**

The following examples show how the **set logging** command and preceding parameters can be used to specify Windows Firewall logging options:

**set logging** *%windir%\pfirewall.log* **4096**

**set logging** *%windir%\pfirewall.log* **4096 ENABLE**

**set logging filelocation** = *%windir%\pfirewall.log* **maxfilesize** = **4096**

**set logging filelocation** = *%windir%\pfirewall.log* **maxfilesize** = **4096droppedpackets** = **ENABLE**

#### set multicastbroadcastresponse

The **set multicastbroadcastresponse** command is used to specify the unicast response to a multicast or broadcast request.

#### Syntax

**set multicastbroadcastresponse** [[**mode** =] {**ENABLE**|**DISABLE**}] [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}]

#### Parameters

**[[mode =] {ENABLE|DISABLE}]**

Specifies whether to enable or disable multicast and broadcast packets. This is a required entry.

- **ENABLE** - Allow responses to multicast/broadcast traffic through Windows Firewall.
- **DISABLE** - Do not allow responses to multicast/broadcast traffic through Windows Firewall.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**

Specifies the names of the profiles used to configure Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

#### Examples

The following examples show how the **set multicastbroadcastresponse** command and preceding parameters can be used to specify the unicast response to a multicast or broadcast request:

**set multicastbroadcastresponse ENABLE**

**set multicastbroadcastresponse DISABLE**

**set multicastbroadcastresponse mode** = **ENABLE**

**set multicastbroadcastresponse mode** = **DISABLE**

#### set notifications

The **set notifications** command is used to specify the behavior of Windows Firewall notifications.

#### Syntax

**set notifications** [[**mode** =] {**ENABLE**|**DISABLE**}] [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}]

#### Parameters

**[[mode =] {ENABLE|DISABLE}]**

Specifies whether to enable or disable notifications. This is a required entry.

**ENABLE** - Allow notifications from Windows Firewall.

**DISABLE** - Do not allow notifications from Windows Firewall.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**

Specifies the names of the profiles used to configure Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

**Examples**

The following examples show how the **set notifications** command and preceding parameters can be used to specify the behavior of Windows Firewall notifications:

**set notifications ENABLE**

**set notifications DISABLE**

**set notifications mode** = **ENABLE**

**set notifications mode** = **DISABLE**

**set opmode**

The **set opmode** command is used to specify the operating mode of Windows Firewall, either globally or for a specific connection (interface).

**Syntax**

**set opmode** [[**mode** =] {**ENABLE**|**DISABLE**}] [[**exceptions** =] {**ENABLE**|**DISABLE**}] [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}] [[**interface** =] *name*]

**Parameters**

**[[mode =] {ENABLE|DISABLE}]**

Specifies whether to enable or disable Windows Firewall. This is a required entry.

**ENABLE** - Enable Windows Firewall.

**DISABLE** - Disable Windows Firewall.

**[[exceptions =] {ENABLE|DISABLE}]**

Specifies whether to enable or disable the Windows Firewall exceptions list. This is a required entry.

**ENABLE** - Enable the Windows Firewall exceptions list.

**DISABLE** - Disable the Windows Firewall exceptions list.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**

Specifies the names of the profiles used to configure Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

**[[interface =] *name*]**

Interface name (optional).

**Remarks**

**profile** and **interface** cannot be specified together; **exceptions** and **interface** cannot be specified together.

**Examples**

The following examples show how the **set opmode** command and preceding parameters can be used to specify the operating mode of Windows Firewall:

**set opmode ENABLE**

**set opmode ENABLE DISABLE**

**set opmode mode** = **ENABLE**

**set opmode mode** = **ENABLE exceptions** = **DISABLE**

#### set portopening

The **set portopening** command is used to modify the settings of a port-based exception.

#### Syntax

**set portopening** [[**protocol** =] {**TCP**|**UDP**|**ALL**}] [[**port** =] **1**-**65535**] [[**name** =] *name*] [[**mode** =] {**ENABLE**|**DISABLE**}] [[**scope** =] {**ALL**|**SUBNET**|**CUSTOM**}] [[**addresses** =] *addresses*] [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}] [[**interface** =] *name*]

#### Parameters

**[[protocol =] {TCP|UDP|ALL}]**

Specifies the protocol of a port. The protocol must be TCP, UDP, or all. This is a required entry.

- **TCP** - Transmission Control Protocol (TCP).
- **UDP** - User Datagram Protocol (UDP).
- **ALL** - All protocols.

**[[port =] 1-65535]**

Specifies the port number. The port number must be between 1 and 65535, inclusive. This is a required entry.

**[[name =] *name*]**

Specifies the friendly name of a port to be added to the exceptions list. This descriptive name is used to represent the entry for Windows Firewall in Control Panel. This is a required entry.

**[[mode =] {ENABLE|DISABLE}]**

Specifies whether to enable or disable a port in the exceptions lists. This is an optional entry.

- **ENABLE** - Allow through Windows Firewall (default).
- **DISABLE** - Do not allow through Windows Firewall.

**[[scope =] {ALL|SUBNET|CUSTOM}]**

Defines the set of limits on which computers (IP addresses) are allowed to send traffic through the specified port. This is an optional entry.

- **ALL** - Allow all traffic through Windows Firewall (default).
- **SUBNET** - Allow only local network (subnet) traffic through Windows Firewall.
- **CUSTOM** - Allow only specified traffic through Windows Firewall.

**[[addresses =] *addresses*]**

Specifies the custom scope addresses in the exceptions list. This is an optional entry.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**

Specifies the names of the profiles used to configure Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.

- **ALL** - All profiles.

**[[interface =] *name*]**
Specifies the interface name. This is an optional entry.

**Remarks**
**profile** and **interface** cannot be specified together; **scope** and **interface** cannot be specified together. **scope** must be **CUSTOM** to specify **addresses**.

**Examples**
The following examples show how the **set portopening** command and preceding parameters can be used to modify the settings of a port-based exception:

**set portopening TCP 80** *MyWebPort*

**set portopening UDP 500** *IKE* **ENABLE ALL**

**set portopening ALL 53** *DNS* **ENABLE CUSTOM** *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**set portopening protocol** = **TCP port** = **80name** = *MyWebPort*

**set portopening protocol** = **UDP port** = **500name** = *IKE* **mode** = **ENABLE scope** = **ALL**

**set portopening protocol** = **ALL port** = **53name** = *DNS* **mode** = **ENABLE scope** = **CUSTOM addresses** = *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**set service**
The **set service** command is used to enable or disable the predefined file and printer sharing, remote administration, Remote Desktop, and UPnP exceptions.

**Syntax**
**set service** [[**type** =] {**FILEANDPRINT**|**REMOTEADMIN**|**REMOTEDESKTOP**|**UPNP**|**ALL**}] [[**mode** =] {**ENABLE**|**DISABLE**}] [[**scope** =] {**ALL**|**SUBNET**|**CUSTOM**}] [[**addresses** =] *addresses* [[**profile** =] {**CURRENT**|**DOMAIN**|**STANDARD**|**ALL**}]

**Parameters**
**[[type =] {FILEANDPRINT|REMOTEADMIN|REMOTEDESKTOP|UPNP|ALL}]**
Specifies the type of service to enable. This is a required entry.

**FILEANDPRINT** - File and printer sharing.

**REMOTEADMIN** - Remote administration.

**REMOTEDESKTOP** - Remote assistance and remote desktop.

**UPNP** - UPnP framework.

**ALL** - All types.

**[[mode =] {ENABLE|DISABLE}]**
Specifies whether to enable or disable a service. This is a required entry.

**ENABLE** - Allow through Windows Firewall (default).

**DISABLE** - Do not allow through Windows Firewall.

**[[scope =] {ALL|SUBNET|CUSTOM}]**
Defines the set of limits on which computers (IP addresses) are allowed to send traffic through the specified service. This is an optional entry.

- **ALL** - Allow all traffic through Windows Firewall (default).
- **SUBNET** - Allow only local network (subnet) traffic through Windows Firewall.
- **CUSTOM** - Allow only specified traffic through Windows Firewall.

**[[addresses =] *addresses***
Specifies the custom scope addresses in the exceptions list. This is an optional entry.

**[[profile =] {CURRENT|DOMAIN|STANDARD|ALL}]**
Specifies the names of the profiles used to configure Windows Firewall. This is an optional entry.

- **CURRENT** - Current profile (default).
- **DOMAIN** - Domain profile.
- **STANDARD** - Standard profile.
- **ALL** - All profiles.

**Remarks**
**scope** is ignored if **mode** is **DISABLE**. **scope** must be **CUSTOM** to specify **addresses**.

**Examples**
The following examples show how the **set service** command and preceding parameters can be used to enable or disable the predefined service exceptions:

**set service FILEANDPRINT**

**set service REMOTEADMIN ENABLE SUBNET**

**set service REMOTEDESKTOP ENABLE CUSTOM** *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**set service type** = **FILEANDPRINT**

**set service type** = **REMOTEADMIN mode** = **ENABLE scope** = **SUBNET**

**set service type** = **REMOTEDESKTOP mode** = **ENABLE scope** = **CUSTOM addresses** = *157.60.0.1,172.16.0.0/16,10.0.0.0/255.0.0.0*,LocalSubnet

**show (all commands)**
The following **show** commands are used to display the current configuration of Windows Firewall:

| Command | Description |
|---|---|
| **show allowedprogram** | Displays the programs that have been added to the exceptions list. |
| **show config** | Displays the local configuration information. |
| **show currentprofile** | Displays the current profile. |
| **show icmpsetting** | Displays the ICMP settings. |
| **show logging** | Displays the logging settings. |
| **show multicastbroadcastresponse** | Displays multicast or broadcast response settings. |
| **show notifications** | Displays the current settings for notifications. |
| **show opmode** | Displays the operational mode. |
| **show portopening** | Displays the ports that have been added to the exceptions list. |
| **show service** | Displays the services. |
| **show state** | Displays the current state information. |

**Remarks**
To use the **show** command parameter, [[**verbose** =] {**ENABLE**|**DISABLE**}], to display more detailed information about the configuration, set the parameter to **ENABLE**. Verbose mode is disabled by default.

**Examples**

**show state**

**show state verbose** = **ENABLE**

**Windows Firewall Log File and Security Log Settings**
Windows Firewall records event data in two locations: the Event Viewer security log and the Windows Firewall log file. Event Viewer security log entries provide a record of Windows Firewall configuration changes, startup status, and behavior. The Windows Firewall log file entries provide a record of network traffic events, such as dropped packets and successful connections. Neither of the logging mechanisms provides intrusion detection or security breach alerting.

**Security Log Entries**
Windows Firewall writes entries to the security log when a computer is started and when a program or system service attempts to listen for unsolicited incoming traffic but is blocked. These entries provide information about the status and configuration of Windows Firewall, including information about the applications and ports that permit traffic through Windows Firewall. These entries also provide information about which ports and protocols a program or system services is trying to use so you can configure the necessary exceptions in Windows Firewall. These security log entries are viewed with Event Viewer, which can filter the entries by Event IDs. The Event IDs associated with Windows Firewall are in the range of 848 through 861.

| **Note** |
|---|
| Windows Firewall events are written to the event log any time the Windows Firewall/Internet Connection Sharing service is running, even if Windows Firewall is turned off (disabled). |

The following table lists the Event IDs associated with Windows Firewall:

| Event ID | Description |
|---|---|
| 848 | Displays the startup configuration of Windows Firewall. |
| 849 | Displays an application exception configuration. |
| 850 | Displays a port exception configuration. |
| 851 | Displays a change made to the application exceptions list. |
| 852 | Displays a change made to the application exceptions list. |
| 853 | Displays a change made to the Windows Firewall operation mode. |
| 854 | Displays a change made to Windows Firewall logging settings. |
| 855 | Displays a change made to ICMP settings. |
| 856 | Displays a change made to the **Windows Firewall: Prohibit unicast response to multicast or broadcast requests** Group Policy setting. |
| 857 | Displays a change made to the remote administration setting. |
| 858 | Displays Windows Firewall Group Policy settings have been applied. |
| 859 | Displays Windows Firewall Group Policy settings have been removed. |
| 860 | Displays a change made to a profile. |
| 861 | Displays an application or service attempting to listen for incoming traffic. |

**Event ID 848**
The following table lists the entries associated with Event ID 848:

| Entry | Possible Values | Notes |
|---|---|---|
| **Group Policy applied** | Yes/No | Specifies whether Group Policy is applied. |

| | | |
|---|---|---|
| **Profile used** | Domain/Local | Specifies if the profile is from the domain or the local computer. |
| **Interface** | All interfaces/<interface name> | Specifies the network adapter (interface) to which the settings apply. |
| **Operational mode** | On/Off/On with no exceptions | Specifies which mode Windows Firewall is in. |
| **File and Printer Sharing** | Enabled/Disabled | Specifies whether File and Printer Sharing is enabled or disabled in the exceptions list. |
| **Remote Desktop** | Enabled/Disabled | Specifies whether Remote Desktop is enabled or disabled in the exceptions list. |
| **UPnP Framework** | Enabled/Disabled | Specifies whether UPnP is enabled or disabled in the exceptions list. |
| **Allow remote administration** | Enabled/Disabled | Specifies whether Remote Assistance is enabled or disabled in the exceptions list. |
| **Allow unicast responses to multicast/broadcast traffic** | Enabled/Disabled | Specifies whether Windows Firewall will allow unicast traffic that is in response to multicast or broadcast traffic through Windows Firewall. |
| **Log dropped packets** | Enabled/Disabled/"-" | Specifies the log file setting. |
| **Log successful connections** | Enabled/Disabled/"-" | Specifies the log file setting. |
| **Allow incoming echo request** | Enabled/Disabled/"-" | Specifies the ICMP setting. |
| **Allow incoming timestamp request** | Enabled/Disabled/"-" | Specifies the ICMP setting. |
| **Allow incoming mask request** | Enabled/Disabled/"-" | Specifies the ICMP setting. |
| **Allow incoming router request** | Enabled/Disabled/"-" | Specifies the ICMP setting. |
| **Allow outgoing destination unreachable** | Enabled/Disabled/"-" | Specifies the ICMP setting. |
| **Allow outgoing source quench** | Enabled/Disabled/"-" | Specifies the ICMP setting. |
| **Allow outgoing parameter problem** | Enabled/Disabled/"-" | Specifies the ICMP setting. |
| **Allow outgoing time exceeded** | Enabled/Disabled/"-" | Specifies the ICMP setting. |
| **Allow redirect** | Enabled/Disabled/"-" | Specifies the ICMP setting. |

| **Note** |
|---|
| The hyphen ("-") is used to indicate that this setting has not been configured. |

**Event ID 849**

The following table lists the entries associated with Event ID 849:

| Entry | Possible Values | Notes |
|---|---|---|
| **Policy origin** | Local Policy/Group Policy | Specifies whether the application was added to the exceptions list through local policies or domain-wide Group Policy. |

| | | |
|---|---|---|
| **Profile used** | Standard/Domain | Specifies the profile in which the application is listed as an exception. |
| **Name** | <file name> | Specifies the display name, if any, of the executable file. |
| **Path** | <path> | Specifies the path to the application. |
| **State** | Enabled/Disabled | Specifies whether the application is enabled or disabled in the exceptions list. |
| **Scope** | All interfaces/Local subnet/<custom scope> | Specifies the conditions under which the application is processed as an exception. |

**Event ID 850**

The following table lists the entries associated with Event ID 850:

| Entry | Possible Values | Notes |
|---|---|---|
| **Policy origin** | Local Policy/Group Policy | Specifies whether the port was added to the exceptions list through local policies or domain-wide Group Policy. |
| **Profile used** | Standard/Domain | Specifies the profile in which the port is listed as an exception. |
| **Interface** | All interfaces/<interface name> | Specifies the network adapter (interface) to which the settings apply. |
| **Name** | <name> | Specifies the name of the port. |
| **Port number** | <port number> | Specifies the number of the port. |
| **Protocol** | TCP/UDP | Specifies the protocol of the port. |
| **State** | Enabled/Disabled | Specifies whether the port is enabled or disabled in the exceptions list. |
| **Scope** | All interfaces/Local subnet/<custom scope> | Specifies the conditions under which the port is processed as an exception. |

**Event ID 851**

The following table lists the entries associated with Event ID 851:

| Entry | Possible Values | Notes |
|---|---|---|
| **Policy origin** | Local policy/Group Policy | Specifies whether the change was made through local policies or domain-wide Group Policy. |
| **Profile changed** | Standard/Domain | Specifies the profile in which the change occurred. |
| **Change type** | Add/Remove/Modify | Specifies whether the application was added or removed from the exceptions list, or whether exception list settings were modified for the application. |
| **New Settings: Name** | <name> | Specifies the new display name, if any, of the executable file. |
| **New Settings: Path** | <path> | Specifies the new path to the application. |
| **New Settings: State** | Enabled/Disabled | Specifies whether the application is currently enabled or disabled in the exceptions list. |

| | | |
|---|---|---|
| **New Settings: Scope** | All interfaces/Local subnet/<custom scope> | Specifies the new conditions under which the application is processed as an exception. |
| **Old Settings: Name** | <name> | Specifies the old display name, if any, of the executable file. |
| **Old Settings: Path** | <path> | Specifies the old path to the application. |
| **Old Settings: State** | Enabled/Disabled | Specifies whether the application was previously enabled or disabled in the exceptions list. |
| **Old Settings: Scope** | All interfaces/Local subnet/<custom scope> | Specifies the old conditions under which the application was processed as an exception. |

**Event ID 852**

The following table lists the entries associated with Event ID 852:

| Entry | Possible Values | Notes |
|---|---|---|
| **Policy origin** | Local policy/Group Policy | Specifies whether the change was made through local policies or domain-wide Group Policy. |
| **Profile changed** | Standard/Domain | Specifies the profile in which the change occurred. |
| **Change type** | Add/Remove/Modify | Specifies whether the port was added or removed from the exceptions list, or whether exception list settings were modified for the port. |
| **Interface** | All interfaces/<interface name> | Specifies the network adapter (interface) to which the settings apply. |
| **New Settings: Name** | <name> | Specifies the new name of the port. |
| **New Settings: Port number** | <port number> | Specifies the new number of the port. |
| **New Settings: Protocol** | TCP/UDP | Specifies the new protocol of the port. |
| **New Settings: State** | Enabled/Disabled | Specifies whether the port is enabled or disabled in the exceptions list. |
| **New Settings: Scope** | All interfaces/Local subnet/<custom scope> | Specifies the new conditions under which the port is processed as an exception. |
| **Old Settings: Name** | <name> | Specifies the old name of the port. |
| **Old Settings: Port number** | <port number> | Specifies the old number of the port. |
| **Old Settings: Protocol** | TCP/UDP | Specifies the old protocol of the port. |
| **Old Settings: State** | Enabled/Disabled | Specifies whether the port was previously enabled or disabled in the exceptions list. |

**Event ID 853**

The following table lists the entries associated with Event ID 853:

| Entry | Possible Values | Notes |
|---|---|---|
| **Policy origin** | Local policy/Group Policy | Specifies whether the change was made through local policies or domain-wide Group Policy. |
| **Profile changed** | Standard/Domain | Specifies the profile in which the change occurred. |
| **Interface** | All interfaces/interface name | Specifies the network adapter (interface) to which the new setting applies. |
| **New Setting: Operation mode** | On/On with no exceptions/Off | Specifies which mode Windows Firewall is in currently. |
| **Old Setting: Operation mode** | On/On with no exceptions/Off | Specifies which mode Windows Firewall was in previously. |

**Event ID 854**

The following table lists the entries associated with Event ID 854:

| Entry | Possible Values | Notes |
|---|---|---|
| **Policy origin** | Local policy/Group Policy | Specifies whether the change was made through local policies or domain-wide Group Policy. |
| **Profile changed** | Standard/Domain | Specifies the profile in which the change occurred. |
| **New Settings: Log dropped packets** | Enabled/Disabled/"-" | Specifies the new log file setting. |
| **New Settings: Log successful connections** | Enabled/Disabled/"-" | Specifies the new log file setting. |
| **Old Setting: Log dropped packets** | Enabled/Disabled/"-" | Specifies the old log file setting. |
| **Old Setting: Log successful connections** | Enabled/Disabled/"-" | Specifies the old log file setting. |

| **Note** |
|---|
| The hyphen ("-") is used to indicate that this setting has not been configured. |

**Event ID 855**

The following table lists the entries associated with Event ID 855:

| Entry | Possible Values | Notes |
|---|---|---|
| **Policy origin** | Local policy/Group Policy | Specifies whether the change was made through local policies or domain-wide Group Policy. |
| **Profile changed** | Standard/Domain | Specifies the profile in which the change occurred. |
| **Interface** | All interfaces/interface name | Specifies the network adapter (interface) to which the new setting applies. |
| **New Setting: Allow incoming echo request** | Enabled/Disabled/"-" | Specifies the new ICMP setting. |
| **New Setting: Allow incoming timestamp request** | Enabled/Disabled/"-" | Specifies the new ICMP setting. |

| | | |
|---|---|---|
| **New Setting: Allow incoming mask request** | Enabled/Disabled/"-" | Specifies the new ICMP setting. |
| **New Setting: Allow incoming router request** | Enabled/Disabled/"-" | Specifies the new ICMP setting. |
| **New Setting: Allow outgoing destination unreachable** | Enabled/Disabled/"-" | Specifies the new ICMP setting. |
| **New Setting: Allow outgoing source quench** | Enabled/Disabled/"-" | Specifies the new ICMP setting. |
| **New Setting: Allow outgoing parameter problem** | Enabled/Disabled/"-" | Specifies the new ICMP setting. |
| **New Setting: Allow outgoing time exceeded** | Enabled/Disabled/"-" | Specifies the new ICMP setting. |
| **New Setting: Allow redirect** | Enabled/Disabled/"-" | Specifies the new ICMP setting. |
| **Old Setting: Allow incoming echo request** | Enabled/Disabled/"-" | Specifies the old ICMP setting. |
| **Old Setting: Allow incoming timestamp request** | Enabled/Disabled/"-" | Specifies the old ICMP setting. |
| **Old Setting: Allow incoming mask request** | Enabled/Disabled/"-" | Specifies the old ICMP setting. |
| **Old Setting: Allow incoming router request** | Enabled/Disabled/"-" | Specifies the old ICMP setting. |
| **Old Setting: Allow outgoing destination unreachable** | Enabled/Disabled/"-" | Specifies the old ICMP setting. |
| **Old Setting: Allow outgoing source quench** | Enabled/Disabled/"-" | Specifies the old ICMP setting. |
| **Old Setting: Allow outgoing parameter problem** | Enabled/Disabled/"-" | Specifies the old ICMP setting. |
| **Old Setting: Allow outgoing time exceeded** | Enabled/Disabled/"-" | Specifies the old ICMP setting. |
| **Old Setting: Allow redirect** | Enabled/Disabled/"-" | Specifies the old ICMP setting. |

| **Note** |
|---|
| The hyphen ("-") is used to indicate that this setting has not been configured. |

**Event ID 856**

The following table lists the entries associated with Event ID 856:

| Entry | Possible Values | Notes |
|---|---|---|
| **Unicast response to multicast broadcasts is** | On/Off | Specifies whether the option is enabled or disabled. |

**Event ID 857**

The following table lists the entries associated with Event ID 857:

| Entry | Possible Values | Notes |
|---|---|---|

| | | |
|---|---|---|
| **Policy origin** | Local policy/Group policy | Specifies whether the change was made through local policies or domain-wide Group Policy. |
| **Profile changed** | Standard/Domain | Specifies the profile in which the change occurred. |
| **New setting: Allow remote administration** | Enabled/Disabled | Specifies whether the option is enabled or disabled. |
| **Old setting: Allow remote administration** | Enabled/Disabled | Specifies whether the option is enabled or disabled. |

**Event ID 858**

| **Note** |
|---|
| There are no entries associated with Event ID 858. |

**Event ID 859**

| **Note** |
|---|
| There are no entries associated with Event ID 859. |

**Event ID 860**

The following table lists the entries associated with Event ID 860:

| Entry | Possible Values | Notes |
|---|---|---|
| **Active profile** | Standard/Domain | Specifies if the profile has switched from standard to domain, or vice versa. |

**Event ID 861**

The following table lists the entries associated with Event ID 861:

| Entry | Possible Values | Notes |
|---|---|---|
| **Name** | <name> | Specifies the name of the application or service. |
| **Path** | <path> | Specifies the path to the application or service. |
| **Process identifier** | <process identifier> | Specifies the identifier (label) used to determine the process involved in the listening activity. |
| **User account** | <user account> | Specifies the user's account. |
| **User domain** | <user domain> | Specifies the user's domain. |
| **Service** | Yes/No | Specifies whether the listener is a service. |
| **RPC server** | Yes/No | Specifies whether the listener is on an RPC server. |
| **IP version** | IPv4/IPv6 | Specifies the IP version of the application or service. |
| **IP protocol** | TCP/UDP | Specifies the IP protocol being used by the application or service. |
| **Port number** | <port number> | Specifies the port being used by the application or service. |
| **Allowed** | Yes/No | Specifies if the application or service is allowed to listen for unsolicited incoming network traffic. |
| **User notified** | Yes/No | Specifies whether the user was notified of the listening activity. |

**Windows Firewall Log File Entries**

When the Windows Firewall log file is enabled, Windows Firewall generates a plaintext security log file (Pfirewall.log), which is found in %Windir%\pfirewall.log. The security log has two sections: the header and the body.

The following table lists the entries contained in the header:

| Item | Description | Example |
|---|---|---|
| #Version: | Displays which version of the Windows Firewall security log is installed. | 1.5 |
| #Software: | Displays the name of the security log. | Microsoft Windows Firewall |
| #Time: | Indicates that all of the timestamps in the log are in local time. | Local |
| #Fields: | Displays a static list of fields that are available for security log entries, if data is available. These fields are listed in the following table.<br><br>**Note** The hyphen (-) is used for fields for which no information is available. | src-ip |

The body is the report of information gathered about traffic or attempts to cross Windows Firewall. The body of the security log is a dynamic list; new entries appear at the bottom of the log.

The following table lists the information contained in the body of the log file:

| Item | Description | Example |
|---|---|---|
| Date | Displays the year, month, and day that the recorded transaction occurred. Dates are recorded in the format:<br><br>YYYY-MM-DD | 2001-01-27 |
| Time | Displays the hour, minute, and seconds at which the recorded transaction occurred. Times are recorded in the format:<br><br>HH:MM:SS | 21:36:59 |
| Action | Displays which operation was observed by Windows Firewall. The options available are OPEN, OPEN-INBOUND, CLOSE, DROP, and INFO-EVENTS-LOST. An INFO-EVENTS-LOST action indicates the number of events that occurred but were not recorded in the log. | OPEN |
| Protocol | Displays the protocol that was used for the communication. The options available are TCP, UDP, ICMP, and a protocol number for packets that are not TCP, UDP, or ICMP. | TCP |
| src-ip | Displays the source IP address (the IP address of the computer attempting to establish communications). | 192.168.0.1 |
| dst-ip | Displays the destination IP address of a communication attempt. | 192.168.0.1 |
| src-port | Displays the source port number of the sending computer. Only TCP and UDP display a valid src-port entry. All other protocols display a src-port entry of -. | 4039 |
| dst-port | Displays the port number of the destination computer. Only TCP and UDP display a valid dst-port entry. All other protocols display a dst-port entry of -. | 53 |
| size | Displays the packet size, in bytes. | 60 |

| | | |
|---|---|---|
| tcpflags | Displays the TCP control flags found in the TCP header of an IP packet:<br>• **A**ck Acknowledgment field significant<br>• **F**in No more data from sender<br>• **P**sh Push function<br>• **R**st Reset the connection<br>• **S**yn Synchronize sequence numbers<br><br>**U**rg Urgent Pointer field significant | FAP |
| tcpsyn | Displays the TCP sequence number in the packet. | 1315819770 |
| tcpack | Displays the TCP acknowledgement number in the packet. | 2515999782 |
| tcpwin | Displays the TCP window size, in bytes, in the packet. | 64240 |
| icmptype | Displays a number that represents the Type field of the ICMP message. | 8 |
| icmpcode | Displays a number that represents the Code field of the ICMP message. | 0 |
| info | Displays an information entry that depends on the type of action that occurred. For example, an INFO-EVENTS-LOST action will result in an entry of the number of events that occurred but were not recorded in the log from the time of the last occurrence of this event type. | 23 |
| Path | Displays the direction of the communication. The options available are SEND, RECEIVE, FORWARD, and UNKNOWN. | RECEIVE |

# Storage Technologies Collection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Storage Technologies Collection**
Much of the data stored on Microsoft Windows-based servers is critically important for the day-to-day activities in business organizations. Because it is important that employees are able to access and store data reliably, data storage and recovery are a concern for many IT managers. In response to the expanding needs for storage in distributed computing environments, Windows Server 2003 includes many storage technologies that are designed to help you store, access, and manage data on servers.

Storage technologies include the following components:

- File Services Technologies
- File Systems Technologies
- Disks and Volumes
- Storage Services Technologies

**File Services Technologies**
File services are the underlying technologies that enable file servers to share data within an organization. These essential services allow users to store and share data on servers across the network.

Windows Server 2003 offers a number of file server solutions, such as disk quotas, Shadow Copies for Shared Folders, Distributed File System (DFS), and File Replication service (FRS), for enhancing the manageability, scalability, and availability of file servers.

**File Systems Technologies**
A file system is the structure in which files are named, stored, and organized. Windows Server 2003 supports the following file systems: FAT16, FAT32, and NTFS. You can use any combination of these file systems on a hard disk, but each volume on a hard disk can use only one file system. By default, Windows Server 2003 uses the NTFS file system.

NTFS provides performance, reliability, and advanced features not found in any version of FAT. For example, NTFS includes built-in security features such as file and folder permissions and the Encrypting File System (EFS), which is the technology used to store encrypted files on NTFS volumes. NTFS also provides support for volumes up to 256 terabytes in size, support for disk quotas and compression, and support for mounted drives.

**Disks and Volumes**
Windows Server 2003 offers two types of disks for storing information about your server: basic and dynamic. Basic disks use the same disk structures as those used by the Microsoft MS-DOS operating system and all previous versions of Microsoft Windows. Dynamic disks were introduced in Windows 2000 and they provide features that basic disks do not, such as the ability to create volumes that span multiple disks, including fault-tolerant mirrored and RAID-5 volumes.

**Storage Services Technologies**
In response to the expanding needs for storage in distributed computing environments, Windows Server 2003 includes several storage technologies that are designed to help you store, access, and manage data on servers.

**Storage Technologies Scenarios**
This section describes some of the most common scenarios for using storage technologies.

**File Services Scenarios**
The following sections describe the scenarios in which organizations deploy file services in Windows Server 2003.

**DFS**
DFS is used in organizations that want to achieve the following goals:

- Provide an intuitive way for users to access multiple file servers throughout the organization.

- Make data on multiple file servers appear as though it were available on a single file server.
- Make data available in multiple sites so that users in each site use fast, inexpensive bandwidth to access the data.
- Reduce delays that occur when users access heavily used shared folders.
- Provide fault-tolerant access to shared folders.
- Consolidate file servers or migrate data without affecting how users locate data.

**Disk Quotas**
Disk quotas are used in organizations that want to achieve the following goals:

- Limit the amount of data that users can store on a particular volume.
- Monitor how much disk space each user is using.

**FRS**
FRS is used in organizations that want to achieve the following goals:

- Ensure data availability if a file server fails or is taken offline for maintenance.
- Make data available in multiple sites to provide inexpensive access to users within each site.

**Shadow Copies for Shared Folders**
Shadow Copies for Shared Folders is used in organizations that want to achieve the following goals:

- Provide access to previous versions of files on the file server.
- Reduce the cost associated with restoring files for users.

**File Systems Scenarios**
**FAT or FAT32 file systems**
The FAT and FAT32 file systems are used in organizations that want to achieve the following goals:

- Provide compatibility with older operating systems, such as Windows 98.
- Provide a way to switch between different versions of the Windows operating system on the same computer by using a dual-boot configuration.

**NTFS file system**
The NTFS file system is used in organizations that want to achieve the following goals:

- Keep files secure. The NTFS file system is more secure than either FAT or FAT32.
- Use the advanced features provided by NTFS, such as disk quotas, file and folder permissions, encryption, large volume support, and sparse file management.

**Disk and Volume Scenarios**
The following sections describe the scenarios in which organizations use basic and dynamic disks and volumes in Windows Server 2003.

**Basic disks and volumes**
Basic disks and volumes are used in organizations that want to achieve the following goals:

- Provide simple data storage.

- Provide separate volumes for operating system and business data so that when a new version of the operating system is released, the boot or system volume can be reformatted and a new operating system installed, leaving the business data, located on the second volume, untouched.

- Provide separate volumes that are individually secured to limit access to specific, authorized users.

**Dynamic disks and volumes**
Dynamic disks and volumes are used in organizations that want to achieve the following goals:

- Increase the size of an existing disk by extending it onto a second disk.

- Increase the speed at which data is read and written.

- Provide fault-tolerance for business critical data that will be read more often than it is written by creating a RAID-5 volume.

- Provide good write performance with fault-tolerance for business critical data by creating a mirrored volume.

- Provide a way to easily move data from a smaller disk to a larger disk in the same computer by using a mirrored volume.

**Storage Services Scenarios**
The following sections describe the scenarios in which organizations use storage services technologies in Windows Server 2003.

**Virtual Disk Service Scenarios**
The Virtual Disk Service is used in organizations that want to achieve the following goals:

- Manage LUNs on diverse hardware storage devices.

- Manage disks and volumes.

- Manage end-to-end storage operations.

**Removable Storage Scenarios**
Removable Storage is used in organizations that want to achieve the following goals:

- Manage stand-alone drive libraries.

- Manage automated libraries.

**Remote Storage Scenarios**
Remote Storage is used in organizations that want to achieve the following goals:

- Conserve disk space on managed volumes.

- Extend disk space on managed volumes.

- Generate multiple media copies of removable media.

- Replace damaged removable media while Remote Storage is running.

- Recover from loss of Remote Storage metadata.

# File Services Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

File services are the underlying technologies that enable file servers to share data within an organization. File servers running basic services, such as folder sharing and permissions, are easy to set up, but many organizations require a higher level of manageability, scalability, and availability for their file servers. The Microsoft Windows Server 2003 operating system provides files services such as Distributed File System (DFS), disk quotas, File Replication Service (FRS), and Shadow Copies for Shared Folders to help organizations meet these needs.

For information about File and Storage Services in Windows Server 2012, see File and Storage Services Overview. For information about File Services in Windows Server 2008 R2, see File Services for Windows Server 2008 R2.

**File Services Components**
File Services technologies include the following components.

**DFS**
A DFS namespace links together shared folders on different servers to create a hierarchical structure that behaves like a single high-capacity hard disk. Users can navigate the namespace without having to know the physical server names or shared folders that host the data. DFS also provides increased availability, storage scalability, load sharing, and simplified maintenance.

**Disk Quotas**
Windows Server 2003 provides disk quota functionality that tracks quotas on a per-user, per-volume basis. After you enable the warning level and limit, they apply to all users who own files stored on the volume. Any user who creates a new file is automatically assigned the current warning level and limit.

**FRS**
FRS is a multimaster replication service used to replicate files and folders in the SYSVOL shared folder on domain controllers and in DFS shared folders. FRS works by detecting changes to file and folders in a replica set, and then replicating those changes to other replica members, which are connected in a replication topology. Because FRS is a multimaster replication service, any member of a replica set can generate changes. In addition, FRS can resolve file and folder conflicts to make data consistent among the replica members.

**Shadow Copies for Shared Folders**
Shadow Copies for Shared Folders provides point-in-time copies of files that are located on file servers. With Shadow Copies for Shared Folders, users can quickly recover deleted or changed files stored on the network without administrator assistance, increasing productivity and reducing administrative costs.

**File Services Scenarios**
The following sections describe the scenarios in which organizations deploy file services in Windows Server 2003.

**DFS**
DFS is used in organizations that want to achieve the following goals:

- Provide an intuitive way for users to access multiple file servers throughout the organization.
- Make data on multiple file servers appear as though it were available on a single file server.
- Make data available in multiple sites so that users in each site use fast, inexpensive bandwidth to access the data.
- Reduce delays that occur when users access heavily used shared folders.
- Provide fault-tolerant access to shared folders.
- Consolidate file servers or migrate data without affecting how users locate data.

**Disk Quotas**
Disk quotas are used in organizations that want to achieve the following goals:

- Limit the amount of data that users can store on a particular volume.
- Monitor how much disk space each user is using.

**FRS**

FRS is used in organizations that want to achieve the following goals:

- Ensure data availability if a file server fails or is taken offline for maintenance.
- Make data available in multiple sites to provide inexpensive access to users within each site.

**Shadow Copies for Shared Folders**

Shadow Copies for Shared Folders is used in organizations that want to achieve the following goals:

- Provide access to previous versions of files on the file server.
- Reduce the cost associated with restoring files for users.

# Disk Quotas Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Disk Quotas Technical Reference**
Disk quotas track and control disk space usage for NTFS volumes, allowing administrators to control the amount of data that each user can store on a specific NTFS volume. By using disk quotas, you can configure Microsoft Windows Server 2003 to do the following:

- Log an event when a user exceeds a specified disk space warning level. The warning level specifies the point at which a user is nearing the quota limit.
- Prevent further use of disk space or log an event when a user exceeds a specified disk space limit.

Disk quotas are not available for FAT volumes.

# What Are Disk Quotas?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Common Core Scenarios for Using Disk Quotas
- Dependencies on Other Technologies
- Related Information

Disk quotas track and control disk space usage for NTFS volumes, allowing administrators to control the amount of data that each user can store on a specific NTFS volume. By using disk quotas, you can configure Microsoft Windows Server 2003 to do the following:

- Log an event when a user exceeds a specified disk space warning level. The warning level specifies the point at which a user is nearing the quota limit.
- Prevent further use of disk space or log an event when a user exceeds a specified disk space limit.

If users are sharing file disk space on a server, they can consume considerable disk space when saving documents, graphics, and other files. This can be problematic if some users need to use more disk space than other users, resulting in some users not having enough disk space to store their files on the volume.

An administrator can solve this problem by enacting a Group Policy or a computer policy that limits the amount of disk space each user has on the volume. The administrator can also adjust quotas to the user's needs because user's are tracked on a per-user basis, per-volume.

**Common Core Scenarios for Using Disk Quotas**
Disk quotas can be used in several ways, depending on the needs and resources of your organization.

**Limited number of servers**
When you have a limited number of file servers and applications installed on those servers, you can use disk quotas to track disk usage. If you have a large number of users accessing a small group of file servers, you can set disk quotas to allocate the amount of space each user is allowed on a particular server. The disk quotas apply to all users whether they are local or remote users of the server.

**Limited space on a server volume**
When you have limited space on a server volume with multiple local and remote users accessing applications on that volume, you can set a specific amount of hard disk space for each user by enabling disk quotas.

**Monitoring but not limiting disk space usage**
If you have plenty of disk space on a volume, as well as enough servers in your organization, you might not want to enforce disk quotas. However, by enabling disk quotas, you can monitor the disk space usage of each user without restricting any user from accessing additional space when a limit is reached. You can then adjust the quota according to the demands of the job. Later, you can increase or decrease allocated space as necessary.

**Dependencies on Other Technologies**
Disk quotas rely on the following technologies:

**NTFS**
The server volume must be formatted as NTFS. Disk quotas do not work on FAT volumes.

**Active Directory**
The Active Directory directory Service is required if you want to set a Group Policy for a computer or for a group of users. You must be the system administrator in the domain in which the server resides. Disk Quotas obtains a list of the user account names from the domain controller or from Local Users and Groups in the Computer Management console.

**Group Policy**

Using Group Policy you can create and apply a disk quota policy setting to a set of targeted users and computers in an Active Directory environment.

The following figure, "Relationship of Disk Quotas to Other Windows Server 2003 Technologies," shows the relationship of disk quotas to other technologies in Windows Server 2003.

**Relationship of Disk Quotas to Other Windows Server 2003 Technologies**

In the preceding diagram, "Relationship of Disk Quotas to Other Windows Server 2003 Technologies," an administrator accesses an NTFS volume on a server running Windows Server 2003 to set disk quotas. When the administrator uses Disk Management to set disk quotas, Active Directory returns a list of users in the domain. Based on the names in the list, the administrator can create a disk quota Group Policy or computer policy for each user on that particular NTFS volume, regardless of where the user is located.

# How Disk Quotas Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Disk Quota Architecture**

The following figure, "Disk Quota Architecture," shows the architecture of disk quotas on an NTFS volume.

**Disk Quota Architecture**

The following table, "Components of Disk Quota Architecture," describes the components of the preceding figure, "Disk Quota Architecture."

**Components of Disk Quota Architecture**

| Architecture Component | Description |
|---|---|
| Active Directory Domain | Domain where the NTFS volume must reside. Disk quotas are based on all users within the domain. |
| Administrator Interface | Volume Quota Property Page user interface where administrators set Group Policy for disk quotas on an NTFS volume. |
| User Policy | Applies disk quota Group Policy at the computer or user level for the NTFS volume. Group Policy is determined by the users and groups in the Active Directory domain account. |
| Dskquota.dll | Implements the disk quota Group Policy on the client side. The dll is loaded when the client computer processes the policy. |
| Dskquoui.dll | Implements the user interface associated with managing disk quotas. |
| System Log | Records an audit entry whenever disk quota events occur, such as a user approaching a limit. |
| Quota Settings | Disk quota settings enabled by the administrator. |
| Volume Quota Property Page | User interface page allowing administrators to set and manage disk quotas. |
| Ntioapi_h | Windows Server 2003 header file identifying NT systems. The header includes functions for setting disk quotas and querying volumes for disk quotas. |
| NtQueryQuotaInformationFile | Function declared in ntioapi_h. Sets information for users on the volume. |

| | |
|---|---|
| NtSetQuotaInformationFile | Function declared in ntioapi_h. Queries quota information for users on the volume. |
| NtQueryVolumeInformationFile | Function declared in ntioapi_h. Queries the volume quota information to determine if quotas are enabled. |
| NtSetVolumeInformationFile | Function declared in ntioapi_h. Identifies the volume ID. Sets volume quota information. |
| Registry | System-defined database in which information and configuration data for disk quotas is stored. |
| Security Identifier | A variable-length number that uniquely identifies a user in a domain. |
| User File | File owned by a user saving the file to the local NTFS volume. |

When a user saves a file to a share on an NTFS volume, dskquota.dll accesses Group Policy to determine what, if any, disk quotas are applicable. Group Policy checks the user's name from a list of user names in the domain to determine if that user is a member of the domain.

A user who is an administrator and wants to set disk quotas can do so by using Disk Management in the Computer Management console. When this is done, dskquota.dll recognizes that the administrator is logged on. Dskquota.dll calls dskquoui.dll and opens the Volume Quota Property Page, allowing the administrator to create and administer disk quotas. A list of user names and associated security identifiers (SIDs) are provided to the administrator from the domain controller. After a disk quota policy is created, modified, and saved, it is written to the registry. Policy data is applied to the user of the NTFS volume and to a user's SID. Each file a user saves to a volume has an associated SID that identifies that file with the user. The SID in the file is then compared to the SID of the user from the Group Policy.

If the user is a member of the domain, Group Policy determines if disk quotas are enabled. If the user is approaching the disk quota limit, an event is written to the System log. If enforcement is enabled, the administrator can access the System log to determine what follow-up actions to take, such as preventing the user from accessing more disk space or allocating additional disk space to the user. A user who has not reached the warning level or disk quota limit can save the file to the local NTFS volume.

#### Disk Quota Interfaces

Disk quota relies on several disk management interfaces to correctly process disk quota control and logging of events. The following table, "Disk Quota Management Interfaces," lists the interfaces used in setting and managing disk quotas on an NTFS volume.

**Disk Quota Management Interfaces**

| Disk Management Interface | Description |
|---|---|
| IDiskQuotaControl | Controls disk quota facilities of an NTFS volume. |
| IDiskQuotaEvents | Calls by the system whenever significant quota events occur. |
| IDiskQuotaUser | Represents single user quota entry in the volume quota information file. |
| IDiskQuotaBatch | Enables the administrator to add multiple quota user objects to a container. |
| IEnumDiskQuotaUsers | Enumerates user quota entries on the volume. |
| IUnknown | Provides pointers to other interfaces in any given object. |
| WMI | Windows Management Instrumentation. Enables identification and manipulation of objects. |

**Disk Quota Interface**

When the Component Object Model (COM) accesses disk quotas, the IUnknown pointer is invoked. IUnknown has no functions for disk quota operations, so it calls QueryInterface to ask an object for an interface by which the disk quota operations can be invoked. WMI is then used to access the five-disk quota interfaces.

**Disk Quota Physical Structure**

The following figure, "Disk Quota Physical Structure," shows the physical structure of the environment in which disk quotas are used.

**Disk Quota Physical Structure**

**Disk Quota Physical Structure Components**

| Component | Description |
|---|---|
| Domain Controller | A server in an Active Directory domain running Windows Server 2003 that manages security for a domain. The domain controller must be in the same domain as the domain users. |
| Domain Users | All users in the domain who have access to the NTFS volume. Users must be in the same domain as the domain controller and the NTFS volume, and can be local or remote. |
| Disk Quota Policy | Applies disk quota policy at the computer or user level for the NTFS volume. The policy is determined for the users and groups in the Active Directory domain account. |
| NTFS Volume | NTFS-formatted volume. The volume can be a separate server from the domain controller, or be a partition on the domain controller. |
| User Accounts | A list of users in the domain, provided by the domain controller |

In an Active Directory domain, when an NTFS volume is accessed by a domain user, Group Policy applies any disk quotas to

those users if the administrator has enabled disk quotas. If a user is saving a file to the NTFS volume, Group Policy determines if disk quotas are enabled for the user. Disk quotas check the list of names against the names provided by the domain controller of the domain to determine if disk quotas are applicable to the user. If they are, disk quotas can do any of the following:

- Allow the user to save the file to the NTFS volume
- Prevent a user who has reached the quota from writing to the volume
- Allow a user who has reached the quota to write to the volume.
- Warn the user that the disk quota limit has been reached.

**Disk Quota Processes and Interactions**

Disk quotas are depend on NTFS. The information in the following sections discuss how Active Directory domains are used to provide information to set and store disk quotas, as well as how NTFS tracks disk quotas, and how disk quotas can be transferred from one volume to another.

Disk quotas are tracked on a per-user, per-volume basis; users are charged only for the files they own. Quotas are tracked per volume, even if the hard disk contains multiple volumes. If multiple shared folders are on the same volume, the quotas apply to all shared folders equally, and a user's total use of all shared folders cannot exceed the assigned quota on that volume.

**Setting Disk Quotas**

The Disk Management snap-in in the Computer Management console allows an administrator to set a disk quota Group Policy. Dskquota.dll recognizes an administrator who logs on and opens the Computer Management console. The administrator is provided with a list of names from the domain controller. These names are then matched to the security identifier (SID) for current volume users, and the administrator is allowed to enable disk quotas. The administrator can set a policy that controls the use of a computer, domain, or site to enable quota management on individual volumes. The policy is applied to local or remote users as long as the users are located within the same domain as the NTFS volume. At the same time, the administrator can register an event for when a disk quota is reached by a user, such as simply warning the user that a limit has been reached, or preventing the user from saving additional files to the volume.

Enforcement of the user or computer policy is optional. When users reach an enforced disk quota limit, the system responds as though the physical space on the volume were exhausted. When users reach an unenforced limit they can continue to write to the volume as long as physical space is available, but an event is logged to the System log.

**Storing Disk Quotas on a Volume**

NTFS volumes contain a master file table (MFT), which stores information about all of the files on the volume. Within the MFT are metadata files of attributes of files on the volume.

One of the file attributes of the MFT is $Extend metadata record, one function of which is storing disk quota information for a file. The $Extend attribute is further defined by $Quota. When disk quotas are enabled, NTFS uses a Quota bit in the Standard Information file record attribute, and copies the file size to the Standard Information attribute. Because the attribute is considered a resident attribute, an attribute which can fit within the MFT file record for that file, the MFTcan quickly scan the record to determine the quota assigned to a user.

Disk quotas are stored in the $Quota metadata record. $Quota uses two indexes, $O and $Q. The first index, $O, indexes the owner of a file by the owner's SID. The second index, $Q, keeps track of the default quotas, thresholds, and quota attributes. When a user is assigned a quota or adds files to a volume with disk quotas enabled, the user's SID is added to the $O index then assigned an entry in the $Q index specifying the quota limit.

**Tracking File Sizes**

Disk quotas track the file size against the allocated disk file using the SID to look up the user's disk quota entry allowance.

SIDs are stored in a user's profile within the NTFS structure on the volume. The user's name is obtained from a list of names in the domain in which the volume resides. NTFS tracks the user's volume usage by tagging files and directories with the SID. When a user saves a file to the NTFS volume with disk quotas enabled, the SID in the file is resolved against the name in a cache file of stored SID names and quota information on the volume. When the file or directory is saved to the volume, the size of files and directories a user owns count against the set quota limit.

**Transferring Disk Quota Settings Between Volumes**

Transferring disk quotas between NTFS volumes saves an administrator from having to create identical disk quotas on multiple volumes.

When disk quotas are exported from one volume and imported on into another, disk quotas creates a transfer file, which is imported into another volume. The following figure, "Transferring Settings Between Volumes,"shows the information included in a Quota Settings Transfer file.

**Transferring Settings Between Volumes**

In the preceding figure,, the GUID contains a record for each user for whom the disk quotas policy applies. The SID is a unique structure that identifies the users or groups. cbSID identifies the size of the SID buffer. These settings are applied to an export file, and applied to a different volume when imported into that volume.

# Disk Quotas Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Disk Quota Tools
- Disk Quota Registry Entries
- Disk Quota Group Policy Settings
- Disk Quota WMI Classes
- Related Information

The following tools, registry settings, Group Policy settings, and Windows Management Instrumentation (WMI) classes are associated disk quotas on NTFS volumes.

**Disk Quota Tools**
Disk Quota Tools describes the tools installed with Microsoft Windows Server 2003 as well as downloadable support tools. The tools in this list are those used to create and maintain disk quotas on NTFS volumes.

**Dskmgmt.msc: Disk Management**
**Category**
Operating system tool.

**Version compatibility**
Runs on Windows Server 2003.

Use the Disk Management snap-in for MMC to set disk quota limits on NTFS-formatted volumes for Windows Server 2003.

**Dskuse.exe: User Disk Tool**
**Category**
Downloadable support tool.

**Version compatibility**
Runs on Windows Server 2003. Works on NTFS volumes only.

Scans a single directory, a directory tree, or an entire drive and reports the amount of space used by each user or all users.

To find more information about Dskuse, see "Resource Kit Tools" in Tools and Settings Collection

**Fsutil.exe: File Systems Utilities**
**Category**
Operating System tool.

**Version compatibility**
Windows Server 2003. Requires NTFS as the file system on the volume.

Perform file system tasks such as disabling long file names, checking whether a volume is flagged as dirty, viewing NTFS-related information about a volume, creating hard links, and managing quotas and sparse files.

To find more information about Fsutil, see "Command Line References" in Tools and Settings Collection.

**Disk Quotas Registry Entries**
The registry entries listed in this section are associated with file systems.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft

Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**DiskQuota**
The file registry entries for DiskQuota can be found under HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota.

**ApplyToRemovableMedia**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota

**Version**
Microsoft Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Extends the disk quota policies to NTFS file system volumes on removable media.

To find more information about this registry entry, see "Registry Reference" in Tools and Settings Collection.

**Enable**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota

**Version**
Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Enables and disables disk quota management on all NTFS file system volumes of the computer, and prevents users from changing disk quota settings.

To find more information about this registry entry, see "Registry Reference" in Tools and Settings Collection.

**Enforce**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota

**Version**
Windows NT 4.0 Server and Windows NTNT 4.0 Workstation and later.

Determines whether disk quota limits are enforced, and prevents users from changing the setting.

To find more information about this registry entry, see "Registry Reference" in Tools and Settings Collection.

**Limit**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota

**Version**
Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Specifies the number of units in the default disk quota limit for new users of an NTFS file system volume.

To find more information about this registry entry, see "Registry Reference" in Tools and Settings Collection.

**LimitUnits**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota

**Version**
Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Specifies the units used in the default disk quota limit for new users of an NTFS volume.

To find more information about this registry entry, see "Registry Reference" in Tools and Settings Collection.

**LogEventOverLimit**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota

**Version**
Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Determines whether the system records an event in the local Application Log when users reach the disk quota limit on a volume, and prevents users from changing the logging setting.

To find more information about *registry setting*, see "Registry Reference" in Tools and Settings Collection.

**LogEventOverThreshold**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota

**Version**
Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Determines whether the system records an event in the local Application Log when users reach the disk quota warning level, and prevents users from changing the logging setting.

To find more information about this registry entry, see "Registry Reference" in Tools and Settings Collection.

**Threshold**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota

**Version**
Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Specifies the number of units in the default disk quota warning level for new users of an NTFS volume.

To find more information about this registry entry, see "Registry Reference" in Tools and Settings Collection.

**ThresholdUnits**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows NT\DiskQuota

**Version**
Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Specifies the units for the default disk quota warning level for new users of an NTFS volume.

To find more information about this registry entry, see "Registry Reference" in Tools and Settings Collection.

**Disk Quotas Group Policy Settings**
The following table, "Group Policy Settings Associated with Disk Quotas," lists and describes the Group Policy settings that are associated with disk quotas.

**Group Policy Settings Associated with Disk Quotas**

| Group Policy Setting | Description |
|---|---|
| DiskQuotaEnable | Enables disk quotas on an NTFS volume. This policy is not used on FAT volumes. |
| DiskQuotaLimit | Specifies the disk quota limit and warning level. This policy is not used on FAT volumes. |
| DiskQuotaLogEventOverThreshold | Specifies whether an application log event is created when a user exceeds disk quota limit. This policy is not used on FAT volumes. |
| DiskQuotaApplyToRemovableMedia | Specifies whether disk quotas policies are applied to removable media. This policy is not used on FAT volumes. |

To find more information about Group Policy settings, see "Group Policy Settings Reference" in Tools and Settings Collection.

**Disk Quota WMI Classes**
The following table, "WMI Classes Associated with Disk Quotas," lists and describes the WMI classes that are associated with disk quotas.

**WMI Classes Associated with Disk Quotas**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_DiskQuota | //root/cimv2 | Windows XP and Windows Server 2003 |

| | | |
|---|---|---|
| Win32_QuotaSetting | //root/cimv2 | Windows XP and Windows Server 2003 |
| Win32_VolumeQuota | //root/cimv2 | Windows Server 2003 |
| Win32_VolumeQuotaSetting | //root/cimv2 | Windows XP and Windows Server 2003 |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Related Information**

The following resources contain additional information that is relevant to this section.

- For more information about NTFS, see the NTFS Technical Reference.

# DFS Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DFS Technical Reference**
Distributed File System (DFS) allows administrators to group shared folders located on different servers by transparently connecting them to one or more DFS namespaces. A DFS namespace is a virtual view of shared folders in an organization. Using the DFS tools, an administrator selects which shared folders to present in the namespace, designs the hierarchy in which those folders appear, and determines the names that the shared folders show in the namespace. When a user views the namespace, the folders appear to reside on a single, high-capacity hard disk. Users can navigate the folders in the namespace without needing to know the server names or shared folders hosting the data. DFS also provides many other benefits, including fault tolerance and load-sharing capabilities, making it ideal for all types of organizations.

# What Is DFS?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Common DFS Scenarios
- Technologies Related to DFS
- DFS Dependencies
- Related Information

One of the goals of most information technology (IT) groups is to manage file server resources efficiently while keeping them available and secure for users. As networks expand to include more users and servers—whether they are located in one site or in geographically distributed sites—administrators find it increasingly difficult to keep users connected to the files they need. On one hand, distributing resources across a network makes them more available to more people and promotes cross-organizational efforts. On the other hand, storing files on different file servers located throughout an organization makes it difficult for users to know where to look for information. Administrators also find it difficult to keep track of all the servers and all of the people who use those servers. The task of swapping out an old server becomes a major communication chore when users across an organization must be notified to update links and file paths.

To help administrators address these problems, Windows Server 2003 includes Distributed File System (DFS). DFS allows administrators to group shared folders located on different servers by transparently connecting them to one or more DFS namespaces. A DFS namespace is a virtual view of shared folders in an organization. Using the DFS tools, an administrator selects which shared folders to present in the namespace, designs the hierarchy in which those folders appear, and determines the names that the shared folders show in the namespace. When a user views the namespace, the folders appear to reside on a single, high-capacity hard disk. Users can navigate the namespace without needing to know the server names or shared folders hosting the data. DFS also provides other benefits, including the following:

**Simplified data migration**
DFS simplifies the process of moving data from one file server to another. Because users do not need to know the name of each physical server or shared folder that contains the data, administrators can physically move data to another server without needing to reconfigure applications and shortcuts and without needing to reeducate users about where they can find their data. This minimizes the impact of server consolidation on users. It also allows administrators to deploy additional file servers and present the folders on those new servers as new folders within an existing namespace.

**Increased availability of file server data**
In the event of a server failure, DFS refers client computers to the next available server, so users can always access shared folders without interruption.

**Load sharing**
DFS provides a degree of load sharing by mapping a given logical name to shared folders on multiple file servers. For example, suppose that \\Company\StockInfo is a heavily used shared folder. Administrators can use DFS to associate this location with multiple shared folders on different servers, even if the servers are located in different sites.

**Security integration**
Administrators do not need to configure additional security for DFS namespaces because file and folder security is enforced by existing the NTFS file system and shared folder permissions on each target. For example, a user navigating a DFS namespace is permitted to access only the files or folders for which he or she has appropriate NTFS or shared folder permissions.

**Common DFS Scenarios**
DFS is commonly used in the following scenarios:

**Server Consolidation**
Many organizations today are consolidating older file servers throughout the organization into fewer, larger, more powerful file servers. Consolidation reduces the cost of managing multiple file servers and increases the efficiency of storage allocation and backup tasks. Organizations that have implemented DFS can perform server consolidations without impacting the way users' access data. The following figure illustrates this benefit.

### How DFS Eliminates the Impact of Server Consolidation on Users

**Publishing Applications**

DFS is commonly used to publish applications to users throughout the organization. Using DFS in this scenario provides a number of benefits, such as the ability to use multiple servers to host application data and distribute the load across servers. A feature in DFS known as "least expensive target selection" ensures that users are connected to the closest server. The following figure illustrates a DFS namespace used to publish applications in an organization based in San Francisco with offices in Miami and Dallas.

### Using DFS to Publish Applications

This organization has three types of software:

- Business-critical software and operating systems that must be available at all times.
- Previous versions of software that are still in use in the Dallas branch office.
- Multimedia software used primarily in San Francisco.

The organization uses four servers to host the business-critical software and operating systems, including two servers in the San Francisco site. Using two servers to host the applications ensures that a failure on one server does not cause the data to become unavailable. All users can access this software at \\Software\Public\Applications, and users are automatically directed

to the server in their site (San Francisco, Dallas, or Miami).

Because the archived software is used only in the Dallas office and the data is not business-critical, only a single server hosts that data. The multimedia software is not business-critical, but the organization uses two servers for this software to improve server response times because the client portion of the multimedia software accesses files from the server.

**Increasing Data Availability**
As described in the scenario for publishing applications, administrators can use DFS to increase the availability of data by storing the data on multiple servers. DFS makes this process transparent by presenting to users what appears to be a single folder in the namespace. Administrators can use File Replication service (FRS) or some other replication method, such as the Windows Resource Kit Tool Robocopy, to keep the data synchronized on the servers. If one of the servers hosting data is unavailable, clients are referred to another server that hosts the data.

**Technologies Related to DFS**
File Replication service (FRS) can be used to keep data in DFS shared folders synchronized among servers. However, DFS and FRS are two separate technologies, and DFS does not require FRS. You can use other replication methods, such as manual copying, the Resource Kit Tool Robocopy, or other replication tools to keep DFS shared folders synchronized. Conversely, if you want to use FRS to keep data in shared folders synchronized, you must use DFS.

**DFS Dependencies**
DFS has the following dependencies:

- **Active Directory replication.** Domain-based DFS requires that Active Directory replication is working properly so that the DFS object resides on all domain controllers in the domain.

- **Server Message Block (SMB).** Clients must access DFS root servers by using the SMB protocol.

- **Remote Procedure Call (RPC) service and Remote Procedure Call Locater service.** The DFS tools use RPC to communicate with the DFS service running on DFS root servers.

- **Distributed File System service dependencies.** The Distributed File System service must be running on all DFS root servers and domain controllers so that DFS can work properly. This service depends on the following services:

    - The Server service, Workstation service, and Security Accounts Manager (SAM) service on DFS root servers. The Distributed File System service also requires an NTFS volume to store the physical components of DFS on root servers.

    - The Server service and Workstation service on domain controllers.

**Related Information**
The following resources contain additional information that is relevant to this section.

- FRS Technical Reference

- Resource Kit Tools in the Tools and Settings Collection for information about Robocopy.

# How DFS Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- DFS Terminology
- DFS Client and Server Compatibility
- Characteristics of Namespace Types
- DFS Architecture
- DFS Physical Structures and Caches
- DFS Processes and Interactions
- DFS Protocols
- DFS Interfaces
- Network Ports Used by DFS
- Related Information

Distributed File System (DFS) allows administrators to group shared folders located on different servers by transparently connecting them to one or more DFS namespaces. A DFS namespace is a virtual view of shared folders in an organization. Using the DFS tools, an administrator selects which shared folders to present in the namespace, designs the hierarchy in which those folders appear, and determines the names that the shared folders show in the namespace. When a user views the namespace, the folders appear to reside on a single, high-capacity hard disk. Users can navigate the namespace without needing to know the server names or shared folders hosting the data. DFS also provides many other benefits, including fault tolerance and load-sharing capabilities, making it ideal for all types of organizations. For more information about the scenarios in which DFS is commonly used, see "What Is DFS?".

For information about DFS on later versions of Windows Server, see DFS Namespaces and DFS Replication Overview.

These sections provide an in-depth view of how DFS works in an optimal environment. An optimal environment for DFS is defined as follows:

- Domain Name System (DNS) and Active Directory replication are working properly.
- Sites and site costs in Active Directory are configured properly.
- The domain controller acting as the primary domain controller (PDC) emulator is working properly.
- The Distributed File System (DFS) service is running on all domain controllers and root servers.
- Client computers are running one of the following operating systems: Windows NT 4.0 with Service Pack 6a, Windows 2000 with Service Pack 4 or later, Windows XP with Service Pack 1 or later, or Windows Server 2003.
- Client computers are properly joined to the domain.
- No firewalls block remote procedure call (RPC) ports used by DFS and the DFS root server that hosts DFS. These ports are described in "Network Ports Used by DFS" later in this section.
- The **Bridge all site links** option in Active Directory must be enabled. (This option is available in the Active Directory Sites and Services snap-in.) Turning off **Bridge all site links** can affect the ability of DFS to refer client computers to target computers that have the least expensive connection cost. An Intersite Topology Generator that is running Windows Server 2003 relies on the **Bridge all site links** option being enabled to generate the intersite cost matrix that DFS requires for its site-costing functionality.

If you turn off this option, you must create site links between the Active Directory sites for which you want DFS to calculate accurate site costs. Any sites that are not connected by site links will have the maximum possible cost. For more information about site link bridging, see "Active Directory Replication Topology Technical Reference."

- Windows 2000 domain controllers and Windows 2000 DFS root servers do not have the **restrictanonymous** registry entry set to 2. (This registry entry is located at HKEY_LOCAL_MACHINE/SYSTEM/CurrentControlSet/Control/Lsa.) For more information about this registry entry, see "DFS Client and Server Compatibility" and "How Site Discovery Works" later in this section.

#### DFS Terminology

Before you review the DFS components and processes, it is helpful to understand DFS terminology. The following sections provide terms and definitions, an illustration of DFS namespaces, and a brief description of the client and server roles in DFS.

#### DFS Terms and Definitions

The following terms are used to describe the basic components of DFS.

**DFS namespace**

A virtual view of shared folders on different servers as provided by DFS. A DFS namespace consists of a root and many links and targets. The namespace starts with a root that maps to one or more root targets. Below the root are links that map to their own targets.

**DFS link**

A component in a DFS path that lies below the root and maps to one or more link targets.

**DFS path**

Any Universal Naming Convention (UNC) path that starts with a DFS root.

**DFS root**

The starting point of the DFS namespace. The root is often used to refer to the namespace as a whole. A root maps to one or more root targets, each of which corresponds to a shared folder on a separate server. The DFS root must reside on an NTFS volume. A DFS root has one of the following formats: *ServerName**RootName* or *DomainName**RootName*.

**domain-based DFS namespace**

A DFS namespace that has configuration information stored in Active Directory. The path to access the root or a link starts with the host domain name. A domain-based DFS root can have multiple root targets, which offers fault tolerance and load sharing.

**link referral**

A type of referral that contains a list of link targets for a particular link.

**link target**

The mapping destination of a link. A link target can be any UNC path. For example, a link target could be a shared folder or another DFS path.

**referral**

A list of targets, transparent to the user, which a DFS client receives from DFS when the user is accessing a root or a link in the DFS namespace. The referral information is cached on the DFS client for a time period specified in the DFS configuration.

**root referral**

A type of referral that contains a list of root targets for a particular root.

**root target**

A physical server that hosts a DFS namespace. A domain-based DFS root can have multiple root targets, whereas a stand-alone DFS root can only have one root target. Root targets are also called root servers.

**stand-alone DFS namespace**

A DFS namespace whose configuration information is stored locally in the registry of the root server. The path to access the root or a link starts with the root server name. A stand-alone DFS root has only one root target. Stand-alone roots are not fault tolerant; when the root target is unavailable, the entire DFS namespace is inaccessible. You can make stand-alone DFS roots fault tolerant by creating them on server clusters.

#### DFS Namespaces Illustrated

The following figure illustrates a physical view of file servers and shared folders in the Contoso.com domain. Without a DFS

namespace in place, users need to know the names of six different file servers, and they need to know which shared folders reside on each file server.

**Example of Physical Servers and Shared Folders in Contoso.com**

When the IT group in Contoso.com implements DFS, they must first decide the type of namespace to implement. Windows Server 2003 offers two types of namespaces: stand-alone and domain-based. The IT group also chooses a root name, which is similar to the shared folder name in a Universal Naming Convention (UNC) path *ServerName**SharedFolderName*.

The following figure illustrates two namespaces as users would see them. Notice how the address format differs — one begins with a server name, Software, and the other begins with a domain name, Contoso.com. These differences illustrate the two types of roots: stand-alone roots, which begin with a server name, and domain-based roots, which begin with a domain name. Valid formats for domain names include *NetBIOSDomainName**RootName* and *DNSDomainName**RootName*.

**Examples of DFS Namespaces**

A root can have one or more root targets. A root target, also known as a root server, is a physical server that hosts a namespace. A domain-based root can have multiple root servers to provide redundancy and high availability, whereas a stand-alone root can only have one root server. (Stand-alone roots created on server clusters provide high availability.) Root servers are transparent to users, who see only a single folder, whereas administrators can view the physical root servers by using the Distributed File System snap-in, the Dfscmd.exe command-line tool, or the Dfsutil.exe command-line tool (available as part of the Windows Support Tools). The following figure illustrates roots and root servers.

**Roots and Root Servers**

Below the root, administrators can create multiple links. For example, if an administrator creates a link named Templates, users browsing the domain-based namespace shown above would see the path \\Contoso.com\Public\Templates. If an administrator wants to create a deeper hierarchy in the namespace, the administrator can use subfolder names in the link name, such as Templates\Presentations or Templates\Specs. Users who browse the namespace would see \\Contoso.com\Public\Templates. If the user opens the Templates folder, the user would see two subfolders: Presentations and Specs.

Each link can correspond to one or more link targets. A link target can be any UNC path. For example, a link target could be a shared folder (such as \\NOAMFS3\Users), a folder underneath a shared folder, or a path to another DFS namespace (such as \\Contoso.com\Public\Users). Link targets are transparent to users but are visible to administrators by using the DFS tools.

**Overview of Client and Server Roles in DFS**

In addition to understanding the namespace components (roots, root targets, links, and link targets), it is also helpful to understand the client and server roles involved in DFS. The following sections summarize client and server roles in DFS. These roles are described in more detail later in this document.

**DFS clients**

DFS clients are the computers used to access namespaces. DFS clients are typically end-user computers; computers running Windows-

based server operating systems can also access namespaces. DFS clients in this section are assumed to run one of the operating systems described in "DFS Client and Server Compatibility" later in this section.

**Domain controllers**
Domain controllers play numerous roles in DFS:

- DFS clients access domain controllers to get a list of trusted domains and domain controllers for those domains.
- When a DFS client first attempts to access a domain-based namespace, a domain controller provides a list of root servers to the client. This list of root servers is known as a root referral.
- Domain controllers store DFS metadata in Active Directory about domain-based namespaces. DFS metadata consists of information about entire namespace, including the root, root targets, links, link targets, and settings. By default, root servers that host domain-based namespaces periodically poll the domain controller acting as the primary domain controller (PDC) emulator master to obtain an updated version of the DFS metadata and store this metadata in memory.
- Whenever an administrator makes a change to a domain-based namespace, the change is made on the domain controller acting as the PDC emulator master and is then replicated (via Active Directory replication) to other domain controllers in the domain.
- Domain controllers acting as the Intersite Topology Generator generate site cost information. This information describes the relative cost of the connection between two sites. DFS uses this information to sort targets in order of lowest cost in referrals when least-expensive target selection is enabled.

**Root servers**
Root servers (also called root targets) are the servers on which administrators create stand-alone and domain-based namespaces. A root server can be a member server or a domain controller. Root servers play the following roles in DFS:

- For stand-alone namespaces, the DFS metadata is stored in the registry of the root server. For domain-based namespaces, DFS metadata is stored in Active Directory. Root servers also keep the DFS metadata for each namespace in a memory cache.
- Root servers host shared folders that act as the root (known as the root folder) and subfolders (under the root folders) that correspond to every link (known as link folders) in those namespaces.
- When a client attempts to access a root or link in a stand-alone namespace, or a link in a domain-based namespace, the root server provides a referral to the client.

**Link targets**
Link targets are typically shared folders or folders within shared folders. Link targets can be served by any network file system that is accessible by a UNC path, such as Server Message Block (SMB), NetWare Core Protocol (NCP) for NetWare, or Network File System (NFS) for UNIX. (The client computers must have the appropriate redirector installed to access link targets.) The UNC path can lead to shared folders in any workgroup, shared folders within the same domain as the namespace, shared folders in trusted domains, and shared folders in trusted forests.

Shared folders that are specified as link targets have no special settings that indicate that they are part of a DFS namespace. All existing shared folder permissions and NTFS permissions on the shared folder still apply when users access the shared folder through the namespace.

A link target can also be a DFS path in another namespace. For example, the Software link in \\Contoso.com\Public\Software might have a link target of \\Software\Public, which is a root within a stand-alone namespace. When using DFS paths as link targets, it is important to ensure that client failover works correctly. For more information, see "Linking to Different DFS Namespaces" later in this section.

**DFS Client and Server Compatibility**
The following table describes the types of clients and servers that can act as DFS clients, root servers, and link targets.

### DFS Compatibility

| Platform | Act As DFS Clients? | Act As a Root Server? | Act As a Link Target? |
|---|---|---|---|

| | | | |
|---|---|---|---|
| Microsoft Windows Server 2003, Web Edition | Yes | Yes<br><br>Can host one stand-alone namespace or one domain-based namespace per server. | Yes |
| Windows Server 2003, Standard Edition | Yes | Yes<br><br>Can host one stand-alone namespace or one domain-based namespace per server. | Yes |
| Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition | Yes | Yes<br><br>Can host multiple stand-alone namespaces and multiple domain-based namespaces per server. | Yes |
| Windows Storage Server 2003 | Yes | Yes<br><br>Can host multiple stand-alone namespaces and multiple domain-based namespaces per server. | Yes |
| Windows XP | Yes | No | Yes |
| Windows Preinstallation Environment (WinPE) | Yes<br><br>Can access stand-alone namespaces but cannot access domain-based namespaces. | No | No |
| Windows 2000 Server family | Yes | Yes<br><br>Can host one stand-alone namespace or domain-based namespace per server. | Yes |
| Windows 2000 Professional | Yes | No | Yes |
| Windows NT Server 4.0 with Service Pack 6a | Yes | Yes<br><br>Can host a single stand-alone namespace per server. | Yes |
| Windows NT Workstation 4.0 with Service Pack 6a | Yes | No | Yes |
| Windows 98 | Yes<br><br>Client for stand-alone DFS included; install the Active Directory client extension for Windows 95 or Windows 98 to access domain-based DFS namespaces. | No | Yes |

When evaluating client compatibility, review the following important considerations:

- Client computers must be members of a local or trusted domain before they can access a domain-based namespace by using the format *NetbiosDomainName**RootName*. If clients are members of a workgroup or an untrusted domain and can resolve DNS names, they can access domain-based namespaces by using the format *DNSDomainName**RootName*. For information about how clients determine the list of trusted domains, see "DFS Physical Structures and Caches on DFS Clients."

- Link targets can be shared folders served by other protocols, such as NetWare Core Protocol (NCP) for NetWare and Network File System (NFS) for UNIX, but client computers must have the appropriate redirector installed to access those link targets.

- In organizations that have a large number of domains and forest trusts, clients might have difficulty accessing link targets in other domains or forests. For more information, see "DFS-Related Processes on Clients" later in this section.

- If a Windows 2000 Server root server has the **restrictanonymous** registry entry set to 2, and the root server is not a domain controller, then DFS clients in a workgroup cannot access DFS namespaces that are hosted on the root server. (This registry entry

is located at HKEY_LOCAL_MACHINE/SYSTEM/CurrentControlSet/Control/Lsa.)

**Caution**

- Incorrectly editing the registry might severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

#### Characteristics of Namespace Types

The following table provides a general overview of the differences between domain-based and stand-alone namespaces.

**Characteristics of Namespace Types**

| Characteristic | Domain-based | Stand-Alone |
|---|---|---|
| Path to namespace | *NetbiosDomainName**RootName*<br><br>*DNSDomainName**RootName* | *ServerName**RootName* |
| Where DFS metadata is stored | In Active Directory. Also stored in a memory cache on the root server. | In the registry of the root server. Also stored in a memory cache on the root server. |
| Group memberships required to create or delete namespaces | DFS administrators must be members of the Domain Admins group to create or delete domain-based namespaces or have delegated permissions to the DFS-Container object in Active Directory. | DFS administrators must be members of the local Administrators group on the local server to create or delete stand-alone namespaces. |
| Group memberships required to administer namespaces | DFS administrators must be members of the local Administrators group on each of the root servers to add or delete links, link targets, roots, and root targets.* | DFS administrators must be members of the local Administrators group on the local server to add or delete links, link targets, roots, and root targets. |
| DFS namespace size restrictions | We recommend that you keep the size of the DFS object in Active Directory below 5 megabytes (MB) by using fewer than 5,000 links in domain-based namespaces. | The largest recommended namespace size for a stand-alone namespace is 50,000 links. |
| Supported methods to ensure DFS root availability | Create multiple root targets in the same domain. | Create a stand-alone root on a server cluster. |
| Supported methods to ensure link target availability | Create multiple link targets and replicate files by using one of the following methods:<br>• Enabling FRS<br>• Copying files manually or by using scripts<br>• Using another replication tool | Create multiple link targets and replicate files by using one of the following methods:<br>• Copying files manually or by using scripts<br>• Using another replication tool |

*To ensure that the administrator can reliably administer the namespace, we recommend that the administrator be a member of the local Administrators group on each root server. If a DFS administration tool sends a request to a root server on which the administrator is not a member of the local Administrators group, the request will fail. If the administrator is a member of the local Administrators group on some but not all root servers, the administrator's ability to administer the namespace will be inconsistent.

#### DFS Architecture

The DFS service (Dfssvc.exe) is the core component of the DFS architecture and runs on root servers and domain controllers. The primary functions of the DFS service include handling referrals, managing namespaces, and communicating with the DFS driver (Dfs.sys).

The components of the DFS architecture on DFS clients and root servers are illustrated in the following figure. In this figure, the DFS architecture of the domain controller is simplified to show only the DFS object.

**DFS Client and Root Server Architecture**

The following figure illustrates the DFS architecture of a domain controller and a simplified view of the DFS client and root server architecture. Note that domain controllers use DFS architecture similar to root servers; this is because domain controllers play a role in referring client computers to domain-based roots. It is also possible for domain controllers to host namespaces and play the role of root server. In this case, the domain controller also hosts the DFS metadata cache (regardless of namespace type) and the stand-alone DFS metadata in its registry (for stand-alone namespaces).

**DFS-Related Architecture on Domain Controllers**

The following tables describe the components of the DFS architecture.

**Components of DFS Tools Described in the Figure Titled "DFS Client and Root Server Architecture"**

| Component | Description |
|---|---|
| Dfsshlex.dll | Displays the DFS tab when you use a DFS client to view the properties of a folder in a DFS namespace using Windows Explorer. |

| | |
|---|---|
| Distributed File System snap-in (Dfsgui.msc and Dfsui.dll) | The graphical user interface tool used for administering DFS namespaces. By default, the Distributed File System snap-in (Dfsgui.msc) is installed on servers running Windows Server 2003. You can administer namespaces remotely from a computer running Windows XP with Service Pack 1 by installing the Windows Server 2003 Administration Tools Pack, which the includes Distributed File System snap-in. |
| Distributed File System command-line utility (Dfscmd.exe) | The DFS command-line tool used to perform basic DFS tasks, such as configuring DFS roots, links, and targets. Also supports scripting. Dfscmd.exe is available on all servers running a member of the Windows Server 2003 family. |
| Distributed File System utility (Dfsutil.exe) | The DFS command-line tool used to perform basic and advanced DFS tasks, such as enabling root scalability mode, least expensive target selection, and same-site target selection. When installed on DFS clients, Dfsutil.exe can be used to view and clear the referral cache (PKT cache), domain cache (SPC cache), and MUP cache. Also supports scripting. Dfsutil.exe is included with the Windows Support Tools and is available on the Microsoft Download Center Web site. |
| Netapi32.dll | Contains the NetDFS*xxx* APIs that are used to administer remote root servers. Also contains the APIs that are used to view and clear the referral cache (PKT cache), domain cache (SPC cache), and MUP cache on clients. |

**Components of DFS Client Architecture Described in the Figure Titled "DFS Client and Root Server Architecture"**

| Component | Description |
|---|---|
| Domain cache | Contains the domain name referrals and domain controller referrals that are stored in memory on each client computer. The domain cache stores NetBIOS and DNS domain names for the local domain, all trusted domains in the forest, domains in trusted forests, and the mappings of the domain names to the domain controllers. The domain cache (also called SPC cache) is maintained in Mup.sys. |
| I/O Manager | Plays a role in handling the file I/O in redirecting the UNC paths to Mup.sys. I/O Manager is part of the core kernel (Ntoskrnl.exe) of the operating system. |
| Mrxsmb.sys | Handles communications to the root servers, domain controllers, and Windows-based file servers that use the CIFS protocol. |
| Mup.sys | Implements DFS client support and redirector selection. "Mup" stands for "multiple UNC provider."<br><br>Mup.sys is a networking component that handles input/output (I/O) requests for a file or device that has a UNC name (that is, a name that begins with \\). If the UNC name is a DFS path, Mup.sys resolves it to the physical UNC path. After the path is resolved, or if the path was not a DFS path, Mup.sys determines the local redirector that handles the UNC path. |
| Ntlanman.dll | Handles the establishment of drive letter and unnamed connections for DFS and SMB paths. |
| Nwrdr.sys and Mrxdav.sys | The redirectors for Netware and Web Distributed Authoring and Versioning (WebDAV), respectively. |
| Referral cache | Stores the root referrals and link referrals received by the client when it accesses a namespace. The referral cache (also known as the PKT cache) is maintained in Mup.sys. |
| Workstation service (Wkssvc.dll) | Sends domain controller information and domain names to Mup.sys. Mup.sys uses this information to generate the referrals in the client's domain cache. This service is also a component of the Server Message Block (SMB) client. Also manages the loading and unloading of the Mrxsmb.sys. |

**Components of the DFS Root Server and Domain Controller Architecture Described in the Figure "DFS-Related Architecture on Domain Controllers"**

| Component | Description |
|---|---|
| Dfs.sys | The DFS driver. Dfs.sys runs only on Windows-based server operating systems and reflects referral requests from DFS clients to the DFS service running in user mode. Dfs.sys also handles the processing of links when they are encountered during file system access. |
| DFS metadata cache | The in-memory copy of DFS metadata maintained in Dfssvc.exe on root servers. DFS metadata consists of information about entire namespace, including the root, root targets, links, link targets, and settings. |

| | |
|---|---|
| Dfssvc.exe | The DFS service. Provides server-side support for NetDFS*xxx* APIs that configures and maintains DFS namespaces. The DFS service is also responsible for maintaining an up-to-date version of the DFS metadata and for giving referrals to clients who attempt to access the namespace. |
| Domain-based root referral cache and site caches | The in-memory copies of domain-based root referrals and site information that enable Dfssvc.exe to perform fast lookups. These caches are described in the next section. |
| Registry | Where the DFS metadata is stored for stand-alone DFS namespaces. |
| Srv.sys | The SMB Service server driver. Plays a role in DFS by passing on referral requests from DFS clients to Dfs.sys. |
| Active Directory | Where the DFS object is stored. The DFS object stores the DFS metadata for a domain-based namespace. |

**DFS Physical Structures and Caches**

The following figure illustrates the physical structures and caches on domain controllers, root servers, and DFS clients. These physical structures and caches are described in the sections that follow.

**DFS Physical Structures and Caches**

**DFS Physical Structures and Caches on Domain Controllers**

Domain controllers play an important role for domain-based namespaces. They store the DFS metadata for domain-based namespaces, and they provide referrals to DFS clients to help them access domain-based namespaces. There are a number of physical structures and caches that support these processes; these structures and caches are illustrated in the following figure.

**Physical Structures and Caches on Domain Controllers**

The following sections describe each of the physical structures and caches on domain controllers. Domain controllers can also host roots; in this case, the domain controller also contains the physical structures and caches described in "DFS Physical Structures and Caches on Root Servers" later in this section.

**DFS Object in Active Directory**

The DFS object stores the DFS metadata for a domain-based namespace. The DFS object is created in Active Directory when you create a domain-based root, and Active Directory replicates the entire DFS object to all domain controllers in a domain. When a client requests a referral for a domain-based namespace, the domain controller first checks its domain-based root referral cache (described later in this section) for an existing referral. If none exists, the domain controller locates the DFS object for that namespace and uses the metadata in the object to create the referral.

The following figure illustrates the location of the DFS objects in Active Directory. Each DFS object (class **fTDfs**) corresponds to a domain-based namespace.

**Hierarchy of DFS Objects in Active Directory**

Each DFS object has the following four important attributes:

- **pKT.** A binary representation of the DFS metadata for this root.
- **pKTGuid.** The globally unique identifier (GUID) of the DFS metadata.
- **remoteServerName.** Lists the root targets for the root.
- **Security descriptor.** Controls who can modify the DFS object. The security descriptor on the DFS-Configuration object controls who can create or delete a DFS object.

It is important to be aware of the size of the DFS object. An entry in the metadata uses approximately 400 bytes per DFS link. (This figure does not include any comments that you add to describe the namespace.) A mid-sized DFS namespace with 100 links requires approximately 40 kilobytes (KB). Any change to the namespace causes the entire DFS object to be replicated to all domain controllers in the domain. We recommend that the DFS object for a domain-based namespace be less than 5 megabytes (MB) (which is equivalent to approximately 5,000 links) to reduce the impact of network traffic originating from changes to the namespace.

For more information about how domain-based root servers discover changes to the DFS object in Active Directory, see "How DFS Discovers Changes to the Namespace" later in this section.

**DFS Registry Entries**

DFS supports several registry entries for configuring DFS behavior on domain controllers. DFS registry entries are located in the registry under the following subkeys:

- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DFS
- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\Parameters

For a list of DFS registry entries, see "DFS Tools and Settings."

**Domain Name Referral Cache**
A domain name referral contains the NetBIOS and DNS names of the local domain, all trusted domains in the forest, and domains in trusted forests. A DFS client requests a domain name referral from a domain controller to determine the domains in which the clients can access domain-based namespaces.

By default, domain controllers store domain name referrals in a memory cache for 12 hours; this period is defined by the **DomainNameIntervalinSeconds** registry entry on the domain controller. Restarting the DFS service on the domain controller will cause this cache to be cleared. If a domain name changes, or if domains are added or removed from the forest or trusted forests, these changes are reflected in domain name referrals after 12 hours or after this cache is cleared.

**Domain Controller Referral Cache**
A domain controller referral contains the NetBIOS and DNS names of the domain controllers for the list of domains it has cached. A DFS client requests a domain controller referral from a domain controller (in the client's domain) to determine which domain controllers can provide a referral for a domain-based namespace.

Domain controllers store these domain controller referrals in a memory cache for 10 minutes; you cannot change this setting. Restarting the DFS service on the domain controller will cause this cache to be cleared. If a domain controller name changes, or if domain controllers are promoted or demoted from the domain, these changes are reflected in domain controller referrals after 10 minutes or after this cache is cleared.

**Domain-based Root Referral Cache**
A domain-based root referral contains a list of root targets that host a given domain-based namespace. Domain controllers provide domain-based root referrals to clients that attempt to access a domain-based namespace.

By default, domain controllers store domain-based root referrals in a memory cache for 15 minutes; this period is defined by the **RootReferralTimeoutInSeconds** registry entry on the domain controller. Restarting the DFS service on the domain controller will cause this cache to be cleared. If root targets are added or removed, or if settings are changed on the root, these changes are reflected in domain-based root referrals after 15 minutes or after this cache is cleared.

### Note

- The domain-based root referrals in this memory cache do not store targets in any particular order. The targets are sorted according to the target selection method only when requested from the client. Also, these referrals are based on DFS metadata stored on the local domain controller, not the PDC emulator master.

**Client Site Cache**
When a client requests a referral from a domain controller, the DFS service on the domain controller uses the site information defined in Active Directory (through the DSAddressToSiteNames API) to determine the site of the client, based on the client's IP address. DFS stores this information in the client site cache, which contains mappings of client IP addresses to site names. DFS uses this cache to quickly determine the site that a client belongs to.

By default, domain controllers keep entries in the client site cache for up to 24 hours. This period is defined by the **SiteSupportIntervalInSeconds** registry entry (12 hours) on the domain controller, multiplied by two. If a site name changes, or if a client moves from one site to another and uses the same IP address, the site information in this cache will be out-of-date for a maximum of twice the value of the **SiteSupportIntervalInSeconds** registry entry (24 hours) or until the DFS service is restarted on the domain controller.

When a cleanup process begins after the configured time interval, entries are handled as follows:

- If a site name that corresponds to a client was accessed since the last cleanup process, the entry is refreshed.
- If a site name that corresponds to a client has not been accessed since the last cleanup process, the entry is purged.

By default, DFS can store 200,000 entries in the client site cache. This limit is determined by the **MaxClientsToCache** registry entry.

**Target Site Cache**
The DFS service on domain controllers uses the site information defined in Active Directory (through the DSAddressToSiteNames API) to determine the site for domain-based root targets and domain controllers based on their current IP addresses. DFS stores this information in its target site cache, which contains mappings of root server names and domain controller names to site names. DFS uses this information to quickly determine the site that a root server or domain controller belongs to.

By default, domain controllers keep entries in the target site cache for up to 24 hours. This interval is defined by the **SiteSupportIntervalInSeconds** registry entry value (12 hours) on the domain controller, multiplied by two. After the configured time interval, DFS refreshes the site information in this cache. If a site name changes or a root target moves from one site to another, the site information in this cache will be out-of-date for a maximum of twice the value of the **SiteSupportIntervalInSeconds** registry entry (24 hours) or until the DFS service is restarted on the domain controller.

#### Site Cost Cache

The site cost cache on domain controllers contains a mapping of sites to their associated cost information as defined in Active Directory. (Costs are configured by administrators and are based on the expense of transferring data over the connection.) DFS populates this cache only when least expensive target selection is enabled. DFS uses the site cost cache to quickly determine the connection cost associated with domain controllers and domain-based root targets so that DFS can sort targets in order of lowest cost in referrals.

The DFS service obtains site cost information for domain controllers and domain-based root targets as needed to fulfill client referral requests. By default, entries in the site cost cache are maintained for up to 12 hours. This period is defined by the **SiteSupportIntervalInSeconds** registry entry value (12 hours) on the local domain controller. If the connection cost between two sites is changed in Active Directory, the site cost information in this cache will be out-of-date for a maximum of the **SiteSupportIntervalInSeconds** registry entry (12 hours) or until the DFS service is restarted.

The **QuerySiteCostTimeoutinSeconds** registry entry on domain controllers is also used for this cache to specify a time-out period for site cost queries. After the time-out period, the DsQuerySitesByCost API calls for site cost information in Active Directory will fail. By default, the time-out period is 30 seconds. If DFS cannot determine a site cost within 30 seconds, DFS assumes the maximum possible cost for that site.

#### DFS Physical Structures and Caches on Root Servers

The physical structures and caches on a root server vary according to the type of namespace the root server hosts (domain-based or stand-alone). Servers running Windows 2003 Server, Enterprise Edition, and Windows Server 2003, Datacenter Edition, can host multiple stand-alone and domain-based roots.

The following figure illustrates the physical structures and caches on root servers.

**Physical Structures and Caches on Root Servers**

The following sections describe each of the physical structures and caches on root servers.

#### Stand-Alone DFS Metadata in the Registry

The stand-alone DFS metadata contains information about the root, root target, links, link targets, and settings defined for each stand-alone namespace. This metadata is maintained in the registry of the root server at HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfs\Roots\Standalone.

### Note

- Domain-based root servers have a registry entry for each root under KEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfs\Roots\Domain, but these entries do not contain the domain-based DFS metadata. When the DFS service starts on a root server, the service checks this path for registry entries that correspond to domain-based roots. If these entries exist, the root server polls the PDC emulator master to obtain the DFS metadata for each domain-based namespace and stores the metadata in memory.

#### Root and Link Folders

Each root and link in a namespace has a physical representation on an NTFS volume on each root server that hosts the namespace. The DFS root corresponds to a shared folder, known as the root folder, on the root server. When you use the DFS tools to add links to the root, DFS creates special folders under each root folder. These folders, called link folders, are actually reparse points, and they display an error message similar to the following message if you try to access them on the local server:

"E:\Public\GroupData is not accessible. The network location cannot be reached."

DFS clients that access the link folders from across the network are redirected to the appropriate link target by using the process described in "The Referral Process" later in this section.

The following figure illustrates volume E:\ on the local storage of a root server. The volume contains root folder and link folders for the \\Contoso.com\Public namespace.

**Link Folders on a Root Server**

For more information about how these folders are created, see "Root and Link Creation Process" later in this section.

**DFS Registry Entries**

DFS supports several registry entries for configuring DFS behavior on root servers. The DFS service registry entries are located in the registry under the following subkeys:

- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DFS
- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\Parameters

For a list of these DFS registry entries, see "DFS Tools and Settings."

**DFS Metadata Cache**

The DFS metadata cache on root servers contains information about the root, root targets, links, link targets, and settings defined in a namespace. For domain-based namespaces, this metadata is also stored in the DFS object in Active Directory. For stand-alone namespaces, this metadata is also stored in the root server's registry.

This cache is updated each time the root server polls the DFS object in Active Directory (for domain-based namespaces) and the registry (for stand-alone namespaces). For more information, see "How DFS Discovers Changes to the Namespace" later in this section.

**Domain-based Root Referral Cache**

When a client computer contacts a domain-based DFS root server directly by using the syntax *ServerName**RootName*, the root server provides a domain-based root referral to the client computer. One scenario in which this occurs is when a client attempts to access a link target that points to a path within another domain-based namespace. For more information, see "Linking to Different DFS Namespaces" later in this section.

By default, root servers store these domain-based root referrals in a memory cache for 15 minutes; this period is defined by the **RootReferralTimeoutInSeconds** registry entry on the root server. Restarting the DFS service on the root server will cause this cache to be cleared. If root targets are added or removed, or if settings are changed on the root, these changes are reflected in domain-based root referrals (provided by root servers) after 15 minutes or after the cache is cleared.

**Note**

- The domain-based root referral cache does not store targets in any particular order. The targets are sorted according to the target selection method only when requested from the client. Also, these referrals are based on DFS metadata stored on the local domain controller, not the PDC emulator master.

**Client Site Cache**

When a client requests a referral from a root server, the DFS service on the root server uses the site information defined in Active Directory (via the DSAddressToSiteNames API) to determine the site of the client, based on the client's IP address. DFS stores this information in the root server's client site cache, which contains mappings of client IP addresses to site names. DFS uses this cache to quickly determine the site that a client belongs to.

By default, root servers keep entries in the client site cache for up to 24 hours. This period is defined by the **SiteSupportIntervalInSeconds** registry entry (12 hours) on the root server, multiplied by two. If a site name changes, or if a client moves from one site to another and uses the same IP address, the site information in this cache will be out-of-date for a maximum of twice the value of the **SiteSupportIntervalInSeconds** registry entry (24 hours) or until the DFS service is restarted on the root server.

When a cleanup process begins after the configured time interval, entries are handled as follows:

- If a site name that corresponds to a client was accessed since the last cleanup process, the entry is refreshed.
- If a site name that corresponds to a client has not been accessed since the last cleanup process, the entry is purged.

By default, DFS can store 200,000 entries in the client site cache. This limit is determined by the **MaxClientsToCache** registry entry.

**Target Site Cache**
When the DFS service starts on a root server, it uses the site information defined in Active Directory (through the DSAddressToSiteNames API) to determine the site for all link targets, based on the current IP address of each link target. The DFS service also obtains site information when new link targets are added. DFS caches this information in the root server's target site cache. The target site cache contains mappings of link target server names to site names. DFS uses this information to quickly determine the site that a link target belongs to.

By default, root servers keep entries in the target site cache for up to 24 hours. This interval is defined by the **SiteSupportIntervalInSeconds** registry entry value (12 hours) on the root server, multiplied by two. After the configured time interval, DFS refreshes the site information in this cache. If a site name changes or a link target server moves from one site to another, the site information in this cache will be out-of-date for a maximum of twice the value of the **SiteSupportIntervalInSeconds** registry entry (24 hours) or until the DFS service is restarted.

**Site Cost Cache**
The site cost cache on root servers contains a mapping of sites to their associated cost information, as defined in Active Directory. (Costs are based on the expense of transferring data over the connection.) DFS populates this cache only when least expensive target selection is enabled. DFS uses the site cost cache to quickly determine the connection cost associated with link targets, so that DFS can sort link targets in referrals in order of lowest cost.

The DFS service obtains site cost information for link targets (through the DsQuerySitesByCost API) as needed to fulfill client referral requests. By default, root servers keep entries in the site cost cache for up to 12 hours. This period is defined by the **SiteSupportIntervalInSeconds** registry entry value (12 hours) on the root server. If the connection cost between two sites is changed in Active Directory, the site cost information in this cache will be out-of-date for a maximum of the **SiteSupportIntervalInSeconds** registry entry (12 hours) or until the DFS service is restarted.

The **QuerySiteCostTimeoutinSeconds** registry entry on root servers is also used for this cache to specify a time-out period for site cost queries. After the time-out period, the DsQuerySitesByCost API calls for site cost information in Active Directory will fail. By default, the time-out period is 30 seconds. If DFS cannot determine a target's site cost within 30 seconds, DFS assumes the maximum possible cost for the target server.

**DFS Physical Structures and Caches on DFS Clients**
DFS clients running Windows XP and Windows 2000 store referrals from domain controllers and root servers to improve performance. A client can use the referrals in its cache when reaccessing a target in the namespace, rather than recontacting domain controllers and root servers for referrals. DFS clients also have registry entries used for customizing DFS behavior on the client.

The following figure illustrates the physical structures and caches on DFS clients.

**Caches on DFS Clients**

These physical structures and caches are described in the sections that follow. For information about how clients update their caches, see "DFS-Related Processes on Clients" later in this section.

**DFS Registry Entries**
DFS registry entries are located in the DFS client's registry under the following subkeys:

- HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\LanmanWorkstation\
- HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\System\DFSClient\.

For a list of DFS registry entries, see "DFS Tools and Settings.

**Domain Cache on Clients**
The domain cache on clients contains two types of referrals:

- **Domain name referrals,** which are the NetBIOS and DNS domain names for the client's local domain, trusted domains in the forest, and domains in trusted forests.

- **Domain controller referrals,** which are the mappings of the domain names to the domain controllers that host those domains.

You can view the domain cache on a client computer by using the Dfsutil.exe command-line tool with the **/spcinfo** parameter. The following text illustrates the output displayed when you use this command.

```
[*][dc-01.contoso.com]
[*][CONTOSO]
[*][contoso.com]
[+][contoso.com]
        [-dc-02.contoso.com]
        [+dc-01.contoso.com]
        [-dc-04.contoso.com]
        [-dc-03.contoso.com]
[-][AFRICA]
[-][EUROPE]
[+][CONTOSO]
        [-DC-02]
        [+DC-01]
        [-DC-03]
        [-DC-04]
[-][europe.contoso.com]
[-][africa.contoso.com]
```

The preceding sample output can be interpreted as follows:

- Entries preceded by [*] are provided by the Workstation service.

- The [+] next to the domain controller named DC-01 under [contoso.com] and [CONTOSO] indicates that it is the active domain controller for that domain. The client will contact this domain controller as needed to obtain domain name referrals, domain controller referrals, and domain-based root referrals.

- The client has already contacted DC-01 to receive domain name referrals for Contoso.com, Europe.Contoso.com, and Africa.Contoso.com.

- The client has already contacted DC-01 to receive domain controller referrals for the Contoso.com domain.

For information about how clients update their domain caches, see “DFS-Related Processes on Clients” later in this section.

**MUP Cache**

The multiple UNC provider (MUP) cache stores information about which redirector, such as DFS, SMB, or WebDAV, is required for each UNC path that a client computer attempts to access. Entries in the MUP cache are held for 15 minutes. You can use Dfsutil.exe’s **/PurgeMupCache** parameter to clear the MUP cache. This might be necessary when a folder is changed from an SMB shared folder to a WebDAV or DFS root folder or vice versa.

For information about how clients update their MUP caches, see “DFS-Related Processes on Clients” later in this section.

**Referral Cache on Clients**

DFS clients store root referrals and link referrals in the referral cache (also called the PKT cache). These referrals allow clients to access the root and links within a namespace. You can view the contents of the referral cache by using Dfsutil.exe with the **/pktinfo** parameter on a DFS client. The following figure illustrates the output displayed when you use this command on a Windows XP client computer.

**Sample Referral Cache Output**

```
--mup.sys--
5 entries...
1 Entry: \contoso.com\netlogon
  ShortEntry: \contoso.com\netlogon
  Expires in 0 seconds
  UseCount: 0 Type:0x1 ( DFS )
     0:[\dc-01.contoso.com\netlogon] State:0x31 (ACTIVE)
     1:[\dc-02.contoso.com\netlogon] State:0x21 ( )
     2:[\dc-64.contoso.com\netlogon] State:0x21 ( )
     3:[\dc-04.contoso.com\netlogon] State:0x21 ( )

  Entry: \contoso.com\SysVol
1 ShortEntry: \contoso.com\SysVol
  Expires in 180 seconds
  UseCount: 0 Type:0x1 ( DFS )
     0:[\dc-02.contoso.com\SysVol] State:0x31( ACTIVE )
     1:[\dc-01.contoso.com\SysVol] State:0x21( )
     2:[\dc-64.contoso.com\SysVol] State:0x21( )
     3:[\dc-04.contoso.com\SysVol] State:0x21( )

  Entry: \contoso.com\public
2 ShortEntry: \contoso.com\public
  Expires in 0 seconds
  UseCount: 0 Type:0x81 ( REFERRAL_SVC DFS )
     0:[\root-dfs-01\public] State:0x19 ( ACTIVE )
     1:[\root-dfs-02\public] State:0x09 ( )

  Entry: \software\public
3 ShortEntry: \software\public
  Expires in 300 seconds
  UseCount: 0 Type:0x81 ( REFERRAL_SVC DFS )
     0:[\SOFTWARE\Public] State:0x19 ( ACTIVE )

  Entry: \software\public\Applications
4 ShortEntry: \software\public\Applications
  Expires in 1800 seconds
  UseCount: 0 Type:0x1 ( DFS )
     0:[\software2\apps$] State:0x31 ( ACTIVE )
     1:[\software4\apps$] State:0x21 ( )
     2:[\software3\apps$] State:0x21 ( )
```

The previous figure shows four types of referrals: (1) NETLOGON and SYSVOL referrals, (2) domain-based root referrals, (3) stand-alone root referrals, and (4) link referrals. Each of these referrals contains the following information:

**Entry and ShortEntry**
Entry specifies the full name of the path. ShortEntry specifies the short name (eight characters followed by a period and a three more characters) of the path. Root servers and domain controllers running Windows Server 2003 use the full name when populating Entry and ShortEntry.

**Expires in seconds**
Specifies the Time to Live of the referral. Zero (0) seconds indicates that the referral has expired and that the client will obtain a new referral the next time the client tries to access the target server.

**UseCount and Type**
UseCount is the number of open connections and files for this path. If a client has a mapped drive to a DFS path, its use count goes up by 1. On clients running Windows 2000, Windows XP, and Windows Server 2003, you cannot clear a referral until its use count is 0.

Type indicates the type of referral. Some common types include:

- **Type 0x81 ( REFERRAL_SVC DFS ).** Indicates a root referral.
- **Type 0x1 ( DFS ).** Indicates a link referral that has physical shared folders as link targets.
- **Type 0x10 ( OUTSIDE_MY_DOM).** Indicates a link referral whose link target is a path in a domain-based namespace.

**Target list**
The target list contains the root targets or link targets that correspond to the path specified in Entry. Targets are listed in order, according to the target selection method configured for the root or link. A target marked Active indicates that the client either has used this target or will use this target the next time the user tries to access this portion of the namespace.

**DFS Processes and Interactions**
DFS is a complex service that involves many processes and interactions between clients, root servers, and domain controllers. The major categories of the processes and interactions, along with the names of the relevant sections, are described as follows.

**Processes Related to Referrals**
The referral process is the process by which domain controllers and root servers refer clients to different targets in the namespace. Numerous processes take place so that DFS can provide an optimal list of targets in the referral. These processes are described in the following sections:

- See “How Site Discovery Works” for information about how DFS determines the sites to which clients and targets belong.
- See “How Target Selection Works” for information about the logic that DFS uses to sort targets in a referral. There are three target selection methods: default target selection, same-site target selection, and least expensive target selection.

- See “How DFS Works in Environments Without WINS” for information about how DFS can use either NetBIOS names or DNS names of targets in referrals.

- See “The Referral Process” for the actual steps involved in the referral process.

- See “How DFS Is Used During the Logon Process” for information about the two special types of referrals, SYSVOL and NETLOGON referrals, which are used when a client first logs on to the domain.

- See “Linking to Different DFS Namespaces” for information about how link targets can point to other namespaces (instead of physical shared folders) and the referral process involved when a client navigates from one DFS namespace to another.

- See “What Happens During Failover” for information about how clients react when a target in a referral is not available and how clients react when they have a session enabled with a target and the target server fails.

**Creating and Changing Namespaces**
These following sections describe what happens when you create or change a namespace.

- See “Root Folder and Link Folder Creation Process” for information about how DFS-related folders are created on root servers.

- See “How DFS Discovers Changes to the Namespace” for information about what happens when a namespace changes. This section also provides information about where DFS data is stored so that you can determine how long it takes before clients can see an updated view of the namespace.

- See “How Root Scalability Mode Works” for information about a special mode in which domain-based root servers discover namespace changes by contacting the closest domain controller.

**What Happens During DFS Operations**
See the section “What Happens When You Check Target Status” for information about how DFS works when you check target status by using the Distributed File System snap-in.

**DFS Interoperability**
See the sections “How DFS Works on Server Clusters” and “How DFS Works with Offline Files” for information about how DFS operates on server clusters and the Offline Files feature.

**Client Processes**
See the section “DFS-Related Processes on Clients” for information about the processes that DFS clients perform to update their domain caches, MUP caches, and referral caches. Entries in these caches are used during the referral process.

**How Site Discovery Works**
Site discovery, also called site awareness, is the process that DFS uses to determine which site a root target, link target, or client belongs to. A site is one or more TCP/IP subnets as defined in Active Directory. DFS uses this site information to determine the order in which to sort the targets in a referral.

DFS determines the site of targets and clients as follows:

- When the DFS service starts, DFS determines the site of each target by converting the target’s name to an IP address (using the GetHostbyName API) and then querying Active Directory (using the DSAddressToSiteNames API) to convert the IP address to a site name based on the subnet-to-site mappings as defined in Active Directory.

- When a client attempts to access the DFS namespace, DFS determines the site of a client by querying Active Directory (using the DSAddressToSiteNames API) to convert the client’s IP address to a site name based on the subnet-to-site mappings as defined in Active Directory.

Site discovery in Windows Server 2003 works regardless of the operating system that the target server is running. For example, if a link target is running Windows NT 4.0 or a non-Windows operating system, DFS can determine the target’s site using its IP address. For server clusters and multihomed clients and targets, site discovery works as follows:

- If a target is part of a virtual server in a server cluster, DFS uses the virtual server’s IP address to determine the target’s site.

- When a target server is multihomed (that is, the server has multiple IP addresses), the root server or domain controller determines the target’s site by using the GetHostbyName API, and the first IP address returned is what is used to determine the site.

- When a multihomed client requests a referral, the root server or domain controller uses the source IP address from the client's network request, which could be arbitrary based on the client's network configuration. Or, if a client request goes through a NAT gateway, the root server or domain controller uses the source IP address of the request as rewritten by the NAT gateway.

After root servers and domain controllers obtain site information about client computers and target servers, they store the information in the following memory caches:

- **Target site cache.** The target site cache contains mappings of target server names to site names.

- **Client site cache.** The client site cache contains mappings of client IP addresses to site names.

Site information remains in the client site cache and the target site cache for up to two times the duration specified in the **SiteSupportIntervalInSeconds** registry entry (set to 12 hours, by default). Because site information is cached and not immediately updated after it changes, it is important to understand how out-of-date cached site information affects site discovery for target servers and client computers.

- Target site information can become out-of-date when a target server is moved from one site to another and the target's IP address changes so that the target belongs to a subnet that is mapped to a different site in Active Directory. Changing site names can also cause target site information to become out-of-date. Eventually DFS discovers the new site information when the old site information is updated in the target site cache, which occurs within 24 hours, by default. Until site information is refreshed in the cache, DFS might sort affected targets in referrals based on their old site information, possibly causing clients to connect to target servers outside of their own site or to targets that are not closest to the client computer.

- Client site information can become out-of-date when a client computer moves to another site but keeps the same IP address, when the client's subnet is moved to a different site, or when the site names change. In these scenarios, DFS discovers new site information for the client within 24 hours, by default. Until site information is refreshed in the cache, DFS might sort targets in referrals based on the client's old site information, possibly causing the client to contact target servers outside of its own site or to targets that are not closest to the client.

When reviewing how site discovery works in Windows Server 2003, it is also important to understand how site discovery is affected when your organization uses a combination of root servers and domain controllers running Windows Server 2003 and Windows 2000 Server. These issues are described in the sections that follow.

**Differences in where site information is stored**

In Windows 2000 Server, DFS stores a copy of site information for root and link targets in the DFS metadata stored in the DFS object in Active Directory (for domain-based namespaces) and in the registry (for stand-alone namespaces). In environments that have domain-based DFS namespaces hosted on multiple root servers running Windows 2000 Server and Windows Server 2003, the following conditions can arise:

- Root servers and domain controllers running Windows Server 2003 ignore any site information in the DFS metadata. They obtain site information dynamically from Active Directory.

- Root servers and domain controllers running Windows 2000 Server retrieve the target's site information from the DFS metadata if the target was created by using Windows 2000 Server. However, if the target was created by using Windows Server 2003, no site information is stored for that target in the DFS metadata. As a result, Windows 2000 Server cannot determine the site of such a target. If this occurs, a referral from a Windows 2000 Server could lead the client computer to a random target, possibly outside of the client's site.

To enable root servers and domain controllers running Windows 2000 to sort targets based on site, you can use the **/UpdateWin2kStaticSiteTable** parameter in Dfsutil.exe to update the static site information for all root and link targets in the DFS object in Active Directory. This tool must be run each time a target server's site information is changed, such as after the target is moved to another site or after the target's site name changes.

When all root servers and domain controllers are running Windows Server 2003, you can use the **/PurgeWin2kStaticSiteTable** parameter in Dfsutil.exe to remove site information from the DFS object in Active Directory. We recommend using this method to decrease the size of the DFS object in Active Directory.

**How the restrictanonymous registry entry affects site discovery**

Root servers running Windows 2000 Server or Windows Server 2003 and that are not domain controllers cannot determine a DFS client computer's site when the **restrictanonymous** registry entry is set to 2 on domain controllers running Windows 2000 Server. (This registry entry is located at HKEY_LOCAL_MACHINE/SYSTEM/CurrentControlSet/Control/Lsa.) As a result, these DFS root servers

sort targets in link referrals and root referrals randomly, regardless of the namespace type (stand-alone or domain-based), target selection method, or client operating system.

#### How Target Selection Works

When a client computer attempts to access a root or link in the namespace, a domain controller or root server provides a referral to the client. The referral contains a list of target servers, and this list is sorted according to the currently configured target selection method. These methods are described using the following figure as an example.

**Example of Client and Target Sites**

**Note**

- Out-of-date or misconfigured site information can cause DFS to sort referrals incorrectly. For more information about how DFS caches site information and when this information is refreshed, see "How Site Discovery Works" earlier in this section.

#### Default Target Selection

By default, DFS places target servers in the referral in the following order:

1. Targets in the same site as the client are listed in random order at the top of the referral.
2. Targets outside of the client's site are listed in random order.

Using the previous figure as an example, when default target selection is enabled, DFS places the target servers in the referral in the following order:

**Default Referral Order**

If no same-site target servers are available, the client computer is referred to a random target server no matter how expensive the connection is or how distant the target is. This is the default DFS behavior in Windows 2000 Server and Windows Server 2003.

#### Same-Site Target Selection

In this method, also called in-site target selection, the referral contains the targets that are in the same site as the client. These same-site targets are listed in random order. If no same-site targets exist, clients in that site do not receive a referral and cannot access that portion of the namespace.

Using the figure "Example of Client and Target Sites" as an example, when same-site target selection is enabled, DFS places the target servers in the referral in the following order:

**Same-Site Target Selection Referral Order**

You enable this setting on a DFS root or on individual links in the namespace by using Dfsutil.exe with the **/InSite** parameter. If you enable this setting on the root, root referrals and link referrals return only targets that are in the same site as the client. If no root or link targets exist in the client's site, then no referral is returned and the client cannot access that portion of the namespace. If this

setting is enabled on a link, and no link targets exist in the client's site, then no referral is returned and the client cannot access the link.

Same-site target selection works differently in Windows 2000 Server and Windows Server 2003. In Windows 2000 Server, if this setting is enabled on a root, the setting applies to all links but not the root itself. If a client attempts to access a namespace but no root targets exist in the client's site, the out-of-site root targets are returned in the root referral. Like Windows Server 2003, DFS in Windows 2000 Server does not return link referrals if no link targets exist in the client computer's site.

**Least Expensive Target Selection**
In this method, also called closest site selection or site costing, DFS uses the DsQuerySitesByCost API to retrieve minimum communication cost between two sites from Active Directory. The following figure illustrates sites and their associated site link costs.

**Example of Sites and Site Link Costs**

When least expensive target selection is enabled, DFS places targets in the referral in the following order:

1. Targets in the same site as the client are listed in random order at the top of the referral.

2. Targets outside of the client's site are listed in order of lowest cost to highest cost. Referrals with the same cost are grouped together and within each group the targets are listed in random order.

Using the previous figure as an example, when least expensive target selection is enabled, DFS places the targets in the referral in the following order:

**Least Expensive Target Selection Referral Order**

If the DsQuerySitesByCost API call fails, no cost information is returned to the root server. In this case, DFS assumes the maximum possible cost for that target.

Least expensive target selection works in both stand-alone and domain-based namespaces, as long as all root servers and all domain controllers are running Windows Server 2003. These requirements ensure that:

- All domain controllers can provide root referrals based on site cost.

- All root servers can provide root and link referrals based on site cost.

- The domain controllers acting as Intersite Topology Generators can calculate site cost information. (One domain controller in each site is selected as the Intersite Topology Generator, and the role is automatically given to a domain controller running Windows Server 2003, if one is available for the site.)

Least expensive target selection is not available in the following situations:

- When a stand-alone namespace is hosted on a root server that is not part of any domain.

- When a root server or domain controller is running Windows 2000 Server.

- The **Bridge all site links** option in Active Directory is disabled. (This option is available in the Active Directory Sites and Services snap-in.) Turning off **Bridge all site links** can affect the ability of DFS to sort targets in referrals in order of lowest cost. An Intersite Topology Generator that is running Windows Server 2003 relies on the **Bridge all site links** option being enabled to generate the intersite cost matrix that DFS requires for its site-costing functionality. If you turn off this option, you must create site links between any Active Directory sites for which you want DFS to calculate accurate site costs. Any sites that are not connected by site links will have the maximum possible cost. For more information about site link bridging, see "Active Directory Replication Topology Technical Reference.

In these situations, DFS uses the default target selection method. For more information about site costs, see "DNS Support for Active Directory Technical Reference."

**Situations in Which Clients Access Unexpected Targets**

Even when least expensive or same-site target selection is enabled, clients might still access high-cost or out-of-site targets. Also, when default target selection is enabled, a client computer might access a target server outside of its own site, even though a same-site target exists. These problems are typically caused by one of the following situations:

- The same-site target is temporarily unavailable (due to server or network issues), and the client fails over to the next target, which could be outside of the client's site.

- The out-of-site or high-cost target has incorrect site information that makes DFS interpret the target as being in the client's site. This problem can occur when subnets are not configured correctly. If no same-site targets exist and a client unexpectedly chooses a high-cost target, it might be caused by an incorrect site cost setting.

- The client's IP address is not in a subnet that is defined in Active Directory and so DFS cannot obtain site information about the client.

- The target's IP address is not in a subnet that is defined in Active Directory and so DFS cannot obtain site information about the target.

- The client is using a cached referral that contains outdated information about the site of the target server.

- Site information has changed, but the old site information is still cached on the root server or domain controller in the target site cache, client site cache, or site cost cache.

- The DFS object is not up-to-date when the root server polls a domain controller. This can be caused by Active Directory replication latency or failure.

- The **Bridge all site links** option is disabled, as described earlier.

- Site awareness is not working correctly because the **restrictanonymous** registry entry located at HKEY_LOCAL_MACHINE/SYSTEM/CurrentControlSet/Control/Lsa is set to 2 on Windows 2000 domain controllers. If this registry entry is set to 2, DFS root servers that are not domain controllers (and are running either Windows 2000 Server or Windows Server 2003) randomly sort the targets in a referral, regardless of the namespace type (stand-alone or domain-based), target selection method, or client operating system.

**How DFS Works in Environments Without WINS**

The default behavior of DFS is to use NetBIOS names for all target servers in the namespace. This allows clients that support NetBIOS-

only name resolution to locate and connect to targets in a DFS namespace. Administrators can use NetBIOS names when specifying target names and those exact paths are added to the DFS metadata. For example, an administrator can specify a target \\FS1\Users, where FS1 is the NetBIOS name of a server whose DNS or FQDN name is FS1.contoso.com.

Organizations that do not use NetBIOS and WINS can still use DFS, but before setting up namespaces the administrators must create the **DFSDnsConfig** registry entry on all root servers and then restart the DFS service on all root servers. Administrators must then use the DNS names for when adding all targets to the namespace. When these steps are complete, the referrals will contain the DNS names of targets accessed by clients. If a namespace already exists, the administrator must perform the following steps:

1. Export the namespace to a data file by using Dfsutil.exe.
2. Delete the namespace.
3. In the exported data file, change the NetBIOS names to DNS names for all targets.
4. Recreate all root targets by using DNS names.
5. Import the updated data file.

For more information about the **DFSDnsConfig** registry entry and Dfsutil.exe, see "DFS Tools and Settings.

**The Referral Process**
The referral process describes the steps that client computers, root servers, and domain controllers perform when a client attempts to access a target server in a namespace. The following sections provide general and in-depth descriptions of the referral process for domain-based and stand-alone namespaces. These processes assume that all targets are available. For more information about how clients respond when a target is unavailable, see "What Happens During Failover" later in this section.

**Overview of the Referral Process**
The general steps that occur when a client accesses a domain-based or stand-alone namespace are described below. These processes assume the following:

- The client's domain cache contains the necessary domain name referrals and domain controller referrals.
- The client's referral cache does not contain existing referrals for the targets that the client is attempting to access.
- The first root target and link target in each referral are available.
- The link target is a shared folder on a physical server, not a DFS path in another namespace. The referral process that occurs when a link points to a DFS path is described in "Linking to Different DFS Namespaces" later in this section.

**Simplified Referral Process for Domain-based Namespaces**

1. A user attempts to access a link in a domain-based namespace, such as by typing \\Contoso.com\Public\Software in the **Run** dialog box.
2. The client computer sends a query to the active domain controller to discover a list of root targets for the domain-based namespace.
3. The domain controller returns a list of root targets defined for the requested namespace.
4. The client selects the first root target in the referral and sends a query to the root server for the requested link.
5. The root server constructs a list of link targets in the referral. The order in which the link targets are sorted depends on the target selection method. The root server sends the referral to the client.
6. The client establishes a connection to the first link target in the list.

**Simplified Referral Process for Domain-based Namespaces**

**Simplified Referral Process for Stand-Alone Namespaces**

1. A user attempts to access a DFS path, such as by typing \\Software\Public\Antivirus in the **Run** dialog box.

2. The DFS client computer sends a query to the root server that hosts the stand-alone namespace.

3. The root server returns a root referral to the client. The root referral contains the single root target.

4. The client sends a query to the root server for the requested link.

5. The root server constructs a list of link targets in the referral. The order in which the link targets are sorted depends on the target selection method. The root server sends the referral to the client.

6. The client establishes a connection to the first link target in the list.

**Simplified Referral Process for Stand-Alone Namespaces**

**Referral Process for Domain-based Namespaces**

The referral process for domain-based namespaces is as follows:

1. A user attempts to access a link in a domain-based namespace, such as by typing \\Contoso.com\Public\Software in the **Run** dialog box.

2. The client checks its domain cache for an existing domain name referral for the Contoso.com domain. If this referral is in the domain cache, the client proceeds to step 3. If no domain name referral is in the domain cache, the client connects to the IPC$ shared folder of the active domain controller in the context of the LocalSystem account and sends a domain name referral request with a null string. The domain controller returns the list of local and trusted domains to the client.

3. The client checks its referral cache for the longest prefix match from a previous referral. This might be a root referral (\\Contoso.com\Public) or a link referral (\\Contoso.com\Public\Software). If the client finds a valid entry, it goes to step 5 or 6 depending on the type of the referral. If not, the client continues to the next step.

4. The client checks its domain cache for an existing domain controller referral for the Contoso.com domain. If this referral is in the cache, the client proceeds to step 5. If no domain controller referral is in the domain cache, the client connects to the IPC$ shared folder of the active domain controller in the context of the LocalSystem account and sends a domain controller referral request containing the appropriate domain name (Contoso.com). The domain controller returns the list of domain controllers in the Contoso.com domain. The domain controllers in the clients site are at the top of the list. If least-expensive target selection is enabled, domain controllers outside of the targets site are sorted by lowest cost. If same-site target selection is enabled, DFS ignores this setting and lists the remaining domain controllers in random order.

5. The client checks its referral cache for an existing domain-based root referral. If this referral is in the cache, the client proceeds to

step 6. If no domain-based root referral exists in the referral cache, the client connects to the IPC$ shared folder of the active domain controller in the context of the LocalSystem account and requests a domain-based root referral. The domain controller determines the clients site and returns a list of root targets. By default, the root targets in the clients site are at the top of the list, followed by the remaining root targets in random order. If least-expensive target selection is enabled, the remaining root targets are ordered by lowest cost. If same-site target selection is enabled, only root servers in the clients site are listed in the referral.

6. The client chooses the first root target in the domain-based root referral. The client connects to the root server and navigates the subfolders under the root folder. When a client encounters a link folder, the root server sends a STATUS_PATH_NOT_COVERED status message to the client, indicating that this is a link folder that requires redirection.

7. The client checks its referral cache for an existing link referral. If this link referral is in the cache, the client computer connects to the first link target in the list. If the link referral is not in the cache, the client connects to the IPC$ shared folder of the root server in the context of the LocalSystem account and requests a link referral from the root server. The root server returns a list of link targets. At the top of the target list are the link targets that are in the same site as the client. The root server puts the remaining link targets in the target list using one of the following methods:

   - By default, the link targets outside of the clients site are put in random order.
   - If same-site target selection is enabled, the root server does not add out-of-site link targets to the referral.
   - If least-expensive target selection is enabled, the root server checks its site cost cache to determine whether cost information exists for the connection between the clients site and the link targets site. If the site cost data is not in the cache, the root server contacts the domain controller acting as the Intersite Topology Generator and uses the DsQuerySitesByCost API to retrieve site cost data. The root server then sorts the remaining link targets by lowest cost.

**Referral Process for Stand-Alone Namespaces**

The referral process for stand-alone namespaces is as follows:

1. A user attempts to access a DFS path, such as by typing \\Software\Public\Antivirus in the **Run** dialog box.

2. The client checks its domain cache and determines that the DFS path is not a domain-based DFS path (that is, Software is not the name of a domain).

3. The client checks its referral cache to determine if an existing stand-alone root referral is in the cache. If the root referral is in the cache, the client proceeds to Step 5. If the referral is not in the cache, the client connects to the IPC$ shared folder of the root server in the context of the LocalSystem account and sends a root referral request. The root server responds with a root referral so that all future requests are funneled through DFS.

4. The client connects to the root server and navigates the subfolders under the root folder. When a client encounters a link folder, the root server sends a STATUS_PATH_NOT_COVERED status message to the client, indicating that this is a link folder that requires redirection.

5. The client checks its referral cache for an existing link referral. If the link referral is in the referral cache, the client connects to the first link target in the list. If the link referral is not in the referral cache, the client connects to the IPC$ shared folder of the root server in the context of the LocalSystem account and requests a link referral from the root server. The root server returns a list of link targets. At the top of the target list are the link targets that are in the same site as the client. The root server puts the remaining link targets in the target list using one of the following methods:

   - By default, the link targets outside of the clients site are put in random order.
   - If same-site target selection is enabled, the root server does not add out-of-site link targets to the referral.
   - If least-expensive target selection is enabled, the server checks its site cost cache to determine whether cost information exists for the connection between the clients site and the link targets site. If the site cost data is not in the cache, the root server contacts the domain controller acting as the Intersite Topology Generator and uses the DsQuerySitesByCost API to retrieve site cost data. The root server then sorts the remaining link targets by lowest cost.

**How DFS Is Used During the Logon Process**

When a client logs on to a domain, the client contacts a domain controller and requests a special type of referral, known as a SYSVOL

or NETLOGON referral, to gain access to the scripts and policies stored in the SYSVOL and NETLOGON shared folders on domain controllers. (Specifically, the client requests SYSVOL and NETLOGON referrals from the active domain controller, which is preceded by a + under the appropriate domain in the client's domain cache.) These referrals map the paths *DomainName*\Sysvol and *DomainName*\Netlogon to a list of SYSVOL and NETLOGON shared folders for all domain controllers. Clients store these referrals in their referral cache. To see examples of these referrals, see the figure "Sample Referral Cache Output" earlier in this section.

DFS objects do not exist in Active Directory for these shared folders; instead, the domain controller simply recognizes that it is responsible for these paths and responds to queries of the form *DomainName*\Sysvol and *DomainName*\Netlogon. These referrals are distinct in that although the targets are hosted on a domain controller, the targets are not roots themselves and do not appear in any of the DFS tools, nor can the SYSVOL and NETLOGON shared folders host links.

Domain controllers generate SYSVOL and NETLOGON referrals each time a client requests a referral. By default, the list of domain controllers listed in a SYSVOL or NETLOGON referral are sorted as follows:

1. All domain controllers in the client's site are grouped in random order at the top of the list.

2. Domain controllers outside of the client's site are listed in random order.

It is possible to configure DFS to sort the domain controllers outside of the client's site in order of lowest cost. You can enable this feature by adding the **SiteCostedReferrals** registry entry on each domain controller and then restarting the DFS service on each domain controller. The DFS service then obtains site cost information for all domain controllers and stores this information in its site cost cache.

**Linking to Different DFS Namespaces**

When you create a link and specify the link target, you can use any UNC path, including a path to another namespace. For example, the Apps link in a stand-alone namespace \\Dev\Team\Apps might have a link target of \\Contoso.com\Public\Software, which is a link within a domain-based namespace. These types of links are often called interlinks, and DFS namespaces that point to other namespaces are often called cascaded namespaces.

Linking to different namespaces requires that certain rules be followed so that clients can fail over correctly if one of the targets is unavailable. The rules are as follows:

- DFS clients can perform a maximum of eight hops through other DFS namespaces. This means that a given link can point to a DFS path, and that path can point to another DFS path, and so on, up to a maximum of eight times.

- A link that points to a different namespace can correspond to only one of the following options:

    - A link target can point to one or more stand-alone DFS paths anywhere in the stand-alone DFS namespace. For example, a link target can be \\Software\Public (a DFS path with just the root) or \\Software\Public\Applications (a DFS path with a root and link).

    - A link target can point to a single domain-based DFS path anywhere in the domain-based DFS namespace. For example, a link target can be \\Contoso.com\Public or \\Contoso.com\Public\Users.

The referral process that occurs when a client accesses a link whose target is a DFS path is as follows:

1. A user attempts to access a link that points to another namespace.

2. If necessary, the DFS client requests domain and domain controller referrals (for domain-based namespaces) and root referrals (for both types of namespaces) by following the steps described in "The Referral Process" earlier in this section.

3. The root server provides a link referral. Because the link points to another namespace, the link target in the referral shows the DFS path, not the physical path.

4. The client attempts to access the DFS path provided in the link referral and requests the necessary referrals.

5. The client receives the referrals and accesses the intended target.

The following figure illustrates a client's referral cache after the client attempts to access the Apps link within a stand-alone namespace (\\Dev\Team\Apps) that points to a link in a domain-based namespace (\\Contoso.com\Public\Software). Note that the link target in the link referral for Apps is listed as Contoso.com\Public\Software and that the type is shown as type 0x10, OUTSIDE_MY_DOM. This type is used when a link points to a path in a domain-based namespace.

**DFS Client Referral Cache**

Root referrel for stand-alone namespace \\Dev\Team

Link referral for link named "Apps"

Root referral for \\Contoso.com\Public

Link referral for \\Contoso.com\Public\Software

```

**What Happens During Failover**

DFS failover is the process in which clients attempt to access another target in a referral after one of the targets fails or is no longer part of the namespace. Failover can occur in five scenarios:

- A client attempts to access the currently active target in a referral, but the target is unavailable.
- A client attempts to access a domain controller to request a domain referral or a domain-based root referral, but the currently active domain controller in the referral is unavailable.
- The DFS client has a session enabled with a target, and the target server fails.
- The DFS client has a session enabled with a target, and the hard disk on the server fails or the shared folder is disabled.
- A referral expires for a DFS client running Microsoft Windows XP with Service Pack 2 (SP2) or Windows Server 2003 with Service Pack 1 (SP1), and the previous active target is not in the new referral.

When reviewing the different types of failovers, note the following:

- Clients must access a domain-based namespace by using the format *DomainName**RootName*. If a client accesses a domain-based namespace directly on the root server (*RootServer**RootName*), root target failover does not occur.
- DFS failover is only performed when a client opens a file or folder. If a client has files or folders open and attempts to read or write to them when the target server is unavailable, the application will receive a failure on that operation.

The following scenarios describe different types of failures and what is involved in the failover process in each case.

**The active target in a referral is unavailable**

When a DFS client accesses a namespace, the client always chooses the first target in the target list in the referral. If the first target is available, a session setup is performed and client credentials are passed to the server, unless a prior connection already exists with the selected target. If the selected target cannot be accessed, the client attempts to access the next target in the list, and so on, until all targets are exhausted. If all targets are unavailable, then the client cannot access that portion of the DFS namespace.

**Note**

- When DFS attempts to access a target in the target list, and the first target or subsequent targets are not available, DFS does not attempt to access those targets again during later failovers until it has reached the bottom of the list.

**A domain controller fails**

When a client attempts to request a domain-based root referral or a domain name referral from a domain controller, and the first domain controller (for a given domain) in the client's domain cache is unavailable, the client will fail over to the next domain controller in the cache. If all domain controllers for the given domain are unavailable, the client cannot access the domain-based DFS namespace for that domain.

**A client is accessing the target server when it becomes unavailable**
In the following scenario, assume that a client application is accessing a target in the namespace when the server hosting the physical shared folder loses power or drops off the network. If the referral contains more than one target, the client will attempt a failover the next time the client attempts to open any file or folder in that portion of the DFS namespace. The amount of time it takes to detect that the hosting computer is offline depends on the protocol that the client is using. Many protocols, such as TCP/IP, account for slow and loosely connected WAN links, and, as such, might have retry counts of up to two minutes before the protocol times out. After the protocol returns an error, DFS returns a failure to the application. The next time the application attempts to open a file or folder in that portion of the namespace, DFS will fail over to the next target. If the DFS client reaches the bottom of the list, it will start again at the top until it has attempted to connect to all targets.

**A client is accessing the target server when a hard drive failure occurs or folder sharing is stopped**
In the following scenario, assume that a client is accessing a target in the namespace when the server hosting the physical shared folder loses the hard disk containing the folder, or an administrator stops sharing the folder. If the referral contains more than one target, the client will attempt a failover as in the previous scenario. However, in this scenario, the server hosting the shared folder is still responding to the client request; therefore, the failover to a new target is much faster than the previous scenario because DFS does not rely on the protocol to detect a failure.

**A referral expires for a DFS client running Windows XP with SP2 or Windows Server 2003 with SP1**
The behavior of the Time to Live value has changed for DFS clients running Microsoft Windows XP with SP2 or Windows Server 2003 with SP1. These clients do not renew the Time to Live value each time they access a target using a cached referral. As a result, the referral expires after the Time to Live value lapses, regardless of whether the client has accessed or is currently accessing the target. In terms of DFS failover, this new behavior can cause the DFS client to fail over to a new target if the previously active target is not in the new referral, such as when the namespace is changed to remove the target that the client had accessed.

For more information about the Time to Live value, see “How DFS Discovers Changes to the Namespace” later in this section.

**Root Folder and Link Folder Creation Process**
When you first create a DFS namespace, you specify a shared folder to use as the root folder. When you add links to the namespace, DFS creates a special folder, called a link folder, under the root folder to represent each link. The hierarchy of the root folder and link folders on the root server’s local storage matches the actual namespace. If you create a link by using the format *FolderName\FolderName\LinkName*, DFS creates the hierarchy of empty folders and then creates the link folder. Root and link folders are illustrated in the following figure.

### Roots, Links, Root Folders, and Link Folders

When you use a DFS tool to create a link, DFS checks whether a folder that has the same name as the link appears under the root. DFS then takes one of the following actions:

- If no folder exists, DFS creates the link folder and sets a reparse point on the folder.
- If an empty folder with the same name as the link exists, DFS sets a reparse point on that folder.
- If a non-empty folder with the same name as the link exists, DFS renames the non-empty folder to DFS.*GUIDLinkName*, creates a new link folder, and sets a reparse point on the folder. An example folder name is DFS.cf13c05f-5c10-4879-9acb-04ced8f46c7aTemplates, where cf13c05f-5c10-4879-9acb-04ced8f46c7a is the *GUID* and Templates is the *LinkName*.

The reparse points set on the link folders prevent data from being stored in the link folders and prevent administrators from deleting link folders by using traditional methods, such as by using Windows Explorer or the command prompt. If an administrator needs to remove a link folder, the administrator can use Dfsutil.exe to remove all DFS reparse points under a specified root folder and then delete the link by using the DFS tools. When the DFS service is started, it checks that the link folders are configured correctly and recreates link folders and reparse points as necessary. It also cleans up stale reparse points that are no longer part of any namespace.

When you add a new root target to an existing domain-based namespace, you specify an existing shared folder or create a new shared folder to use as the root. DFS creates the link folders on the new root target after the root server obtains the DFS metadata by polling the PDC emulator master (or the closest domain controller if root scalability mode is enabled). When a root server obtains the DFS metadata after polling and detects that a link has been removed, the root server removes the reparse point and the link folder for the deleted link.

**How DFS Discovers Changes to the Namespace**
To ensure that clients have an up-to-date view of the namespace, DFS must maintain a consistent version of the namespace on all root

servers. A change to the namespace can include the following types of changes:

- Adding, changing, or removing root targets, links, and link targets.
- Changing the settings on a namespace, including the Time to Live for roots and links, target selection method (for example, changing to least expensive or same-site target selection), enabling root scalability mode, and so forth.
- Enabling or disabling a referral to a link target.

The following sections describe how changes are discovered in stand-alone and domain-based namespaces.

**Note**

- These sections assume that site information is up-to-date in the client site cache, target site cache, and site cost cache on root servers and domain controllers. If these caches contain outdated site information, DFS might not sort targets in referrals correctly. Client and target site information can be out of date for up to 24 hours, and site cost information can be out-of-date up to 12 hours. For more information about how site information is updated, see "How Site Discovery Works" earlier in this section.

#### How Changes Are Discovered in Stand-Alone Namespaces

Changes made to a stand-alone namespace are updated immediately in the DFS metadata in the root server's registry and in the root server's in-memory DFS metadata cache. Therefore, stand-alone root servers typically provide up-to-date root referrals and link referrals.

Clients do not request new root and link referrals until the referrals expire or are cleared from their cache. You can use the following table to determine the maximum length of time that out-of-date referrals are used in stand-alone namespaces.

**When Referrals to Stand-Alone Namespaces Expire**

| Where Referrals Are Cached | Referral Type | Default Expiration Time | Where Expiration Time Is Stored |
|---|---|---|---|
| DFS clients | Stand-alone root referral | 5 minutes | Time to Live of root (configured using the DFS tools) |
| DFS clients | Link referral | 30 minutes | Time to Live of link (configured using the DFS tools) |

For DFS clients that are not running Windows XP with Service Pack 2 (SP2) or Windows Server 2003 with SP1, the Time to Live for a referral determines the earliest time that a client will request a new referral, but only if the existing referral expires before it is accessed again. Clients that use a cached referral will renew the Time to Live of the referral and thus use the referral indefinitely until the client's referral cache is cleared or the client is restarted.

This behavior has changed for clients running Windows XP with SP2 or Windows Server 2003 with SP1. Specifically, the Time to Live value is not reset each time a client accesses a target using a cached referral. Instead, the referral expires after the Time to Live value lapses. This change has several effects:

- Clients running Windows XP with SP2 or Windows Server 2003 with SP1 will request referrals more frequently than other DFS clients, which can cause moderately increased load on the stand-alone DFS root server.
- Because they request new referrals more frequently, clients running Windows XP with SP2 or Windows Server 2003 with SP1 will discover namespace updates more quickly than other DFS clients.

#### How Changes Are Discovered in Domain-based Namespaces

The update process for domain-based namespaces is more complex because there are multiple locations of the DFS metadata — the DFS metadata is stored in the DFS object in Active Directory on each domain controller and is stored in a memory cache on multiple root servers. To ensure that all root servers discover changes to the namespace, DFS uses two methods of keeping root servers up to date:

- Root server notification
- Periodic polling of the PDC emulator master

These methods are described in the sections that follow.

**Root server notification**

To maintain a consistent namespace across root servers, DFS depends on the domain controller acting as the primary domain controller (PDC) emulator master to be the gatekeeper for all updates to the namespace. Having all root servers running Windows Server 2003 poll the PDC emulator master after the namespace changes ensures that root servers can obtain the updated DFS metadata relatively quickly without needing to wait for Active Directory replication to replicate the DFS object to all domain controllers.

Root server notification in Windows Server 2003 works as follows:

1. The DFS tool that an administrator uses to make the change contacts the closest root server for that namespace.

2. The root server updates the DFS metadata in the DFS object in Active Directory on the PDC emulator master.

3. The root server sends a change notification message to all other root servers hosting the namespace.

4. When root servers running Windows Server 2003 receive the change notification message, they poll the PDC emulator master to obtain an updated version of the DFS metadata. (Root servers running Windows 2000 Server ignore change notification messages and poll the PDC emulator master every hour.) If a Windows Server 2003 root server does not receive the change notification message, for example, if the root server is temporarily offline, it will poll the PDC emulator master at the next polling interval.

This update process can cause an increased load on the PDC emulator master in namespaces that have more than 16 root targets and in namespaces that change frequently. In these environments, we recommend enabling root scalability mode. For more information, see "How Root Scalability Mode Works" later in this section.

**Periodic polling of the PDC emulator master**
By default, root servers poll the PDC emulator master during the following events:

- When the root server starts up or the DFS service is restarted.

- When any DFS API is called against the root server. For example, using the Dfscmd.exe command-line tool with the **/**view *****dfsname******dfsshare* **/**fullparameter causes the root server to poll the PDC emulator master. (This command calls the NetDfsEnum API.)

- At the interval specified in the **SyncIntervalInSeconds** registry entry (on the root server), which is one hour by default. Organizations that have stable namespaces can increase this value so that root servers contact the PDC emulator master less frequently.

If the PDC emulator master is unavailable when a root server attempts polling, the root server will poll its closest domain controller. If the DFS object has replicated from the PDC emulator master to the domain controller closest to the root server, the root server receives the up-to-date version of the DFS object at the next polling.

**When changes to domain-based namespaces are reflected in referrals**
Even if the DFS metadata (stored in a memory cache on root servers and present in the DFS object in Active Directory on domain controllers) is identical and up-to-date, DFS root servers and domain controllers can provide outdated domain-based root referrals until those referrals expire or are cleared from the domain-based root referral cache. On the other hand, link referrals are up-to-date as soon as the root server receives an updated copy of the DFS object. After the root servers and domain controllers begin providing up-to-date referrals, clients might continue to use outdated referrals until the referrals expire or are flushed from the client's referral cache.

You can use the following table to determine the maximum length of time that out-of-date referrals are used in domain-based namespaces. This table assumes that the root servers and domain controllers have received the most recent version of the DFS metadata.

**When Referrals to Domain-based Namespaces Expire**

| Where Referrals Are Cached | Referral Type | Default Expiration Time | Where Expiration Time Is Stored |
|---|---|---|---|
| Domain controller | Domain-based root referral | 15 minutes | **RootReferralTimeoutInSeconds** registry entry |
| Root server | Domain-based root referral | 15 minutes | **RootReferralTimeoutInSeconds** registry entry |

| | | | |
|---|---|---|---|
| DFS client | Domain-based root referral | 5 minutes | Time to Live of root (configured using the DFS tools) |
| DFS client | Link referral | 30 minutes | Time to Live of link (configured using the DFS tools) |

Based on the default values in the previous table, domain controllers and root servers can provide updated domain-based root referrals after 15 minutes, assuming that the domain controller or root server has received the most recent version of the DFS object in Active Directory. Any latency in Active Directory replication could cause additional delay.

If settings on a link change, root servers can provide up-to-date link referrals as soon as the root server has obtained an updated version of the DFS metadata (in the DFS object) from the PDC emulator master. As described earlier, root servers contact the PDC emulator master soon after they receive the change notification message. If root servers are connected by high-speed network connections to each other and to the PDC emulator master, any changes to links are reflected in referrals almost immediately. A root server will provide out-of-date information in a link referral if any of the following conditions apply:

- The root server does not receive a change notification message due to network problems or other issues. In this case, the root server will contact the PDC emulator to obtain the updated DFS metadata at the polling interval described earlier. (Note that root servers running Windows 2000 Server ignore change notification messages and poll the PDC emulator master every hour.)

- Root scalability mode is enabled. In this case, root servers obtain the DFS metadata from the closest domain controller every hour, so you must factor in an additional one-hour delay plus the time required for Active Directory replication to replicate the updated DFS object to each domain controller.

For DFS clients that are not running Windows XP with SP2 or Windows Server 2003 with SP1, the Time to Live for a referral determines the earliest time that a client will request a new referral, but only if the existing referral expires before it is accessed again. Clients that use a cached referral will renew the Time to Live of the referral and thus use the referral indefinitely until the client's referral cache is cleared or the client is restarted.

This behavior has changed for clients running Windows XP with SP2 or Windows Server 2003 with SP1. Specifically, the Time to Live value is not reset each time a client accesses a target using a cached referral. Instead, the referral expires after the Time to Live value lapses. This change has several effects:

- Clients running Windows XP with SP2 or Windows Server 2003 with SP1 will request referrals more frequently than other DFS clients, which can cause moderately increased load on the domain-based DFS root servers and domain controllers.

- Because they request new referrals more frequently, clients running Windows XP with SP2 or Windows Server 2003 with SP1 will discover namespace updates more quickly than other DFS clients.

**How Root Scalability Mode Works**

Root scalability mode allows organizations to use more than the recommended 16 root targets per domain-based root. When root scalability mode is enabled, DFS root servers do not send change notification messages to other root servers when the namespace changes or poll the PDC emulator master every hour. Instead, they poll their closest domain controller every hour to discover updates to the namespace.

Root scalability mode reduces network traffic to the PDC emulator master at the expense of faster updates to all root servers. Updates are still made to the DFS object in Active Directory on the PDC emulator master, but root servers do not discover those changes until the updated DFS object replicates (using Active Directory replication) to the closest domain controller for each root server. After root scalability mode is enabled, clients might have an inconsistent view of the namespace until the most up-to-date version of the DFS object is replicated to all domain controllers and the DFS root servers poll a domain controller to discover the changes.

Root scalability mode does not entirely eliminate traffic to the PDC emulator master. The PDC emulator master is still used as follows:

- As described earlier, changes to the namespace are still made on the PDC emulator master.

- If the closest domain controller is the PDC emulator master, then the root server will poll the PDC emulator master every hour.

- When the DFS service starts on the root server (when the server reboots, for example), the DFS service polls the PDC emulator master. On the next polling interval, the root server polls the closest domain controller to get an initial copy of the DFS metadata. This behavior occurs because the root scalability setting is stored in the DFS object in Active Directory, so when a root server first starts up, it polls the PDC emulator master, determines that root scalability mode is enabled, and begins polling the domain controller at regular intervals.

- If a domain-based root has root targets running Windows 2000 Server and Windows Server 2003, root servers running

Windows 2000 Server poll the PDC emulator master every hour.

**What Happens When You Check Target Status**

You can use the Distributed File System snap-in to check the status of roots, links, and root and link targets. The snap-in verifies the namespace elements as follows:

- When you check the status of a root or link, the snap-in calls the GetFileAttributes API on each target to verify that they can be accessed. If this succeeds, the snap-in calls the GetFileAttributes API on the root folder or link folder to verify that it can be accessed.

- When you check the status of a root target or link target, the snap-in calls the GetFileAttributes API on the target to verify that the target can be accessed.

The following tables list the possible status indicators for DFS roots, links, and targets. These status indicators remain on the namespace element until you restart the snap-in or choose the **Refresh** command on the **Action** menu.

**DFS Status Flags for Roots and Links**

| Root or Link | Description |
|---|---|
| Folder icon (yellow) | No known status. |
| Folder icon with green check mark | All targets are reachable on the network and their referrals are enabled. |
| Folder icon with yellow exclamation point | Indicates one of the following conditions:<br>• All corresponding targets are reachable on the network but one or more targets has its referral disabled.<br>• Some corresponding targets are not reachable on the network. |
| Folder icon with red X | Indicates one of the following conditions<br>• All corresponding targets are not reachable on the network.<br>• All corresponding targets have their referrals disabled.<br>• The root path is unreachable. |

**DFS Status Flags for Targets**

| Target | Description |
|---|---|
| Folder icon (yellow) | No known status. |
| Folder icon with green check mark | Target is reachable on the network. |
| Folder icon with red X | Target is not reachable on the network. |

**How DFS Works on Server Clusters**

A server cluster is a group of individual computer systems, called nodes, working together cooperatively to provide increased computing power and continuous availability of business-critical applications or resources. A cluster can be configured so that the workload is distributed among the group, and if one of the nodes fails, another node automatically assumes its duties.

Using DFS in conjunction with server clusters can result in the increased availability of stand-alone roots in an organization. DFS is supported on server clusters as follows:

- **Link targets.** Link targets can consist of any File Share resource on shared cluster storage and any shared folder on a cluster node's local (non-shared) storage. The fact that a link target exists on a server cluster is transparent to DFS, so you can select these link targets as you would link targets on non-clustered file servers. If a link target is hosted on a cluster node's local storage, and the node fails or is taken offline, the link target is not available.

- **Stand-alone roots.** Stand-alone roots are supported on shared cluster storage and on a cluster node's local storage. When a

stand-alone root is created on shared cluster storage, the root is available as long as one of the nodes in the server cluster is available. If a stand-alone root is hosted on a cluster node's local storage, and the node fails or is taken offline, the namespace is not available.

- **Domain-based roots.** Domain-based roots are not supported on shared cluster storage. Domain-based roots are supported only on a cluster node's local storage. If a domain-based root is hosted on a cluster node's local storage, and the node fails or is taken offline, the namespace is not available unless there is another root target (either on another node's local storage or on another server in the domain).

If you plan to create stand-alone roots on shared cluster storage, it is important to understand the resource dependencies for DFS roots and the processes related to the creation and failover of DFS roots. The following sections describe these issues. For more information about how server clusters work in general, see "Server Clusters Technical Reference."

**Resource Dependencies of Stand-Alone Roots**

Using Cluster Administrator, you choose the File Share resource type to create a stand-alone DFS root on a server cluster's shared storage. The resource group that hosts the DFS root must contain the following resources:

- File Share resource (select the **DFS Root** option)
- Network Name resource (this is the virtual server name that is used by the clients to access this DFS root)
- IP Address resource (for the network name)
- Physical Disk resource (hosts the DFS root)

The dependencies for these resources must be configured correctly so that DFS can fail over if the node hosting the DFS root fails. The dependency tree is illustrated in the following figure.

**File Share Resource Dependency Tree**

**How Stand-Alone Roots on Server Clusters Work**

When the DFS service starts on a cluster node, the DFS service uses the Cluster APIs to determine whether the current node is part of a cluster. This process is important for two reasons

- Stand-alone roots on cluster nodes can be put in standby mode by using the NetDfsSetInfo API. When a root is put on this state, the DFS service does not provide referrals for it. Note that only stand-alone roots on cluster nodes can be put on this state. This state is not supported for normal stand-alone or domain-based roots. When the root is in standby mode, the operations of removing the root and bringing the cluster to online mode are supported.
- The referrals for stand-alone roots on cluster nodes must contain the respective virtual server name rather than the name of the node that is currently hosting the root.

When a stand-alone root is first created on shared cluster storage, the DFS service (on the node that hosts the resource group that contains the DFS root resource) creates the DFS metadata for the root in a registry entry at KEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfs\Roots\Standalone. The Cluster service propagates this registry information to the cluster database on the quorum resource, which is a resource that maintains the configuration data that is necessary for the recovery of the resource group. When a link is added or removed, or when the settings on the namespace are changed, the DFS service on the hosting node makes these changes in the DFS metadata in the registry. These changes to the registry are propagated to the cluster database. The physical folder acting as the root folder and any link folders are maintained on the shared cluster storage.

DFS registers a callback function with the Cluster service when a root is first created on a node and when the root is created on another node during cluster failover. The callback function is important because it allows DFS to determine whether the root is created on shared cluster storage. When DFS registers a callback function, the Cluster service enumerates all the File Share resources in the

cluster, and DFS determines if the root it is currently creating is a cluster resource.

If the node that hosts the DFS root fails, the following actions occur on another node (for example, Node 2):

1. The Cluster service reads the root's registry settings from the quorum resource and places these settings in the registry (of Node 2).

2. The Cluster service brings the resources online in the order of dependency.

3. The Cluster service creates an SMB shared folder on the root folder in the shared cluster storage.

4. The Cluster service informs DFS about the new root information in the registry and starts the DFS service if it is not already running.

5. DFS creates the internal data structures necessary for the DFS service to provide referrals for this root.

If a client attempts to access the root between steps 3 and 4, the client cannot access links under the root. This problem occurs because the DFS root is not yet created, so the SMB redirector claims the UNC path, causing the client's MUP cache to contain entries indicating that the resource is an SMB shared folder, and not a DFS root. Clearing the client's MUP cache by using Dfsutil.exe's **/PurgeMupCache** parameter will correct this problem.

**How DFS Works with Offline Files**
By using the Offline Files feature, you can make shared folders that correspond to DFS root targets and link targets available offline to client computers running Windows XP Professional or Windows Server 2003. The following sections describe two important interactions between Offline Files and DFS. These sections assume that the client computers are running either Windows XP Professional or Windows Server 2003.

**Offline Settings on Root Targets and Link Targets**
The Offline Files feature provides three settings for shared folders:

- Only the files and programs that users specify will be available offline.

- All files and programs on the share will be available offline.

- No files or programs on the share will be available offline.

Offline settings for root targets and link targets are set on the individual shared folders that are specified as targets. Although link targets appear subordinate to root targets in the namespace, link targets do not inherit or otherwise use the offline settings set on root targets. In addition, if a root or link has multiple targets, and those targets have different offline settings, the client will use whatever settings are applied to the target to which the client connects. Therefore, it is important for administrators to apply offline settings consistently to all targets for a DFS root or link.

**How the Offline Files Feature Interprets DFS Paths**
The Offline Files feature does not distinguish DFS paths from UNC paths. This can cause the client to interpret the entire namespace as unavailable if a target is down when a client attempts to access it. For example, if \\Contoso.com\Public is a domain-based root with several root targets and numerous links, the Offline Files feature interprets this namespace as a single server named \\Contoso.com. If a client is accessing or attempts to access a target in the \\Contoso.com\Public namespace, and the target is unavailable, the client interprets the entire namespace as unavailable and will attempt to open a user's locally cached files (if they exist). The client cannot access any target in the namespace until the target comes back online. The client will check every 10 minutes to detect whether the target has come back online. Alternatively, the user can use the Synchronization Manager to attempt to synchronize the offline files with those stored on the network. The user can also use Synchronization Manager to go back online without synchronizing changes.

**DFS-Related Processes on Clients**
The following sections describe how DFS clients running Windows XP and Windows 2000 update the memory caches described in "DFS Physical Structures and Caches on DFS Clients" earlier in this section.

**How Clients Update the Domain Cache**
DFS clients periodically discover new domains in the local forest and in trusted forests. This discovery process, which occurs every 15 minutes by default, runs against a domain controller from the domain that hosts the client's computer account. To avoid real-time queries to domain controllers in the domain, the referrals received during the discovery process are stored in a special table, called the domain cache or SPC cache. As a result of this process, clients can more quickly distinguish queries for fully qualified domain names from fully qualified computer names.

The process by which DFS clients update the domain cache is as follows:

1. When a DFS client starts up, the Workstation service calls the DFS client driver (Mup.sys) with information about the NetBIOS

and DNS names of the domain to which the client is joined. The Workstation service also provides the name of one domain controller in that domain. For this example, assume that the domain controller is called ClientDC.

2. The client saves the domain information and opens the IPC$ connection (\\ClientDC\IPC$) to the domain controller and sends a request with an empty name to request a list of trusted domains (in the client's forest and in trusted forests).

   If the client cannot connect to the domain controller or the domain controller fails in its response, the failure is sent to the Workstation service. This causes the Workstation service to find another domain controller for the client's domain and to pass that information to the DFS client. If this also fails, the Workstation service stops attempting to locate a domain controller. Regardless of whether previous attempts have succeeded, the Workstation service performs this process every 15 minutes (to ensure that DFS has a current working domain controller). The **DfsDcNameDelay** registry entry on the DFS client specifies the 15-minute interval.

3. If the referral request for the domain name information is successful, the client fills in its domain cache. This cache contains the domain information returned to the client as a response to the empty referral request. This information is updated every time the Workstation service calls the DFS client driver.

4. Any UNC request on the client comes to DFS first before any of the network redirectors. DFS checks its domain cache to determine whether the name is a domain name. If it is (meaning that the UNC path request is for a domain-based namespace), DFS checks its referral cache to detect whether it already has a referral to this namespace. If no referral exists, and the name is a domain name, the client proceeds to the next step.

5. The client determines whether the domain name is expanded. An expanded domain name is one in which the domain controllers are cached for the domain. If the domain name is not expanded, the client requests a domain controller referral from ClientDC.

DFS clients request new domain name referrals and domain controller referrals every 15 minutes, by default. You can configure this interval by using the **DfsDcNameDelay** registry entry on the client. Domain name referrals and domain controller referrals remain in the client's domain cache until the client receives updated referrals at the next interval or the client computer is restarted.

**Note**

- Without the proper domain name referrals and domain controller referrals, clients cannot access domain-based namespaces. This problem can occur when clients are logged on using cached credentials. DNS problems can also cause a client to be missing referrals.

If an organization has a large number of trusted domains and forests, it is possible that clients will not be able to access all domain-based namespaces within the trusted domains and forests. If a client can access a link target in another trusted domain or trusted forest by using the target's UNC path, the client can also access the link target by using its DFS path, but only if the list of domains fits into the client's buffer. By default, DFS clients send a 4-KB (2,048 Unicode character) buffer to a domain controller when requesting domain name referrals. If the list of domains is too large to fit into the 4-KB buffer, DFS clients automatically increase their buffer size to accept the list of domains, up to a maximum of 56 KB.

If the list of domains exceeds 56 KB, DFS puts as many domains in the buffer as it can until the buffer reaches 56 KB. DFS then writes an entry with the ID 14536 in the system event log of the domain controller that provided the domain referral. When populating the buffer, DFS gives preference to local and explicitly trusted domains by filling the buffer with their names first. Consequently, by creating explicit trust relationships with domains that host important DFS namespaces, you can minimize the possibility that those domain names might be dropped from the list that is returned to the client.

**Note**

- To make sure that clients can access link targets in other trusted domains or trusted forests, use DNS names for all link targets and configure DFS to use fully qualified domain names in referrals. For more information about using DNS names, see "How DFS Works in Environments Without WINS" earlier in this section.

**How Clients Update the MUP Cache**

When a Windows-based client attempts to access a UNC path, Windows sends the request to the multiple UNC provider (Mup.sys) to identify which redirector should handle the request. When Mup.sys receives the request, Mup.sys determines whether the path is in a DFS namespace. If it is, Mup.sys passes the request to DFS. If the path is a shared folder or WebDAV folder, for example, Mup.sys checks its internal cache, known as the MUP cache, to see whether the connection had been made previously. Mup.sys then sends the request to each redirector that handles each request synchronously and attempts to identify a resource on the network that matches the request. After all redirectors return, Mup.sys chooses the redirector that the application will use (based on response and priority).

**How Clients Update the Referral Cache**

When users access DFS roots and links, the client sends a referral request to the DFS server (either a domain controller or root server, depending on the type of referral requested). The DFS server puts the referral response in a 4 KB buffer (2,048 Unicode characters) and returns the buffer to the client. Root servers and domain controllers send referrals up to 4 KB if there is room for at least one target in the referral. If the paths of the targets are so long that the 4-KB buffer cannot hold even one target, DFS makes the client request a larger response limit (up to 56 KB).

After a client receives a referral, the client stores the referral in the referral cache and accesses the first available target (either a particular root target or link target) in the list of targets provided in the referral. The client will continue to access that target until one of the following occurs:

- The client computer is restarted, which clears the referral cache.
- The user manually clears the referral cache by using Dfsutil.exe with the **/pktflush** parameter.
- The target server becomes unavailable.
- The Time to Live value for the root or link referral expires. Windows Server 2003 uses a default Time to Live value of 300 seconds (5 minutes) for root referrals and 1800 seconds (30 minutes) for link referrals.

After any of these events, the client will obtain a new referral the next time it attempts to access the target. If the client continues to access the target within the Time to Live value, the Time to Live value is renewed and the client never requests a new referral. If the Time to Live value is not renewed, it is decremented by 4 minutes (240 seconds) until it reaches zero. If the Time to Live value is set less than 240 seconds, the referral will not expire for 240 seconds.

**DFS Protocols**

DFS uses the Common Internet File System (CIFS) for communication between DFS clients, root servers, and domain controllers. CIFS is an extension of the Server Message Block (SMB) file sharing protocol. Examining network captures of CIFS communications between a DFS client and server is helpful for understanding and troubleshooting DFS processes. The following sections illustrate two network captures created when a client receives different types of referrals.

**Network Capture of a Client Receiving Domain Name Referrals and Domain Controller Referrals**

The following network capture (taken using Microsoft Network Monitor) shows what happens when a client first receives domain name referrals and domain controller referrals. This network capture was taken on a domain controller (named DC-01) after the client (named DFSCLIENT) was restarted. Only SMB frames are shown. Note that this network capture is an example of client and domain controller communication and might differ from network captures taken in your environment.

### Network Capture of a Client Receiving Domain Name Referrals and Domain Controller Referrals

| Frame | Protocol | Description | Src Other Addr | Dst Other Addr |
|---|---|---|---|---|
| 13 | SMB | C negotiate, Dialect = NT LM 0.12 | DFSCLIENT | DC-01.CONTOSO.CO |
| 14 | SMB | R negotiate, Dialect # = 5 | DC-01.CONTOSO.CO | DFSCLIENT |
| 15 | SMB | C session setup & X | DFSCLIENT | DC-01.CONTOSO.CO |
| 18 | SMB | R session setup & X | DC-01.CONTOSO.CO | DFSCLIENT |
| 20 | SMB | C tree connect & X, Share = \\DC-01.CONTOSO.COM\IPC$ | DFSCLIENT | DC-01.CONTOSO.CO |
| 22 | SMB | R tree connect & X, Type = IPC | DC-01.CONTOSO.CO | DFSCLIENT |
| 23 | SMB | C transact2 NT Get DFS Referral | DFSCLIENT | DC-01.CONTOSO.CO |
| 24 | SMB | R transact2 NT Get DFS Referral (response to frame 23) | DC-01.CONTOSO.CO | DFSCLIENT |
| 25 | SMB | C transact2 NT Get DFS Referral | DFSCLIENT | DC-01.CONTOSO.CO |
| 26 | SMB | R transact2 NT Get DFS Referral (response to frame 25) | DC-01.CONTOSO.CO | DFSCLIENT |
| 27 | SMB | C transact2 NT Get DFS Referral | DFSCLIENT | DC-01.CONTOSO.CO |
| 28 | SMB | R transact2 NT Get DFS Referral (response to frame 27) | DC-01.CONTOSO.CO | DFSCLIENT |

The following sections provide a partial printout of the SMB data for each frame and explain the processes that occur in each frame. These processes are explained in more detail in “DFS Physical Structures and Caches on DFS Clients” and “The Referral Process” earlier in this section.

**Frames 20 and 22: Client connects to IPC$**

The client connects to IPC$ on DC-01.

**Frame 23: Client requests domain name referral**

The client sends a request with an empty name to the domain controller to request a domain name referral.

```
SMB: Transaction parameters
SMB: DFS Max Referral Level = 3 (0x3)
SMB: DFS Request Filename =
```

**Frame 24: Domain controller provides a domain name referral**

The domain controller provides a domain name referral that contains the names of all trusted domains in the client’s forest and in trusted forests. In this particular example, there is only one domain.

```
SMB: Transaction data
SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = Unknown Server Type
SMB: DFS TimeToLive = 600 (0x258)
SMB: DFS Special Name =\contoso.com
SMB: DFS Number of Expanded Names = 0 (0x0)
SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = Unknown Server Type
SMB: DFS TimeToLive = 600 (0x258)
SMB: DFS Special Name =\CONTOSO
SMB: DFS Number of Expanded Names = 0 (0x0)
```

**Frame 25: Client requests a domain controller referral**

The client requests a domain controller referral for Contoso.com. Note that the client is sending the DNS name (Contoso.com).

```
SMB: Transaction parameters
SMB: DFS Max Referral Level = 3 (0x3)
SMB: DFS Request Filename = \contoso.com
```

**Frame 26: Domain controller provides a domain controller referral**

The domain controller provides domain controller referrals for the three domain controllers in the Contoso.com domain. The domain controller names are returned as DNS names.

```
SMB Transaction data
SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = Unknown Server Type
SMB: DFS TimeToLive = 600 (0x258)
SMB: DFS Special Name =\contoso.com
SMB: DFS Number of Expanded Names = 3 (0x3)
SMB: DFS Expanded Name =\Dc-01.contoso.com
SMB: DFS Expanded Name =\Dc-03.contoso.com
SMB: DFS Expanded Name =\Dc-02.contoso.com
```

**Frame 27: Client requests a domain controller referral**

The client requests a domain controller referral for Contoso, the NetBIOS name of the domain.

```
SMB: Transaction parameters
SMB: DFS Max Referral Level = 3 (0x3)
SMB: DFS Request Filename =\CONTOSO
```

**Frame 28: Domain controller provides a domain controller referral**

The domain controller provides domain controller referrals for the three domain controllers in the Contoso.com domain. The domain controller names are returned as NetBIOS names.

```
SMB Transaction data
SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = Unknown Server Type
SMB: DFS TimeToLive = 600 (0x258)
SMB: DFS Special Name =\
SMB: DFS Number of Expanded Names = 3 (0x3)
SMB: DFS Expanded Name =\Dc-01
SMB: DFS Expanded Name =\Dc-03
SMB: DFS Expanded Name =\Dc-02
```

**Network Capture of a Client Accessing a Domain-based Namespace**

The following network capture shows what happens when a client accesses a link (Software) in the \\Contoso.com\Public namespace. This network capture was taken on a DFS client (named DFSCLIENT) and includes referrals from a domain controller (named DC-01), a root server (ROOT-DFS-03), and a link target server (NOAM-FS-1). Only SMB frames are shown, and some frames were removed for brevity. Note that this network capture is an example of client, root server, and link target communication and might differ from network captures taken in your environment.

### Network Capture of a Client Accessing a Domain-based Namespace

| Frame | Protocol | Description | Src Other Addr | Dst Other Addr |
|---|---|---|---|---|
| 352 | SMB | C tree connect & X, Share = \\DC-01.CONTOSO.COM\IPC$ | DFSCLIENT | DC-01.CONTOSO.CO |
| 353 | SMB | R tree connect & X, Type = IPC | DC-01.CONTOSO.CO | DFSCLIENT |
| 354 | SMB | C transact2 NT Get DFS Referral | DFSCLIENT | DC-01.CONTOSO.CO |
| 355 | SMB | R transact2 NT Get DFS Referral (response to frame 354) | DC-01.CONTOSO.CO | DFSCLIENT |
| 365 | SMB | C negotiate, Dialect = NT LM 0.12 | DFSCLIENT | ROOT-DFS-03 |
| 366 | SMB | R negotiate, Dialect # = 5 | ROOT-DFS-03 | DFSCLIENT |
| 369 | SMB | C session setup & X | DFSCLIENT | ROOT-DFS-03 |
| 370 | SMB | R session setup & X | ROOT-DFS-03 | DFSCLIENT |
| 374 | SMB | C tree connect & X, Share = \\ROOT-DFS-03\PUBLIC | DFSCLIENT | ROOT-DFS-03 |
| 375 | SMB | R tree connect & X, Type = A: | ROOT-DFS-03 | DFSCLIENT |
| 377 | SMB | C transact2 Query path info, File = \contoso.com\public | DFSCLIENT | ROOT-DFS-03 |

| Frame | Protocol | Description | Src Other Addr | Dst Other Addr |
|---|---|---|---|---|
| 561 | SMB | C transact2 Query path info, File = \contoso.com\public\Software | DFSCLIENT | ROOT-DFS-03 |
| 562 | SMB | R transact2 - NT error, System, Error, Code = (599) STATUS_PATH_NOT_COVERED | ROOT-DFS-03 | DFSCLIENT |
| 563 | SMB | C tree connect & X, Share = \\ROOT-DFS-03\IPC$ | DFSCLIENT | ROOT-DFS-03 |
| 564 | SMB | R tree connect & X, Type = IPC | ROOT-DFS-03 | DFSCLIENT |
| 565 | SMB | C transact2 NT Get DFS Referral | DFSCLIENT | ROOT-DFS-03 |
| 567 | SMB | R transact2 NT Get DFS Referral (response to frame 565) | ROOT-DFS-03 | DFSCLIENT |
| 577 | SMB | C negotiate, Dialect = NT LM 0.12 | DFSCLIENT | NOAM-FS-1 |
| 578 | SMB | R negotiate, Dialect # = 5 | NOAM-FS-1 | DFSCLIENT |
| 587 | SMB | C session setup & X | DFSCLIENT | NOAM-FS-1 |
| 588 | SMB | R session setup & X | NOAM-FS-1 | DFSCLIENT |
| 589 | SMB | C tree connect & X, Share = \\NOAM-FS-1\APPS | DFSCLIENT | NOAM-FS-1 |
| 590 | SMB | R tree connect & X, Type = A: | NOAM-FS-1 | DFSCLIENT |
| 591 | SMB | C transact2 Query path info, File = | DFSCLIENT | NOAM-FS-1 |
| 592 | SMB | R transact2 Query path info (response to frame 591) | NOAM-FS-1 | DFSCLIENT |
| 593 | SMB | C transact2 Findfirst, File = * | DFSCLIENT | NOAM-FS-1 |
| 594 | SMB | R transact2 Findfirst (response to frame 593) | NOAM-FS-1 | DFSCLIENT |

The following sections provide a partial printout of the SMB data for each frame and explain the processes that occur in each frame. These processes are explained in more detail in "The Referral Process" earlier in this section.

**Frames 352-353: Client connects to IPC$**
The client connects to IPC$ on DC-01.

**Frame 354: Client requests a root referral**
The client requests a root referral for the \\Contoso.com\Public namespace.

```
SMB: Transaction parameters
SMB: DFS Max Referral Level = 3 (0x3)
SMB: DFS Request Filename = \contoso.com\public
```

**Frame 355: Domain controller provides a root referral**
The domain controller provides a root referral that contains three root servers, \\Root-DFS-03\Public, \\Root-DFS-02\Public, and \Root-DFS-01\Public.

```
SMB Transaction data
SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = SMB Server
SMB: DFS TimeToLive = 300 (0x12C)
SMB: DFS Filename =\contoso.com\public
SMB: DFS 8.3 Filename =\contoso.com\public
SMB: DFS Sharename =\Root-DFS-03\public
SMB: Servicesite GUID = 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00

SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = SMB Server
SMB: DFS TimeToLive = 300 (0x12C)
SMB: DFS Filename =\contoso.com\public
SMB: DFS 8.3 Filename =\contoso.com\public
SMB: DFS Sharename =\Root-DFS-02\public
SMB: Servicesite GUID = 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00

SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = SMB Server
SMB: DFS TimeToLive = 300 (0x12C)
SMB: DFS Filename =\contoso.com\public
SMB: DFS 8.3 Filename =\contoso.com\public
SMB: DFS Sharename =\Root-DFS-01\public
SMB: Servicesite GUID = 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00
```

**Frames 365-377: Client connects to Root-DFS-03**
The client establishes a connection with the first root server in the referral, Root-DFS-03.

**Frame 561: Client navigates to Software link folder**

The client navigates to the Software link folder on the root server.

**Frame 562: Root server provides STATUS_PATH_NOT_COVERED message**
The root server responds with the STATUS_PATH_NOT_COVERED message, which indicates that this is a link folder and that the client must request a link referral.

**Frames 563-564: Client connects to IPC$ on root server**
The client connects to IPC$ on the root server.

**Frame 565: Client requests a link referral**
The client requests a link referral to the Software link.

```
SMB: Transaction parameters
SMB: DFS Max Referral Level = 3 (0x3)
SMB: DFS Request Filename =\contoso.com\public\Software\
```

**Frame 567: Root server provides a link referral**
The root server sends a link referral that contains three link targets for the Software link: \\Noam-FS-1\Apps, \\Noam-FS-3\Apps, and \\Noam-FS-2\Apps.

```
SMB Transaction data
SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = Unknown Server Type
SMB: DFS TimeToLive = 1800 (0x708)
SMB: DFS Filename =\contoso.com\public\software
SMB: DFS 8.3 Filename =\contoso.com\public\software
SMB: DFS Sharename =\noam-fs-1\apps
SMB: Servicesite GUID = 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00

SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = Unknown Server Type
SMB: DFS TimeToLive = 1800 (0x708)
SMB: DFS Filename =\contoso.com\public\software
SMB: DFS 8.3 Filename =\contoso.com\public\software
SMB: DFS Sharename =\noam-fs-3\apps
SMB: Servicesite GUID = 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00

SMB: DFS Version 3 Referral
SMB: DFS Version Number = 3 (0x3)
SMB: DFS Server Type = Unknown Server Type
SMB: DFS TimeToLive = 1800 (0x708)
SMB: DFS Filename =\contoso.com\public\software
SMB: DFS 8.3 Filename =\contoso.com\public\software
SMB: DFS Sharename =\noam-fs-2\apps
SMB: Servicesite GUID = 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00
```

**Frames 577-589: Client connects to \\Noam-FS-1\Apps**
The DFS client sets up a session with the first link target in the referral, \\Noam-FS-1\Apps.

**DFS Interfaces**
The following APIs are associated with DFS. For more information about these APIs, see DFS in the Microsoft Platform SDK on MSDN.

### DFS APIs

| API Name | Description |
|---|---|
| NetDfsAdd | Creates a new Dfs link or adds targets to an existing link in a DFS root. |
| NetDfsAddFtRoot | Creates a new domain-based root. If the domain-based root already exists, the function adds the specified root target to the root. |
| NetDfsAddStdRoot | Creates a new stand-alone root. |
| NetDfsEnum | Enumerates all links in the named root. It also lists all roots in a domain and all roots on a server. |
| NetDfsGetClientInfo | Returns the information about cached referrals on a client for a given DFS root or link path. |
| NetDfsGetInfo | Retrieves information about a root or a link in the named root. |

| | |
|---|---|
| NetDfsRemove | Removes a link target from a link or removes a link. If the specified target is the last target of the link, then the NetDfsRemove function also removes the link. |
| NetDfsRemoveFtRoot | Removes the specified root target from a domain-based root. If the target is the last target of the root, the function also deletes the root. |
| NetDfsRemoveFtRootForced | Removes the specified root target from a domain-based root, even if the server is offline. If the target is the last root target, the function also deletes the root. |
| NetDfsRemoveStdRoot | Deletes the stand-alone root. |
| NetDfsSetClientInfo | Modifies information about cached referrals on a client for a given DFS root or link path. |
| NetDfsSetInfo | Sets or modifies the information associated with a link in the named root, or with the root itself. |

**Network Ports Used by DFS**

DFS uses the following network ports.

**Network Ports Used by DFS**

| Service Name | Relevant Computers | UDP | TCP |
|---|---|---|---|
| NetBIOS Name Service | Domain controllers; root servers that are not domain controllers; servers acting as link targets; client computers acting as link targets | 137 | 137 |
| NetBIOS Datagram Service | Domain controllers; root servers that are not domain controllers; servers acting as link targets; client computers acting as link targets | 138 | |
| NetBIOS Session Service | Domain controllers; root servers that are not domain controllers; servers acting as link targets; client computers acting as link targets | | 139 |
| LDAP Server | Domain controllers | 389 | 389 |
| Remote Procedure Call (RPC) endpoint mapper | Domain controllers | | 135 |
| Server Message Block (SMB) | Domain controllers; root servers that are not domain controllers; servers acting as link targets; client computers acting as link targets | 445 | 445 |

# DFS Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- DFS Tools
- DFS Registry Entries
- DFS Group Policy Settings
- Network Ports Used by DFS
- Related Information

**DFS Tools**
The following tools are associated with Distributed File System (DFS).

**Dfscmd.exe: Distributed File System command-line tool**

**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
Windows Server 2003.

Dfscmd allows administrators to perform and script basic Distributed File System (DFS) tasks, such as configuring DFS roots, links, and targets.

**Dfsgui.msc: Distributed File System snap-in**

**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
Windows Server 2003.

Dfsgui.msc is also part of the Windows Server 2003 Administration Tools Pack; you can install this pack on computers running Windows XP with Service Pack 1 (SP1) or later.

Dfsgui.msc allows administrators to create DFS namespaces, add and remove targets, set the Time to Live for targets, enable and disable referrals, enable replication for DFS root or link targets, create custom replication schedules and topologies, and so forth.

**Dfsutil.exe: Distributed File System utility**

**Category**
Windows Support Tools for Windows Server 2003.

**Version compatibility**
Windows XP, Windows 2000, and Windows Server 2003.

Dfsutil allows administrators to perform advanced DFS tasks, such as enabling root scalability mode, least expensive target selection, and same-site target selection. Dfsutil is also useful for determining the size of a namespace, exporting or importing namespaces, checking the site name of a computer or IP address, adding and removing root targets, and updating site information for root servers running Windows 2000 Server. When installed on DFS clients, Dfsutil can be used to view and clear the referral cache (PKT cache), domain cache (SPC cache), and MUP cache.

**DFS Registry Entries**
The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It

is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following registry entries are associated with DFS.

For more information about registry entries, see the Registry Reference in the Tools and Settings Collection.

**DFS Domain Controller Registry Entries**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs on domain controllers. These registry entries are not used on DFS root servers unless the root server is also a domain controller. All entries are REG_DWORD.

**DomainNameIntervalInSeconds**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\Parameters\

**Version**
Domain controllers running Windows Server 2003.

Specifies how long (in seconds) domain controllers cache domain name referrals. The default value is 43,200 seconds (12 hours). The minimum is 600 seconds (10 minutes). There is no maximum value.

**SiteCostedReferrals**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\Parameters\

**Version**
Domain controllers running Windows Server 2003.

When set to 0 (the default), SYSVOL and NETLOGON referrals contain domain controllers in the client's site listed first in random order, followed by a random list of domain controllers. When set to 1, SYSVOL and NETLOGON referrals sort domain controllers in order of lowest cost. Domain controllers in the clients site are at the top of the referral list, followed by domain controllers sorted by lowest cost.

**DFS Domain Controller and Root Server Registry Entries**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs on root servers and domain controllers. All entries are REG_DWORD.

**DfsDnsConfig**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\

**Version**
Domain controllers and root servers running Windows Server 2003.

When set to 1, specifies that this server will use fully qualified domain names (FQDN) in referrals. When set to 0 (the default), specifies that this server will use NetBIOS names in referrals.

**LdapTimeoutValueInSeconds**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\Parameters\

**Version**
Domain controllers and root servers running Windows Server 2003.

Determines the time-out value (in seconds) for DFS LDAP calls. The default value is 30 seconds, the minimum value is 3 seconds, and the maximum value is 300 seconds (5 minutes).

**MaxClientsToCache**

**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\Parameters\

**Version**
Domain controllers and root servers running Windows Server 2003.

Specifies the maximum number of entries that can be maintained in the client site cache. When this limit is hit, unused cached entries are dropped. Client site entries are regenerated as needed. The default value is 200,000 entries, and the minimum value is 20,000 entries. There is no maximum value.

**QuerySiteCostTimeoutinSeconds**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\Parameters\

**Version**
Domain controllers and root servers running Windows Server 2003.

Specifies the time-out period (in seconds) after which DsQuerySitesByCost API calls for site cost information in Active Directory will fail. By default, the time-out period is 30 seconds. The minimum value is 3 seconds, and the maximum value is 300 seconds (5 minutes). If DFS cannot determine a target's site cost within this time-out period, DFS assumes the maximum possible cost for the target.

**RootReferralTimeoutInSeconds**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\Parameters\

**Version**
Domain controllers and root servers running Windows Server 2003.

Specifies how long (in seconds) domain controllers and root servers cache domain-based root referrals. The default and minimum value is 900 seconds (15 minutes). There is no maximum value.

**SiteSupportIntervalInSeconds**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\Parameters\

**Version**
Domain controllers and root servers running Windows 2000 Server and Windows Server 2003.

Specifies how long (in seconds) entries are maintained in the client site cache, target site cache, and site cost cache. The default value is 43,200 seconds (12 hours), and the minimum value is 300 seconds (5 minutes). Due to internal DFS processes, the entries in the client site cache and target site can remain for up to two times the value of this registry entry.

**SyncIntervalinSeconds**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dfs\

**Version**
Domain controllers and root servers running Windows Server 2003.

Specifies how often domain-based root servers and domain controllers poll the primary domain controller (PDC) emulator master to obtain updated DFS metadata. The minimum value is 900 seconds (15 minutes), and the default value is 3600 seconds (60 minutes).

**DFS Client Registry Entries**
The following registry entries are available for DFS clients running Windows XP and Windows 2000 Server. All entries are REG_DWORD.

**Client Referral Time to Live**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DfsClientDriver\Paramaters

**Version**
Client computers running Windows XP and Windows 2000.

Specifies referral Time To Live (TTL) values, overriding those provided by the server.

There are six keys that you can specify to control referral TTL values:

- **MinReferralTTL**The minimum TTL for non-domain referrals, in seconds. The default is **300** (five minutes).
- **MaxReferralTTL**The maximum TTL for non-domain referrals, in seconds. The default is **10080** (one week).
- **MinDomainTTL**The minimum TTL for domain referrals, in seconds. The default is **900** (15 minutes).
- **MaxDomainlTTL**The maximum TTL for domain referrals, in seconds. The default is **10080** (one week).
- **ReferralTTLMultiplier**The number of failed attempts to validate a non-domain referral before the client will stop testing the referral. The minimum value is **1**; the maximum is **100**; the default is **4**.
- **DomainTTLMultiplier**The number of failed attempts to validate a domain referral before the client will stop testing the referral. The minimum value is **1**; the maximum is **100**; the default is **4**.

**DfsDcNameDelay**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\lanmanworkstation\

**Version**
Client computers running Windows XP and Windows 2000.

Specifies the interval at which DFS clients discover new domains in the local forest and in trusted forests. This discovery process runs against a domain controller from the domain that is hosting the client's computer account. The default value for this entry is 900 seconds (15 minutes).

**DisableDFS**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Mup\

**Version**
Client computers running Windows Server 2003, Windows XP and Windows 2000.

When set to 0 (the default), clients can access DFS namespaces, including the SYSVOL and NETLOGON shared folders on domain controllers. When set to 1, disables DFS processing on the client.

**ProviderCacheTimeoutInMinutes**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Mup\

**Version**
Client computers running Windows Server 2003 or Windows XP.

Specifies the length of time that a multiple UNC provider (MUP) cache entry is held until it is reevaluated. The default and minimum value is 15 minutes, and the maximum value is 720 minutes (12 hours).

**DFS Group Policy Settings**
The following table lists and describes the Group Policy settings are associated with DFS.

### Group Policy Settings Associated with DFS

| Group Policy Setting and Path | Description |
|---|---|

| | |
|---|---|
| Computer Configuration\Administrative Templates\Network\Sets how often a DFS Client discovers DC's | Configures how often a DFS client attempts to discover domain controllers on the network. By default, a DFS client attempts to discover domain controllers every 15 minutes. This value is specified in minutes. If you disable this setting or do not configure it, the default value (15 minutes) is used.<br><br>The minimum value you can select is 15 minutes. If you specify a value of less than 15 minutes, the default value of 15 minutes is used. |
| User Configuration\Administrative Templates\Shared Folders\Allow DFS roots to be published | Determines whether the user can publish DFS roots in Active Directory. If you enable this setting or do not configure it, users can use the "Publish in Active Directory" option to publish DFS roots as shared folders in Active Directory. If you disable this setting, the user cannot publish DFS roots in Active Directory, and the "Publish in Active Directory" option is disabled.<br><br>The default is to allow shared folders to be published when this setting is not configured. |

For more information about Group Policy settings, see the Group Policy Settings Reference in the Tools and Settings Collection.

**Network Ports Used by DFS**

The following table lists the network ports used by DFS.

**Network Ports Used by DFS**

| Service Name | Relevant Computers | UDP | TCP |
|---|---|---|---|
| NetBIOS Name Service | Domain controllers; root servers that are not domain controllers; servers acting as link targets; client computers acting as link targets | 137 | 137 |
| NetBIOS Datagram Service | Domain controllers; root servers that are not domain controllers; servers acting as link targets; client computers acting as link targets | 138 | |
| NetBIOS Session Service | Domain controllers; root servers that are not domain controllers; servers acting as link targets; client computers acting as link targets | | 139 |
| LDAP Server | Domain controllers | 389 | 389 |
| Remote Procedure Call (RPC) endpoint mapper | Domain controllers | | 135 |
| Server Message Block (SMB) | Domain controllers; root servers that are not domain controllers; servers acting as link targets; client computers acting as link targets | 445 | 445 |

# FRS Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**FRS Technical Reference**
File Replication service (FRS) is a technology that replicates files and folders stored in the SYSVOL shared folder on domain controllers and Distributed File System (DFS) shared folders. When FRS detects that a change has been made to a file or folder within a replicated shared folder, FRS replicates the updated file or folder to other servers. Because FRS is a multimaster replication service, any server that participates in the replication of a shared folder can generate changes. In addition, FRS can resolve file and folder conflicts to make data consistent among servers.

**In this section**

- Common FRS Scenarios
- Technologies Related to FRS
- FRS Dependencies
- Related Information

File Replication service (FRS) is a technology that replicates files and folders stored in the SYSVOL shared folder on domain controllers and Distributed File System (DFS) shared folders. When FRS detects that a change has been made to a file or folder within a replicated shared folder, FRS replicates the updated file or folder to other servers. Because FRS is a multimaster replication service, any server that participates in replication can generate changes. In addition, FRS can resolve file and folder conflicts to make data consistent among servers.

By keeping files and folders synchronized across servers, FRS enables organizations to increase the availability of data. If one server becomes unavailable, the files are still available, because they exist on another server. Using multiple servers to host data also helps organizations that have offices in multiple geographic locations, because clients can access servers in or closest to their current site and do not need to use expensive WAN links to access data.

There are numerous methods for keeping files synchronized on servers. Although SYSVOL requires FRS, DFS shared folders can be kept synchronized by using methods other than FRS, such as manual copying, Robocopy, or other replication tools. FRS provides numerous benefits that other replication methods do not. These benefits include the following:

**Authenticated RPC with encryption**
To provide secure communications, FRS uses Kerberos authentication protocol for authenticated remote procedure call (RPC) to encrypt the data sent between members of a replica set.

**Compression**
To save network bandwidth, FRS compresses files in the staging folder by using NTFS compression. Files sent between servers participating in replication, known as replica members, remain compressed when transmitted over the network.

**Conflict resolution**
FRS resolves file and folder name conflicts to make data consistent among the replica members. If identically named files are created or modified on two or more replica members, FRS uses a “last writer wins” rule; this means that the most recently created or modified version of a file becomes the version that is replicated to the other replica members. If identically named folders are created on two or more replica members, FRS identifies the conflict during replication and renames the folder that was most recently created. Both folders are replicated to all servers in the replica set, and administrators can merge the contents of two folders or take some other measure to reestablish the single folder.

**Continuous replication**
FRS provides continuous replication, subject to replication schedule, server load, and network load. When a file or folder is changed and closed, FRS begins replicating the changed file or folder to other replica members within three seconds.

**Fault-tolerant replication path**
FRS does not rely on broadcast technology, and it can provide fault-tolerant distribution by way of multiple connection paths between members. If a replica member is unavailable, the data will take a different route. FRS prevents an identical file from being sent more than once to any replica member.

**Replication scheduling**
You can schedule replication to occur at specified times and durations as needed by your organization. For example, scheduling replication to occur during evening hours can reduce the cost of transmitting data over expensive WAN links. Replicating data during off-hours also frees up network bandwidth for other uses.

**Replication integrity**
Files are replicated only after they have been changed and closed. FRS relies on the update sequence number (USN) journal to log records of files that have changed on a replica member. As a result, FRS does not lose track of a changed file even if a

replica member shuts down abruptly. After the replica member comes back online, FRS replicates new or updated files that originated from other replica members, as well as replicating locally created or updated files that occurred before the shutdown. This replication takes place according to the replication schedule.

**Common FRS Scenarios**
FRS is commonly used in the following scenarios:

**SYSVOL Replication**
Every domain controller has a shared folder in its local file system that is the file system component of Active Directory. This shared folder, named SYSVOL, contains files and folders that must be available and synchronized between domain controllers in a domain, including:

- The NETLOGON shared folder, which includes system policies and user-based logon and logoff scripts for non-Windows Server 2003 and non-Windows 2000 network clients, such as clients running Windows 95, Windows 98, and Windows NT 4.0.
- Windows Server 2003 and Windows 2000 system policies.
- Group Policy settings (templates), including Group Policy settings for domain controllers running Windows Server 2003 or Windows 2000.

When you add, remove, or modify the contents in the SYSVOL shared folder, FRS replicates the changed contents to the SYSVOL shared folders on all other domain controllers in the domain. The following figure illustrates how SYSVOL shared folders are kept in sync on domain controllers in the corp.contoso.com domain.

**SYSVOL Replication**

**Publishing Applications**
FRS and DFS can be combined to distribute and publish applications. DFS allows administrators to group shared folders located on different servers by transparently connecting them to one or more hierarchical namespaces that behave like a single high-capacity hard disk. Users can navigate the namespace without having to know the physical server names or shared folders hosting the data. Administrators can also host data on multiple servers in multiple sites; users see a single copy of the data and DFS can refer users to the closest server to access the data.

When using DFS and FRS to publish applications, an administrator defines the topology used to distribute the data. The topology defines the path along which files are replicated; common topologies for distributing applications are hub-and-spoke, a multilevel tree, and redundant hub-and-spoke. New applications are typically deployed or updated on a single computer (usually the hub or root of the topology or another centrally located computer), and FRS then replicates the files to the spoke computers. The following figure illustrates a hub-and-spoke topology where applications are deployed on the hub and then replicated to the spokes.

**Publishing Applications Using a Hub-and-Spoke FRS Topology**

**Publishing Data**

DFS and FRS can also be used to publish data across an organization. Common examples of data include documents, diagrams, and operational procedures. This scenario often uses similar topologies (hub-and-spoke, a multilevel tree, or a redundant hub-and-spoke) as those used for publishing applications.

Another method of publishing data is known as reverse publication. In reverse publication, data flows from a number of different servers to a central server. Reverse publication is often used to gather log files and reports from individual computers and collect them in one central location. Reverse publication is also used in backup scenarios where data is collected from multiple servers and then backed up from the central server.

The following figure illustrates the reverse publication method.

**Reverse Publication**

**Ensuring That Personal Folders Are Available**

Organizations that store users' personal folders on file servers can increase the availability of those folders by using DFS and FRS to store the folders on multiple servers. The following figure illustrates a DFS namespace, \\Corp.Contoso.Com\Users, hosted by two servers, ServerA and ServerB. DFS equally distributes the client load between the two servers, and FRS keeps the data synchronized on the two servers. If one of the servers fails, DFS refers clients to the remaining server. Even when one of the servers is unavailable, users can continue to access the \\Corp.Contoso.com\Users namespace.

**How DFS and FRS Keep Data Available**

**Technologies Related to FRS**

FRS is closely related to the following two technologies.

**Active Directory replication**

Active Directory replication is the process by which the changes that are made to Active Directory objects on one domain controller are automatically synchronized with other domain controllers. This replication method does not use FRS and does not include SYSVOL replication. However, FRS replicates SYSVOL by using the connection object topology and schedule that the Knowledge Consistency Checker (KCC) creates for Active Directory replication. In addition, FRS has its own Active Directory objects that are replicated using Active Directory replication.

**DFS**

FRS can be used to keep data in DFS shared folders synchronized among replica members. However, DFS and FRS are two separate technologies, and DFS does not require FRS. You can use other replication methods, such as manual copying, the Windows Resource Kit tool Robocopy, or other replication tools to keep DFS shared folders synchronized. Conversely, if you want to use FRS to keep data in shared folders synchronized, you must use DFS.

**FRS Dependencies**

FRS has the following dependencies:

- **Active Directory replication**. FRS requires that Active Directory replication is working properly so that FRS Active Directory objects reside on all domain controllers in the domain.

- **DFS**. If you want to use FRS to keep data in folders synchronized on multiple servers, you must first set up a DFS namespace. (This dependency is not applicable to SYSVOL.)

- **DNS**. FRS requires that DNS is properly designed and deployed so that FRS can correctly resolve DNS names of replica members. (DNS is also required for Active Directory replication.)

- **Kerberos authentication**. FRS requires that Kerberos authentication is properly designed and deployed.

- **NTFS**. To detect changes to files and folders, FRS relies on the USN journal on NTFS volumes. FRS is not supported on FAT file system volumes.

- **Remote procedure call (RPC)**. FRS requires Internet Protocol (IP) connectivity and the Remote Procedure Call (RPC) for communication between replication partners and communication with domain controllers.

**In this section**

- FRS Terminology
- FRS Architecture
- FRS Protocols
- FRS Interfaces
- FRS Physical Structures
- FRS Processes and Interactions
- Network Ports Used by FRS
- Related Information

File Replication service (FRS) is a technology that replicates files and folders stored in the SYSVOL shared folder on domain controllers and Distributed File System (DFS) shared folders. When FRS detects that a change has been made to a file or folder within a replicated shared folder, FRS replicates the updated file or folder to other servers. Because FRS is a multimaster replication service, any server that participates in replication can generate changes. In addition, FRS can resolve file and folder conflicts to make data consistent among servers.

These sections provide an in-depth view of how FRS works in an optimal environment. An optimal environment for FRS is defined as follows:

- DNS and Active Directory replication are working properly.
- FRS Active Directory objects are properly configured and present on all domain controllers.
- Kerberos authentication is working properly.
- No firewalls prevent replication from working.
- All servers that participate in replication (known as replica members) have adequate free space on NTFS file system volumes to support the FRS physical structures.
- All replica members have hardware that is sized appropriately for the roles that the servers perform and the hardware is functioning properly.
- No replica members have network, disk, RAM, or CPU bottlenecks.
- All members are running Windows Server 2003 with Service Pack 1 (SP1) or the pre-SP1 release of Ntfrs.exe (as described in article 823230, "Issues That Are Fixed in the Pre-Service Pack 1 Release of Ntfrs.exe," in the Microsoft Knowledge Base).
- For SYSVOL replica sets, the number of domain controllers in a domain falls well below the recommended limit of 1,200 domain controllers.
- No replica members are running disk defragmentation, backup, or antivirus software that is known to be incompatible

with FRS.

- The update sequence number (USN) journal and staging folder on all replica members are sized according to Microsoft's recommendations.
- The system clocks on all replica members are set to within 30 minutes of each other.
- No files are blocking replication by being held open for an extended period of time on any replica member.
- Changes to a particular file are only made on one replica member so that no conflict resolution is required.
- Administrators do not attempt to copy files from one replica member to another in an attempt to help replication.

**FRS Terminology**

Before you review the FRS components and processes, it is helpful to understand FRS terminology. The following sections provide a brief introduction and illustration of the basic components of FRS as well as a glossary of terms.

**Basic FRS Components**

When you set up DFS replication, you choose a shared folder whose contents you want to replicate. For the SYSVOL shared folder on domain controllers, replication is established automatically during the domain controller promotion process. The set of data to be replicated to all servers is known as the replica tree, and the servers to receive this replica tree are known as replica members. The group of replica members that participates in the replication of a given replica tree is known as a replica set. Replica members are connected in a topology, which is a framework of connections between servers and defines the replication path. There are a number of common topologies, such as full mesh, ring, and hub and spoke.

The following figure illustrates these terms.

**Basic FRS Components (Ring Topology)**

It is also helpful to understand the terminology used to describe the relationship between two members. This terminology is illustrated in the following figure.

**Replication Partner Terminology**

As illustrated in the figure, any two replica members with a direct connection between them are known as direct replication partners. In the figure, ServerA and ServerB are direct replication partners, as are ServerB and ServerC. Although changes that originate on ServerA are eventually replicated to ServerC, these two servers do not have a direct connection to each other, so they are known as transitive replication partners.

When a changed file or folder is received on a server, either because the change originated there or because the server received the file or folder from another partner, that server becomes the upstream partner, also known as inbound partner, for any direct replication partner that has not yet received the change. For example, in the figure titled "Replication Partner Terminology," a change originates on ServerA, and ServerA is considered the upstream or inbound partner for ServerB. ServerB is considered the downstream (also known as outbound) partner for ServerA.

**Glossary of FRS Terms**

The following terms are used to describe the components and processes of FRS.

**Active Directory object**

A distinct set of named attributes that represents a network resource. FRS uses Active Directory objects to represent servers that participate in replica sets and the topology that FRS uses to replicate data.

**Authoritative restore (also called D4)**

The process whereby one replica member is made the authoritative member, and all the data in its replica tree is replicated to all other replica members. This procedure should be used only in extreme circumstances under the supervision of your support provider or Microsoft Product Support Services. This process is informally referred to as a "D4" in reference to the registry setting used to invoke this process.

**Burflags**

Short for "backup restore flags," an FRS-related registry entry used to change the behavior of the FRS service at startup. The values for this registry entry are D2 (for nonauthoritative restores) and D4 (for authoritative restores).

**Change order**

A message that contains information about a file or folder that has changed on a replica member. The change order is sent to the member's outbound partners. If the outbound partners accept the change, the partners request the associated staging file. After installing the changed file in their individual replica trees, the partners propagate the change order to their outbound partners.

**Directed change order**

A change order that is directed to a single outbound partner and primarily produced when the partner is doing a vvjoin, such as during initial synchronization or a nonauthoritative restore (D2).

**File event time**

The time at which a change to a file or folder is made. This might not be the same as the file create or last-write time. For example, restoring a file from a backup tape preserves the file create and last-write times, but the file event time is the time when the actual file restoration was performed.

**File GUID**

An identifying property of a file or folder in a replica tree. FRS creates and manages file globally unique identifiers (GUIDs), which, along with the replication version number and event time, are stored in the file ID table in the FRS database. Each file

and folder stores its file GUID as part of its NTFS attributes; therefore, corresponding files and folders across all replica set members have the same file GUID.

**File ID table**

A table in the FRS database that contains an entry with version and identity information for each file and folder in the replica tree.

**File version number**

A property of a file and folder in a replica tree that is incremented each time the file or folder is updated. The file version number is used to resolve concurrent updates originating from more than one member of the replica set. The version number is only incremented by the member that originated the file update. Other members that propagate the update do not change the version number.

**Filter**

A setting that excludes subfolders (and their contents) or files from replication.

**FRS debug logs**

Text files in the *systemroot*\Debug folder that store FRS transaction and event detail.

**Inbound connection**

For a given replica member, a component of the NTFRS Member object in Active Directory that identifies inbound partners. An inbound connection exists for each inbound partner.

**Inbound log**

A table in the FRS database that stores pending change orders to be processed. As entries are processed, acknowledgments are sent to the inbound partners.

**Knowledge Consistency Checker (KCC)**

A built-in process that runs on all domain controllers and generates replication topology for the Active Directory forest. The KCC creates separate replication topologies depending on whether replication is occurring within a site (intrasite) or between sites (intersite). The KCC also dynamically adjusts the topology to accommodate new domain controllers, domain controllers moved to and from sites, changing costs and schedules, and domain controllers that are temporarily unavailable.

**Link target**

In a DFS namespace, the mapping destination of a link, typically a shared folder on a server. FRS can be used to keep link targets (shared folders) synchronized on different servers.

**Local change order**

A change order that is created because of a change to a file or folder on the local server. The local server becomes the originator of the change order and constructs a staging file.

**MD5 checksum**

A cryptographically secure one-way hashing algorithm that is used by FRS to verify that a file on each replica member is identical.

**Morphed folder**

A folder that FRS creates when resolving a name conflict between two or more identically named directories that originate on different replica members. FRS identifies the conflict during replication, and the receiving member protects the original copy of the folder and renames (morphs) the later inbound copy of the folder. The morphed folder names have a suffix of "_NTFRS_xxxxxxxx," where "xxxxxxxx" represents eight random hexadecimal digits.

**Nonauthoritative restore (also called D2)**

The process whereby a given replica member is reinitialized by obtaining a replica tree from another replica member. This process is often used to resynchronize a replica member's replica tree with one of its inbound partners, such as after a server failure. This process is informally referred to as a "D2" in reference to the registry setting used to invoke this process.

**Originator GUID**

A globally unique identifier (GUID) that is associated with each replica member. All change orders produced by a given replica member carry the replica member's originator GUID, which is saved in the file ID table.

**Outbound connection**

For a given replica member, a component of the NTFRS Member object in Active Directory that identifies outbound partners. An outbound connection exists for each outbound partner.

**Outbound log**

A table in the FRS database that stores pending change orders to be sent to outbound partners. The changes can originate locally or come from an inbound partner. These change orders are eventually sent to all outbound replica partners.

**Parent GUID**

The globally unique identifier (GUID) of the parent folder that contains a particular file or folder in the replica tree.

**Preinstall folder**

A hidden subfolder under the root of the replica tree. When a newly created file or folder is replicated to a downstream partner, the file or folder is first created in the preinstall folder on the downstream partner. After the file or folder is completely replicated, it is renamed to its target location in the replica tree. This process is used so that partially constructed files are not visible in the replica tree.

**Reanimation change order**

A change order that FRS uses to reconcile a recently received change order against a previously deleted file or folder.

**Remote change order**

A change order received from an inbound (or upstream) partner that originated elsewhere in the replica set.

**Retry change order**

A change order that is in some state of completion but was blocked for some reason and must be retried later.

**Schedule**

The frequency at which data replicates.

**Staging folder**

A folder that acts as a queue for changed files and folders to be replicated to downstream partners.

**Staging file**

A file that FRS constructs in the staging folder as a result of a file or folder change. FRS constructs staging files by using backup application programming interfaces (APIs) and then replicates the staging files to downstream partners. Downstream partners use restore APIs to reconstruct the staging files in the preinstall folder before renaming the files into the replica tree. Staging files are compressed to reduce the network bandwidth used during replication.

**SYSVOL**

On a domain controller, a shared folder that stores a copy of the domain's public files, including system policies and Group Policy settings, that are replicated to all other domain controllers in the domain by FRS.

**Update sequence number (USN)**

A monotonically increasing sequence number for each volume. The USN is incremented every time a modification is made to a file on the volume.

**USN journal**

On NTFS volumes, a persistent log that tracks all changes on the volume, including file creations, deletions, and changes. The USN journal has a configurable maximum size and is persistent across reboots and system crashes. FRS uses the USN journal to monitor changes made in the replica tree.

**USN journal wrap**

An error that occurs when large numbers of files change so quickly that the USN journal must discard the oldest changes

(before FRS has a chance to detect the changes) to stay within the specified size limit. To recover from a journal wrap, you must perform a nonauthoritative restore on the server to synchronize its files with the files on the other replica members.

### Version vector

A vector of volume sequence numbers (VSNs), with one entry per replica set member. All change orders carry the originator GUID of the originating member and the associated VSN. As each replica member receives the update, it tracks the VSN in a vector slot that is assigned to the originating member. This vector describes whether the replica tree is current with each member. The version vector is then used to filter updates from inbound partners that might have already been applied. The version vector is also delivered to the inbound partner when the two members join. When a new connection is created, the version vector is used to scan the file ID table for more recent updates that are not seen by the new outbound partner.

### Version vector join (vvjoin)

The process in which a downstream partner joins with an upstream partner for the first time.

#### FRS Architecture

The File Replication service (Ntfrs.exe) is the primary component of the FRS architecture. This service and its related components are illustrated in the following figure.

### FRS Architecture

The following table describes the components related to the FRS architecture.

### Components of the FRS Architecture

| Component | Description |
|---|---|
| Active Directory | Where FRS topology and schedule information is stored. FRS periodically polls Active Directory to retrieve updated information about the FRS topology and schedule. FRS uses Lightweight Directory Access Protocol (LDAP) to connect to Active Directory using port 389. |
| Esent.dll | The dynamic link library of the Jet database. |
| File Replication service event log (NtFrs.Evt) | The log where events and error messages related to FRS are logged in Event Viewer. The FRS event log file is located in *Systemroot*\System32\Config\. |
| FRS debug logs | Text files where FRS stores transaction and event details. The FRS debug logs are typically used for troubleshooting FRS. |

| | |
|---|---|
| FRS Jet database (Ntfrs.jdb) | The database where FRS transactions are stored. |
| Ntfrs.exe | The executable file for the File Replication service. Runs as LocalSystem on all domain controllers and members of DFS replica sets. |
| Ntfrsapi.dll | The dynamic link library file that allows other applications to get information about FRS via remote procedure call (RPC). These applications include Active Directory Installation Wizard (Dcpromo), Ntfrsutl.exe (part of the Windows Support Tools), Windows Backup, and Volume Shadow Copy service. |
| Ntfrsprf.dll | The dynamic link library file that allows System Monitor to connect to FRS and collect performance-related information via local remote procedure call (LRPC). |
| Ntfrsres.dll | The dynamic link library file where event log messages are stored. When events occur, the event log messages are displayed in the File Replication service event log. |
| Registry | Where FRS configuration data is stored. Some FRS-related registry keys are recognized when changes to those keys occur; other registry keys are read only when the File Replication service is first started or restarted. |
| Replica tree | The contents of a folder that is replicated among replica members in a replica set. |
| Staging folder | A folder that acts as a queue for changed files to be replicated to downstream partners. |
| USN journal (also called NTFS change journal) | A persistent log of changes made to files on an NTFS volume. NTFS uses the change journal to track information about added, deleted, and modified files for each volume.The USN journal describes the nature of any changes to files on the volume. When any file or folder is created, modified, or deleted, NTFS adds a record to the USN journal for that volume. |

**FRS Protocols**
FRS stays at application layer of Open Systems Interconnection (OSI) model, and uses RPC as transport medium for communication between replica members.

**FRS Interfaces**
Windows Server 2003 includes an FRS writer for the Volume Shadow Copy service. The FRS writer allows Volume Shadow Copy service-compatible backup programs, such as Windows Backup, to make point-in-time, consistent backups of the replica tree. Using a Volume Shadow Copy service-compatible backup program ensures that replica tree backups do not contain partial files (which can occur when a replica member receives an updated file and begins overwriting the previous version of the file in the replica tree with the updated version of the file). This process, known as the install process, creates a window during which the file is half-written. The window exists because FRS must move the updated file from the preinstall folder and overwrite the existing file in the replica tree.

Before a Volume Shadow Copy service-compatible backup program takes a shadow copy of a replica tree, the program instructs FRS to stop requesting new work items from the install command server queue. After all currently active installations are complete, FRS enters a frozen state during which no installations occur. Shadow copies made while FRS is in a frozen state will not contain partial files. The install service thaws either when the backup program signals a thaw or at a predetermined time-out period.

For more information about the Volume Shadow Copy service, see "Volume Shadow Copy Service Technical Reference."

**FRS Physical Structures**
FRS requires a number of physical structures to be stored in Active Directory and on each replica member. These structures are illustrated in the following figure and are described in the sections that follow.

### Overview of FRS Physical Structures

**FRS Files and Folders on Replica Members**

Each replica member contains a number of files and folders used by FRS for SYSVOL and DFS replica sets. The following figure illustrates the files and folders that are stored on a DFS replica member.

**FRS Files and Folders on DFS Replica Members**

The following figure illustrates the files and folders stored on domain controllers. Note how the location of these folders differs from DFS replica members.

**FRS Files and Folders on Domain Controllers**

The following sections briefly describe each of these folders.

**Replica tree on DFS replica members**

The replica tree is the set of files and folders that are kept in sync on all replica members. The replica tree begins at the replica root, which is the shared folder where all the replicated data is stored. The replica tree can exist on any NTFS volume for DFS replica members, and FRS does not impose limits on the size of the replica tree.

**SYSVOL folder domain controllers**

SYSVOL is a folder that stores numerous FRS-related folders and a copy of the domain's public files, including system policies and Group Policy settings that are replicated to all other domain controllers in the domain by FRS. The actual replica root begins at the *systemroot*\SYSVOL\domain folder, but the folder that is actually shared is the *systemroot*\SYSVOL\sysvol folder. These folders appear to contain the same content because SYSVOL uses junction points (also called reparse points). A junction point is a physical location on a hard disk that points to data that is located elsewhere on the hard disk or on another storage device. The following table lists the folders in SYSVOL that contain junction points and the locations to which these junction points resolve:

**SYSVOL Junction Points**

| Location of Junction Point | Where the Junction Point Resolves |
|---|---|
| SYSVOL\staging areas*domainname* | SYSVOL\staging\domain |
| sysvol*domainname* | SYSVOL\domain |

**Staging folder**

The staging folder is a hidden folder that acts as a queue for changed files to be replicated to downstream partners. After the changes are made to a file and the file is closed, FRS creates the file in the staging folder by using backup application programming interfaces (APIs) and replicates the file according to schedule. Files in the staging folder are called staging files. Any further use of corresponding files in the replica tree does not prevent FRS from replicating the staging files to other members. In addition, if the file is replicated to multiple downstream partners or to members with slow data links, using staging files ensures that the underlying files in the replica tree can still be accessed.

The default size of the staging folder is approximately 660 megabytes (MB), the minimum size is 10 MB, and the maximum size is 2 terabytes. For performance and disk space purposes, the staging folder can be located on a volume other than where the replica tree is stored.

For more information about the staging folder, see "How the Staging Folder Works" later in this section.

**Preinstall folder**

The preinstall folder is a hidden system folder named DO_NOT_REMOVE_NtFrs_PreInstall_Directory. When a downstream partner begins receiving a new file (or folder), the file is installed in the preinstall folder on the downstream partner so that a partially constructed file is not added to the replica tree. After the downstream partner receives the entire file in the preinstall folder, the file is renamed to its target location in the replica tree.

**FRS Jet database**

FRS creates a Microsoft Jet database at *systemroot*\ntfrs\jet\ to store FRS transactions. FRS does not impose size limits on the Jet database, but replication stops working if the volume where the database is stored runs out of disk space. For performance and disk space purposes, the Jet database can be moved to a volume other than where the replica tree is stored.

For more information about the FRS Jet database, see "FRS Database Tables" later in this section.

**FRS debug logs**
FRS creates debug logs in the *systemroot*\Debug folder. By default, the debug logs store FRS transaction and event detail in sequentially numbered files from Ntfrs_0001.log through Ntfrs_0005.log. The characteristics of the debug logs are determined by the values of several registry entries. These values allow you to set the number of log files used, the number of entries per log, the level of detail logged, and so forth.

FRS creates another log file, Ntfrsapi.log, to track events that occur during the promotion and demotion of domain controllers. Information in the Ntfrsapi.log file includes which server was chosen as the parent for the initial replication (seeding) process and the creation of registry keys. Because errors during the promotion and demotion processes are also tracked in this file, Ntfrsapi.log is useful for troubleshooting problems where the SYSVOL and Netlogon shared folders are not shared correctly.

For performance and disk space purposes, the debug logs can be moved to a volume other than the one on which the replica tree is stored.

For more information about the FRS debug logs, see "How FRS Debug Logs Work" later in this section.

**Pre-existing data folder**
The pre-existing folder, named NtFrs_PreExisting___See EventLog, is an optional folder that is located under the replica root. If the pre-existing data folder is present on a replica member, FRS created it after one of the following events:

- The server was added to a replica set but the server already had one or more files in the shared folder that became the replica tree. In this case, FRS moved that data into the pre-existing data folder and then replicated the replica tree from one of the upstream partners to the new member.

- The replica member had a nonauthoritative restore (also called D2) performed on it by an administrator. This process is used to bring a replica member back up to date with its partners after problems such as assertions in the FRS service, corruption of the local FRS Jet database, journal wrap errors, and other replication failures. When you perform a nonauthoritative restore on a server, FRS moves the existing data in the replica tree to the pre-existing data folder and then receives the replica tree from one of the upstream partners.

- The server was prestaged before it was added to the replica set. During the prestaging process, files in the replica tree are temporarily moved from the replica tree to the pre-existing data folder. For more information about the prestaging process, see "How Prestaging Works" later in this section.

Only one pre-existing data folder can exist at a time. If one of the previously listed events occurs, causing the pre-existing data folder to be created, and then another one of the events occurs, the previous pre-existing data folder is deleted and replaced with another pre-existing data folder.

**FRS Database Tables**
The Jet database (Ntfrs.jdb) used by FRS has a set of five tables:

- Connection record table

- Version vector table

- File ID table

- Inbound change order table

- Outbound change order table

You can view the contents of three of these tables (the file ID table, inbound change order table, and outbound change order table) by using Ntfrsutl.exe (a Windows Support Tool), though doing so is typically only necessary for troubleshooting purposes. Windows Server 2003 provides several Windows Support Tools scripts, Topchk.cmd, Connstat.cmd, and Iologsum.cmd, that can present the output of Ntfrsutl in a more readable format.

The following sections briefly describe the tables in Ntfrs.jdb.

**Connection record table**
The connection record table tracks the state of each inbound and outbound connection for the replica set and tracks the delivery state of each outbound change order.

**Version vector table**
The version vector table contains a vector of volume sequence numbers (VSNs), one entry per replica member. All change orders carry the originator globally unique identifier (GUID) of the originating member and the associated volume sequence number. As each replica set member receives the update, it tracks the VSN in a vector slot assigned to the originating member. This vector now describes how up-to-date this member's replica tree is with respect to each member. The version vector is then used to filter out updates from inbound partners that might have already been applied. The version vector is also delivered to the inbound partner when two members join. When a new connection is created, the version vector is used to scan the file ID table for more recent updates not seen by the new outbound partner.

**File ID table**
The file ID table lists all files in the replica sets on the local server of which FRS is aware. Data stored in the file ID table includes the file name, file GUID, NTFS file ID, parent GUID, parent file ID, version number, event time, and originator GUID. You can view entries in the file ID table by using Ntfrsutl.exe with the **idtable** parameter.

**Inbound change order table (inbound log)**
The inbound change order table, referred to as the inbound log, stores pending change orders to be processed. As entries are processed, acknowledgments are sent to the inbound partners. State variables in the record track the progress of a change order and determine where to continue after a system crash or a retry of a failed operation. Data stored in the inbound log includes the change order's GUID, file name, originator GUID, file GUID, version number, and event time. You can view change orders in the inbound log by using Ntfrsutl.exe with the **inlog** parameter.

**Outbound change order table (outbound log)**
The outbound change order table, referred to as the outbound log, stores pending change orders to be sent to outbound partners. By default, change orders remain in the outbound log for seven days, even if all replication partners have received the change. Also in the outbound log is the leading (next change) and trailing (last acknowledged) index for each partner. You can view change orders in the inbound log by using Ntfrsutl.exe with the **outlog** parameter.

**FRS Change Orders**
A change order is a message that contains information about a file or folder that has changed on a replica member. Change orders are stored in the inbound and outbound logs on each replica member and contain information such as the change order's GUID, the originator GUID, the file GUID, the file name, event time, and file version number.

You can view change orders in the inbound and outbound logs by using Ntfrsutl.exe with the **inlog** and **outlog** parameters. You can also use the Windows Support Tools script lologsum.cmd to parse the Ntfrsutl output into a more readable format.

FRS uses the following five types of change orders:

**Local change order**
A change order that is created because of a change to a file or folder on the local server. The local server becomes the originator of the change order and constructs a staging file.

**Remote change order**
A change order received from an upstream partner that originated elsewhere in the replica set.

**Retry change order**
A change order that is in some state of completion but was blocked for some reason and must be retried later. This is a change order property in that both local and remote change orders can become retry change orders.

**Directed change order**
A change order that is directed to a single outbound partner and primarily produced when the partner is performing an initial sync (vvjoin) or a nonauthoritative restore (D2).

**Reanimation change order**
A change order that FRS uses to reconcile a recently received change order against a previously deleted file or folder.

**FRS Registry Entries**
FRS registry entries are located in the registry under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs. For a list of FRS registry entries, see "FRS Tools and Settings."

**File Replication Service Event Log**
The File Replication service event log contains events logged by FRS. It is created when FRS is first enabled on a server, and the

creation process involves setting registry keys under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Eventlog\File Replication Service. The event log file name is NtFrs.Evt, which is located under *systemroot*\System32\Config.

**FRS Objects in Active Directory**

For FRS to function properly, certain critical Active Directory objects (as well as their attributes and parent containers) must exist in Active Directory. These objects, which define a replica set's topology, schedule, and filters, are created in Active Directory when you use the Distributed File System snap-in to configure replication for DFS or when you promote a server to a domain controller using the Active Directory Installation Wizard (Dcpromo.exe). Active Directory replication is used to replicate these objects to all domain controllers in a domain, and missing or corrupted objects can cause FRS replication to fail.

**Hierarchy of FRS Objects in Active Directory for DFS Replica Sets**

The following figure illustrates the hierarchy of FRS-related Active Directory containers and objects for DFS replica sets. The figure also illustrates how several of these objects are linked together using reference attributes. For example, in the NTFRS Member object, there is an attribute called **frsComputerReference** that refers to the computer object for the server.

**FRS Containers and Objects in Active Directory for DFS Replica Sets**

The following sections briefly describe the Active Directory objects, containers, and their attributes for DFS replica sets. The class name of each object is shown in parentheses.

**NTFRS Settings object**

The NTFRS Settings object (class **nTFRSSettings**) is used as a container for the NTFRS Replica Set objects. The NTFRS Settings object can contain other NTFRS Settings objects; therefore, it provides a way to form a hierarchy to better organize the NTFRS Replica Set objects.

**NTFRS Replica Set object**

Every NTFRS Replica Set object (class **nTFRSReplicaSet**) represents a set of computers that replicate a specified folder tree and a common set of data among them. There is one NTFRS Replica Set object for every replica set. The NTFRS Replica Set object must be directly under an NTFRS Settings object.

The most commonly used attributes on this object are **fRSReplicaSetType** (set to 3 for DFS replica sets), **fRSFileFilter**, **fRSDirectoryFilter**, and **Schedule**. If you set the **Schedule** attribute, it applies to all the NTDS Connection objects in the replica set that do not have a **Schedule** attribute.

**NTFRS Member object**

Every NTFRS Member object (class **nTFRSMember**) corresponds to a computer that is part of the replica set. The relationship between the NTFRS Member object and the computer object is indicated by the **frsComputerReference** attribute. The NTFRS Member object can contain one or more NTDS Connection objects that define the inbound partners that a member replicates from. NTDS Connection objects refer to other member objects in the same replica set object using the **fromServer** attribute.

**NTDS Connection object**

NTDS Connection objects (class **nTDSConnection**) define the inbound and the outbound partners of a replica member. NTDS Connection objects are located under the NTFRS Member object in the domain naming context for DFS replica sets.

The NTDS Connection object is inbound to the NTFRS Member object that it is located under, and it is outbound from the NTFRS Member object that its **fromServer** attribute points to.

**Computer object**
Each computer object represents a computer in the domain. The relationship between the NTFRS Member object and the computer object is indicated by the **frsComputerReference** attribute.

**NTFRS Subscriptions container**
The NTFRS Subscriptions object (class **nTFRSSubscriptions**) is similar to the NTFRS Settings object in that it is primarily used as a container to group NTFRS Subscriber objects. The **fRSWorkingPath** attribute defines the location of the Ntfrs.jdb file, which is typically located in the %SystemRoot%\Ntfrs folder.

**NTFRS Subscriber object**
Every NTFRS Subscriber object (class **nTFRSSubscriber**) under a computer's computer object corresponds to a replica set that the computer is a member of. The **fRSMemberReference** attribute of the NTFRS Subscriber object points to the NTFRS Member object of the replica set that it corresponds to. Every NTFRS Subscriber object also has both an **fRSRootPath** attribute that specifies the folder tree to replicate and an **fRSStagingPath** attribute that specifies the folder to store the staging files under.

**Hierarchy of FRS Objects in Active Directory for SYSVOL Replica Sets**
SYSVOL replica sets have a different hierarchy of objects in Active Directory than do DFS replica sets. This hierarchy is illustrated in the following figure.

**FRS Containers and Objects in Active Directory for SYSVOL Replica Sets**

The following sections describe any attributes and relationships that are specific to SYSVOL replica sets. In some cases, the objects for DFS and SYSVOL replica sets are identical.

**NTFRS Settings object**
Same as for DFS replica sets.

**NTFRS Replica Set object**
Same as for DFS replica sets except that only one NTFRS Replica Set object can be of the SYSVOL type in a domain. In this case, the **fRSReplicaSetType** attribute is set to 2.

**NTFRS Member object**
In SYSVOL replica sets, the **serverReference** attribute of the NTFRS Member object points to the NTDS Settings objects (class **nTDSDSA**) that contain the NTDS Connection objects that this member replicates from.

**NTDS Connection object**

For SYSVOL replica sets, FRS uses both manually generated connection objects and connection objects that are generated by Knowledge Consistency Checker (KCC) that are located in the NTDS Settings object in the configuration naming context. (You can use the Active Directory Sites and Services snap-in to view these connection objects.) These connection objects are also used during Active Directory replication.

For SYSVOL replica sets, the NTDS Connection object is inbound to the NTFRS Member object that corresponds to the NTDS Settings object that the NTDS Connection object is located under. It is outbound from the NTFRS Member object that corresponds to the NTDS Settings object that its **fromServer** attribute points to.

**Computer object**
Same as for DFS replica sets.

**NTFRS Subscriptions container**
Same as for DFS replica sets.

**NTFRS Subscriber object**
Same as for DFS replica sets.

**FRS Processes and Interactions**
The following figure illustrates four categories of FRS processes and interactions described in this section.

**FRS Processes and Interactions**

The following sections describe the four categories of processes and interactions.

**How changes to topology, schedule, filters, and settings are detected**
FRS periodically polls Active Directory to obtain new or updated information about replica set topology, schedule, and file and folder filters. FRS also polls the registry to detect updated settings. For information about the Active Directory and registry polling process and the intervals at which polling occurs, see “How FRS Polling Works” later in this section.

**How new and existing partners communicate**
Replica members communicate with each other to determine whether new or changed files and folders need to be replicated from one member to another. When a downstream partner joins an upstream partner for the first time, the process is known as a version vector join (vvjoin). For more information, see “How the Vvjoin Process Works” later in this section. Routine communication between members is described in “How the Partner Join Process Works” later in this section.

**How replica sets are created and how members are added and removed**
The creation of new replica sets and the addition and removal of replica members involves many processes. For example, when a new replica member is added to a replica set, the FRS physical structures are created on the member and in Active Directory, the FRS service is started, registry keys are created, the member polls the registry and Active Directory, the new member vvjoins with an upstream partner, and so on.

The following sections describe these processes and interactions:

- What Happens When You Create a DFS Replica Set
- "What Happens When SYSVOL Is Created During Domain Controller Promotion"
- How Prestaging Works
- What Happens When You Remove a Member from a Replica Set

**How changed files and folders are tracked and replicated**
A number of processes occur when a file or folder is changed, closed, and then replicated from one member to another. Change orders are generated and flow from one member to another, staging files are built in the staging folder, and file and folder filters prevent files and folders with specified names or extensions from replicating. Replication takes place according to a schedule, change orders are periodically removed from the outbound log, and details about these processes are written to the FRS debug logs. You can find information about these processes in the following sections:

- Types of Changes That Trigger Replication
- How Files and Folders Are Replicated
- How the Staging Folder Works
- How Replication Schedules Work
- How File and Folder Filters Work
- How the Outbound Log Cleanup Process Works
- How FRS Debug Logs Work

**How FRS Polling Works**
FRS periodically polls Active Directory (using LDAP) to obtain new or updated information about replica set topology, schedules, and file and folder filters. (This information is stored in the Active Directory objects described in "FRS Objects in Active Directory" earlier in this section.) FRS also polls the registry to detect updated settings, such as staging directory size, USN journal size, debug log settings, and so forth. Polling takes place after FRS starts up, such as when the host computer or the service starts (when **net start ntfrs** is typed at the command line, for example) and during regular intervals after that.

The following sections describe the polling process and the intervals at which polling occurs.

**How Active Directory Polling Works**
The Active Directory polling process is as follows. Note that if any of these steps fails, replication does not occur. Failure is typically caused by network connectivity issues or missing, damaged, or duplicate Active Directory objects.

1. FRS locates the computer object for the server it is running on and enumerates the NTFRS Subscriber objects.
2. For a given subscriber, FRS follows the **fRSMemberReference** attribute to the NTFRS Member object
3. Next, FRS reads the NTFRS Replica Set object (always directly above the NTFRS Member object) to determine whether it is SYSVOL or DFS replica set.

After FRS determines the replica type (SYSVOL or DFS), FRS enumerates the connection objects. This process is different for SYSVOL and DFS.

**How FRS enumerates connection objects for DFS replica sets**

1. FRS finds all the NTDS Connection objects that represent an inbound (or upstream) connection to this member. (All NTDS Connection objects that represent an inbound connection are directly under the NTFRS Member object.)

2. FRS finds all the NTDS Connection objects that represent an outbound (or downstream) connection to this member. (All NTDS Connection objects that represent an outbound connection have this member's name in the **fromServer** attribute.)

3. FRS forms a list of NTFRS Member objects that have an inbound or outbound connection with this member. This list is a combined list for all the replica sets that this server is a member of.

4. FRS forms a list of the computers corresponding to the members in the member list. All members have an **frsComputerReference** attribute pointing to the computer object.

5. FRS finds the DNS name of each of the computers in the computer list. This is the name that FRS uses to bind to its inbound and outbound partners.

**How FRS enumerates connection objects for SYSVOL replica sets**

1. FRS finds all the NTDS Connection objects that represent an inbound connection to this member. The **serverReference** attribute on the NTFRS Member object points to the NTDS Settings object. (All the NTDS Connection objects that represent an inbound connection are directly under the NTDS Settings object.)

2. FRS finds all NTDS Connection objects that represent an outbound connection to this member. (All NTDS Connection objects that represent an outbound connection have this member's name in the **fromServer** attribute.)

3. FRS forms a list of member objects that have an inbound connection or outbound connection with this member. Forming the list of members is a two-step process for SYSVOL replica sets. First, FRS forms the list of NTDS Settings objects, and then FRS finds the NTFRS Member objects that point to each of these NTDS Settings objects. This list is a combined list for all the replica sets that this server is a member of.

4. FRS forms a list of the computers corresponding to the members in the member list. All members have an **frsComputerReference** attribute pointing to the computer object.

5. FRS finds the DNS name of each of the computers in the computer list. This is the name that FRS uses to bind to its inbound and outbound partners.

**How Registry Polling Works**

FRS polls Active Directory and the registry at the same interval. Some settings stored in Active Directory are also stored in the registry, but the Active Directory settings override the registry settings. Though some registry changes are detected and applied during polling, other changes are not applied until the FRS service is stopped and restarted. For more information about registry entries that require the service to be restarted, see Registry Reference in Tools and Settings Collection.

**Polling Intervals**

Each time a replica member is started or the FRS service is started, FRS polls the registry and the computer object in Active Directory in eight short intervals. If no changes in Active Directory are detected, FRS polls in long intervals until it detects configuration or subscriber list changes in Active Directory. The lengths of the short and long intervals are as follows:

- For domain controllers, the default short and long polling intervals are five minutes each. (Domain controllers always use the short interval, regardless of the long interval setting.)

- For member servers, the default short polling interval is five minutes and the long polling interval is 60 minutes.

### Note

- These polling intervals are specified in the **DS Polling Long Interval in Minutes** and **DS Polling Short Interval in Minutes** registry values. To view the current interval and the length of the long and short polling interval, use the Ntfrsutl.execommand with the **poll** parameter.

If there have been no FRS configuration changes in Active Directory after the completion of eight short polling intervals, FRS automatically begins polling according to the long polling interval. If one of the following events occurs, the polling cycle is reset:

- A replica member is added or removed.
- A connection is added or removed.
- A schedule is changed.
- A file or folder filter is changed.

Unlike changes in Active Directory, registry changes do not affect the polling cycle.

**How the Vvjoin Process Works**

A version vector is an array that contains pairings of the member originator GUID of the originating member and the VSN of the change. The VSN is a monotonically increasing sequence number assigned to each change that originates on a given replica member. Although the VSN is similar to the USN, FRS does not store the actual USN of the change in the version vector because a replica set can be moved to a different volume, or the volume could be formatted and the replica tree restored from backup. In these cases, the USN could be reset.

The following graphic illustrates a version vector on three servers, ServerA, ServerB, and ServerC.

**Example of Three Version Vectors**

Each entry in the version vector is considered the high water mark as to the most recent change order received from the corresponding originator. For example, the version vector on ServerA indicates that this member has received and processed all changes up to VSN 9 originating on ServerC, VSN 12 originating on ServerD, and VSN 32 originating on ServerE. ServerB's version vector shows that its replica tree is not as up-to-date as the replica tree on ServerA. The new member, ServerF, has an empty version vector.

A version vector join (vvjoin) is the process by which a downstream partner joins with an upstream partner for the first time. During this process, the two members compare version vectors to determine which files need to be replicated from the upstream partner to the downstream partner. Vvjoins can occur in a number of scenarios, which are explained using the following figure as an example.

**Sample Replica Members for Vvjoin Scenarios**

In this figure, ServerA and ServerB are members of a replica set. ServerA is upstream and ServerB is downstream for connection C. Using this figure as an example, a vvjoin can occur in the following scenarios:

**Scenario A**

Connection C is new, or connection C is deleted and a new connection is created in its place.

**Scenario B**

Connection C is disabled and later enabled.

**Scenario C**

ServerA polled a domain controller that has not seen the NTDS Connection object for connection C yet. At this point ServerA acts as though the connection is deleted. Later the NTDS Connection object for connection C replicates to this domain controller and ServerA reads it. The effect is similar to Scenario B.

**Scenario D**

ServerB is a newly added member of the replica set.

**Scenario E**

ServerA or ServerB performs a nonauthoritative restore (D2).

**Scenario F**

ServerA performs an authoritative restore (D4), and ServerB performs a nonauthoritative restore (D2).

**Scenario G**

ServerB is offline for longer than the **Outlog Change History In Minutes** registry entry, which is 10080 minutes (seven days) by default.

Vvjoins take place when the schedule first opens between the two members in the previous scenarios. The type of vvjoins performed in these scenarios can be either full or optimized vvjoins. These vvjoins are explained in the following sections.

#### When Optimized Vvjoins Occur

In scenarios A, B, C, and D, FRS attempts to perform an optimized vvjoin instead of a full vvjoin. An optimized vvjoin occurs when the upstream partner's outbound log contains all the changes that the downstream partner is missing.

Optimized vvjoins are desirable in scenarios where a downstream partner (ServerB in the previous figure) needs to vvjoin and has almost all files in the replica tree already. For example, assume the connection between ServerA and ServerB is new, but ServerB was offline for two days and only missed changes from a prior upstream partner, say ServerC, for those two days. In this case, the new upstream partner (ServerA) retains the change orders in the outbound log for seven days and sends its outbound log to the downstream partner (ServerB) instead of enumerating its entire database. ServerA also sends its existing staging files, so ServerA needs to regenerate staging files only for staging files that were purged if the staging folder reached 90 percent of its limit or that were purged during the staging folder cleanup process. The staging folder cleanup process is described in "How the Outbound Log Cleanup Process Works" later in this section.

#### When Full Vvjoins Occur

If the upstream partner's outbound log does not contain all the changes that the downstream partner is missing, a full vvjoin occurs. A full vvjoin requires the upstream partner to enumerate its entire database before determining whether to send changed files and folders to the downstream partner. As a result, the full vvjoin process is not as efficient as an optimized vvjoin, but a full vvjoin does not necessarily mean that the upstream partner sends the entire replica across the network to the downstream partner. The following sections describe the scenarios in which full vvjoins are performed and whether all or part of the data is replicated.

#### When a new replica member is prestaged and added to the replica set

In scenario D, the new member (ServerB) has been prestaged with a restored version of the replica tree. When you prestage files, you use a backup program to back up the replica tree and restore it on the new member. Using a backup program is required to preserve the file GUIDs and security descriptors.

Although it might seem that an optimized vvjoin would work in this scenario, optimized vvjoins do not look for prestaged content. Therefore, you must either clear the outbound log of the direct upstream partners or wait until the replica set is at least seven days old (or the duration specified in the **Outlog Change History In Minutes** registry value). Either of these steps will trigger a full vvjoin, which looks for prestaged content and replicates to the new member only the files and folders that have changed since the new member was prestaged. If these steps are not followed, an optimized vvjoin is performed instead, causing all the data in the replica to be replicated across the network to the new member.

**Note**

- The **Outlog Change History In Minutes** registry entry does not take effect until the next polling interval or until you use the **Ntfrsutl poll /now** command.

For more information about prestaging, see "How Prestaging Works" later in this section.

#### When a new replica member is not prestaged and the replica set is more than seven days old

In scenario D, if the new member (ServerB) has not been prestaged with a restored copy of the replica tree, and the replica set is more than seven days old (or older than the duration specified in the **Outlog Change History In Minutes** registry value), ServerA enumerates its entire database, sends directed change orders for every file and folder in the replica tree, generates staging files for every file in the replica tree, and then sends all files in the replica tree across the network. In this scenario, the full vvjoin requires a lot of CPU time, disk I/O, and network bandwidth.

**An existing replica member was offline for more than seven days**
In scenario G, if a server rejoins a replica set after being offline for more than seven days (or longer than the duration specified in the **Outlog Change History In Minutes** registry value), the upstream partner enumerates its database but only sends across the network files and folders that have changed since the server was offline.

For more information about what happens when a server is offline for more than seven days, see "How the Outbound Log Cleanup Process Works" later in this section.

**How the Partner Join Process Works**
The partner join process is a handshake between two existing partners before they begin replicating. The process begins after any of the following events:

- The connection schedule opens.
- The FRS service is started while the schedule is open.
- A connection is reestablished after the loss of network connectivity or server shutdown while the schedule is open.

During the partner join process, which is similar to a server message block (SMB) session setup, the partners negotiate capability level, exchange version vectors, and test for compression support. The schedule must be open for a partner join to occur. On a given connection, the upstream partner has the leading (next change) and trailing (last acknowledged) indexes and calculates what files need to be replicated to the downstream partner.

**What Happens When You Create a DFS Replica Set**
After you use the Configure Replication Wizard in the Distributed File System snap-in to configure replication for DFS link targets, the following events take place:

1. FRS-related Active Directory objects and their attributes are created on the server acting as the primary domain controller (PDC) emulator master. (Note that these objects will eventually replicate to all domain controllers.)
2. The FRS service is started on all members and set to automatic, if the members are not currently part of another replica set. The File Replication service event log is also created the first time the service starts.
3. Active Directory is immediately polled after the FRS service starts. If the FRS service was already running, the poll takes place according to the current polling interval. (After FRS detects a change, it begins the eight short polling intervals as described in "How FRS Polling Works" earlier in this section.)
4. If the Active Directory objects have replicated to the domain controller that FRS polls, FRS verifies that the replica root is a valid path, verifies that the staging directory is a valid path (and creates it if necessary), and checks the database path and creates the database. If the Active Directory objects are not yet present on the domain controller that FRS polls, there is a delay in this process until the Active Directory objects are replicated to this domain controller.

The final steps of the process differ for the initial master and the remaining replica members.

**For initial master:**

1. On the initial master, FRS walks the replica tree, adds the files and folders to the file ID table, and stamps a file GUID on every file and folder.
2. FRS declares itself as online and sends a join command to the other members of the replica set. This confirms that FRS is ready to replicate.

**For the remaining replica members:**

1. The remaining replica members come online in the seeding state, which indicates that they are ready to seed (replicate in) the data from an online server.
2. Eventually the remaining replica members vvjoin with other online members.

**What Happens When SYSVOL is Created During Domain Controller Promotion**
The SYSVOL shared folder is built by the Active Directory Installation Wizard (Dcpromo) during the installation of Active Directory. The process is as follows:

1. Dcpromo calls FRS to prepare for promotion. If FRS is already running on the server to be promoted, Dcpromo stops the FRS service.

2. Dcpromo deletes information from previous demotion or promotions (primarily FRS-related registry keys).

3. The Net Logon service stops sharing the SYSVOL shared folder (if it exists), and the **SysvolReady** registry entry is set to 0 (false).

4. Dcpromo creates the SYSVOL folder and the necessary subfolders and junction points.

5. The FRS service is started.

6. Dcpromo makes a call to FRS to start a promotion thread that sets the necessary registry keys.

7. Dcpromo reboots the server.

8. When the server is restarted, FRS detects that the server is a domain controller and then checks the registry for the **SysVol Information is Committed** registry entry. Because this entry is set to 0 (false), FRS creates the necessary Active Directory objects and then populates information from the registry to the Active Directory objects and creates the reference attributes as necessary.

9. FRS begins to source the SYSVOL content from the computer that is identified in the **Replica Set Parent** registry entry. (This key is temporary and is deleted after SYSVOL has been successfully replicated.) The connection to the server specified in Replica Set Parent is also temporary. This connection, called a volatile connection, is used to perform the initial vvjoin so that the new domain controller does not need to rely on Active Directory replication for the new connection objects to be replicated.

10. When SYSVOL is finished replicating, FRS sets the **SysvolReady** registry entry to 1 (true), and then the Net Logon service shares the SYSVOL folder and publishes the computer as a domain controller.

**How Prestaging Works**
Prestaging is the process of restoring a version of the replica tree on a new server before adding it to a replica set, thus avoiding the need to send the replica tree across the network. Prestaging works for both DFS and SYSVOL replica sets, though the process is slightly different:

- Prestaging a DFS replica member requires you to restore a backup of the replica tree on a server before you add the server to an existing replica set.

- Prestaging a domain controller requires you to restore a system state backup (which includes the SYSVOL shared folder) to be used as the data source when promoting a server running Windows Server 2003 to a domain controller.

**How Prestaging DFS Replica Sets Works**
The following procedure describes how FRS responds when you prestage a DFS replica set.

1. Replication is enabled between two members, Server1 and Server2. The initial master, Server1, does not have any data in its replica tree when replication is enabled.

2. After you copy files into the replica tree (using \\Server1\Apps as an example replica root), FRS generates staging files and sends change orders to the downstream partner (Server2). FRS also generates an MD5 (a hash algorithm) checksum during the staging file generation and saves the result in the file ID table on Server1 and in the change order sent to Server2.

3. When Server2 processes this change order, it saves the MD5 checksum in the file ID table on Server2. This process is the only way an MD5 checksum is saved in the file ID table and the presence of the MD5 is necessary to avoid overhead

when new members are added later.

When step 3 is finished, the replicated files exist on both Server1 and Server2, and both file ID tables have MD5 checksums for each file and folder in the replica tree. (You can verify this by using the Ntfrsutil.exe command with the **idtable** parameter. Search for "MD5CheckSum" in the output.)

4. Windows Backup or another backup program is used to back up the contents of the replica tree from either Server1 or Server2. The backup is then restored to another server, for example, Server3.

5. If fewer than seven days have passed since the replica set containing Server1 and Server2 was created, the outbound log must be cleared so that a full vvjoin is triggered when the next member joins. (Setting the **Outlog Change History In Minutes** registry entry to 0 clears the outbound log.)

6. When Server3 is added to the replica set using the Distributed File System snap-in, FRS on Server3 moves all files from the restored target folder (\\Server3\Apps) to the pre-existing data folder, and then initiates a full vvjoin from each computer that Server3 has inbound NTDS Connection objects. Note that the vvjoin process is serialized, meaning that the downstream partner performs a vvjoin with one upstream member at a time. Subsequent vvjoins are much faster because the downstream partner will typically have a complete (or nearly complete) replica tree after the first vvjoin completes.

   The key requirement in this step is that Server3 has inbound connections from an upstream partner, Server1 or Server2 in this case, whose file ID table contains MD5 checksums for files contained in the replica set of interest.

7. FRS on Server1 enumerates all the files and folders in its file ID table and sends directed (that is, single target) change orders to Server3. Because the file ID table has an MD5 checksum, it is included in the change order. As Server3 processes these change orders, this server takes the file GUID for the file or folder from the change order and attempts to locate the corresponding file in the pre-existing data folder. If the server locates the file, it re-computes the MD5 checksum on the content of that file, compares the result to the MD5 checksum it received in the change order and, if they match, uses the pre-existing file instead of attempting to obtain the file from Server1. If Server3 does not find the file, or if the MD5 checksum or attributes do not match, the server obtains the file from Server1. Any change to the file content, such as to the access control lists or data streams, can cause an MD5 mismatch and the file is obtained from Server1 or other upstream partner.

   When all replication activity has settled out, the file ID tables on all three servers have an identical MD5 checksum and identical file content in the replicated folder.

**How Prestaging SYSVOL Works**

The process for prestaging SYSVOL is part of the overall process of using backup media to create additional domain controllers. FRS follows the same method of determining whether the restored files are identical to those on the upstream partner as it does for DFS replica members. Specifically, the following requirements must be met for SYSVOL prestaging to be successful:

- FRS must have constructed MD5 checksum data for the files in the SYSVOL tree. MD5 checksum data is constructed after one of the following events occurs:

    - Every file in SYSVOL is modified after there are two or more domain controllers in the domain.

    - All data is moved to a non-replicated folder outside of SYSVOL and then moved back into SYSVOL after there are two or more domain controllers in the domain.

- The system state backup must contain all files in SYSVOL. If any files in the system state backup are out of date, those files are replicated across the network to the new member.

- The outbound log on the upstream partner must be cleared if SYSVOL is less than seven days old. As described in "How the Vvjoin Process Works" earlier in this section, if the replica set is less than seven days old, FRS attempts an optimized vvjoin, which does not look for prestaged content and will cause the entire replica tree to be replicated across the network to the new member. To work around this, you can clear the outbound log on all upstream partners, or you can clear the outbound log on one upstream partner and then do one of the following steps to make sure that the new

member vvjoins with this partner:

- Create a single inbound connection to the member with the cleared outbound log.
- Set up connection schedules such that the parent with the cleared outbound log is the only schedule that is open.
- Stop the FRS service on all other upstream partners.

**Note**

- When prestaging SYSVOL, do not clear the outbound log on bridgehead servers. Bridgehead servers typically have many outbound connections, and clearing the outbound log can cause full vvjoins to occur for every connection that has pending outbound change orders. If this occurs, the bridgehead server can experience a significant decrease in FRS performance and significantly increased CPU, memory, and bandwidth usage. To avoid this situation, we recommend that you prestage from an upstream replica member that has few outbound connections.

**What Happens When You Remove a Member from a Replica Set**

When a member is removed from a replica set, certain events occur both on the removed member and in Active Directory. The following sections describe what happens when a domain controller is demoted (and thus removed from the SYSVOL replica set) and what happens when you remove a member from a DFS replica set.

**Demoting a Domain Controller**

Dcpromo (via Ntfrsapi.dll) performs the following steps during a domain controller demotion:

1. Dcpromo prepares for demotion by:
   a. Stopping FRS.
   b. Cleaning out old demotion state in the registry (if any).
   c. Restarting FRS.
   d. Binding to Active Directory using a different domain controller in the domain. The binding occurs because the demotion will invalidate the local domain controller and thus Active Directory replication would not take place after the system restarts. (If this is the last domain controller in the domain then this step is not performed.)
2. Dcpromo starts the demotion by:
   a. Setting the SYSVOL **Replica Set Command** registry entry to Delete.
   b. Instructing FRS to tombstone the SYSVOL replica set.
3. Dcpromo commits the demotion by:
   a. Stopping the FRS service and setting the service to manual.
   b. Setting the **Sysvol Ready** registry entry to 0.
   c. Deleting the NTFRS Subscription object and NTFRS Replica Set object for SYSVOL.

**Removing a Member from a DFS Replica Set**

The following process occurs when you use the Distributed File System snap-in to remove a replica member from a replica set.

1. If the topology is hub and spoke and the hub member is removed, the topology type is changed to custom.
2. The NTFRS Subscriber object and its container are deleted.

3. The connections are adjusted based on current topology preference. For example, if the topology is a ring topology, a ring topology is reformed using the remaining members.

4. The connections from the removed member to other members are deleted.

5. The NTFRS Member object is deleted.

**Types of Changes That Trigger Replication**

Because a file is a basic unit of replication, any change to a file will cause the entire file to be replicated after the handle to the file is closed. (Replication takes place either immediately or when the replication schedule opens.) The following table provides a comprehensive description of all changes that can cause a file to be replicated. This table includes the code logged in the FRS outbound logs to indicate the type of change that caused replication to occur. These changes must be followed by a close record in the USN journal before replication begins.

**Types of Changes That Trigger Replication**

| Change Code in Outbound Log | Explanation |
|---|---|
| Create | A file or folder was created. |
| Delete | A file or folder was deleted. |
| RenNew | A file or folder was renamed. (This type of change also applies to file or folders deleted locally using Windows Explorer, in which case the file or folder is renamed and moved to the Recycle Bin.) |
| DatOvrWrt | Main file data stream was overwritten. |
| DatExt | Main file data stream was extended. |
| DatTrunc | Main file data stream was truncated. |
| Info | Basic information was changed (hidden and read-only attributes, last write time, and so on) Note that some types of basic info changes, such as archive flag or the last access time, do not cause files to be replicated. |
| Oid | Object ID change. |
| StreamNam | Alternate data stream name change. |
| StrmOvrWrt | Alternate data stream was overwritten. |
| StrmExt | Alternate data stream was extended. |
| StrmTrunc | Alternate data stream was truncated. |
| EAChg | Extended file attribute was changed. |
| Security | File permissions, auditing, or ownership were changed. |
| CompressChg | File compression attribute changed. |
| EncryptChg | File encryption changed. Note this type of change triggers replication only when the file is changed from encrypted to not encrypted. |
| Reparse | Reparse point changed. |

The following changes do not trigger replication:

- Changes to a file or folder's last access time

- Changes to a file or folder's archive bit

- Changes to encrypted files
- Changes related to reparse points

The process that FRS uses to determine whether a file has changed is as follows:

1. FRS monitors the USN journal for changes. When FRS detects a close record for a file (a handle being closed will trigger this), FRS gathers relevant information about the recently closed file, including the file's attributes and MD5 checksum, from the file ID table.

2. FRS computes an MD5 checksum for the recently closed file. The MD5 checksum is calculated based on the file's data, including its security descriptors. File attributes are not included in this calculation. If the MD5 checksum and attributes of the recently closed file are identical to the information about the file stored in the file ID table, the file is not replicated. If either the MD5 checksum or the attributes are different, FRS begins the change order process described in "How Files and Folders Are Replicated" later in this section.

Certain types of programs can make identical updates a file without actually changing the file's content (in other words, the file's MD5 checksum for the last change is identical to the previous change to that same file). These programs typically include backup, defragmentation, and antivirus programs that were not written to be compatible with FRS. Setting file system policy on files by using Group Policy can also cause frequent identical updates that trigger replication. These types of updates include:

- Overwriting a file with a copy of the same file.
- Setting the same ACLs on a file multiple times.
- Restoring an identical copy of the file over an existing one.

FRS suppresses excessive replication of files caused by these types of updates and logs FRS event ID 13567 in the File Replication service event log. More specifically, this event is logged when FRS detects that 15 identical updates were made to FRS replicated files within a one-hour period and this condition has occurred over three consecutive hours. The duplicate changes might have occurred on a single file 15 times, or 15 unique files one time each, or any combination between those two.

Note that these thresholds apply only to event logging; FRS suppression works continuously. In addition, FRS suppression does not apply to folders. Therefore, frequent updates to folders affect replication and staging even when suppression is turned on.

**How Files and Folders Are Replicated**

The following figure describes the change order flow process, which begins when a file or folder is added to a replica tree or when a file or folder is changed and then closed in a replica tree. The sections that follow describe each step in the process. The differences in the flow process for file deletions are also described.

### How Change Orders Are Processed

**Step 1: NTFS creates a change journal entry**
When a file in a replica set is changed and closed, NTFS makes an entry in the USN journal. The USN journal records changes to all files on the NTFS volume (such as file creations, deletions, and modifications). In Windows Server 2003, the default journal size is 128 MB (or 512 MB in Windows Server 2003 with SP1 or the pre-SP1 release of Ntfrs.exe) and is persistent across restarts and crashes. If the FRS service is stopped or fails, this will have no effect on the replication of FRS content. Even with the service stopped, file changes are still recorded at the file system level in the USN journal. When the FRS service is restarted, stored USN journal entries will trigger replication.

**Step 2: FRS monitors the USN journal**
FRS monitors the USN journal for changes that apply to the replica trees on ServerA. Only closed files are checked. File and folder filters are applied against changes in the files and folders in the replica tree.

**Step 3: Aging cache is used**
The aging cache is a three-second delay designed to catch additional changes to a file. This prevents replication when a file is undergoing rapid updates.

**Step 4: FRS creates entries in the inbound log and file ID table**
ServerA records the change as a change order in its inbound log. It also creates an entry in the file ID table so that recovery can take place if a crash occurs. The inbound log contains change orders arriving from all inbound partners. Change orders are logged in the order that they arrive. Each change order contains information about a change to a file or folder on a replica member, such as the name of the file or the time it was changed. This information is used to construct a message about the change.

**Step 5: FRS creates the staging file in the staging folder**
ServerA uses backup APIs to create a backup of the changed file or folder in ServerA's staging folder. These backup files, known as staging files, encapsulate the data and attributes associated with a replicated file or folder. By creating the staging file in the staging folder, FRS ensures that file data can be supplied to partners regardless of any activity that might prevent access to the original file. All staging files in the staging folder are compressed to save disk space and network bandwidth during replication.

At step 1 if a file is deleted, FRS does not create a staging file.

**Step 6: FRS creates the entry in the outbound log**
ServerA updates the outbound log. The outbound log contains change orders generated for a specified replica set. These change orders can originate locally or come from an inbound partner. Change orders recorded in the outbound log are eventually sent to all outbound partners.

If a file is deleted, the change order contains the event time of the deletion and the tombstone lifetime (by default 60 days). When the tombstone for the deleted file expires, the file's entry in the file ID table is purged.

**Step 7: FRS sends a change notification**
ServerA sends a change notification to ServerB.

**Step 8: FRS records and acknowledges the change notification**
ServerB stores the change order in its inbound log and file ID table. If ServerB decides to accept the change order, it sends a change order acknowledgement (CO ACK) to ServerA to replicate the modified file's staging file.

**Step 9: FRS replicates the staging file**
ServerB copies the staging file from ServerA to the staging folder on ServerB. ServerB then writes to its outbound log so other outbound partners can pick up the change.

If the change order is for a deleted file, no staging file is fetched. The change notification for the deleted file is added to ServerB's outbound log,

**Step 10: FRS constructs the staging file and moves it into the replica tree**
ServerB uses restore APIs to reconstruct (that is, restore) the file or folder in the preinstall folder, and then FRS renames the file or folder into the replica tree.

If the change order was for a file deletion, ServerB deletes the file from the replica tree.

**How the Staging Folder Works**
The staging folder is a queue for changes to be replicated to downstream partners. After the changes are made to a file and the file is closed, the file content is compressed, written to the staging folder, and replicated according to schedule. Any further use of that file does not prevent FRS from replicating the staging file to other members.

The following sections describe various aspects of the staging folder.

**Staging folder size**
The size of the staging folder governs the maximum amount of disk space that FRS can use to hold those staging files and the maximum file size that FRS can replicate. The default size of the staging folder is approximately 660 MB, the minimum size is 10 MB, and the maximum size is 2 terabytes. The largest file that FRS can replicate is determined by the staging folder size on both the upstream partner and downstream partners and whether the compressed replicated file can be accommodated by the current staging folder size. Therefore, the largest file that FRS can replicate is 2 terabytes, assuming that the staging folder size is set to the maximum on upstream and downstream partners.

**Staging folder compression**
FRS replica members running Windows 2000 Server with Service Pack 3 (SP3) or later or Windows Server 2003 compress the files replicated among them. Compression reduces the size of files in the staging folder on the upstream partners, over the network between compression-enabled partners, and in the staging folder of downstream partners prior to files being moved into their final location.

All files and subfolders within the staging folder are compressed. However, compression is not enabled on the staging folder itself.

**How the staging folder stays below its maximum size limit**
When FRS tries to allocate space for a staging file and is not successful because the size of the files in the staging folder has reached 90 percent of the staging folder size, FRS starts to remove files from the staging folder. Staged files are removed (in the order of the longest time since the last access) until the size of the staging folder has dropped below 60 percent of the staging folder limit. Additionally, staging files for downstream partners that have been inaccessible for more than seven days are deleted. As a result, FRS does not stop replicating if the staging folder runs out of free space. This means that if a downstream partner goes offline for an extended period of time, the offline member does not cause the upstream partner's staging folder to fill with accumulated staging files.

### Note

- During the process of deleting staging files to reach the 60 percent limit, FRS does not delete staging files that have change orders in the inbound log pending install, because they are still needed by this member.

The fact that FRS removes files from the staging folder does not mean that the underlying file is deleted or will not be replicated. The change order in the outbound log still exists, and the file will eventually be sent to downstream partners when they process the change order. However, before replication can take place, the upstream partner must recreate the staging file in the staging folder, which can affect performance. Recreating the staging file can also cause a replication delay if the file on the upstream partner is in use, preventing FRS from creating the staging file.

**Staging folder cleanup**
Staging files are cleaned up during the outbound log cleanup process. Specifically, staging files are deleted from the staging folder after all replica members have acknowledged the change orders that generated the staging files. For more information about the outbound log cleanup process and its effect on the staging folder, see "How the Outbound Log Cleanup Process

Works" later in this section.

**How Replication Schedules Work**
The replication schedule defines the periods during which replication takes place. The following sections describe various aspects of replication schedules.

**SYSVOL Schedules**
The SYSVOL schedule is an attribute associated with each NTFRS Replica Set object and with each NTDS Connection object. FRS replicates SYSVOL using the same intrasite connection objects and schedule built by the KCC for Active Directory replication. FRS uses two replication protocols for SYSVOL:

- **SYSVOL connection within a site**. The connection is always considered to be on; any schedule is ignored and changed files are replicated immediately.

- **SYSVOL connection between sites**. SYSVOL replication is initiated between two intersite members at the start of the 15-minute interval, assuming the schedule is open. The connection is treated as a trigger schedule. The upstream partner ignores its schedule and responds to any request by the downstream partner. When the schedule closes, the upstream partner unjoins the connection only after the current contents of the outbound log, at the time of join, have been sent and acknowledged.

The SYSVOL replication schedule can be configured so that replication takes place four, two, one, or zero times per hour.

- When set to four times per hour, replication starts at 0:00, 0:15, 0:30, and 0:45. This schedule is essentially continuous replication.

- When set to two times per hour, replication occurs at 15-minute intervals starting at 0:15 and 0:45.

- When set to one time per hour, replication starts at 0:00 and ends at 0:15 assuming that all changes have been replicated.

It is possible to change the SYSVOL schedule, but this should be done only after careful consideration of the implications and alternatives. Also, note that schedules exist on both site links and NTDS Connection objects. If you change the schedule on an NTDS Connection objects, the connection then becomes a manual connection that cannot be managed by KCC.

**DFS Replica Set Schedules**
For DFS replica sets, FRS uses the NTDS Connection objects, topology, and schedule built by the Distributed File System snap-in. The snap-in sets the schedule as follows:

- When you view the properties of a link and set the schedule in the ***Linkname* Properties** dialog box, the snap-in applies the schedule to all NTDS Connection objects for this replica set. The snap-in does not apply the schedule to the NTFRS Replica Set object.

- If you view individual connections in the **Customize Topology** dialog box and modify the schedule on a connection, the snap-in applies that schedule to the NTDS Connection object for the connection.

- If you add a new member to an existing replica set, the new member's NTDS Connection objects get the default "always on" schedule.

- If you use the snap-in to set schedules on individual connections, and then you view the schedule from the ***Linkname* Properties** dialog box, the snap-in displays the schedule for the last enumerated NTDS Connection object. If you click **OK** in this dialog box, the schedule shown is applied to all NTDS Connection objects. To avoid this, click **Cancel** to close the dialog box.

When replication is set to available, replication occurs continuously. Unlike SYSVOL schedules, DFS replica set schedules are on/off schedules. As long as the schedule is open, the connection stays in the joined state and change orders are sent out as they are processed by the upstream partner. Any queued change orders in the upstream partner's outbound log are sent first. When the schedule closes, FRS unjoins the connection.

**How Local Time Affects the Schedule**
Replication schedules are stored in Coordinated Universal Time (UTC). However, when you view the schedule, the schedule is shown in the local time of the server. Daylight savings time causes the schedule to shift by an hour for any server that is

located in an affected time zone.

**How File and Folder Filters Work**
Filters exclude subfolders (and their contents) or files from replication. You exclude subfolders by specifying their name, and you exclude files by using wildcard characters to specify file names and extensions. By default, no subfolders are excluded. The default file filters exclude the following files from replication:

- File names starting with a tilde (~) character
- Files with .bak or .tmp extensions

Filtering takes place when FRS monitors the USN journal for changed files and folders. If a new or updated file meets a filter that excludes it from replication, FRS ignores the change in the USN journal and does not generate a change order.

Because filtering occurs at the USN journal, filters act as exclusion filters only for new files and folders added to a replica set. They have no effect on existing files in the replica set. For example, if you change the existing file filter from "*.tmp, *.bak" to "*.old, *.bak," FRS does not go through the replica set and exclude all files that match *.old, nor does it go through the replica set and begin to replicate all files that match *.tmp. After the filter change, new files matching *.old that are added to the replica set are not replicated. New files matching *.tmp that are added to the replica set are replicated.

Any file in the replica set that was excluded from replication under the old file filter (such as Test.tmp, created when the old filter was in force) is automatically replicated under the new file filter only after the file is modified. Likewise, changes to any file that was not excluded from replication under the old filter (such as Test.old, created when the old filter was in force) continue to replicate under the new filter, until you explicitly delete the file.

These rules apply in the same manner to the folder exclusion filter. If a folder is excluded, all subfolders and files under that folder are also excluded.

Regardless of the filters you set, FRS always excludes the following from replication:

- NTFS mounted drives.
- Files encrypted by using EFS.
- Any reparse points except those associated with DFS namespaces. If a file has a reparse point used for Hierarchical Storage Management (HSM) or Single Instance Store (SIS), FRS replicates the underlying file but not the reparse point.
- Files on which the temporary attribute has been set.

**How the Outbound Log Cleanup Process Works**
The outbound log cleanup process runs periodically to remove change orders from the outbound log. The process is scheduled by the outlog thread, and the first cleanup is scheduled to run 60 seconds after the outlog thread starts. Service initialization code starts the outlog thread.

At every scheduled cleanup, the time it took to perform the last cleanup is calculated and the next scheduled time is set. The time before the next scheduled cleanup is set to 50 multiplied by the time it took to run the last cleanup. This interval is then adjusted so that it is not less than 60 seconds, it is not more than the **Outlog Change History In Minutes** registry entry (which is seven days, by default), and it is not more than eight hours. As a result, the cleanup process tries not to take more than 2 percent of the processing time. For large outbound logs, the cleanup can take several minutes to run.

The cleanup process does not need to run every time it is scheduled. The cleanup process only runs for the replica sets that have received at least one change order acknowledgement (ACK) since the last time cleanup ran on that replica set. In situations where a replica member does not receive ACKs from any partners for a long time, there is an interval after which the cleanup process runs on that replica member, even if it has not received an ACK from its partners. The interval is either the amount specified in the **Outlog Change History In Minutes** registry entry (seven days, by default) or eight hours, whichever is smaller.

The cleanup function goes through all the change orders in the outbound log and does the following.

1. Deletes all vvjoin change orders and their corresponding staging files if they have been acknowledged by the partner they were meant for. (Vvjoin change orders are deleted because they are directed change orders, which means they are generated for a specific partner and are of no use after they are acknowledged by that partner.)

2. Deletes staging files for all the change orders that have been acknowledged by all the partners. Staging files are not kept longer than required; only change orders are kept. Staging files are regenerated as needed.

3. Deletes change orders that have been in the outbound log for more than the **Outlog Change History In Minutes** registry entry. If there is a connection that has not yet sent the change order that is being deleted, that connection is marked for deletion at the next poll. The deletion of these connections will take them out of the list of active connections and trigger cleanup on the change orders that were backed up for them. Because these connections are not actually deleted from Active Directory, they will reappear at the second poll and will rejoin and go through a complete vvjoin. This functionality provides a way for FRS to clean up change orders in the outbound log and staging files for members that have not accepted changes for a long time.

**How FRS Debug Logs Work**

FRS creates text-based logs in the *systemroot*\Debug folder to help you debug problems. The Ntfrs log files store transaction and event detail in sequentially numbered files (Ntfrs_0001.log through Ntfrs_0005.log). Transactions and events are written to the log with the highest sequence number in existence at that time. The characteristics of the log files are determined by the values of several registry entries in the HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters subkey. After the number of logs specified by the value of the **Debug Log Files** registry entry has been filled, the lowest log version is deleted and the remaining log file names are decreased by *n*–1 to make room for a new log file.

Log detail is controlled by the value of the **Debug Log Severity** registry entry, ranging from 0 to 5, with 5 providing the most detail. Log size is determined by the value of the **Debug Maximum Log Messages** registry entry. The default value of 20,000 lines for **Debug Maximum Log Messages** results in a log file of approximately 2 MB, for a total of 10 MB of logs (**Debug Log Files** * [**Debug Maximum Log Message** * 120]). Setting **Debug Log Messages** to 50,000 results in log files of approximately 5 MB and 25 MB of total log space with default settings.

Solving problems by using the Ntfrs logs requires ensuring that the value of the **Debug Log Severity** registry entry is set high enough to capture the events needed to identify the problem. Severity settings range from 0 to 5 and are cumulative, meaning that a setting of 4 includes log events with a severity of 0 to 3. Error logs hold a severity setting of 0 and are always displayed. Setting the severity level at 5 will cause every action to be logged and can make finding more important information difficult. The default log setting is 2.

All log records have a date and time stamp and an identifying string annotated by **::** with a letter or pair of letters between each colon. These identifying strings make it easy for you to identify errors, warning messages, and milestone events in the log files and filter out less important information. For example, a log entry that has a **:U:** as an identifying string includes information related to the USN journal. A log entry containing information about Active Directory polling will have an identifying string of **:DS:**. A tracking log entry has an identifying string of **:T:** and summarizes a change order that has finished or is in the process of updating a given file or folder. The following table lists the log record identifiers.

**Log Record Identifiers**

| Identifier | Description |
|---|---|
| :: | Change order trace records |
| ++ | Continuation records |
| :DS: | DS access entries |
| :FK: | FRS registry Key entries |
| :H: | Log header entries |
| :S: | Service startup and shutdown entries |
| :SC: | Service controller entries |
| :SR: | Send / Receive command server entries |
| :T: | Tracking record |
| :U: | USN journal entries |

| | |
|---|---|
| :V: | Version Vector join entries |
| :X: | Communication entries |

Tracking record entries (**:T:**) can be a helpful way to identify and understand problems that can occur during the change order process. A tracking record entry will tell you what files have been changed and where the change originated.

The following tracking record entry describes a remote change order that is creating a new file called test_file in Replica-A. The version number is zero.

```
7/31-08:40:08 :T: CoG: d42cda60 CxtG: 000001b7 [RemCo   ] Name: test_file
7/31-08:40:08 :T: EventTime: Mon Jul 31, 2003 08:40:04 Ver: 0
7/31-08:40:08 :T: FileG: ceff96a6-5c9f-433a-989c841454a1593b FID: 61a70000 0000036c
7/31-08:40:08 :T: ParentG: 1a89f4e1-a0c0-43e4-aedbe869f767f372 Size: 00000000 00000008
7/31-08:40:08 :T: OrigG: 2eea81b4-f92d-4941-9f269d4bbdd7ea05   Attr: 00000020
7/31-08:40:08 :T: LocnCmd: Create State: IBCO_COMMIT_STARTED         ReplicaName:
Replica-A (1)
7/31-08:40:08 :T: CoFlags: 0000040c   [Content Locn NewFile ]
7/31-08:40:08 :T: UsnReason: 00000002 [DatExt ]
```

The individual fields that comprise the tracking log entry are described in the following table. In some cases only the first DWORD of a GUID is actually displayed in the log.

**Tracking Log Entries**

| **Identifier** | **Description** |
|---|---|
| :T: | Identifying string. |
| CoG: | Change order GUID - Uniquely identifies a create/delete/rename/modify action for a file. |
| CxtG: | Connection GUID - Identifies the connection object in the topology connecting an upstream member to the member that delivered this change order. |
| [ ] - RemCo<br>[ ] - RemCo, Abort<br>[ ] - LclCo<br>[ ] LclCo, Abort | Identifies a remote change order.<br>Identifies a remote changer order that was aborted.<br>Identifies a local change order.<br>Identifies a local change order that was aborted. |
| Name: | File name. |
| EventTime: | Time on the originating member at which the change was performed. |
| Ver: | Version number of the file. Increases by one each time a local change order is created. |
| FileG: | File GUID - Uniquely identifies the file or folder and is used as the NTFS object ID on the file or folder. The corresponding file/folder on each replica member has the same file GUID. |
| FID: | File ID - The NTFS volume-specific file ID (file reference number). |
| ParentG: | Parent GUID - The GUID of the parent folder that contains this file or folder. |
| Size: | The approximate size of the file or folder noted in hexadecimal. |
| OrigG: | Originator GUID - The GUID associated with the member of the replica set that originated this update. |
| Attr: | File attributes - The attribute flags for the file/folder. |
| LocnCmd: | Location command - One of Create, Delete, NoCmd, MoveDir; indicating that the file is being created, deleted, updated, or is changing parent folders. |

| | |
|---|---|
| State: | The change order state - One of IBCO_STAGING_RETRY, IBCO_FETCH_RETRY, IBCO_INSTALL_RETRY, IBCO_COMMIT_STARTED, IBCO_INSTALL_REN_RETRY, IBCO_INSTALL_DEL_RETRY, and IBCO_FETCH_REQUESTED indicating that the change order is being retried later because of inability to complete the fetch of the staging file, or inability to install the change to the file. Finished change orders have a state of IBCO_COMMIT_STARTED. |
| ReplicaName: | The name of the replica set containing this file or folder. |
| CoFlags: | Change 0rder flags<br>• Abort - Set when CO is being aborted.<br>• VVAct - Set when VV activate request is made.<br>• Content - Valid content command.<br>• Locn - Valid location command.<br>• LclCo- CO is locally generated.<br>• Retry - CO needs to retry.<br>• InstallInc - Local install not completed.<br>• Refresh - CO is an upstream-originated file refresh request.<br>• OofOrd - Don’t check/update version vector.<br>• NewFile - If CO fails, delete IDTable entry.<br>• DirectedCo - This CO is directed to a single connection.<br>• DemandRef - CO is a downstream demand for refresh.<br>• VVjoinToOri - CO is from vvjoin to originator.<br>• MorphGen - CO generated as part of name morph resolution.<br>• MoveinGen - This CO was generated as part of a sub-dir MOVEIN.<br>• OidReset - All CO did was reset the object identifier back to FRS defined value.<br>• CmpresStage - The stage file for this CO is compressed. |

| | |
|---|---|
| UsnReason: | Flags set in the NTFS change log describing modifications to the file.<br>• Close - Change log close record.<br>• Create - File or folder was created.<br>• Delete - File or folder was deleted.<br>• RenNew - File or folder was renamed.<br>• DatOvrWrt - Main file data stream was overwritten.<br>• DatExt - Main file data stream was extended.<br>• DatTrunc - Main file data stream was truncated.<br>• Info - Basic info change (attrib, last write time, and so forth).<br>• Oid - Object ID change.<br>• StreamNam - Alternate data stream name change.<br>• StrmOvrWrt - Alternate data stream was overwritten.<br>• StrmExt - Alternate data stream was extended.<br>• StrmTrunc - Alternate data stream was truncated.<br>• EAChg - Extended file attribute was changed.<br>• Security - File access permissions changed.<br>• IndexableChg - File change requires reindexing.<br>• Hlink - Hard link change.<br>• CompressChg - File compression attribute changed.<br>• EncryptChg - File encryption changed.<br>• Reparse - Reparse point changed. |

The following tracking log entry describes a local change order (a change order originating on the computer where the log was produced) that is updating the same file, test_file. The version number is now 1. Notice that the originator GUID is different from that of the tracking log entry above. The file GUID and parent GUID of both log entries are the same for both change orders because the same file is involved and it has not changed parent directories.

```
7/31-08:56:55 :T: CoG: cd55ad6f CxtG: 37b12c93  [LclCo ]  Name: test_file
7/31-08:56:55 :T: EventTime: Mon Jul 31, 2003 08:56:52   Ver:  1

```

**Network Ports Used by FRS**

FRS uses the following two network ports:

**Network Ports Used by FRS**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | | 389 |
| RPC | | Dynamic |

By default, FRS replication over remote procedure calls (RPCs) occurs dynamically over an available port by using RPC Endpoint Mapper (also known as Remote Procedure Call Server Service or RPCSS) on port 135; the process is the same for Active Directory replication.

# FRS Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- FRS Tools
- FRS Registry Entries
- Network Ports Used by FRS

**FRS Tools**
The following tools are associated with File Replication service (FRS).

**Connstat.cmd: FRS Connection Status Report**
**Category**
Windows Support Tools for Windows Server 2003 and Windows 2000

**Version compatibility**
Runs on and collects information from servers running Windows 2000 Server or Windows Server 2003. Requires PERL 5.005 521e or 522e on the server where ConnStat is running.

ConnStat processes the output generated when the NtfrsUtl tool is run with the **sets** parameter. Using the NtfrsUtl sets output as its data source, ConnStat creates a report that summarizes the status of the FRS replication connections to and from a specified computer.

**Dfsgui.msc: Distributed File System snap-in**
**Category**
Windows Server 2003 operating system tool

**Version compatibility**
Runs on Windows Server 2003. This snap-in is also part of the Windows Server 2003 Administration Tools Pack; you can install this pack on computers running Windows XP with Service Pack 1 (SP1) or later.

The Distributed File System snap-in is used to enable replication for DFS root or link targets, create custom replication schedules and topologies, set replication filters and connection priorities, and so forth.

**FRSDiag.exe: FRS Diagnostics**
**Category**
Diagnostic tool for Windows Server 2003 and Windows 2000. This tool is available from the Microsoft Download Center on the Microsoft Web site.

**Version compatibility**
Runs on any computer running Windows 2000 Server, Windows 2000 Professional, Windows Server 2003, or Windows XP. Requires that NET Framework version 1.1 be installed on the computer where FRSDiag is running. Collects information from servers running Windows 2000 and Windows Server 2003.

FRSDiag is an easy-to-use tool that replaces the Health_Chk tool used to gather FRS information. FRSDiag provides a graphical user interface for choosing which information to gather and analyzes the results to identify common FRS and Active Directory problems.

**FrsFlags.vbs: File Replication Service Flags**
**Category**
Resource Kit Tools for Windows Server 2003

**Version compatibility**
Runs on Windows Server 2003.

FrsFlags is a command-line tool that enables and disables the Install Override feature of FRS. It sets and clears the FrsFlags attribute of replica objects in Active Directory.

**Health_chk.cmd: FRS Health Check**

**Category**
Windows Support Tools for Windows Server 2003 and Windows 2000

**Version compatibility**
Runs on and collects information from servers running Windows 2000 Server or Windows Server 2003.

Health_Chk retrieves FRS-related state information from the specified domain controller or server. It collects and provides administrators with in-depth data that can be used to monitor or troubleshoot an FRS system. Health_Chk calls a series of tools for the output they produce. It can be run against a remote server, though running the script directly on the server to be analyzed enables the tools to gather additional useful data that is not available when the script is run remotely.

**Iologsum.cmd: FRS Inbound and Outbound Logs Summary Report Tool**
**Category**
Windows Support Tools for Windows Server 2003 and Windows 2000

**Version compatibility**
Runs on and collects information from servers running Windows 2000 Server or Windows Server 2003. Requires PERL 5.005 521e or 522e on the server where IOLogSum is running.

IOLogSum processes the output generated when the NtfrsUtl tool is run with the **inlog**, **outlog**, or **idtable** parameters. Running NtfrsUtl **inlog** or NtfrsUtl **outlog** creates a summary inbound or outbound NtfrsUtl log report showing the pending change orders for the replica member. Running NtfrsUtl **idtable** creates a report with version information for each file in the replica tree; this version information tracks the last change order accepted for that particular file or directory. Running IOLogSum then sorts and formats this NtfrsUtl output.

**Ntfrsutl.exe:File Replication Utility**
**Category**
Windows Support Tools for Windows Server 2003 and Windows 2000

**Version compatibility**
Runs on and collects information from servers running Windows 2000 Server or Windows Server 2003.

NtfrsUtl dumps the internal tables, thread, and memory information for FRS.

**Sonar.exe: Sonar**
**Category**
Resource Kit Tools for Windows Server 2003 and Windows 2000. This tool is available from the Microsoft Download Center on the Microsoft Web site.

**Version compatibility**
Runs on any computer running Windows 2000 Server, Windows 2000 Professional, Windows Server 2003, and Windows XP. Requires .NET Framework version 1.1 on the computer where Sonar is running. Can be used to monitor servers running Windows 2000 and Windows Server 2003.

Sonar is a tool designed for monitoring key statistics about FRS members in a replica set. Sonar can collect basic status information from FRS running on either Windows 2000 (all service packs) or Windows Server 2003. You can use Sonar to easily watch coarse statistics on a replica set, and to monitor traffic levels, backlogs, free space, and other issues. Sonar allows definition of filters that define rules for which rows to display, and also allows definition of column sets that can be viewed.

**Topchk.cmd: DFS and SYSVOL Replication Topology Analysis Tool**
**Category**
Windows Support Tools for Windows Server 2003 and Windows 2000

**Version compatibility**
Runs on and collects information from servers running Windows 2000 Server or Windows Server 2003. Requires PERL 5.005 521e or 522e on the server where TopChk is running.

TopChk processes the output generated when the NtfrsUtl tool is run with the **ds** parameter. Using the NtfrsUtl **ds** output as its data source, TopChk creates a report that summarizes the replication topology of one or more replica sets.

**Ultrasound.exe: Ultrasound**
**Category**
Monitoring and troubleshooting tool for Windows Server 2003 and Windows 2000. This tool is available from the Microsoft Download Center on the Microsoft Web site.

**Version compatibility**
The user interface component of Ultrasound can be run on computers running Windows 2000 Server, Windows 2000 Professional, Windows Server 2003, or Windows XP. Ultrasound requires that .NET Framework version 1.1 and Microsoft Data

Access Components (MDAC) 2.6 be installed on the computer where the user interface component is running. Ultrasound also requires a database server running either Microsoft SQL Server 2000 Desktop Engine (MSDE) or SQL Server 2000 with SP3a. Ultrasound is used to monitor FRS on servers running Windows 2000 and Windows Server 2003 on which you install Ultrasound WMI providers.

Ultrasound is a powerful monitoring and troubleshooting tool used to measure the health of FRS replica sets. Ultrasound shows health ratings and historical information about replica sets and allows administrators to monitor the progress of replication and detect problems that can cause replication to become backlogged or stopped. Ultrasound also provides detailed views for troubleshooting and a framework for customizing alerts and views to suit an organization's needs.

**FRS Registry Entries**
The following registry entries are associated with FRS. The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs. The headings reflect the path beyond Ntfrs, such as Parameters or Parameters\Backup/Restore\Process at Startup, and the entries under each path are alphabetized.

**Parameters**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters.

**Compress Staging Files**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Disables the compression of staging files in the staging folder. Staging files are compressed by default.

**Debug Disable**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Disables the FRS debug log files. By default, FRS records its actions in debug log files. These log files are named NtFrs_000*n*.log and are located in the *Systemroot*\Debug directory. These files are typically used to investigate FRS replication problems.

To find more information aboutthis registry entry, see Registry Reference in Tools and Settings Collection.

**Debug Log File**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Specifies where FRS stores its debug log files. If you change the value of this entry, FRS creates new debug log files in the directory specified, but it does not move existing debug log files to the new location. Also, FRS does not delete or maintain log files in the original location.

To find more information aboutthis registry entry, see Registry Reference in Tools and Settings Collection.

**Debug Log Files**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Specifies how many FRS debug log files can be active simultaneously. FRS creates a set of sequential log files named

NtFrs_000*n*.log. The files are numbered, beginning with 0001, so that the log with the highest number contains the most recently logged entries. The log files are retained until the number of files reaches the value of this entry, and then FRS deletes NtFrs_0001.log and renumbers all remaining logs accordingly.

To find more information aboutthis registry entry, see Registry Reference in Tools and Settings Collection.

**Debug Log Severity**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Specifies the level of detail that FRS records in its debug log files (NtFrs_000*n*.log). FRS assigns severity levels to different log print statements in the FRS code. The value of this entry determines which severity levels are written to the log. The higher the value of this entry, the more detail the log records.

If the value of this entry is 0, only the most severe events are recorded in the log. If the value of this entry is 5, all events are recorded in the log. The default value is set to 2 so that tracking records are displayed, as well as warning and error messages.

To find more information aboutthis registry entry, see Registry Reference in Tools and Settings Collection.

**Debug Maximum Log Messages**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Specifies how many entries can be stored in each FRS debug log file (NtFrs_000*n*.log). When the number of event entries reaches the value of **Debug Maximum Log Messages**, the system closes the current log file and starts a new one. The log files are numbered sequentially, so when FRS closes NtFrs_0001.log, it begins NtFrs_0002.log.

To find more information aboutthis registry entry, see Registry Reference in Tools and Settings Collection.

**DS Polling Short Interval in Minutes**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

The interval at which FRS polls Active Directory at service startup or after configuration changes. FRS performs eight short polling intervals and then switches to long polling intervals if it is not interrupted by configuration changes that cause the short polling sequence to start over.

**DS Polling Long Interval in Minutes**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

The interval at which FRS polls Active Directory for configuration changes after eight short polling intervals have finished without interruption. FRS performs eight short polling intervals and then switches to long polling intervals if it is not interrupted by configuration changes. Configuration changes cause the short polling sequence to begin again.

**Enable Sharing Violation Logging**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003

Enables FRS to log sharing violation events (event ID 13573) in the File Replication service event log. When this is enabled, FRS keeps track of change orders that encounter sharing violations during install and other scenarios, and then logs event ID 13573 if the same change order encounters sharing violations equal to the **Sharing Violation Events Counter** registry entry per hour.

**Max Sharing Violation Event**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003

Specifies the maximum number of sharing violation events that are posted to the File Replication service event log in one hour. The default value is 10, which means that FRS logs ten sharing violation events per hour at most. Note that if multiple change orders encounter sharing violations for the same file, FRS posts a single event to the log.

**Ntfs Journal Size in MB**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Controls the size of the update sequence number (USN) journal. In Windows Server 2003, the default journal size is 128 megabytes (MB); in the pre-SP1 release of Ntfrs.exe, the default USN journal size is 512 MB. This setting applies to all volumes hosting an FRS replica tree. When the USN journal is set to 128 MB on a server that contains more than 100,000 files (or 400,000 files if the server is running the pre-SP1 release of Ntfrs.exe), we recommend that you increase the USN journal size by 128 MB per 100,000 additional files managed by FRS on the server.

To increase the size of the USN journal, you must stop and restart the NTFRS service. To decrease the size of the USN journal, you must reformat all volumes containing FRS replicated content.

**Outlog Change History In Minutes**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Controls outbound log change-order retention. FRS retains change orders even after they are sent to all current downstream partners. This feature permits FRS to vvjoin with a new downstream partner from the outbound log and avoids a full file ID table scan. As a result, this feature is helpful in environments where the topology changes frequently and during a rollout, when many new members come online within a short time.

**RPC TCP/IP Port Assignment**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Specifies the port that FRS uses for replication traffic. By default, FRS replication over remote procedure calls (RPCs) occurs dynamically over an available port by using RPC Endpoint Mapper (also known as RPCSS) on port 135. You can override this default functionality and specify the port that all FRS replication traffic passes through. When you do so, you can limit replication to a static port. The preferred port range to select from is 49152 to 65535, which is the range for private and dynamic ports that is specified by Internet Assigned Numbers Authority (IANA).

**Sharing Violation Events Counter**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003

Specifies how often FRS logs sharing violation events in the File Replication service event log. The default is 10, which means that FRS logs a sharing violation event for every ten sharing violations that a change order encountered.

**Staging Space Limit in KB**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Specifies the maximum amount of disk space used for the staging folder. The size of the staging folder governs the maximum amount of disk space that FRS can use to hold those staging files and the maximum file size that FRS can replicate. When FRS tries to allocate space for a staging file and is not successful because the amount of space in use has reached 90 percent of the staging space limit parameter, FRS starts to delete staging files. Staged files are deleted (in the order of the longest time since the last access) until the amount of space in use has dropped below 60 percent of the staging space limit parameter.

To find more information aboutthis registry entry, see Registry Reference in Tools and Settings Collection.

**Suppress Identical Updates to Files**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Specifies whether FRS tries to identify and suppress updates that do not change the content of a file (everything that is used to calculate the MD5 and attributes).

**Working Directory**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters

**Version**
Windows Server 2003 and Windows 2000

Specifies the location of the Ntfrs.jdb file and associated log files. The Jet database should reside on an NTFS volume.

**Parameters\Access Checks\Get Ds Polling Interval**
The following registry entries are located under
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Get Ds Polling Interval.

**Access checks are [Enabled or Disabled]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Get Ds Polling Interval

**Version**
Windows Server 2003 and Windows 2000

Specifies whether a user or process can get information about the Active Directory polling interval (by using Ntfrsutl.exe with the **poll** parameter, for example). Set to Enabled by default.

**Access checks require [Full Control or Read]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Get Ds Polling Interval

**Version**
Windows Server 2003 and Windows 2000

Specifies the permissions with which a user or process can get information about the Active Directory polling interval. Set to Read by default.

**Parameters\Access Checks\Get Internal Information**
The following registry entries are located under
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Get Internal Information.

**Access checks are [Enabled or Disabled]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Get Internal Information

**Version**
Windows Server 2003 and Windows 2000

Specifies whether a user or process can get internal information about FRS (by using Ntfrsutl.exe, for example). Set to Enabled by default.

**Access checks require [Full Control or Read]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Get Internal Information

**Version**
Windows Server 2003 and Windows 2000

Specifies the permissions with which a user or process can get internal information about FRS (by using Ntfrsutl.exe, for example). Set to Full Control by default.

**Parameters\Access Checks\Get Perfmon Data**
The following registry entries are located under
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Get Perfmon Data.

**Access checks are [Enabled or Disabled]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Get Perfmon Data

**Version**
Windows Server 2003 and Windows 2000

Specifies whether a user or process can collect performance-related information about FRS. Set to Enabled by default.

**Access checks require [Full Control or Read]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Get Perfmon Data

**Version**
Windows Server 2003 and Windows 2000

Specifies the permissions with which a user or process can collect performance-related information about FRS. Set to Read by default.

**Parameters\Access Checks\Set Ds Polling Interval**
The following registry entries are located under
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Set Ds Polling Interval.

**Access checks are [Enabled or Disabled]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Set Ds Polling Interval

**Version**
Windows Server 2003 and Windows 2000

Specifies whether a user or process can change the Active Directory polling interval. Set to Enabled by default.

**Access checks require [Full Control or Read]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Set Ds Polling Interval

**Version**
Windows Server 2003 and Windows 2000

Specifies the permissions with which a user or process can change the Active Directory polling interval. Set to Full Control by default.

**Parameters\Access Checks\Start Ds Polling**
The following registry entries are located under
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Start Ds Polling.

**Access checks are [Enabled or Disabled]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Start Ds Polling

**Version**
Windows Server 2003 and Windows 2000

Specifies whether a user or process can trigger Active Directory polling (by using Ntfrsutl.exe with the **poll /now** parameter, for example). Set to Enabled by default.

**Access checks require [Full Control or Read]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Start Ds Polling

**Version**
Windows Server 2003 and Windows 2000

Specifies the permissions with which a user or process can trigger Active Directory polling (by using Ntfrsutl.exe with the **poll /now** parameter, for example). Set to Read by default.

**Parameters\Access Checks\Writer Commands**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Writer Commands.

**Access checks are [Enabled or Disabled]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Writer Commands

**Version**
Windows Server 2003 and Windows 2000

Specifies whether the FRS VSS writer can issue commands. Set to Enabled by default.

**Access checks require [Full Control or Read]**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Access Checks\Writer Commands

**Version**
Windows Server 2003 and Windows 2000

Specifies the permissions with which the FRS VSS writer can issue commands. Set to Full Control by default.

**Parameters\Backup/Restore\Process at Startup**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\ Backup/Restore\Process at Startup.

**Burflags**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Backup/Restore\Process at Startup

**Version**
Windows Server 2003 and Windows 2000

Short for “backup restore flags,” Burflags is used to perform nonauthoritative or authoritative restores on FRS members of DFS or SYSVOL replica sets.

**Parameters\SysVol Seeding**
**Replica Set Parent**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\SysVol Seeding

**Version**
Windows Server 2003 and Windows 2000

Specifies the RPC binding string for the parent computer from which to seed during the SYSVOL creation process. This registry entry applies only to SYSVOL replica sets.

**Network Ports Used by FRS**
FRS uses the following two network ports:

### Network Ports Used by FRS

| Service Name | TCP |
|---|---|
| LDAP | 389 |
| RPC | Dynamic |

By default, FRS replication over remote procedure calls (RPCs) occurs dynamically over an available port by using RPC Endpoint Mapper (also known as Remote Procedure Call Server Service or RPCSS) on port 135; the process is the same for Active Directory replication.

# File Systems Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**File Systems Technologies**

**In this overview**

- File Systems Components
- File Systems Deployment Scenarios

A file system is a part of the operating system on a volume and it determines how files are named, stored, and organized on basic or dynamic disks. A file system manages files and folders as well as the information required to locate and access these items by local and remote users. The Microsoft Windows Server 2003 operating system supports the NTFS and FAT file systems.

When you format a volume on a hard disk, a file system is always required to access and manage data. You can put only one file system on a volume. If you partition your hard disk into multiple volumes, each volume can have a different file system.

All file systems used by Windows Server 2003 organize hard disks based on cluster size, which is determined by the number of sectors contained by the cluster. When a file is written to disk, the file system tries to find enough contiguous clusters to hold the file. If the file system cannot find contiguous clusters, it saves the file to noncontiguous clusters. The result is file fragmentation. Disk Defragmenter is a file system tool that organizes the clusters on the volume to be more contiguous, which, in turn, improves file system performance.

**File Systems Components**

NTFS is the preferred file system for Windows Server 2003. NTFS addresses many of the limitations of FAT file system-based file systems. It provides improved file security, as well as performance, reliability, and advanced features not found in any version of FAT. Use NTFS wherever possible to gain the maximum benefits from Windows Server 2003.

Although NTFS is the preferred file system for hard disks, Windows Server 2003 uses FAT12 for formatting floppy disks and FAT32 for formatting flash media and DVD-RAM discs.

**FAT**

The two versions of FAT supported by Windows Server 2003 are FAT16 and FAT32. FAT16 is an older file system. It was widely used on Windows NT 4.0, and supports a 16-bit file allocation table. FAT16 provides optimal performance on volumes that are less than 2 gigabytes (GB). FAT32 is the version of FAT introduced with Windows 95 OEM Service Release 2 (OSR2) and Windows 98. FAT32 supports a 32-bit allocation table, and supports smaller cluster sizes than FAT16, in order to more efficiently allocate space. On Windows Server 2003, FAT32 can support volumes up to 32 GB. FAT is also the only file system supported for floppy disks and other removable media.

Some earlier Microsoft Windows operating systems as well as removable disks and floppy disks support only the FAT file system. FAT16 and FAT32 volumes are limited to 4 gigabytes (GB) and 32 GB respectively, so you must use NTFS to create volumes larger than 32 GB.

**Disk Defragmenter**

Disk Defragmenter is a tool that is used to improve the overall performance of disk input or output on either NTFS or FAT-formatted volumes. Disk Defragmenter analyzes local volumes and consolidates fragmented files and folders so that each occupies a single, contiguous space on the volume. As a result, a system can access files and folders and save new ones more efficiently. By consolidating files and folders, Disk Defragmenter also consolidates a volume's free space, making it less likely that new files will be fragmented.

**File Systems Scenarios**

This section describes a few scenarios in which NTFS, FAT, and Disk Defragmenter are used. Before formatting a volume for a file system, you should determine what the volume will be used for, and which operating system will be mounted on that volume. The following scenarios might help you when you are deciding how to format volumes.

**NTFS Scenarios**

This section describes scenarios in which NTFS should be the file system on a volume.

**Increasing reliability**

When a computer is restarted after a system failure, NTFS uses its log file and checkpoint information to restore the file system. In the event of a bad-sector error, NTFS dynamically remaps the cluster containing the bad sector and allocates a new cluster for the data. It also marks the cluster as bad so that it is no longer used. By formatting a POP3 mail server with NTFS, the mail store can offer logging and recovery. In the event of a server failure, NTFS can recover data by using its log files.

**Increasing security**
NTFS allows you to set permissions on a file or folder. You can also specify the groups and users who can access the file or folder, and set specific levels of access (for example, some users can only open the file, while other users can open it and modify it). NTFS also supports Encrypting File System (EFS) technology. Unauthorized users are prevented from accessing encrypted files, even if the unauthorized user has physical access to the computer. If a POP3 mail server is formatted with NTFS, NTFS provides increased security for the mail store (security that is not available with the FAT file system).

**Supporting large volumes**
Clusters are the smallest amount of disk space used to store a file. When you format a volume as NTFS, you can choose the cluster size of the volume. The smaller the cluster size, the more efficiently a disk stores information. You can create an NTFS volume which is up to 16 terabytes in size using the default cluster size (4 kilobytes (KB)) for large volumes, or you can create NTFS volumes of up to 256 terabytes using the maximum cluster size of 64 KB. NTFS also supports larger files and more files per volume than FAT. In addition, NTFS manages disk space more efficiently than FAT by using smaller cluster sizes. Using smaller clusters reduces wasted space on hard disks. NTFS supports the many capabilities of dynamic disks for managing large storage requirements.

**Limited space on a volume**
If your organization has limited space on a volume, NTFS provides support for increasing storage on a server with limited disk space.

- Disk quotas allow you to track and control user disk space usage for NTFS volumes.
- NTFS supports compression as well as adding unallocated space from the same disk or from another disk to increase the size of an NTFS volume.
- Mounted volumes are volumes attached to an empty folder on an NTFS volume. Mounted drives function the same way as any other volume, but are assigned a label or name instead of a drive letter. Mounted drives more easily withstand system changes that occur when devices are added or removed from a computer. They are not subject to the 26-volume limit imposed by drive letters, so you can use them for access to more than 26 volumes on your computer.

**Using features available only in NTFS**
NTFS has a number of features that are not available if you are using a FAT file system. These include:

- **Distributed link tracking.** Distributed link tracking ensures that the integrity of shortcuts and OLE links. You will not break shortcut or OLE links, even if you rename source files, move them to NTFS volumes on different computers within a Windows Server 2003 or Windows 2000 domain, or change the computer name or folder name that stores the target.
- **Sparse files.** Sparse files provide a method for reserving disk space for files that contain meaningful data as well as large sections of data composed of zeros. If an NTFS file is marked as sparse, then NTFS allocates disk clusters only for the data explicitly specified by the application. The result is efficient file system storage and access.
- **NTFS change journal.** A log of changes that are made to files on a volume. NTFS maintains the log on each volume by tracking information about files that are added, deleted, or modified.
- **Hard links.** Hard links are NTFS-based pointers that allow multiple paths to refer to the same file or directory on NTFS volumes. By creating hard links, a single file can appear to exist in multiple folders (but you do not have to take up the space necessary to duplicate the file). By creating hard links, you can:
    - Make a single file appear to reside in different folders.
    - Use multiple names to refer to a single file that resides in a single folder.
    - Use multiple names to refer to files that appear to reside different folders (in reality the links all point to a single file that resides in a single folder).

**Using Windows Server 2003 features that require NTFS**
Windows Server 2003 includes a number of features that require NTFS. A few of these features include:

- **Volume Shadow Copy Service.** Service that provides an infrastructure for creating highly accurate, point-in-time shadow copies. These copies of a single volume or multiple volumes can be made without affecting the performance of a production server. The Volume Shadow Copy service can produce accurate shadow copies by coordinating with business applications, backup applications, and storage hardware.

- **Distributed File System (DFS).** Strategic storage management solution in Windows Server 2003 that allows you to logically group shared files and folders on different servers. With DFS, users no longer need to know the actual physical location of files in order to access them. For example, if you have marketing files on multiple servers in a domain, you can use DFS to make it appear as though all of the marketing files are on a single server.

- **File System Replication (FRS).** Technology that replicates files and folders stored in the SYSVOL shared folder on domain controllers and Distributed File System (DFS) shared folders. When FRS detects that a change has been made to a file or folder within a replicated shared folder, FRS replicates the updated file or folder to other servers.

In addition, NTFS is required before you can promote a server running Windows Server 2003 to a domain controller that hosts the Active Directory directory service.

**FAT Scenarios**
This section describes scenarios in which FAT should be the file system on a volume.

**Mounting a server with a small volume**
Small partitions (less than 512 megabytes) on a server work better with FAT. It uses a small amount of space on the partition, but still performs well.

**Running multiple operating systems**
If you are running multiple operating systems (for example, you are running Windows 98 in addition to Windows Server 2003), you must use FAT16 or FAT32 as Windows 98 is only supported by the FAT file system.

**Using FAT with older operating systems**
Both Windows 95 and Windows 98 use the FAT file system. These operating systems do not support NTFS.

**Using FAT with removable disks**
You must use FAT16 or FAT32 when formatting removable disks (for example, floppy disks). It is not possible to format a floppy disk with the NTFS file system because the file system itself requires too much disk space.

**Disk Defragmenter Scenarios**
This section describes scenarios in which Disk Defragmenter should be run on a volume.

**Installing new software**
Running Disk Defragmenter on a volume after installing software organizes the clusters on the volume.

**Rewriting, updating and deleting files**
Running Disk Defragmenter on a regular basis consolidates space to create more contiguous free clusters on the volume, which allows disk heads to read files and write updates more quickly.

**Operating System Compatibility with NTFS and FAT**
Not all Microsoft operating systems support NTFS or all versions of FAT. The following table lists common operating systems and indicates which file system they support.

### Operating System Compatibility with NTFS and FAT

| Operating System | FAT16 | FAT32 | NTFS |
|---|---|---|---|
| Windows XP | ● | ● | ● |
| Windows Server 2003 | ● | ● | ● |
| Windows 2000 | ● | ● | ● |
| Windows NT 4.0 | ● | | ● |

| | | | |
|---|---|---|---|
| Windows 95 OSR2, Windows 98, and Windows Millennium Edition | • | • | |
| Windows 95 (prior to OSR2) | • | | |
| MS-DOS | • | | |

# NTFS Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NTFS Technical Reference**

A file system is a part of the operating system that determines how files are named, stored, and organized on a volume. A file system manages files and folders, and the information needed to locate and access these items by local and remote users. The Microsoft Windows Server 2003 operating system supports both the FAT and NTFS file systems.

NTFS provides performance, reliability, and advanced features not found in FAT. For example, NTFS includes built-in security features such as file and folder permissions and the Encrypting File System (EFS), which is the technology used to store encrypted files on NTFS volumes. NTFS also provides support for volumes up to 256 terabytes in size, support for disk quotas and compression, and support for mounted drives.

# What Is NTFS?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is NTFS?**

**In this section**

- Common NTFS Scenarios
- Dependencies with Other Technologies
- Related Technology
- Related Information

A file system is a part of the operating system that determines how files are named, stored, and organized on a volume. A file system manages files and folders, and the information needed to locate and access these items by local and remote users. Microsoft Windows Server 2003 supports both the FAT and NTFS file systems.

NTFS allows you to gain the maximum benefits for the needs of today's enterprise business environments from Windows Server 2003, such as increased security, more robust and reliable performance, as well as a design for greater storage growth, features not found in FAT.

**Common NTFS Scenarios**

This section describes a few scenarios in which NTFS should be used as the file system on a server running Windows Server 2003.

**Increasing reliability**

NTFS uses its log file and checkpoint information to restore the consistency of the file system when the computer is restarted in the event of a system failure. In the event of a bad-sector error, NTFS dynamically remaps the cluster containing the bad sector and allocates a new cluster for the data, as well as marking the cluster as bad and no longer using it. For example, by formatting a POP3 mail server with NTFS, the mail store can offer logging and recovery. In the event of a server crash, NTFS can recover data by replaying its log files.

**Increasing security**

NTFS allows you to set permissions on a file or folder, and specify the groups and users whose access you want to restrict or allow, and then select the type of access. NTFS also supports the Encrypting File System (EFS) technology used to store encrypted files on NTFS volumes. Any intruder who tries to access your encrypted files is prevented from doing so, even if that intruder has physical access to the computer. For example, a POP3 mail server, when formatted with an NTFS file system, provides increased security for the mail store, security that would not be available should the server be formatted with the FAT file system.

**Supporting large volumes**

NTFS allows you to create an NTFS volume up to 16 terabytes using the default cluster size (4 KB) for large volumes. You can create NTFS volumes up to 256 terabytes using the maximum cluster size of 64 KB. NTFS also supports larger files and more files per volume than FAT. In addition, NTFS manages disk space more efficiently than FAT by using smaller cluster sizes. For example, a 30-GB NTFS volume uses 4-KB clusters. The same volume formatted by using FAT32 uses 16-KB clusters. Using smaller clusters reduces wasted space on hard disks. NTFS supports the many capabilities of dynamic disks for managing large storage requirements.

**Limited space on a volume**

If your organization has limited space on a volume, NTFS provides support for increasing storage on a server with limited disk space.

- Disk quotas allow you to track and control user disk space usage for NTFS volumes.
- NTFS supports compression as well as adding unallocated space from the same disk or from another disk to increase the size of an NTFS volume.

- Mounted volumes allow you to mount a volume at any empty folder on a local NTFS volume if you run out of drive letters or need to create additional space that is accessible from an existing folder.

#### Using features available only in NTFS

NTFS has a number of features that are not available if you are using a FAT file system. These include:

- **Distributed link tracking.** Maintains the integrity of shortcuts and OLE links. You can rename source files, move them to NTFS volumes on different computers within a Windows Server 2003 or Windows 2000 domain, or change the computer name or folder name that stores the target without breaking the shortcut or OLE links.

- **Sparse files.** Large, consecutive areas of zeros. NTFS manages sparse files by tracking the starting and ending point of the sparse file, as well as its useful (non-zero) data. The unused space in a sparse file is made available as free space.

- **NTFS change journal**. Provides a persistent log of changes made to files on a volume. NTFS maintains the change journal by tracking information about added, deleted, and modified files for each volume.

- **Hard links.** NTFS-based links to a file on an NTFS volume. By creating hard links, you can have a single file in multiple folders without duplicating the file. You can also create multiple hard links for a file in a folder if you use different file names for the hard links. Because all of the hard links reference the same file, applications can open any of the hard links and modify the file.

#### Using Windows Server 2003 features that require NTFS

Windows Server 2003 includes a number of features that require NTFS as the file system. A few of these features include:

- **Volume Shadow Copy service.** Service that provides an infrastructure for creating highly accurate, point-in-time shadow copies. These copies of a single volume or multiple volumes can be made without affecting the performance of a production server. The Volume Shadow Copy Service can produce accurate shadow copies by coordinating with business applications, backup applications, and storage hardware.

- **Distributed File System (DFS)**. Strategic storage management solution in Windows Server 2003 that enables you to group shared folders located on different servers logically by transparently connecting them to one or more hierarchical namespaces.

- **File System Replication (FRS)** Technology that replicates files and folders stored in the SYSVOL shared folder on domain controllers and Distributed File System (DFS) shared folders. When FRS detects that a change has been made to a file or folder within a replicated shared folder, FRS replicates the updated file or folder to other servers.

In addition, NTFS is required before you can promote a server running Windows Server 2003 to a domain controller that hosts the Active Directory directory service.

If the volume is not formatted with the NTFS file system, these Windows Server 2003 features will not be available.

### Note

- Although NTFS is the preferred file system for hard disks, NTFS cannot be used on removable media. Instead, Windows Server 2003 uses FAT12 for formatting floppy disks, and FAT32 for formatting flash media and DVD-RAM discs.

#### Operating System and NTFS Compatibility

NTFS is not supported on versions of Microsoft Windows earlier than Windows NT 4.0 and Windows 2000 Professional or MS-DOS. The table Operating System and NTFS Compatibility shows which operating systems support NTFS.

### Operating System and NTFS Compatibility

| Operating System | NTFS |
|---|---|
| Windows XP | • |
| Windows Server 2003 | • |

| | |
|---|---|
| Windows 2000 | • |
| Windows NT 4.0 | • |
| Windows 95 OSR2, Windows 98, and Windows Millennium Edition | |
| Windows 95 (prior to OSR2) | |
| MS-DOS | |

**Note**

- Computers running Windows NT 4.0 require Service Pack 4 or later to access NTFS volumes previously mounted by Windows 2000, Windows XP, or Windows Server 2003.

**Dependencies on Other Technologies**
NTFS depends on the following technologies:

**Basic Disks and Volumes**
Basic disks and basic volumes are the storage types most often used with Windows operating systems. The term basic disk refers to a disk that contains basic volumes, such as primary partitions and logical drives. The term basic volume refers to a partition on a basic disk. Basic disks, which are found in both x86-based and Itanium-based computers, provide a simple storage solution that can accommodate changing storage requirements.

**Dynamic Disks and Volumes**
Dynamic disks can use the master boot record (MBR) or GUID partition table (GPT) partitioning scheme. All volumes on dynamic disks are known as dynamic volumes. Dynamic disks were first introduced with Windows 2000 and provide features that basic disks do not.

**Related Technology**
NTFS is related to the following technology:

**FAT file system**
The File Allocation Table (FAT) file system is an older file system that relies on an allocation table to keep track of files and folders on a volume. Windows Server 2003 supports both FAT16 and FAT32 file systems.

# How NTFS Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How NTFS Works**

**In this section**

- NTFS Architecture
- NTFS Physical Structure
- NTFS Processes and Interactions
- Related Information

A file system is a required part of the operating system that determines how files are named, stored, and organized on a volume. A file system manages files and folders, and the information needed to locate and access these items by local and remote users.

Microsoft Windows Server 2003 supports the NTFS file system on basic and dynamic disks. Basic disks and volumes are the storage types most often used with Windows operating systems. Dynamic disks offer greater flexibility for volume management because they use a database to track information about dynamic volumes on the disk and about other dynamic disks in the computer.

During the format of a volume you can choose the type of file system for the volume. When you choose the NTFS file system, the formatting process places the key NTFS file data structures on the volume, regardless of whether it is a basic or dynamic volume.

**NTFS Architecture**

During format and setup of a volume file system on a hard disk, a master boot record (MBR) is created. The MBR contains a small amount of executable code called the master boot code as well as a partition table for the disk. When a volume is mounted, the MBR executes the master boot code and transfers control to the boot sector on the disk, allowing the server to boot the operating system on the file system of that specific volume.

**Note**

- The partition table contains a number of fields used to describe the partition. One of these fields is the System ID field, which defines the file system, such as NTFS, on the partition. For NTFS volumes, the system ID is 0x07.

The figure NTFS Architecture shows the architecture of this process.

**NTFS Architecture**

The following table describes the components of an NTFS file system.

**NTFS Architecture Components on an x86-based System**

| Component | Component Description |
|---|---|
| Hard disk | Contains one or more partitions. |
| Boot sector | Bootable partition that stores information about the layout of the volume and the file system structures, as well as the boot code that loads Ntdlr. |
| Master Boot Record | Contains executable code that the system BIOS loads into memory. The code scans the MBR to find the partition table to determine which partition is the active, or bootable, partition. |
| Ntldlr.dll | Switches the CPU to protected mode, starts the file system, and then reads the contents of the Boot.ini file. This information determines the startup options and initial boot menu selections. |
| Ntfs.sys | System file driver for NTFS. |
| Ntoskrnl.exe | Extracts information about which system device drivers to load and the load order. |
| Kernel mode | The processing mode that allows code to have direct access to all hardware and memory in the system. |
| User mode | The processing mode in which applications run. |

**NTFS Physical Structure**

The following information describes how clusters and sectors are organized on an NTFS volume, how the boot sector on the volume determines the file system, and how the Master File Table (MFT) organizes structures on the volume.

**Clusters and Sectors on an NTFS Volume**

A cluster (or allocation unit) is the smallest amount of disk space that can be allocated to hold a file. All file systems used by Windows Server 2003 organize hard disks based on cluster size, which is determined by the number of sectors (units of storage on a hard disk) that the cluster contains. For example, on a disk that uses 512-byte sectors, a 512-byte cluster contains one sector, whereas a 4-kilobyte (KB) cluster contains eight sectors.

Computers access certain sectors on a hard disk during startup to determine which operating system to start and where the partitions are located. The data stored on these sectors varies depending on the computer platform.

**Sequence of Clusters on an NTFS Volume**

Clusters on an NTFS volume are numbered sequentially from the beginning of the partition into logical cluster numbers. NTFS stores all objects in the file system using a record called the Master File Table (MFT), similar in structure to a database.

On NTFS volumes, clusters start at sector zero; therefore, every cluster is aligned on the cluster boundary. Contiguous clusters for file storage allow for faster processing of a file.

**Note**

- Floppy disks do not use NTFS and are always formatted as FAT.

**Limitations of Cluster Sizes on an NTFS Volume**

Because NTFS uses different cluster sizes depending on the size of the volume, each file system has a maximum number of clusters it can support. The smaller the cluster size, the more efficiently a disk potentially stores information because unused space within a cluster cannot be used by other files. And the more clusters a file system supports, the larger the volumes you can create and format by using a particular file system. NTFS uses smaller cluster sizes, which makes it a more efficient file organization structure.

The table Default NTFS Cluster Sizes lists NTFS volume and default cluster sizes.

**Default NTFS Cluster Sizes**

| Volume Size | NTFS Cluster Size |
|---|---|
| 7 megabytes (MB)–512 MB | 512 bytes |
| 513 MB–1,024 MB | 1 KB |
| 1,025 MB–2 GB | 2 KB |
| 2 GB–2 terabytes | 4 KB |

**Maximum Sizes on an NTFS Volume**

Before you format an NTFS volume, evaluate the types of files to be stored on the volume so that you can determine whether to use the default cluster size.

When formatting NTFS volumes, you can specify a cluster size of up to 64 KB using the Disk Management snap-in. If you format a volume, but do not specify a cluster size, default values are used. If you want to change the cluster size after the volume is formatted, you must reformat the volume.

Before you choose a cluster size other than the default, note the following important limitations:

- For Microsoft Windows NT, Windows 2000, Windows XP, and Windows Server 2003, the cluster size of FAT16 volumes ranging from 2 gigabytes (GB) through 4 GB is 64 KB, which can create compatibility issues with some applications. For example, setup programs do not compute free space properly on a volume with 64-KB clusters and cannot run because of a perceived lack of free space. For this reason, you can use either NTFS or FAT32 to format volumes larger than 2 GB.

- Because file compression is not supported on cluster sizes greater than 4 KB, the default NTFS cluster size for Windows Server 2003 never exceeds 4 KB.

In theory, the maximum NTFS volume size is 264 clusters minus 1 cluster. However, the maximum NTFS volume size as implemented in Windows Server 2003 is $2^{32}$ clusters minus 1 cluster. For example, using 64-KB clusters, the maximum NTFS volume size is 256 terabytes minus 64 KB. Using the default cluster size of 4 KB, the maximum NTFS volume size is 16 terabytes minus 4 KB.

**Note**

- If you use large numbers of files in an NTFS folder (300,000 or more), disable short-file name generation for better performance, and especially if the first six characters of the long file names are similar.

The table NTFS Size Limits lists NTFS size limits.

**NTFS Size Limits**

| Description | Limit |
|---|---|
| Maximum file size | Architecturally: 16 exabytes minus 1 KB ($2^{64}$ bytes minus 1 KB)<br><br>Implementation: 16 terabytes minus 64 KB ($2^{44}$ bytes minus 64 KB) |

| | |
|---|---|
| Maximum volume size | Architecturally: $2^{64}$ clusters minus 1 cluster<br><br>Implementation: 256 terabytes minus 64 KB ( $2^{32}$ clusters minus 1 cluster) |
| Files per volume | 4,294,967,295 ($2^{32}$ minus 1 file) |

**Partition Tables on MBR and GUID disks**

Master boot record (MBR) disks use both basic and dynamic volumes. Because partition tables on MBR disks support partition sizes only up to 2 terabytes, you must use dynamic volumes to create NTFS volumes over 2 terabytes. Windows Server 2003 manages dynamic volumes in a special database instead of in the partition table; therefore dynamic volumes are not subject to the 2-terabyte physical limit imposed by the partition table. Dynamic NTFS volumes can be as large as the maximum volume size supported by NTFS. Itanium-based computers that use GUID partition table (GPT) disks also support NTFS volumes larger than 2 terabytes.

**Organization of an NTFS Volume**

The figure Organization of an NTFS Volume illustrates how NTFS organizes structures on a volume.

### Organization of an NTFS Volume

The following table describes each of the organizational structures on the NTFS volume.

### NTFS Volume Components

| Component | Description |
|---|---|
| NTFS Boot Sector | Contains the BIOS parameter block that stores information about the layout of the volume and the file system structures, as well as the boot code that loads Windows Server 2003. |
| Master File Table | Contains the information necessary to retrieve files from the NTFS partition, such as the attributes of a file. |
| File System Data | Stores data that is not contained within the Master File Table. |
| Master File Table Copy | Includes copies of the records essential for the recovery of the file system if there is a problem with the original copy. |

**Boot Sectors**

On MBR disks, the boot sector, which is located at the first logical sector of each partition, is a critical disk structure for starting your computer. It contains executable code and the data required by the code, including information that the file system uses to access the volume. The boot sector is created when you format a volume. At the end of the boot sector is a 2-byte structure called a signature word or end of sector marker, which is always set to 0x55AA. On computers running Windows Server 2003, the boot sector on the active partition loads into memory and starts Ntldr, which loads the boot menu if multiple versions of Windows are installed, or loads the operating system if only one operating system is installed.

GUID partition table (GPT) disks are similar to MBR disks, except they use primary and backup partition structures to provide redundancy. These structures are located at the beginning and the end of the disk. GPT identifies these structures by their logical block address (LBA) rather than by their relative sectors.

A boot sector consists of the following elements:

- An x86-based CPU jump instruction.
- The original equipment manufacturer identification (OEM ID).
- The BIOS parameter block (BPB), a data structure.
- The extended BPB.
- The executable boot code (or bootstrap code) that starts the operating system.

All Windows Server 2003 boot sectors contain the preceding elements regardless of the type of disk (basic disk or dynamic disk).

**Components of a Boot Sector**

The MBR transfers CPU execution to the boot sector, so the first three bytes of the boot sector must be valid, executable x86-based CPU instructions. This includes a jump instruction that skips the next several nonexecutable bytes.

Following the jump instruction is the 8-byte OEM ID, a string of characters that identifies the name and version number of the operating system that formatted the volume. To preserve compatibility with MS-DOS, Windows Server 2003 records "NTFS" in this field.

### Note

- You might also see the OEM ID "MSWIN4.0" on disks formatted by Windows 95 and "MSWIN4.1" on disks formatted by Windows 95 OEM Service Release 2 (OSR2), Windows 98, and Windows Millennium Edition. Windows Server 2003 does not use the OEM ID field in the boot sector except for verifying NTFS volumes.

Following the OEM ID is the BPB, which provides information that enables the executable boot code to locate Ntldr. The BPB always starts at the same offset, so standard parameters are in a known location. Disk size and geometry variables are encapsulated in the BPB. Because the first part of the boot sector is an x86 jump instruction, the BPB can be extended in the future by appending new information at the end. The jump instruction needs only a minor adjustment to accommodate this change. The BPB is stored in a packed (unaligned) format.

**NTFS Boot Sector**

The table Boot Sector Sections on an NTFS Volume describes the boot sector of a volume that is formatted with NTFS. When you format an NTFS volume, the format program allocates the first 16 sectors for the boot sector and the bootstrap code.

### Boot Sector Sections on an NTFS Volume

| Byte Offset | Field Length | Field Name |
|---|---|---|
| 0x00 | 3 bytes | Jump instruction |
| 0x03 | 8 bytes | OEM ID |
| 0x0B | 25 bytes | BPB |
| 0x24 | 48 bytes | Extended BPB |
| 0x54 | 426 bytes | Bootstrap code |
| 0x01FE | 2 bytes | End of sector marker |

On NTFS volumes, the data fields that follow the BPB form an extended BPB. The data in these fields enables Ntldr to find the MFT during startup. On NTFS volumes, the MFT is not located in a predefined sector. For this reason, NTFS can move the MFT if there is a bad sector in the current location of the MFT. However, if the data is corrupted, the MFT cannot be located, and Windows Server 2003 assumes that the volume has not been formatted.

The following example illustrates the boot sector of an NTFS volume that is formatted by using Windows Server 2003. The printout is formatted in three sections:

- Bytes 0x00– 0x0A are the jump instruction and the OEM ID (shown in bold print).
- Bytes 0x0B–0x53 are the BPB and the extended BPB.
- The remaining code is the bootstrap code and the end of sector marker (shown in bold print).

```
Physical Sector: Cyl 0, Side 1, Sector 1
00000000: EB 52 90 4E 54 46 53 20 - 20 20 20 00 02 08 00 00 .R.NTFS ..... ..
00000010: 00 00 00 00 00 F8 00 00 - 3F 00 FF 00 3F 00 00 00 ........?...?...
00000020: 00 00 00 00 80 00 80 00 - 1C 91 11 01 00 00 00 00 ................
00000030: 00 00 04 00 00 00 00 00 - 11 19 11 00 00 00 00 00 ................
00000040: F6 00 00 00 01 00 00 00 - 3A B2 7B 82 CD 7B 82 14 ........:.{..{..
00000050: 00 00 00 00 FA 33 C0 8E - D0 BC 00 7C FB B8 C0 07 .....3.....|....
```

The table BPB and Extended BPB Fields on NTFS Volumes describes the fields in the BPB and the extended BPB on NTFS volumes. The fields starting at 0x0B, 0x0D, 0x15, 0x18, 0x1A, and 0x1C match those on FAT16 and FAT32 volumes. The sample values correspond to the data in this example.

**BPB and Extended BPB Fields on NTFS Volumes**

| Byte Offset | Field Length | Sample Value | Field Name and Definition |
|---|---|---|---|
| 0x0B | 2 bytes | 00 02 | **Bytes Per Sector**. The size of a hardware sector. For most disks used in the United States, the value of this field is 512. |
| 0x0D | 1 byte | 08 | **Sectors Per Cluster**.The number of sectors in a cluster. |
| 0x0E | 2 bytes | 00 00 | **Reserved Sectors**. Always 0 because NTFS places the boot sector at the beginning of the partition. If the value is not 0, NTFS fails to mount the volume. |
| 0x10 | 3 bytes | 00 00 00 | Value must be 0 or NTFS fails to mount the volume. |
| 0x13 | 2 bytes | 00 00 | Value must be 0 or NTFS fails to mount the volume. |
| 0x15 | 1 byte | F8 | **Media Descriptor**. Provides information about the media being used. A value of F8 indicates a hard disk and F0 indicates a high-density 3.5-inch floppy disk. Media descriptor entries are a legacy of MS-DOS FAT16 disks and are not used in Windows Server 2003. |
| 0x16 | 2 bytes | 00 00 | Value must be 0 or NTFS fails to mount the volume. |
| 0x18 | 2 bytes | 3F 00 | Not used or checked by NTFS. |
| 0x1A | 2 bytes | FF 00 | Not used or checked by NTFS. |
| 0x1C | 4 bytes | 3F 00 00 00 | Not used or checked by NTFS. |
| 0x20 | 4 bytes | 00 00 00 00 | The value must be 0 or NTFS fails to mount the volume. |
| 0x24 | 4 bytes | 80 00 80 00 | Not used or checked by NTFS. |
| 0x28 | 8 bytes | 1C 91 11 01 00 00 00 00 | **Total Sectors**. The total number of sectors on the hard disk. |
| 0x30 | 8 bytes | 00 00 04 00 00 00 00 00 | **Logical Cluster Number for the File $MFT**. Identifies the location of the MFT by using its logical cluster number. |
| 0x38 | 8 bytes | 11 19 11 00 00 00 00 00 | **Logical Cluster Number for the File $MFTMirr**. Identifies the location of the mirrored copy of the MFT by using its logical cluster number. |
| 0x40 | 1 byte | F6 | **Clusters Per MFT Record**. The size of each record. NTFS creates a file record for each file and a folder record for each folder that is created on an NTFS volume. Files and folders smaller than this size are contained within the MFT. If this number is positive (up to 7F), then it represents clusters per MFT record. If the number is negative (80 to FF), then the size of the file record is 2 raised to the absolute value of this number. |

| | | | |
|---|---|---|---|
| 0x41 | 3 bytes | 00 00 00 | Not used by NTFS. |
| 0x44 | 1 byte | 01 | **Clusters Per Index Buffer**. The size of each index buffer, which is used to allocate space for directories. If this number is positive (up to 7F), then it represents clusters per MFT record. If the number is negative (80 to FF), then the size of the file record is 2 raised to the absolute value of this number. |
| 0x45 | 3 bytes | 00 00 00 | Not used by NTFS. |
| 0x48 | 8 bytes | 3A B2 7B 82 CD 7B 82 14 | **Volume Serial Number**. The volume's serial number. |
| 0x50 | 4 bytes | 00 00 00 00 | Not used by NTFS. |

**Master File Table**

When you format a volume with NTFS, Windows Server 2003 creates an MFT and metadata files on the partition. The MFT is a relational database that consists of rows of file records and columns of file attributes. It contains at least one entry for every file on an NTFS volume, including the MFT itself.

The MFT stores the information required to retrieve files from the NTFS partition.

**MFT and Metadata Files**

Because the MFT stores information about itself, NTFS reserves the first 16 records of the MFT for metadata files (approximately 16 KB), which are used to describe the MFT. Metadata files that begin with a dollar sign ($) are described in the table Metadata Files Stored in the MFT. The remaining records of the MFT contain the file and folder records for each file and folder on the volume.

**Metadata Files Stored in the MFT**

| System File | File Name | MFT Record | Purpose of the File |
|---|---|---|---|
| Master file table | $Mft | 0 | Contains one base file record for each file and folder on an NTFS volume. If the allocation information for a file or folder is too large to fit within a single record, other file records are allocated as well. |
| Master file table mirror | $MftMirr | 1 | Guarantees access to the MFT in case of a single-sector failure. It is a duplicate image of the first four records of the MFT. |
| Log file | $LogFile | 2 | Contains information used by NTFS for faster recoverability. The log file is used by Windows Server 2003 to restore metadata consistency to NTFS after a system failure. The size of the log file depends on the size of the volume, but you can increase the size of the log file by using the Chkdsk command. |
| Volume | $Volume | 3 | Contains information about the volume, such as the volume label and the volume version. |
| Attribute definitions | $AttrDef | 4 | Lists attribute names, numbers, and descriptions. |
| Root file name index | . | 5 | The root folder. |
| Cluster bitmap | $Bitmap | 6 | Represents the volume by showing free and unused clusters. |
| Boot sector | $Boot | 7 | Includes the BPB used to mount the volume and additional bootstrap loader code used if the volume is bootable. |

| | | | |
|---|---|---|---|
| Bad cluster file | $BadClus | 8 | Contains bad clusters for a volume. |
| Security file | $Secure | 9 | Contains unique security descriptors for all files within a volume. |
| Upcase table | $Upcase | 10 | Converts lowercase characters to matching Unicode uppercase characters. |
| NTFS extension file | $Extend | 11 | Used for various optional extensions such as quotas, reparse point data, and object identifiers. |
| | | 12–15 | Reserved for future use. |

The data segment locations for both the MFT and the backup MFT, $Mft and $MftMirr, respectively, are recorded in the boot sector. The $MftMirr is a duplicate image of either the first four records of the $Mft or the first cluster of the $Mft, whichever is larger. If any MFT records in the mirrored range are corrupted or unreadable, NTFS reads the boot sector to find the location of the $MftMirr. NTFS then reads the $MftMirr and uses the information in $MftMirr instead of the information in the MFT. If possible, the correct data from the $MftMirr is written back to the corresponding location in the $Mft.

**MFT Zone**

To prevent the MFT from becoming fragmented, NTFS reserves 12.5 percent of volume by default for exclusive use of the MFT. This space, known as the MFT zone, is not used to store data unless the remainder of the volume becomes full.

Depending on the average file size and other variables, as the volume fills to capacity, either the MFT zone or the unreserved space on the volume becomes full first.

- Volumes that have a small number of large files exhaust the unreserved space first.
- Volumes with a large number of small files exhaust the MFT zone space first.

In either case, fragmentation of the MFT occurs when one region or the other becomes full. You can change the size of the MFT zone for newly created volumes by to correspond to a percentage of the volume to be used as the MFT zone. The MFT zone sizes follow:

- Setting 1, the default, reserves approximately 12.5 percent of the volume.
- Setting 2 reserves approximately 25 percent.
- Setting 3 reserves approximately 37.5 percent.
- Setting 4 reserves approximately 50 percent.

In most computers, the default setting of 1 is adequate. The default setting accommodates volumes with an average file size of 8 KB. Storing a large number of smaller files might necessitate that you increase the size of the MFT zone for new volumes.

After you increase the size of the MFT zone, NTFS does not immediately allocate space to accommodate the size of the new MFT zone. Instead, NTFS exhausts the original reserved space before increasing the size of the MFT zone. When the original space is exhausted, NTFS looks for the next contiguous space large enough to hold the additional MFT zone, which can cause the MFT to become fragmented. You can adjust the zone size for the MFT if the defaults do not fit your needs.

**NTFS File Record Attributes**

Every allocated sector on an NTFS volume belongs to a file. Even the file system metadata is part of a file. NTFS views each file (or folder) as a set of file attributes. File elements such as its name, its security information, and even its data are file attributes. Each attribute is identified by an attribute type code and an optional attribute name.

File and folder records are 1 KB each and are stored in the MFT, the attributes of which are written to the allocated space in the MFT. Besides file attributes, each file record contains information about the position of the file record in the MFT.

When a file's attributes can fit within the MFT file record for that file, they are called resident attributes. Attributes such as file name and time stamp are always resident. When the amount of information for a file does not fit in its MFT file record, some

file attributes become nonresident. Nonresident attributes are allocated one or more clusters of disk space. A portion of the nonresident attribute remains in the MFT and points to the external clusters. NTFS creates the Attribute List attribute to describe the location of all attribute records. The table NTFS File Attribute Types lists the file attributes currently defined by NTFS.

**NTFS File Attribute Types**

| Attribute Type | Description |
|---|---|
| Standard Information | Information such as access mode (read-only, read/write, and so forth) timestamp, and link count. |
| Attribute List | Locations of all attribute records that do not fit in the MFT record. |
| File Name | A repeatable attribute for both long and short file names. The long name of the file can be up to 255 Unicode characters. The short name is the 8.3, case-insensitive name for the file. Additional names, or hard links, required by POSIX can be included as additional file name attributes. |
| Data | File data. NTFS supports multiple data attributes per file. Each file typically has one unnamed data attribute. A file can also have one or more named data attributes. |
| Object ID | A volume-unique file identifier. Used by the distributed link tracking service. Not all files have object identifiers. |
| Logged Tool Stream | Similar to a data stream, but operations are logged to the NTFS log file just like NTFS metadata changes. This attribute is used by EFS. |
| Reparse Point | Used for mounted drives. This is also used by Installable File System (IFS) filter drivers to mark certain files as special to that driver. |
| Index Root | Used to implement folders and other indexes. |
| Index Allocation | Used to implement the B-tree structure for large folders and other large indexes. |
| Bitmap | Used to implement the B-tree structure for large folders and other large indexes. |
| Volume Information | Used only in the $Volume system file. Contains the volume version. |

NTFS creates a file record for each file and a folder record for each folder created on an NTFS volume. The MFT includes a separate file record for the MFT itself. These file and folder records are 1 KB each and are stored in the MFT. The attributes of the file are written to the allocated space in the MFT. Besides file attributes, each file record contains information about the position of the file record in the MFT. The figure MFT Entry with Resident Record shows the contents of an MFT record for a small file or folder. Small files and folders (typically, 900 bytes or smaller) are entirely contained within the file's MFT record.

**MFT Entry with Resident Record**

Typically, each file uses one file record. However, if a file has a large number of attributes or becomes highly fragmented, it might need more than one file record. If this is the case, the first record for the file, the base file record, stores the location of the other file records required by the file.

Folder records contain index information. Small folder records reside entirely within the MFT structure, while large folders are organized B-tree structures and have records with pointers to external clusters that contain folder entries that cannot be contained within the MFT structure.

The benefit of using B-tree structures is evident when NTFS enumerates files in a large folder. The B-tree structure allows NTFS to group, or index, similar file names and then search only the group that contains the file, minimizing the number of disk accesses needed to find a particular file, especially for large folders. Because of the B-tree structure, NTFS outperforms FAT for large folders because FAT must scan all file names in a large folder before listing all of the files.

**Last Access Time**
Each file and folder on an NTFS volume contains an attribute called Last Access Time. This attribute shows when the file or folder was last accessed, such as when a user performs a folder listing, adds files to a folder, reads a file, or makes changes to a file. The most up-to-date Last Access Time is always stored in memory and is eventually written to disk within two places:

- The file's attribute, which is part of its MFT record.
- A directory entry for the file. The directory entry is stored in the folder that contains the file. Files with multiple hard links have multiple directory entries.

The Last Access Time on disk is not always current because NTFS looks for a one-hour interval before forcing the Last Access Time updates to disk. NTFS also delays writing the Last Access Time to disk when users or programs perform read-only operations on a file or folder, such as listing the folder's contents or reading (but not changing) a file in the folder. If the Last Access Time is kept current on disk for read operations, all read operations become write operations, which impacts NTFS performance.

### Note

- File-based queries of Last Access Time are accurate even if all on-disk values are not current. NTFS returns the correct value on queries because the accurate value is stored in memory.

NTFS eventually writes the in-memory Last Access Time to disk as follows.

**Within the file's attribute**
NTFS typically updates a file's attribute on disk if the current Last Access Time in memory differs by more than an hour from the Last Access Time stored on disk, or when all in-memory references to that file are gone, whichever is more recent. For example, if a file's current Last Access Time is 1:00 P.M., and you read the file at 1:30 P.M., NTFS does not update the Last Access Time. If you read the file again at 2:00 P.M., NTFS updates the Last Access Time in the file's attribute to reflect 2:00 P.M. because the file's attribute shows 1:00 P.M. and the in-memory Last Access Time shows 2:00 P.M.

**Within a directory entry for a file**
NTFS updates the directory entry for a file during the following events:

- When NTFS updates the file's Last Access Time and detects that the Last Access Time for the file differs by more than an hour from the Last Access Time stored in the file's directory entry. This update typically occurs after a program closes the handle used to access a file within the directory. If the program holds the handle open for an extended time, a lag occurs before the change appears in the directory entry.
- When NTFS updates other file attributes such as Last Modify Time, and a Last Access Time update is pending. In this case, NTFS updates the Last Access Time along with the other updates without additional performance impact.

### Note

- NTFS does not update a file's directory entry when all in-memory references to that file are gone.

If you have an NTFS volume with a high number of folders or files, and a program is running that briefly accesses each of these in turn, the I/O bandwidth used to generate the Last Access Time updates can be a significant percentage of the overall I/O bandwidth.

**Multiple Data Streams**
A data stream is a sequence of bytes. An application populates the stream by writing data at specific offsets within the stream. The application can then read the data by reading the same offsets in the read path. Every file has a main, unnamed stream associated with it, regardless of the file system used.

However, NTFS supports additional named data streams in which each data stream is an alternate sequence of bytes as illustrated in the figure Unnamed and Named Streams. Applications can create additional named streams and access the streams by referring to their names. This feature permits related data to be managed as a single unit. For example, a graphics program can store a thumbnail image of bitmap in a named data stream within the NTFS file containing the image.

### Unnamed and Named Streams

FAT volumes support only the main, unnamed stream, so if you try to copy or move Streamexample.doc to a FAT volume or floppy disk, you receive an error message.

**NTFS Processes and Interactions**

The following sections describe NTFS processes and interactions.

**Mounting an NTFS Volume**

When mounting an NTFS volume, the MBR executes code to start up the boot sector. The boot sector then executes additional code to mount the volume.

**Master Boot Code Startup Process**

The MBR contains a small amount of executable code called the master boot code, the disk signature, and the partition table for the disk. During startup, the master boot code performs the following activities:

1. Scans the partition table for the active partition.
2. Finds the starting sector of the active partition.
3. Loads a copy of the boot sector from the active partition into memory.
4. Transfers control to the executable code in the boot sector.

**Boot Sector Startup Process**

Computers use the boot sector to run instructions during startup. The initial startup process is summarized in the following steps:

1. The system BIOS and the CPU initiate the power-on self test (POST).
2. The BIOS finds the boot device, which is typically the first disk the BIOS finds, unless the controller is configured to boot from a different disk.
3. The BIOS loads the first physical sector of the boot device into memory and transfers CPU execution to that memory address.

If the boot device is on a hard disk, the BIOS loads the MBR. The master boot code in the MBR loads the boot sector of the active partition, and transfers CPU execution to that memory address. On computers that are running Windows Server 2003, the executable boot code in the boot sector finds Ntldr, loads it into memory, and transfers execution to that file.

**Note**

- Windows Server 2003 cannot start up from a spanned, striped, or RAID-5 volume on dynamic disks. These disk structures cannot be registered into the MBR partition table; therefore, a system volume that uses these structures cannot start.

If drive A contains a floppy disk, the system BIOS loads the first sector (the boot sector) of the disk into memory. If the disk is a startup disk (formatted by MS-DOS with core operating system files applied), the boot sector loads into memory and uses the executable boot code to transfer CPU execution to Io.sys, a core MS-DOS operating system file. If the floppy disk is not a startup disk, the executable boot code displays an error message.

**Note**

- These messages do not appear on normally functioning systems that are configured to look for the startup files on drive C first. On many computers, an option in the CMOS setup program allows the user to set the sequence of installed disks that the system searches to find the startup files.

If you get similar errors when trying to start the computer from the hard disk, the boot sector might be corrupted.

Initially, the startup process is independent of disk format and operating system. The unique characteristics of operating and file systems become important when the boot sector's executable boot code starts.

**Formatting Volumes**
During volume format, Windows Server 2003 places key NTFS file system structures on the volume, including the boot sector and the MFT as well as replacing Ntldr. Formatting also aligns clusters at the cluster size boundary.

Formatting a volume will check the integrity of all sectors on the volume during the process, as well as allow you to change the cluster size used on the volume. If a volume is formatted using Quick format, the file system structure on the volume is created, but the integrity of every sector in the volume is not checked.

**Converting Volumes**
Windows Server 2003 can convert previous versions of NTFS to the new version of NTFS used in Windows Server 2003.

**Converting NTFS Volumes Formatted By Using Windows 2000**
When Windows Server 2003 first mounts an NTFS volume that was formatted by using Windows 2000, Windows Server 2003 converts the NTFS volume to NTFS 3.1. The conversion consists of changing the NTFS version from 3.0 to 3.1. No other changes are made to existing metadata or files on the volume. However, Windows Server 2003 uses a different header style for new files created on NTFS 3.1 volumes. As a result of this change, some non-Microsoft imaging programs cannot create images of NTFS 3.1 volumes. Contact the manufacturer of your imaging program to find out if a version is available that supports NTFS 3.1 volumes in Windows Server 2003.

Computers running Windows NT 4.0 with Service Pack 4 or later or Windows 2000 can access NTFS 3.1 volumes without any conversion or additional service packs. Also, note that NTFS 3.1 is identical in Windows XP and Windows Server 2003.

**Converting NTFS Volumes Formatted By Using Windows NT 4.0 and Earlier**
When you upgrade the operating system from Windows NT 4.0 to Windows Server 2003, all local volumes formatted by using the version of NTFS used in Windows NT 4.0 and earlier are upgraded to NTFS 3.1. The upgrade occurs when Windows Server 2003 mounts the volume for the first time after Windows Server 2003 Setup is completed. (The upgrade does not take place during Setup.) Any NTFS volumes that are removed or turned off during Setup, or added after Setup, are converted when Windows Server 2003 mounts the volumes.

The Ntfs.sys driver performs the conversion by determining which version of NTFS is used on the volume and converting the volume if necessary. The conversion takes only a few seconds on any size volume and consists of the following new records in the master file table:

- $Secure, which contains unique security descriptors for all files within a volume.
- $Extend, which is used for extensions such as quotas, reparse point data, and object identifiers. The conversion process also adds three new files the to $Extend directory:
    - $Quota, used for disk quotas.
    - $Reparse, used for reparse points.
    - $ObjID, used for distributed link tracking.

Both $Secure and $Extend take the place of previously unused master file table (MFT) records, so sufficient space always exists in the volume for these two records. However, $Quota, $Reparse, and $ObjID are new additions to the MFT, and you must have enough free space in the volume to contain these files, or the conversion fails.

If the conversion fails, the volume is still available, but you can only perform NTFS-related tasks that were available in Windows NT 4.0 or earlier. To convert the volume to NTFS 3.1, you must free disk space by deleting or moving files and then dismount the volume.

**Note**

- Removable media that is formatted by using the previous version of NTFS is upgraded after the installation or upgrade process, or when you insert the media and Windows Server 2003 mounts it.

**Limitations in Converting Volumes**

The conversion is a one-way process. After you convert a volume to NTFS, you cannot reconvert the volume to FAT without backing up your data, reformatting the volume as FAT, and then restoring your data. There should also be a certain amount of free space on the volume and sufficient memory to update the cache.

The following limitations also apply to conversion of a volume from FAT to NTFS:

- In multiple-boot configurations, NTFS volumes are accessible only by using Windows NT 4.0 with Service Pack 4 or later, Windows 2000, Windows XP, or Windows Server 2003.

- When you install Recovery Console onto a volume that is formatted for either the FAT16 or FAT32 file systems, and then convert the volume to NTFS, the Recovery Console no longer runs. This problem occurs because the file-system-specific boot files (in the cmdcons folder of the system volume) that are used to run Recovery Console are not valid for a volume that has been converted to NTFS. You can re-install Recovery Console from the Windows Server 2003 operating system disk after the conversion. You can also use the Windows Server 2003 operating system disk to start Recovery Console.

- Because formatting in Windows Server 2003 aligns FAT data clusters at the cluster size boundary, conversion can preserve the cluster size for the size of the volume (up to 4 KB) instead of using the 512-byte cluster size used in Windows 2000 for converted volumes. The table Cluster Sizes for Volumes Converted to NTFS lists cluster sizes for volumes converted to NTFS.

  **Cluster Sizes for Volumes Converted to NTFS**

| Original FAT Cluster Size | Converted NTFS Cluster Size |
|---|---|
| 512 bytes | 512 bytes |
| 1 KB | 1 KB |
| 2 KB | 2 KB |
| 4 KB and larger | 4 KB |

**File Naming**

Windows Server 2003 supports both long and short file names on NTFS volumes.

**File Names in Windows Server 2003**

Every time you create a file with a long file name, NTFS creates a second file entry that has a similar 8.3 short file name. A file with an 8.3 short file name has a file name containing 1 to 8 characters and a file name extension containing 1 to 3 characters. The file name and file name extension are separated by a period.

File names in Windows Server 2003 can be up to 255 characters and can contain spaces, multiple periods, and special characters that are not allowed in MS-DOS file names. Windows Server 2003 makes it possible for other operating systems to access files that have long names by generating an MS-DOS-readable (8.3) name for each file. These MS-DOS-readable names also enable MS-DOS-based and Windows 3.*x*–based applications to recognize and load files that have long file names. When a program saves a file on a computer running Windows Server 2003, both the 8.3 file name and long file name are retained.

**Note**

- The 8.3 format means that files can have between 1 and 8 characters in the file name. The name must start with a letter or a number and can contain any characters except the following:

- . " / \ [ ] : ; | = , * ? (space)

- An 8.3 file name typically has a file name extension that is from one to three characters long and has the same character restrictions. A period separates the file name from the file name extension.

- Several special file names are reserved by the system and cannot be used for files or folders: CON, AUX, COM1, COM2, COM3, COM4, LPT1, LPT2, LPT3, PRN, NUL

**How NTFS Generates Short File Names**

In Windows Server 2003, both FAT and NTFS use the Unicode character set, which contains several prohibited characters that MS-DOS cannot read, for their names. To generate a short MS-DOS-readable file name, Windows Server 2003 deletes all of these characters from the long file name and removes any spaces. Because an MS-DOS-readable file name can have only one period, Windows Server 2003 also removes extra periods from the file name. If necessary, Windows Server 2003 truncates the file name to six characters and appends a tilde (**~**) and a number. For example, each non-duplicate file name is appended with **~1**. Duplicate file names end with **~2**, then **~3**, and so on. After the file names are truncated, the file name extensions are truncated to three or fewer characters. Finally, when displaying file names at the command line, Windows Server 2003 translates all characters in the file name and extension to uppercase.

**Note**

- You can permit extended characters by using the **fsutil behavior set** command. You must restart the computer before this setting takes effect. For more information about using the **fsutil behavior set** command, see the topic Fsutil: behavior in Help and Support Center in Windows Server 2003.

When five or more files exist that can result in duplicate short file names, Windows Server 2003 uses a slightly different method for creating short file names. For the fifth and subsequent files, Windows Server 2003:

- Uses only the first two letters of the long file name.
- Generates the next four letters of the short file name by mathematically manipulating the remaining letters of the long file name.
- Appends **~1** (or another number, if necessary, to avoid a duplicate file name) to the result.

This method substantially improves performance when Windows Server 2003 must create short file names for a large number of files with similar long file names. Windows Server 2003 uses this method to create short names for files on both FAT and NTFS volumes.

The following table shows the short file names for files created by six tests.

**Short File Names Created by Windows Server 2003 — Example One**

| Long File Name | Short File Name |
|---|---|
| This is test 1.txt | THISIS~1.TXT |
| This is test 2.txt | THISIS~2.TXT |
| This is test 3.txt | THISIS~3.TXT |
| This is test 4.txt | THISIS~4.TXT |
| This is test 5.txt | THA1CA~1.TXT |
| This is test 6.txt | THA1CE~1.TXT |

If the long file names in the preceding table are created in a different order, their short file names are different, as shown in the following table.

**Short File Names Created by Windows Server 2003 — Example Two**

| Long File Name | Short File Name |
|---|---|
| This is test 2.txt | THISIS~1.TXT |

| | |
|---|---|
| This is test 3.txt | THISIS~2.TXT |
| This is test 1.txt | THISIS~3.TXT |
| This is test 4.txt | THISIS~4.TXT |
| This is test 5.txt | THA1CA~1.TXT |
| This is test 6.txt | THA1CE~1.TXT |

When you delete a file, its short file name is also deleted. When you create new files in the same folder, Windows Server 2003 might re-use short file names that have been deleted. For instance, in Example 1, if you delete the file "This is test 1.txt," and then create a new file called "This is test 7.txt," its short file name becomes THISIS~1.TXT.

If you have a large number of files (300,000 or more) in a folder, and the files have long file names with the same initial characters, the time required to create the files increases. The increase occurs because NTFS bases the short file name on the first six characters of the long file name. In folders with more than 300,000 files, the short file names start to conflict after NTFS uses all of the 8.3 names that are similar to the long file names. Repeated conflicts between a generated short file name and existing short file names cause NTFS to regenerate the short file name from 6 to 8 times.

**Compression of Files and Folders**

NTFS supports compression on individual files, all files within a folder, and all files within NTFS volumes. Because compression is implemented within NTFS, any Windows-based program can read and write compressed files without determining the compression state of the file. Compression is set in a bit within the file header, while information about compression is stored in the Data file attribute.

Files and directories are compressed and decompressed by passing FSCTL_SET_COMPRESSION code to DeviceIoControl. A compressed file or directory then has the flag FILE_ATTRIBUTE_COMPRESSED associated with it. Applications can determine a file or directory's compression state using GetFileAttributes.

When a program opens a compressed file, NTFS decompresses only the portion of the file being read and then copies that data to memory. By leaving data in memory uncompressed, NTFS performance is not impacted when it reads or modifies data in memory. NTFS compresses the modified or new data in the file when the data is later written to disk.

The compression algorithms in NTFS support cluster sizes of up to 4 KB. When the cluster size is greater than 4 KB on an NTFS volume, none of the NTFS compression features are available.

**Moving and Copying Files or Folders**

Moving and copying files and folders can change their compression state. The resulting compression state depends on whether you move or copy the files and whether you move the files between NTFS volumes or to FAT volumes.

NTFS supports compression on one file, all files in a directory, or all files on a volume. Compression is set in a bit within the file header, while information about compression is stored in the Data file attribute. When the bit is set, the system compresses the file when it is saved and decompresses it as needed.

Compression adds overhead to the system because a compressed NTFS file is decompressed, copied, and then recompressed as a new file even when the file is copied in the same computer. Any change to the compression attribute is applied to the files you specify for moving or copying. If you compress all files in the volume, the process might take a few minutes to finish, depending on the size of the volume, the number of files to compress, and the speed of the computer. The delay occurs because Windows Server 2003 must change the compression state of every folder on the volume and compress or uncompress every file on the volume.

Changing the compression state of folders is relatively fast because for each folder Windows Server 2003 changes only the compression attribute. However, compressing or uncompressing every file on the volume takes longer because NTFS must read data in its current form (compressed or uncompressed) from the disk, convert the data to its new form in memory, and then write the data back to disk.

**Moving Files or Folders within an NTFS Volume**

When you move an uncompressed file or folder to another folder on the NTFS volume, the file remains uncompressed. The figure Moving an Uncompressed File to a Compressed Folder illustrates the result of moving an uncompressed file to a compressed folder.

### Moving an Uncompressed File to a Compressed Folder

When you move a compressed file to an uncompressed folder, the file remains uncompressed after the move. The figure Moving a Compressed File to an Uncompressed Folder illustrates the result of moving a compressed file or folder to a compressed folder.

**Moving a Compressed File to an Uncompressed Folder**

**Copying Files or Folders within an NTFS Volume**

Copying a file to a folder takes on the compression attribute of the target folder.

If you copy a compressed file to an uncompressed folder, the file is uncompressed when it is copied to the folder, as shown in the figure Copying a Compressed File to an Uncompressed Folder.

**Copying a Compressed File to an Uncompressed Folder**

When you copy a file to a folder that already contains a file of the same name, the copied file takes on the compression attribute of the target file, as shown in the figure Copying a File to a Folder that Contains a File of the Same Name.

**Copying a File to a Folder that Contains a File of the Same Name**

**Copying Files between FAT and NTFS Volumes**

Files copied from a FAT folder to an NTFS folder take on the compression attribute of the target folder. Compressed files copied from an NTFS volume to a FAT volume or floppy disk are uncompressed.

**Mounted Drives on NTFS Volumes**

Mounted drives, also known as volume mount points or drive paths, are volumes attached to an empty folder on an NTFS volume. Mounted drives function the same way as any other volume, but are assigned a label or name instead of a drive letter. Mounted drives are robust against system changes that occur when devices are added or removed from a computer. They are not subject to the 26-volume limit imposed by drive letters, so you can use them for access to more than 26 volumes on your computer.

The version of NTFS included with Windows Server 2003 must be used on the host volume. However, the volume to be mounted can be formatted in any file system supported by Windows Server 2003.

One volume can host multiple mounted drives, providing a way for you to easily extend the storage capacity of any particular volume on a Windows Server 2003 system. Users on the local computer or users who connect to it over a network can continue to use the same drive letter for access to the volume, but multiple volumes can be in use simultaneously from that drive letter.

Only NTFS volumes can hold a mounted drive, although any local drive can be mounted on one.

**Implementing Mounted Drives**
NTFS mounted drives are implemented by using reparse points and are subject to their restrictions. Reparse points are a collection of user-defined data. The format of this data is understood by the application which stores the data, and a file system filter, which you install to interpret the data and process the file. When an application sets a reparse point, it stores this data, plus a reparse tag, which uniquely identifies the data it is storing. When the file system opens a file with a reparse point, it attempts to find the file system filter associated with the data format identified by the reparse tag. If a file system filter is found, the filter processes the file as directed by the reparse data. If a file system filter is not found, the file open operation fails.

The following restrictions apply to reparse points:

- Reparse points can be established for a directory, but the directory must be empty. Otherwise, NTFS fails to establish the reparse point. In addition, you cannot create directories or files in a directory that contains a reparse point.

- Reparse points and extended attributes are mutually exclusive. NTFS cannot create a reparse point when the file contains extended attributes, and it cannot create extended attributes on a file that contains a reparse point.

- Reparse point data cannot exceed 16 kilobytes. Setting a reparse point fails if the amount of data to be placed in the reparse point exceeds this limit.

**Hard Links**
A hard link is an NTFS-only based link to a given file. When you create a hard link to a file on an NTFS volume, NTFS adds a directory entry for the hard link without duplicating the original file. By creating hard links you can:

- Use the same file name as the original file but appear in different folders.

- Use different file names from the original file but appear in the same folder.

- Use different file names from the original file and appear in different folders.

Because a hard link is a directory entry for a file, an application can modify a file by using any of its hard links. Applications that use any other hard link can detect the changes. However, directory entries for hard links are updated only when a user accesses a file by using the hard link. For example, if a user opens and modifies a file by using its hard link, and the size of the original file changes, the hard link that is used to access the file also shows the new size.

Hard links do not have security descriptors; instead, the security descriptor belongs to the original file to which the hard link points. Thus, if you change the security descriptor of any hard link, you actually change the underlying file's security descriptor. All hard links that point to the file allow the newly specified access. You cannot give a file different security descriptors on a per-hard-link basis.

Hard links use the Win32 function CreateHardLink to create hard links between files.

**Distributed Link Tracking**
Distributed link tracking ensures that shell shortcuts and OLE links continue to work after the target file is renamed or moved. When you create a shortcut to a file on an NTFS volume, distributed link tracking stamps a unique object identifier (ID) into the target file, known as the link source. Information about the object ID is also stored within the referring file, known as the link client. Distributed link tracking uses this object ID to locate the link source in any combination of the following events that occur on NTFS volumes within a Windows Server 2003-based domain:

- The link source is renamed.

- The link source is moved to another folder on the same volume or to a different volume on the same computer.

- The link source is moved from one shared network folder to another shared network folder on different computers within the same domain.

- The computer containing the link source is renamed.
- The name of the shared network folder containing the link source has changed.
- The volume containing the link source is moved to another computer within the same domain.

**Note**

- Distributed link tracking works only on NTFS volumes in computers running Windows 2000, Windows XP, or Windows Server 2003. The NTFS volumes cannot be on removable media.

Distributed link tracking attempts to maintain even those links that do not occur within a domain: cross-domain, within a workgroup, or on a single computer that is not connected to a network. Links can always be maintained in these events when a link source is moved within a computer, or when the network shared folder on the link source computer is changed. Typically, links can be maintained when the link source is moved to another computer; however, this form of tracking is less reliable over time.

Distributed link tracking uses different services for client and server:

- The Distributed Link Tracking Client service runs on all Windows 2000-based and Windows Server 2003-based computers. In computers that are not part of a network, the Client service performs all activities related to link tracking.
- The Distributed Link Tracking Server service runs on Windows 2000 and Windows Server 2003 domain controllers. The Server service maintains information relating to the movement of link sources. Because of this service and the information it maintains, links within a domain are more reliable than those outside a domain. For computers that run in a domain, the Distributed Link Tracking Client service takes advantage of this information by communicating with the Distributed Link Tracking Server service.

The Distributed Link Tracking Client service monitors activity on NTFS volumes and stores maintenance information in a file called Tracking.log, which is located at the root of each volume in a hidden folder called System Volume Information. This folder is protected by permissions that allow only the system to have access to it. The System Volume Information folder is also used by other Windows Server 2003 services such as Indexing Service.

**Sparse Files**

Sparse files provide a method of saving disk space for files that contain meaningful data, as well as large sections of data composed of zeros. If an NTFS file is marked as sparse, then NTFS allocates disk clusters only for the data explicitly specified by the application. Non-specified ranges of the file are represented by non-allocated space on the disk. When a sparse file is read from allocated ranges, the data is returned as it was stored. Data read from non-allocated ranges is returned as zeros.

File system application programming interfaces (APIs) allow for the file to be copied or backed as actual bits and sparse stream ranges.File system APIs also allow for querying allocated ranges. Programs that implement these APIs then need only to read allocated ranges to recover all data in the file. The result is efficient file system storage and access. The figure Sparse Data Storage shows how data is stored with and without the sparse file attribute set.

**Sparse Data Storage**

For example, the properties of a file might show that the file is a 1-GB sparse file. Although the file is 1 GB, it occupies only 64 KB of disk space.

### Note

- Only NTFS volumes mounted by Windows 2000, Windows XP, or the Windows Server 2003 family support sparse files. If you copy or move a sparse file to a FAT volume or an NTFS volume mounted by an operating system other than those listed previously, the file is built to its originally specified size. If the required space is not available, the operation fails.

**Disk Quotas**

You can enable disk quotas to restrict the amount of volume space users take up on remote or local computers with NTFS file systems. Disk quotas uses names from the domain in which the server resides. An administrator can then set disk quotas against those users in the domain.

For additional information about Disk Quotas, see the Disk Quotas Technical Reference.

**NTFS Change Journal**

As files, folders, and other NTFS objects are added, deleted, and modified, NTFS enters change journal records in streams, one for each volume on the computer.

The total size of all the records currently in the journal varies, but there is a configurable maximum size. The change journal can exceed the maximum size until the size reaches an outer threshold, at which point a portion of the oldest records are deleted until the change journal is restored to its maximum size. The maximum size of the change journal is configurable but cannot be reduced, only increased.

The change journal conveys significant scalability benefits to applications that might otherwise need to scan an entire volume for changes. File system indexing, replication managers, virus scanners, and incremental backup applications can benefit from using the change journal.

The change journal is much more efficient than time stamps or file notifications for determining changes in a particular namespace. Applications that must rescan an entire volume to determine changes can now scan once and subsequently refer to the change journal. The I/O cost depends on how many files have changed, not on how many files exist on the volume.

The APIs are fully documented and can be leveraged by independent software vendors (ISVs). Microsoft uses the change journal in Windows Server 2003 components such as the Indexing Service and File Replication Service. ISVs can use this feature to enhance the scalability and robustness of a range of products including backup, antivirus, and auditing tools.

**NTFS File System Recoverability**

NTFS is a recoverable file system that guarantees the consistency of the volume by using standard transaction logging and recovery techniques. In the event of a system failure, NTFS runs a recovery procedure that accesses information stored in a transaction log file. The NTFS recovery procedure guarantees that the volume is restored to a consistent state. Transaction logging requires very little overhead.

**Recovering NTFS File Structures**

NTFS views each operation that modifies a file on a volume as a transaction and manages each one as an integral unit. NTFS

might also break a single complex operation into multiple transactions. After a transaction is started, it is either completed, or if an event occurs that causes the operation to fail, it is rolled back, and the NTFS volume returns to its state before the transaction began. Events that can cause an operation to fail include bad sectors, transient low-memory conditions, and disconnected devices.

To ensure that a transaction can either be completed or rolled back, NTFS performs the following steps for each transaction:

1. Records the metadata operations of a transaction in a log file cached in memory.
2. Records the actual metadata operations in memory.
3. Marks the transaction in the cached log file as committed.
4. Flushes the log file to disk.
5. Flushes the actual metadata operations to disk.

Steps 4 and 5 occur in a lazy fashion after the transaction is completed, meaning that the flush operations are not tied to the transaction itself. Instead, NTFS modifies the log and metadata quickly in memory, and then flushes later at a convenient time to boost performance.

NTFS guarantees that the log records containing the metadata operations of the transaction are written to disk before the metadata that is modified in the transaction is written to disk. After NTFS updates the cache, NTFS commits the transaction by recording in the cached log file that the transaction is complete. After the cached log file is flushed to disk, all committed transactions are guaranteed to be completed, even if the system fails before the changes are written to disk.

**Note**

- Applications can specify the FILE_FLAG_WRITE_THROUGH Win32 flag to instruct the system to write through any intermediate cache and go directly to disk. The system can still cache write operations, but cannot lazily flush them.

If a system failure occurs, NTFS has enough information in the log to complete or abort any partial NTFS transaction. During recovery operations, NTFS redoes each committed transaction found in the log file. Then NTFS locates in the log file the transactions that were not committed at the time of the system failure and undoes each metadata operation recorded in the log file. Because NTFS flushes the log to disk before any metadata changes are written to disk, NTFS has complete information available about any metadata changes that need to be rolled back during recovery.

**Note**

- NTFS uses transaction logging and recovery to guarantee that the volume structure is not corrupted. For this reason, all file system data is accessible after a system failure. NTFS guarantees user data only if the program used to create the data uses the FILE_FLAG_WRITE_THROUGH Win32 flag. If the program does not use this flag, user data can be lost due to a system failure. If a system failure does occur, NTFS shows either the previous data, the new data, or zeros. Users do not see random data on the volume as the result of a crash.

**Caching and Data Recovery**

The cache is the area of RAM that contains the most recently used data. When you write data to disk, the lazy-writetechnique in Windows Server 2003 indicates that the data is written when it is still in the cache. Cache memory can also be on the disk controller, such as cache memory available on SCSI controllers, or on the disk unit, such as cache memory available on Advanced Technology Attachment (ATA) disks. The following information can help you decide whether to enable the disk or the controller cache:

- Write caching improves disk performance, particularly if large amounts of data are being written to the disk.
- Control of the write-back cache is a firmware function provided by the disk manufacturer. See the documentation supplied with the disk or disk controller. You cannot configure the write-back cache from Windows Server 2003.
- Write caching does not impact the reliability of the file system's own metadata as long as the firmware provided by the disk manufacturer honors write-through requests issued by the NTFS driver. NTFS instructs the disk device driver to ensure that metadata is written whether or not write caching is enabled. Non-metadata is typically written to disk and

can be cached.

- Read caching in the disk does not affect the reliability of a file system.

**Cluster Remapping**
When NTFS detects a bad sector, NTFS dynamically remaps the cluster containing the bad sector — a recovery technique called cluster remapping — and allocates a new cluster for the data. If the error occurred during a read, NTFS returns a read error to the calling program, and the data is lost. If the error occurs during a write, NTFS writes the data to the new cluster, and no data is lost.

NTFS puts the address of the cluster containing the bad sector in the bad cluster file, $BadClus, in the MFT so that the bad sector is not reused.

**Disk Recovery Operations**
NTFS ensures the integrity of all NTFS volumes by performing disk recovery operations whenever a volume is mounted after the computer is restarted or after the volume is dismounted. NTFS also uses a technique called cluster remapping to minimize the effects of a bad sector on an NTFS volume.

NTFS views each operation that modifies a file on a volume as a transaction and manages each one as an integral unit. NTFS might also break a single complex operation into multiple transactions. After a transaction is started, it is either completed, or if an event occurs that causes the operation to fail, it is rolled back, and the NTFS volume returns to its state before the transaction began. Events that can cause an operation to fail include bad sectors, transient low-memory conditions, and disconnected devices.

NTFS guarantees that the log records containing the metadata operations of the transaction are written to disk before the metadata that is modified in the transaction is written to disk. After NTFS updates the cache, NTFS commits the transaction by recording in the cached log file that the transaction is complete. After the cached log file is flushed to disk, all committed transactions are guaranteed to be completed, even if the system crashes before the changes are written to disk.

If a system failure occurs, NTFS has enough information in the log to complete or abort any partial NTFS transaction. During recovery operations, NTFS redoes each committed transaction found in the log file. Then NTFS locates in the log file the transactions that were not committed at the time of the system failure and undoes each metadata operation recorded in the log file. Because NTFS flushes the log to disk before any metadata changes are written to disk, NTFS has complete information available about any metadata changes that need to be rolled back during recovery.

**Cleanup Operations on Windows NT–Based Volumes**
Because files on volumes formatted by using the version of NTFS included with Windows Server 2003 can be read and written to by Windows NT 4.0 Service Pack 4 or later, Windows Server 2003 might need to perform cleanup operations to ensure the consistency of the data structures of a volume after it is mounted on a computer running Windows NT.

Windows Server 2003 does not perform cleanup operations on volumes previously mounted by using Windows 2000 or Windows XP.

Cleanup operations affect the following features:

**Reparse points**
Computers running Windows NT 4.0 or earlier cannot access files that have reparse points, so no cleanup operations are necessary. Reparse points are files or directories that have blocks of data called reparse data associated with them.

**Disk quotas**
If disk quotas are turned off, Windows Server 2003 performs no cleanup operations. If disk quotas are turned on, Windows Server 2003 cleans up the quota information by rebuilding the index. If a user exceeds the disk quota while the NTFS volume is mounted by a Windows NT 4.0 SP4 or later system, and disk quotas are strictly enforced, all further disk allocations of data by that user using Windows Server 2003 fail. The user can still read and write data to any existing file but cannot increase the size of a file. However, the user can delete and shrink files. When usage falls below the assigned disk quota, disk allocations of data can resume.

**Encryption**
Encrypted files cannot be accessed by computers that are running Windows NT 4.0 or earlier, so no cleanup operations are necessary.

**Sparse files**
Computers running Windows NT 4.0 or earlier cannot access sparse files, so no cleanup operations are necessary.

**Change journal**

Computers that are running Windows NT 4.0 or earlier do not log file changes in the change journal. When Windows Server 2003 starts, the change journals on volumes accessed by Windows NT are reset to indicate that the journal history is incomplete. Applications that use the change journal must be able to accept incomplete journals.

**Object identifiers**
Windows Server 2003 maintains two references to the object identifier: one on the file and one in the volume-wide object identifier index. If you delete a file that has an object identifier, Windows Server 2003 must scan and clean up the entry in the index.

**POSIX Compliance**
NTFS provides a several features to support the Portable Operating System Interface (POSIX) standard, which is defined by the Institute of Electrical and Electronic Engineers (IEEE) standard 1003.1-1990 (also known as ISO/IEC 9945-1:1990).

NTFS includes the following POSIX-compliant features.

**Case-sensitive naming**
For example, POSIX interprets README.TXT, Readme.txt, and readme.txt as separate files.

**Hard links**
A file can have more than one name. This allows two different file names, which can be in different folders on the same volume, to point to the same data.

**Additional time stamps**
These show when the file was last accessed or modified.

The POSIX subsystem included with Windows NT and Windows 2000 is not included with Windows Server 2003. A new subsystem supporting the broad functionality found on most UNIX systems beyond the POSIX.1 standard is shipped as part of Interix 2.2. The Interix subsystem can be certified to the NIST FIPS 151-2 POSIX Conformance Test Suite.

### Note

- You must use Interix-based programs to manage file names that differ only in case. You cannot use standard Windows Server 2003 command-line tools (such as **copy**, **del**, and **move**, or their equivalents in Windows Explorer or My Computer) to manage file names that differ only in case.

# NTFS Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NTFS Tools and Settings**
**In this section**

- NTFS Tools
- NTFS Registry Entries
- NTFS Group Policy Settings
- NTFS WMI Classes

The following tools, registry settings, Group Policy settings, and Windows Management Instrumentation (WMI) classes are associated with NTFS volumes running Microsoft Windows Server 2003.

**NTFS Tools**
NTFS Tools describes the tools installed with Windows Server 2003 as well as downloadable support tools. The tools in this list are those used to create and maintain NTFS volumes.

**Cacls.exe: Set Access Control List**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Cacls.exe runs only on an NTFS volume.

Cacls.exe displays and modifies ACLs of files or folders.

For more information about Cacls, see Command Line References in Tools and Settings Collection.

**Chkdsk.exe: Check Disk**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Chkdsk.exe works on both NTFS and FAT volumes.

Chkdsk is a command-line tool that verifies the logical integrity of a file system on a Windows Server 2003 volume. Setting parameters on the command line will list and fix any errors.

For more information about Chkdsk, see Command Line References in Tools and Settings Collection.

**Chklnks.exe: Link Check Wizard**
**Category**
Resource Kit tool.

**Version compatibility**
Windows Server 2003. Chklnks.exe works only on an NTFS volume.

Chklnks.exe is a command-line tool that scans all the link (shortcut) files on a computer to determine whether or not the shortcuts point to existing applications or documents.

For more information about Chklnks, see Resource Kit Tools in Tools and Settings Collection.

**Chkntfs.exe: Chkntfs**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Chkntfs.exe works on both NTFS and FAT volumes.

Displays or specifies whether automatic system checking is schedule to be run on an NTFS volume when the computer is started.

For more information about Chkntfs, see Command Line References in Tools and Settings Collection.

**Cipher.exe: Cipher**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Cipher.exe works only on an NTFS volume.

Displays or alters the encryption of folders and files on NTFS volumes.

For more information about Cipher, see Command Line References in Tools and Settings Collection.

**Compact.exe: Compact**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Compact.exe works only on an NTFS volume.

Displays and alters the compression of files or directories on NTFS volumes.

For more information about Compact, see Command Line References in Tools and Settings Collection.

**Compress.exe: Compress Files**
**Category**
Resource Kit tool.

**Version compatibility**
Windows Server 2003. Compress.exe works only on an NTFS volume.

Compress.exe is a command-line tool to create compressed copies of one or more files.

For more information about Compress, see Resource Kit Tools in Tools and Settings Collection.

**Convert.exe: Convert**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Convert.exe works on both NTFS and FAT volumes.

Converts a FAT16 or FAT32 volume to NTFS. Conversion is a one-way process. You can convert a FAT file system to NTFS, but you cannot convert an NTFS volume to a FAT file system.

For more information about Convert , see Command Line References in Tools and Settings Collection.

**Defrag.exe: Defragmentation**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Defrag.exe runs on both NTFS and FAT volumes.

Arranges clusters on a disk in an optimized order.

For more information about Defrag, see Command Line References in Tools and Settings Collection.

**DiskPart.exe: Disk Partition**
Disk Partition is a command-line tool that allows you to manage disks and partitions by using scripts or direct input from a command prompt.

**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. DiskPart includes a few 64-bit parameters that are only available on Itanium-based computers.

Locates and consolidates fragmented boot files, data files, and folders on local or remote volumes.

For more information about DiskPart, see Command Line References in Tools and Settings Collection.

**Expand.exe: Expand Compressed Files**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Expand.exe works only on NTFS volumes.

Extracts a file from a cabinet (.CAB) or compressed file.

For more information about Expand, see Command Line References in Tools and Settings Collection.

**Format.exe: Format**
**Category**
Operating system tool

**Version compatibility**
Windows Server 2003. Works on both NTFS and FAT volumes.

Format prepares a volume on the specified disk to accept Windows files.

For more information about Format, see Command Line References in Tools and Settings Collection.

**Fsutil.exe: File Systems Utilities**
**Category**
Operating System tool.

**Version compatibility**
Windows Server 2003. Runs on both NTFS and FAT file systems.

Perform file system tasks such as disabling long file names, checking whether a volume is flagged as dirty, viewing NTFS-related information about a volume, creating hard links, and managing quotas and sparse files.

For more information about Fsutil, see Command Line References in Tools and Settings Collection.

**Hlscan.exe: Hard Link Display Tool**
**Category**
Resource Kit tool.

**Version compatibility**
Windows Server 2003. Hlscan.exe works only on an NTFS volume.

Hlscan.exe is a command-line tool that displays hard links on an NTFS volume or in specified files or directories of the volume.

For more information about Compress, see Resource Kit Tools in Tools and Settings Collection.

**Mountvol.exe: Mount Volume**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Mountvol.exe works only on an NTFS volume.

Creates, deletes, or lists a mounted drive.

For more information about Mountvol, see Command Line References in Tools and Settings Collection.

**Recovery Console**
**Category**
Operating system tool.

**Version compatibility**
Windows Server 2003. Recovery Console works on both NTFS and FAT volumes.

The Recovery Console is a text-mode command-line interpreter that you can use for basic troubleshooting and maintenance. It is separate from the Windows Server 2003 command prompt and grants limited local hard disk access for both FAT and NTFS volumes.

**Vrfydsk.exe: Verify Disk**
**Category**
Resource Kit tool.

**Version compatibility**
Windows Server 2003. Vrfydsk.exe works on both NTFS and FAT volumes.

Vrfydsk is a command-line tool that is a command-line tool that checks the consistency and integrity of the file system (FAT or NTFS) on a specified volume.

For more information about DmDiag, see Resource Kit Tools in Tools and Settings Collection.

**NTFS Registry Entries**
The following registry entries are associated with NTFS.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**FileSystem**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\FileSystem.

**NtfsAllowExtendedCharacterIn8dot3Name**
**Registry Path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem

**Version**
Microsoft Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Allows generation of short (8-character name, 3-character extension) file names on NTFS file systems.

For more information about this registry entry, see the Registry Reference in Tools and Settings Collection.

**NtfsDisable8dot3NameCreation**
**Registry Path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem

**Version**
Microsoft Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Disables generation of short (8-character name, 3-character extension) file names on NTFS file systems.

For more information about this registry entry, see the Registry Reference in Tools and Settings Collection.

**NTFSDisableLastAccessUpdate**
**Registry Path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem.

**Version**
Microsoft Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Disables last accessed timestamp of a file.

For more information about this registry entry, see the Registry Reference in Tools and Settings Collection.

**NTFSEncryptionService**
**Registry Path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem

**Version**
Used in Windows 2000 only.

Specifies which encryption service the NTFS file system used. Encrypting File System (EFS) is the encryption service built into Windows Server 2003.

For more information about this registry entry, see the Registry Reference in Tools and Settings Collection.

**NtfsMftZoneReservation**
**Registry Path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem

**Version**
Microsoft Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Reserves the amount of space allocated to the MFT. This registry entry is not automatically created. You must manually add this key to the registry entry.

Because this is an optional entry that you must add, this registry entry is not documented in the Registry Reference for Windows Server 2003.

**System**
The following registry entry is located under HKEY_LOCAL_MACHINE\SYSTEM\

**MountedDevices**
**Registry Path**
HKEY_LOCAL_MACHINE\SYSTEM\

**Version**
Windows Server 2003.

Stores database information for all NTFS partitions on a volume. This allows NTFS to maintain the persistent names of volumes.

For more information about this registry entry, see the Registry Reference in Tools and Settings Collection.

**NTFS Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with NTFS.

### Group Policy Settings Associated with NTFS

| Group Policy Setting | Description |
|---|---|
| DLT_AllowDomainMode | Enables programs to track linked files that are moved within an NTFS volume, to another NTFS volume on the same computer, or to an NTFS volume on another computer. |
| DiskQuotaEnable | Enables disk quotas on an NTFS volume. This policy is not used on FAT volumes. |
| DiskQuotaLimit | Specifies the disk quota limit and warning level. This policy is not used on FAT volumes. |
| DiskQuotaLogEventOverThreshold | Specifies whether an application log event will be created when a user exceeds his or her disk quota limit. This policy is not used on FAT volumes. |
| DiskQuotaApplyToRemovableMedia | Specifies whether disk quotas policies are to be applied to removable media. This policy is not used on FAT volumes. |
| ExplorerNoResolveSearch | Prevents the system from conducting a comprehensive search of the target drive to resolve a shortcut. FAT volumes do not use tracking features. |
| ExplorerNoResolveTrack | Prevents the system from using NTFS tracking features to resolve a shortcut. FAT volumes do not use tracking features. |

For more information about Group Policy settings, see Group Policy Settings Reference in Tools and Settings Collection.

**NTFS WMI Classes**
The following table lists and describes the WMI classes that are associated with NTFS.

### WMI Classes Associated with NTFS

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_DiskDriveToDiskPartition | //root/cimv2 | Windows 2000 and later |
| Win32_DiskPartition | //root/cimv2 | Windows 2000 and later |

| | | |
|---|---|---|
| Win32_LogicalDisk | //root/cimv2 | Windows 2000 and later |
| Win32_LogicalDiskRootDirectory | //root/cimv2 | Windows 2000 and later |
| Win32_LogicalDiskToPartition | //root/cimv2 | Windows 2000 and later |
| Win32_DiskDrivePhyiscalMedia | //root/cimv2 | Windows 2000 and later |
| Win32_Volume | //root/cimv2 | Windows Server 2003 |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

# FAT Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**FAT Technical Reference**

A file system is a part of the operating system that determines how files are named, stored, and organized on a volume. A file system manages files and folders, and the information needed to locate and access these items by local and remote users. The Microsoft Windows Server 2003 operating system supports both the file allocation table (FAT) and NTFS file systems.

Some earlier Microsoft Windows operating systems, as well as removable disks and floppy disks, support only the FAT file system. For magnetic disks you should use NTFS due to its reliability to ensure metadata integrity for fast recoverability, security, compression, and encryption.

**In this subject**

- How FAT Works
- FAT Tools and Settings

# What Is FAT?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Common FAT Scenarios**
This section describes a few scenarios in which the FAT file systems are used.

**Mounting a server with a small volume**
If you have a small partition (less than 512 megabytes) on a server, the FAT file system imposes the least overhead on a small capacity partition, but still performs well.

**Running multiple operating systems**
In a multiple-boot configuration with NTFS volumes, you also need a FAT volume if you want to access any of the NTFS volumes from one of the other NTFS volumes. For example, to start a Windows Server 2003-based computer in Microsoft MS-DOS, Microsoft Windows 3.*x*, or Microsoft Windows 95, you must use FAT16. For a multiple-boot configuration that has Microsoft Windows 95 OEM Service Release 2 (OSR2), Microsoft Windows 98, or Microsoft Windows Millennium Edition (Me), you must use FAT32.

**Using FAT with older operating systems**
Microsoft Windows 95 and Microsoft Windows 98 use the FAT file system. These operating systems do not support NTFS.

**Using FAT with removable disks**
For removable disks that can be disconnected or ejected unexpectedly, you must use FAT16 or FAT32.

**Operating System and FAT Compatibility**
File systems are designed to allow you to format the volume of a hard disk in the way that is most appropriate for your use. Before formatting a volume for a file system, you can determine what the volume will be used for, and which operating system will be mounted on that volume. Sometimes you need to run more than one operating system on your hard disk. The following table shows which FAT file systems are supported by which operating systems.

### Operating System and File System Compatibility

| Operating System | FAT16 | FAT32 |
|---|---|---|
| Windows XP | ● | ● |
| Windows Server 2003 | ● | ● |
| Windows 2000 | ● | ● |
| Windows NT 4.0 | ● | |
| Windows 95 OSR2, Windows 98, and Windows Me | ● | ● |
| Windows 95 (prior to OSR2) | ● | |
| MS-DOS | ● | |

**Dependencies on Other Technologies**
FAT is dependent upon the following technology.

**Basic disks and volumes**
Basic disks and basic volumes are the storage types most often used with Windows operating systems. The term basic disk refers to a disk that contains basic volumes, such as primary partitions and logical drives. The term basic volume refers to a partition on a basic disk. Basic disks, which are found in both x86-based and Itanium-based computers, provide a simple storage solution that can accommodate changing storage requirements.

**Related Technology**
FAT is related to the following technology:

**NTFS file system**
NTFS allows you to gain the maximum benefits for the needs of today's enterprise business environments from Windows Server 2003, such as increased security, more robust and reliable performance, as well as a design for greater storage growth,

features not found in FAT.

# How FAT Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- FAT Architecture
- FAT Physical Structure
- FAT Processes and Interactions
- Related Information

A file system is a required part of the operating system on a volume that determines how files are named, stored, and organized. A file system manages files and folders, and the information needed to locate and access these items by local and remote users.

Microsoft Windows Server 2003 supports the file allocation table (FAT) file system on basic disks and on readable/writable disks. Basic disks and volumes are the storage types most often used with Windows operating systems.

During the format of a volume, you can choose the type of file system for the volume. When you choose the FAT file system, the formatting process places key file data structures on the volume to tell the hard disk which file system the operating system uses.

**FAT Architecture**

During format and setup of a volume file system on a hard disk, a master boot record (MBR) is created. The MBR contains a small amount of executable code called the master boot code as well as a partition table for the disk. When a volume is mounted, the MBR executes the master boot code and transfers control to the boot sector on the disk, allowing the server to start the operating system on the file system of that specific volume.

**Note**

- The partition table contains a number of fields used to describe the partition. One of these fields is the System ID field, which defines the file system, such as FAT, on the partition. For FAT16 volumes, the system ID is 0x04; for FAT32 volumes, the system ID is 0x0B.

The following figure shows the architecture of this process.

**FAT Architecture**

The following table describes the components of the FAT file system.

**FAT Components**

| Component | Component Description |
|---|---|
| Hard disk | Contains one or more partitions. |
| Boot sector | Bootable partition that stores information about the layout of the volume and the file system structures, as well as the boot code that loads Ntdlr. |
| Master Boot Record | Contains executable code that the system BIOS loads into memory. The code scans the MBR to find the partition table to determine which partition is the active, or bootable, partition. |
| Ntldlr.dll | Switches the CPU to protected mode, starts the file system, and then reads the contents of the Boot.ini file. This information determines the startup options and initial boot menu selections. |
| Fastfat.sys | System file driver for FAT16 and FAT32. |
| Ntoskrnl.exe | Extracts information about which system device drivers to load and the load order. |
| Kernel Mode | The processing mode that allows code to have direct access to all hardware and memory in the system. |
| User Mode | The processing mode in which applications run. |

**FAT Physical Structure**

The following information describes the physical structure of the FAT file system, and includes information about how clusters affect the FAT file system, as well as descriptions of the partition table.

**Clusters and Sectors on a FAT Volume**

A cluster (or allocation unit) is the smallest amount of disk space that can be allocated to hold a file. All file systems used by Windows Server 2003 organize hard disks based on cluster size, which is determined by the number of sectors (units of storage on a hard disk) that the cluster contains. For example, on a disk that uses 512-byte sectors, a 512-byte cluster contains one sector, whereas a 4-kilobyte (KB) cluster contains eight sectors.

Computers access certain sectors on a hard disk during startup to determine which operating system to start and where the partitions are located. The data stored on these sectors varies depending on the computer platform.

**Sequence of Clusters on a FAT Volume**

Clusters are numbered sequentially from the beginning of the partition into logical cluster numbers. Because FAT file system data clusters are located after the BIOS Parameter Blocks (BPB), reserved sectors, and two FAT structures, FAT formatting cannot guarantee that data clusters are aligned on a cluster boundary.

**Limitations of Cluster Sizes on a FAT Volume**

Because FAT16 and FAT32 each use different cluster sizes depending on the size of the volume, each file system has a maximum number of clusters it can support. The smaller the cluster size, the more efficiently a disk stores information because unused space within a cluster cannot be used by other files. And the more clusters a file system supports, the larger the volumes you can create and format by using a particular file system.

The size of each cluster is a multiple of the sector size. The numerals in the names, FAT16 and FAT32 refer to the number of bits required for a file allocation table entry as follows:

- FAT16 uses a 16-bit file allocation table entry (216 clusters).
- FAT32 uses a 32-bit file allocation table entry. However, FAT32 reserves the first 4 bits of a FAT32 file allocation table entry, which means FAT32 has a theoretical maximum of $2^{28}$ clusters.
- Floppy disks are always formatted as FAT.

The following table provides a comparison of FAT16 and FAT32 volume and default cluster sizes.

**Default FAT Cluster Sizes**

| Volume Size | FAT16 Cluster Size | FAT32 Cluster Size |
|---|---|---|
| 7 megabytes (MB)–16 MB | 2 KB | Not supported |
| 17 MB–32 MB | 512 bytes | Not supported |
| 33 MB–64 MB | 1 KB | 512 bytes |
| 65 MB–128 MB | 2 KB | 1 KB |
| 129 MB–256 MB | 4 KB | 2 KB |
| 257 MB–512 MB | 8 KB | 4 KB |
| 513 MB–1,024 MB | 16 KB | 4 KB |
| 1,025 MB–2 gigabytes (GB) | 32 KB | 4 KB |
| 2 GB–4 GB | 64 KB | 4 KB |
| 4 GB–8 GB | Not supported | 4 KB |
| 8 GB–16 GB | Not supported | 8 KB |
| 16 GB–32 GB | Not supported | 16 KB |
| 32 GB–2 terabytes | Not supported | Not supported |

Windows Server 2003 formats FAT32 volumes up to 32 GB regardless of cluster size. To format volumes larger than 32 GB, you must use NTFS. However, Windows Server 2003 can mount FAT32 volumes larger than 32 GB that were created by other operating systems.

**Maximum Sizes on FAT Volumes**

Before you format a volume, you can evaluate the types of files to be stored on the volume so that you can determine whether to use the default cluster size. If you format a volume but do not specify a cluster size, default values are used. If you want to change the cluster size after the volume is formatted, you must reformat the volume.

FAT16 and FAT32 have the following size limitations:

- FAT volumes smaller than 16 MB are formatted as FAT12.
- FAT16 volumes larger than 2 GB are not accessible from computers running MS-DOS, Windows 95, Windows 98, Windows Millennium Edition (Me), and many other operating systems. This limitation occurs because these operating systems do not support cluster sizes larger than 32 KB, which results in the 2 GB limit.
- In theory, FAT32 volumes can be about 8 terabytes; however, the maximum FAT32 volume size that Windows Server 2003 can format is 32 GB. Therefore, you must use NTFS to format volumes larger than 32 GB. However, Windows Server 2003 can read and write to larger FAT32 volumes formatted by other operating systems.

The largest possible file for a FAT32 volume is 4 GB minus 1 byte. FAT32 contains 4 bytes per cluster in the file allocation table; FAT16 contains 2 bytes per cluster; and FAT12 contains 1.5 bytes per cluster. A FAT32 volume must have at least 65,527 clusters

FAT16 supports a maximum of 65,524 clusters per volume. The following table lists FAT16 size limits.

**FAT16 Size Limits**

| Description | Limit |
|---|---|
| Maximum file size | Tested: 4 GB minus 1 byte ($2^{32}$ bytes minus 1 byte) |
| Maximum volume size | Tested: 4 GB |

| | |
|---|---|
| Files per volume | Approximately 65,536 ($2^{16}$ files) |
| Maximum number of files and folders within the root folder | 512 (Long file names can reduce the number of available files and folders in the root folder.) |

A FAT32 volume must have a minimum of 65,527 clusters. Windows Server 2003 can format FAT32 volumes up to 32 GB, but it can mount larger FAT32 volumes created by other operating systems. The following table lists FAT32 size limits.

**FAT32 Size Limits**

| Description | Limit |
|---|---|
| Maximum file size | Tested: 4 GB minus 1 byte ($2^{32}$ bytes minus 1 byte) |
| Maximum volume size | Tested: 32 GB (implementation) |
| Files per volume | 4,177,920 |
| Maximum number of files and subfolders within a single folder | 65,534 (The use of long file names can significantly reduce the number of available files and subfolders within a folder.) |

**Organization of a FAT Volume**

A volume formatted with FAT is organized as illustrated in the following figure.

**Organization of a FAT Volume**

The following table describes each of the organizational structures on a FAT volume.

**FAT Volume Components**

| Component | Description |
|---|---|
| Boot Sector | Contains the BIOS parameter block that stores information about the layout of the volume and the file system structures, as well as the boot code that loads Windows Server 2003. |
| Reserved Sectors | The number of sectors that precede the start of the first FAT, including the boot sector. |
| FAT 1 | Original FAT. |
| FAT 2 (Duplicate) | Backup copy of the FAT. |
| Root folder | Describes the files and folders in the root of the partition. |
| Other folders and all files | Contains the data for the files and folders within the file system. |

**Boot Sectors on MBR and GPT Disks**

On MBR disks (disks that contain a master boot record), the boot sector, which is located at the first logical sector of each partition, is a critical disk structure for starting your computer. It contains executable code and the data required by the code, including information that the file system uses to access the volume. The boot sector is created when you format a volume. At the end of the boot sector is a 2-byte structure called a signature word or end of sector marker, which is always set to 0x55AA. On computers running Windows Server 2003, the boot sector on the active partition loads into memory and starts Ntldr, which loads the boot menu if multiple versions of Windows are installed or loads the operating system if only one operating system is installed.

GUID partition table (GPT) disks are similar to MBR disks, except they use primary and backup partition structures to provide redundancy. These structures are located at the beginning and the end of the disk. GPT identifies these structures by their logical block address (LBA) rather than by their relative sectors.

A boot sector consists of the following elements:

- An x86-based CPU jump instruction.
- The original equipment manufacturer identification (OEM ID).
- The BIOS parameter block (BPB), a data structure.
- The extended BPB.
- The executable boot code (or bootstrap code) that starts the operating system.

All Windows Server 2003 boot sectors contain the preceding elements regardless of the type of disk (basic disk or dynamic disk).

**Components of a Boot Sector**
The MBR transfers CPU execution to the boot sector, so the first three bytes of the boot sector must be valid, executable x86-based CPU instructions. This includes a jump instruction that skips the next several nonexecutable bytes.

Following the jump instruction is the 8-byte OEM ID, a string of characters that identifies the name and version number of the operating system that formatted the volume. To preserve compatibility with MS-DOS, Windows Server 2003 records “MSDOS5.0” in this field on FAT16 and FAT32 disks.

### Note

- You might also see the OEM ID "MSWIN4.0" on disks formatted by Windows 95 and "MSWIN4.1" on disks formatted by Windows 95 OEM Service Release 2 (OSR2), Windows 98, and Windows Me. Windows Server 2003 does not use the OEM ID field in the boot sector except for verifying NTFS volumes.

Following the OEM ID is the BPB, which provides information that enables the executable boot code to locate Ntldr. The BPB always starts at the same offset, so standard parameters are in a known location. Disk size and geometry variables are encapsulated in the BPB. Because the first part of the boot sector is an x86 jump instruction, the BPB can be extended in the future by appending new information at the end. The jump instruction needs only a minor adjustment to accommodate this change. The BPB is stored in a packed (unaligned) format.

**FAT16 Boot Sector**
The following table describes the sections of a boot sector of a volume formatted with the FAT16 file system.

### Boot Sector Sections on a FAT16 Volume

| Byte Offset | Field Length | Field Name |
|---|---|---|
| 0x00 | 3 bytes | Jump instruction |
| 0x03 | 8 bytes | OEM ID |
| 0x0B | 25 bytes | BPB |
| 0x24 | 26 bytes | Extended BPB |
| 0x3E | 448 bytes | Bootstrap code |
| 0x01FE | 2 bytes | End of sector marker |

The following example illustrates a hexadecimal printout of the boot sector on a FAT16 volume. The printout is formatted in three sections:

- Bytes 0x00– 0x0A are the jump instruction and the OEM ID (shown in bold print).
- Bytes 0x0B– 0x3D are the BPB and the extended BPB.
- The remaining section is the bootstrap code and the end of sector marker (shown in bold print).

The following two tables illustrate the layout of the BPB and the extended BPB for FAT16 volumes. The sample values correspond to the data in this example of a hexadecimal printout of the boot sector on a FAT16 volume.

**BPB Fields for FAT16 Volumes**

| Byte Offset | Field Length | Sample Value | Field Name and Definition |
|---|---|---|---|
| 0x0B | 2 bytes | 00 02 | **Bytes Per Sector**.The size of a hardware sector. Valid decimal values for this field are 512, 1024, 2048, and 4096. |
| 0x0D | 1 byte | 40 | **Sectors Per Cluster**.The number of sectors in a cluster. Because FAT16 can track only a limited number of clusters (up to 65,524), FAT16 supports large volumes by increasing the number of sectors per cluster. The default cluster size for a volume depends on the volume size. Valid decimal values for this field are 1, 2, 4, 8, 16, 32, 64, and 128. |
| 0x0E | 2 bytes | 01 00 | **Reserved Sectors**. The number of sectors that precede the start of the first FAT, including the boot sector. The value of this field is typically 1. |
| 0x10 | 1 byte | 02 | **Number of FATs**. The number of copies of the FAT on the volume. The value of this field is typically 2. |
| 0x11 | 2 bytes | 00 02 | **Root Entries**. The total number of 32-byte file and folder name entries that can be stored in the root folder of the volume. On a typical hard disk, the value of this field is 512. One entry can be used as a volume label, and files and folders with long names use multiple entries per file. The largest number of file and folder entries is typically 511; however, if long file names are used, entries usually run out before you reach that number. |
| 0x13 | 2 bytes | 00 00 | **Small Sectors**. The number of sectors on the volume represented in 16 bits (< 65,536). For volumes larger than 65,536 sectors, this field has a value of zero and the **Large Sectors** field is used instead. |

| | | | |
|---|---|---|---|
| 0x15 | 1 byte | F8 | **Media Descriptor**. Provides information about the media being used. A value of 0xF8 indicates a hard disk and 0xF0 indicates a high-density 3.5-inch floppy disk. Media descriptor entries are a legacy of MS-DOS FAT16 and FAT12 disks and are not used in Windows Server 2003. |
| 0x16 | 2 bytes | FC 00 | **Sectors Per FAT**. The number of sectors occupied by each FAT on the volume. The computer uses this number and the number of FATs and reserved sectors to determine where the root directory begins. The computer can also determine where the user data area of the volume begins based on the number of entries in the root directory (512). |
| 0x18 | 2 bytes | 3F 00 | **Sectors Per Track**. Part of the apparent disk geometry used on a low-level formatted disk. |
| 0x1A | 2 bytes | 40 00 | **Number of Heads**. Part of the apparent disk geometry used on a low-level formatted disk. |
| 0x1C | 4 bytes | 3F 00 00 00 | **Hidden Sectors**. The number of sectors on the volume before the boot sector. This value is used during the boot sequence to calculate the absolute offset to the root directory and data areas. |
| 0x20 | 4 bytes | 01 F0 3E 00 | **Large Sectors**. If the value of the **Small Sectors** field is zero, this field contains the total number of sectors in the FAT16 volume. If the value of the **Small Sectors** field is not zero, the value of this field is zero. |

**Extended BPB Fields for FAT16 Volumes**

| Byte Offset | Field Length | Sample Value | Field Name and Definition |
|---|---|---|---|
| 0x24 | 1 byte | 80 | **Physical Drive Number**. Related to the BIOS physical drive number. Floppy drives are identified as 0x00 and physical hard disks are identified as 0x80, regardless of the number of physical disk drives. Typically, this value is set prior to issuing an INT 13h BIOS call to specify the device to access. This value is only relevant if the device is a boot device. |
| 0x25 | 1 byte | 00 | **Reserved**. FAT16 volumes are always set to zero. |
| 0x26 | 1 byte | 29 | **Extended Boot Signature**. A field that must have the value 0x28 or 0x29 to be recognized by Windows Server 2003. |
| 0x27 | 4 bytes | A8 8B 36 52 | **Volume Serial Number**. A random serial number that is created when a volume is formatted and that helps to distinguish between disks. |
| 0x2B | 11 bytes | NO NAME | **Volume Label**. A field that was once used to store the volume label. The volume label is now stored as a special file in the root directory. |
| 0x36 | 8 bytes | FAT16 | Not used by Windows Server 2003. |

**FAT32 Boot Sector**

The FAT32 boot sector is structurally very similar to the FAT16 boot sector, but the FAT32 BPBcontains additional fields. The FAT32 extended BPB uses the same fields as FAT16, but the offset addresses of these fields within the boot sector are different than those found in FAT16 boot sectors. Volumes formatted in FAT32 are not readable by operating systems that are incompatible with FAT32.

The following table describes the sections of a boot sector of a volume formatted with the FAT32 file system.

**Boot Sector Sections on a FAT32 Volume**

| Byte Offset | Field Length | Field Name |
|---|---|---|
| 0x00 | 3 bytes | Jump instruction |
| 0x03 | 8 bytes | OEM ID |
| 0x0B | 53 bytes | BPB |
| 0x40 | 26 bytes | Extended BPB |
| 0x5A | 420 bytes | Bootstrap code |

| | | |
|---|---|---|
| 0x01FE | 2 bytes | End of sector marker |

The following example illustrates a hexadecimal printout of the boot sector on a FAT32 volume. The printout is formatted in three sections:

- Bytes 0x00– 0x0A are the jump instruction and the OEM ID (shown in bold print).
- Bytes 0x0B– 0x59 are the BPB and the extended BPB.
- The remaining section is the bootstrap code and the end of sector marker (shown in bold print).

The following two tables illustrate the layout of the BPB and the extended BPB for FAT32 volumes. The sample values correspond to the data in this example of a hexadecimal printout of the boot sector on a FAT32 volume.

**BPB Fields for FAT32 Volumes**

| Byte Offset | Field Length | Sample Value | Field Name and Definition |
|---|---|---|---|
| 0x0B | 2 bytes | 00 02 | **Bytes Per Sector**. The size of a hardware sector. Valid decimal values for this field are 512, 1024, 2048, and 4096. |
| 0x0D | 1 byte | 10 | **Sectors Per Cluster**.The number of sectors in a cluster. The default cluster size for a volume depends on the volume size. Valid decimal values for this field are 1, 2, 4, 8, 16, 32, 64, and 128. The Windows Server 2003 implementation of FAT32 allows for creation of volumes up to a maximum of 32 GB. However, larger volumes created by other operating systems (Windows 95 OSR2 and later) are accessible in Windows Server 2003. |
| 0x0E | 2 bytes | 24 00 | **Reserved Sectors**. The number of sectors that precede the start of the first FAT, including the boot sector. |

| | | | |
|---|---|---|---|
| 0x10 | 1 byte | 02 | **Number of FATs**. The number of copies of the FAT on the volume. The value of this field is always 2. |
| 0x11 | 2 bytes | 00 00 | **Root Entries (FAT12/FAT16 only)**. For FAT32 volumes, this field must be set to zero. |
| 0x13 | 2 bytes | 00 00 | **Small Sectors (FAT12/FAT16 only)**. For FAT32 volumes, this field must be set to zero. |
| 0x15 | 1 byte | F8 | **Media Descriptor**. Provides information about the media being used. A value of 0xF8 indicates a hard disk and 0xF0 indicates a high-density 3.5-inch floppy disk. Media descriptor entries are a legacy of MS-DOS FAT16 disks and are not used in Windows Server 2003. |
| 0x16 | 2 bytes | 00 00 | **Sectors Per FAT (FAT12/FAT16 only)**. For FAT32 volumes, this field must be set to zero. |
| 0x18 | 2 bytes | 3F 00 | **Sectors Per Track**. Contains the "sectors per track" geometry value for disks that use INT 13h. The volume is broken down into tracks by multiple heads and cylinders. |
| 0x1A | 2 bytes | FF 00 | **Number of Heads**. Contains the "count of heads" geometry value for disks that use INT 13h. For example, on a 1.44-MB, 3.5-inch floppy disk this value is 2. |
| 0x1C | 4 bytes | 3F 00 00 00 | **Hidden Sectors**. The number of sectors on the volume before the boot sector. This value is used during the boot sequence to calculate the absolute offset to the root directory and data areas. This field is generally only relevant for media that are visible on interrupt 13h. It must always be zero on media that are not partitioned. |
| 0x20 | 4 bytes | 1D 91 11 01 | **Large Sectors**. Contains the total number of sectors in the FAT32 volume. |
| 0x24 | 4 bytes | 2A 22 00 00 | **Sectors Per FAT (FAT32 only)**. The number of sectors occupied by each FAT on the volume. The computer uses this number and the number of FATs and reserved sectors (described in this table) to determine where the root directory begins. The computer can also determine where the user data area of the volume begins based on the number of entries in the root directory. |
| 0x28 | 2 bytes | 00 00 | Not used by Windows Server 2003. |
| 0x2A | 2 bytes | 00 00 | **File System Version (FAT32 only)**. The high byte is the major revision number; the low byte is the minor revision number. This field supports the ability to extend the FAT32 media type in the future with concern for old FAT32 drivers mounting the volume. Both bytes are zero in Windows Server 2003, Windows 2000, and Windows Me and earlier. |
| 0x2C | 4 bytes | 02 00 00 00 | **Root Cluster Number (FAT32 only)**. The cluster number of the first cluster of the root directory. This value is typically, but not always, 2. |
| 0x30 | 2 bytes | 01 00 | **File System Information Sector Number (FAT32 only)**. The sector number of the File System Information (FSINFO) structure in the reserved area of the FAT32 volume. The value is typically 1. A copy of the FSINFO structure is kept in the Backup Boot Sector, but it is not kept up-to-date. |
| 0x32 | 2 bytes | 06 00 | **Backup Boot Sector (FAT32 only)**. A value other than zero specifies the sector number in the reserved area of the volume where a copy of the boot sector is stored. The value of this field is typically 6. No other value is recommended. |
| 0x34 | 12 bytes | 00 00 00 00 00 00 00 00 00 00 00 00 | **Reserved (FAT32 only)**. Reserved space for future expansion. The value of this field must always be zero. |

**Extended BPB Fields for FAT32 Volumes**

| Byte Offset | Field Length | Sample Value | Field Name and Definition |
|---|---|---|---|

| | | | |
|---|---|---|---|
| 0x40 | 1 byte | 80 | **Physical Drive Number**. Related to the BIOS physical drive number. Floppy drives are identified as 0x00 and physical hard disks are identified as 0x80, regardless of the number of physical disk drives. Typically, this value is set prior to issuing an INT 13h BIOS call to specify the device to access. This value is only relevant if the device is a boot device. |
| 0x41 | 1 byte | 00 | **Reserved**. FAT32 volumes are always set to zero. |
| 0x42 | 1 byte | 29 | **Extended Boot Signature**. A field that must have the value 0x28 or 0x29 to be recognized by Windows Server 2003. |
| 0x43 | 4 bytes | F1 9E 5E 5E | **Volume Serial Number**. A random serial number that is created when a volume is formatted and that helps to distinguish between disks. |
| 0x47 | 11 bytes | NO NAME | **Volume Label**. A field that was once used to store the volume label. The volume label is now stored as a special file in the root directory. |
| 0x52 | 8 bytes | FAT32 | **System ID**. A text field with a value of FAT32. |

**FAT 1 and FAT 2**

The file allocation table, FAT 1, identifies each cluster in the volume as one of the following:

- Unused
- Cluster in use by a file
- Bad cluster
- Last cluster in a file

Because the file allocation table is so important, a copy of the table, FAT 2, is maintained on the volume. This allows the file system driver or consistency-checking program to access the duplicate copy if it cannot access FAT 1.

**FAT Root Folder**

The root folder describes the files and folders in the root of the partition. It has a maximum number of available entries fixed at 512. The maximum number of entries on a floppy disk depends on the size of the disk.

**FAT Root Folder Structure**

| Root Folder Entry | Size | Description |
|---|---|---|
| Name | 11 bytes | Name in 8.3 format. |
| Attribute byte | 1 byte | Information about the entry. |
| Creation time and date | 5 bytes | Time and date file was created. |
| Last access date | 2 bytes | Date file was last accessed. |
| Last modification time and date | 4 bytes | Time and date file was last modified. |
| First cluster | 2 bytes | Starting cluster number in the file allocation table. |
| File size | 4 bytes | Size of the file. |

**Note**

- Three bytes in each 32-byte folder entry are held in reserve.

The information stored in the root folder is used by all operating systems that support FAT. Windows Server 2003 can store additional timestamps in a FAT folder entry. These timestamps show when the file was created or last accessed.

The attribute byte for each entry in a folder describes what kind of entry it is. For example, one bit indicates that the entry is for a subfolder, and another bit marks the entry as a volume. Typically, the operating system controls the settings of these bits.

The attribute byte includes four bits that can be turned on or off by the user — archive, system, hidden, and read-only.

**FAT Processes and Interactions**
FAT is affected by many factors, such as cluster size, fragmentation level, and the use of programs such as antivirus software.

**Mounting a FAT Volume**
When mounting a FAT volume, the MBR executes code to start up the boot sector. The boot sector then executes additional code to mount the volume.

**Master Boot Code Startup Process**
The MBR contains a small amount of executable code called the master boot code, the disk signature, and the partition table for the disk. During startup, the master boot code performs the following activities:

1. Scans the partition table for the active partition.
2. Finds the starting sector of the active partition.
3. Loads a copy of the boot sector from the active partition into memory.
4. Transfers control to the executable code in the boot sector.

**Boot Sector Startup Process**
Computers use the boot sector to run instructions during startup. The initial startup process is summarized in the following steps:

1. The system BIOS and the CPU initiate the power-on self test (POST).
2. The BIOS finds the boot device, which is typically the first disk the BIOS finds, unless the controller is configured to boot from a different disk.
3. The BIOS loads the first physical sector of the boot device into memory and transfers CPU execution to that memory address.

If the boot device is on a hard disk, the BIOS loads the MBR. The master boot code in the MBR loads the boot sector of the active partition, and transfers CPU execution to that memory address. On computers that are running Windows Server 2003, the executable boot code in the boot sector finds Ntldr, loads it into memory, and transfers execution to that file.

### Note

- Windows Server 2003 cannot start up from a spanned, striped, or RAID-5 volume on dynamic disks. These disk structures cannot be registered into the MBR partition table; therefore, a system volume that uses these structures cannot start.

If drive A contains a floppy disk, the system BIOS loads the first sector (the boot sector) of the disk into memory. If the disk is a startup disk (formatted by MS-DOS with core operating system files applied), the boot sector loads into memory and uses the executable boot code to transfer CPU execution to Io.sys, a core MS-DOS operating system file. If the floppy disk is not a startup disk, the executable boot code displays an error message.

### Note

- These messages do not appear on normally functioning systems that are configured to look for the startup files on drive C first. On many computers, an option in the CMOS setup program allows the user to set the sequence of installed disks that the system searches to find the startup files.

If you get similar errors when trying to start the computer from the hard disk, the boot sector might be corrupted.

Initially, the startup process is independent of disk format and operating system. The unique characteristics of operating and file systems become important when the boot sector's executable boot code starts.

**File Processing on FAT Clusters**

When a file is saved to a FAT-formatted volume, it stores file information in clusters on the hard disk. If a file requires space greater than the cluster's size, FAT continues to store file information in the next available cluster until all information about the file is stored. The following figure shows an example of how FAT stores and retrieves file information from clusters.

**File Processing on a FAT Volume**

In this figure, 10 clusters (0 through 9) contain 3 files. One file occupies clusters 2, 3, 6, and 8; a second file occupies clusters 4 and 5; and a third file occupies cluster 7. The starting cluster number is the address of the first cluster used by the file. Each cluster contains a pointer to the next cluster in the file, or an end-of-file indicator (0xFFFF), which indicates that this cluster is the end of the file.

The attribute byte for each entry in a folder describes what kind of entry it is. For example, one bit indicates that the entry is for a subfolder, and another bit marks the entry as a volume. Typically, the operating system controls the settings of these bits.

The attribute byte includes four bits that can be turned on or off by the user — archive, system, hidden, and read-only.

**FAT16 File System**

FAT16 works best on small disks with simple folder structures. It is included in Windows Server 2003 for the following reasons:

- It provides backward compatibility in the form of an upgrade path for earlier versions of Windows-compatible products.
- It is compatible with most other operating systems.

Because FAT16 uses a larger cluster size, a FAT16 volume does not efficiently manage disk space when relatively small files are placed on it. A small file still uses a full cluster, even if the file does not require all the space allocated by the cluster. The cluster, once used by a file, cannot be used by any other file. This results in wasted space. Therefore, FAT16 is not recommended for volumes larger than 511 MB, and you cannot use FAT16 on volumes larger than 4 gigabytes(GB).

In the file allocation table of a FAT16 volume, files are given the first available location on the volume.

**FAT32 File System**

Because FAT32 requires 4 bytes to store cluster values, many internal and on-disk data structures have been revised or expanded. Most programs are unaffected by these changes; however, disk tools that read the on-disk format must be updated to support FAT32.

The most significant difference between FAT16 and FAT32 is the maximum number of clusters supported, which in turn affects a volume's maximum size and storage efficiency. FAT32 breaks the 4-GB volume limitation of FAT16 by extending the maximum number of clusters, and therefore works well on large disks with complex folder structures.

Due to the greater number of available clusters within FAT32, each cluster can be made smaller for a particular volume, increasing the efficiency of data storage. For example, FAT16 volumes between 2 and 4 GB use a 64-KB cluster, whereas FAT32 volumes between 16 GB and 32 GB use a 16-KB cluster.

The largest possible file for a FAT32 volume is 4 GB minus 1 byte. FAT32 contains 4 bytes per cluster in the file allocation table; FAT16 contains 2 bytes per cluster; and FAT12 contains 1.5 bytes per cluster. A FAT32 volume must have at least 65,527 clusters.

**Formatting Volumes**

During volume format, Windows Server 2003 places key file system structures on the volume, including the boot sector as well as replacing Ntldr. A check of the integrity of all sectors on the volume is performed, and you have the opportunity to change the cluster size used on the volume. If a volume is formatted using Quick format, the file system structure on the volume is created, but the integrity of every sector in the volume is not checked.

The version of FAT that Setup uses depends on the size of the volume. For volumes smaller than 2 GB (2048 MB), Setup uses FAT16. For volumes 2 GB or larger, Setup uses FAT32. For volumes 32 GB or larger, Setup uses NTFS and does not offer FAT.

Disk Management requires volumes on dynamic disks and GPT disks to be formatted as NTFS.

**Converting Volumes**

Windows Server 2003 can convert FAT16 or FAT32 to NTFS. This type of conversion is a one-way process. After you convert a volume to NTFS, you cannot reconvert the volume to FAT without backing up your data, reformatting the volume as FAT, and then restoring your data.

During the formatting process, Windows Server 2003 aligns FAT data clusters at the cluster size boundary. Convert.exe can preserve the cluster size for the size of the volume (up to 4 KB) instead of using the 512-byte cluster size used in Windows 2000 for converted volumes. The following table lists cluster sizes for volumes converted to NTFS.

**Cluster Sizes for Volumes Converted to NTFS**

| Original FAT Cluster Size | Converted NTFS Cluster Size |
|---|---|
| 512 bytes | 512 bytes |
| 1 KB | 1 KB |
| 2 KB | 2 KB |
| 4 KB and larger | 4 KB |

**Lack of Support for Compression**

Unlike NTFS, FAT does not support compression of files. If you move or copy a file from a folder on a FAT volume to a folder on an NTFS volume, the file takes on the attributes of the folder on the NTFS volume. Compressed files copied or moved from an NTFS volume to a FAT volume automatically uncompress, because FAT does not support compression.

**How Cluster Fragmentation Affects Performance**

Lack of disk space can become an issue on a volume, especially when multiple users access the volume to create, open, modify, or delete files.

Fragmentation occurs when the virtual clusters of a file are on non-contiguous logical clusters. Because the file is spread out across the disk, access is slower, so fragmentation affects the performance of the file system. As users create new files or change the size of existing ones, the file system uses additional free clusters. If the file system cannot use contiguous clusters, it will find any available cluster on the disk. The closer that clusters for each file are located on the hard disk, the more efficiently the disk can retrieve the information. Disk defragmentation is a process that groups all the virtual clusters of a file into contiguous logical clusters, and is usually done in order to improved disk drive performance.

**File Naming**

Windows Server 2003 supports both long and short file names on FAT volumes.

**File Names on FAT Volumes**

Files created or renamed on FAT volumes use attribute bits to support long file names in a way that does not interfere with how MS-DOS gains access to the volume.

When you create a file that has a long file name, Windows Server 2003 creates a conventional 8.3 name for the file and one or more secondary folder entries for the file, one for each set of 13 characters in the long file name. Each secondary folder entry stores a corresponding part of the long file name in Unicode. MS-DOS accesses the file by using the conventional 8.3 file name contained in the folder entry for the file.

Windows Server 2003 marks the secondary folder entries as part of a long file name by setting the volume ID, read-only, system, and hidden attribute bits. MS-DOS typically ignores folder entries with all these attribute bits set.

The following figure shows all of the folder entries for the file Thequi~1.fox, which has a long name, "The quick brown.fox." The long name is in Unicode and each character in the name uses 2 bytes in the folder entry. The attribute field for the long-name entries has the value 0x0F. The attribute field for the short name has the value 0x20.

**Long File Name on a FAT Volume**

**Note**

- Windows NT and Windows Server 2003 do not use the same algorithm to create long and short file names as Windows 95, Windows 98, and Windows Me. However, on computers that use a multiple-boot configuration to start these operating systems, files that you create while running one operating system can be accessed while running another.

By default, Windows Server 2003 supports long file names on FAT volumes. You can disable long file names on FAT volumes if you use MS-DOS–based disk tools regularly on the computer. These tools might either eliminate the long file names created by Windows Server 2003 or delete the files that have long file names.

**Note**

- It is advised that you do not disable long file names on FAT volumes.

**How Windows Server 2003 Creates File Names**

File names in Windows Server 2003 can be up to 255 characters and can contain spaces, multiple periods, and special characters that are not allowed in MS-DOS file names. Windows Server 2003 makes it possible for other operating systems to access files that have long names by generating an MS-DOS-readable (8.3) name for each file. These MS-DOS-readable names also enable MS-DOS-based and Windows 3.*x*–based applications to recognize and load files that have long file names. When a program saves a file on a computer running Windows Server 2003, both the 8.3 file name and long file name are retained.

**Note**

- The 8.3 format means that files can have between 1 and 8 characters in the file name. The name must start with a letter or a number and can contain any characters except the following:

- . " / \ [ ] : ; | = , * ? (space)

- An 8.3 file name typically has a file name extension that is from one to three characters long and has the same character restrictions. A period separates the file name from the file name extension.

- Several special file names are reserved by the system and cannot be used for files or folders: CON, AUX, COM1, COM2, COM3, COM4, LPT1, LPT2, LPT3, PRN, and NUL.

When you create a file that has a long file name, Windows Server 2003 creates a conventional 8.3 name for the file and one or more secondary folder entries for the file, one for each set of 13 characters in the long file name. Each secondary folder entry stores a corresponding part of the long file name in Unicode. MS-DOS accesses the file by using the conventional 8.3 file name contained in the folder entry for the file.

Windows Server 2003 marks the secondary folder entries as part of a long file name by setting the volume ID, read-only, system, and hidden attribute bits. MS-DOS typically ignores folder entries with all these attribute bits set.

**Generating Short File Names**

In Windows Server 2003, FAT uses the Unicode character set, which contains several prohibited characters that MS-DOS cannot read, for their names. To generate a short MS-DOS-readable file name, Windows Server 2003 deletes all of these

characters from the long file name and removes any spaces, but ensures that the generated short file name is unique. Because an MS-DOS-readable file name can have only one period, Windows Server 2003 also removes extra periods from the file name.

# FAT Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- FAT Tools
- FAT Registry Entries
- FAT WMI Classes

The following tools, registry settings, and Windows Management Instrumentation (WMI) classes are associated with FAT volumes.

**FAT Tools**
The following tools are associated with FAT. The tools in this list are used to create and maintain FAT volumes.

**Chkdsk.exe: Check Disk**
**Category**
Operating system tool

**Version compatibility**
Windows Server 2003. Chkdsk.exe works on FAT and NTFS volumes.

Chkdsk is a command-line tool that verifies the logical integrity of a file system on a Windows Server 2003 volume. Setting parameters on the command line will list and fix any errors.

For more information about Chkdsk, see Command Line References in the Tools and Settings Collection.

**Chkntfs.exe: Chkntfs**
**Category**
Operating system tool

**Version compatibility**
Windows Server 2003. Chkntfs.exe works on FAT and NTFS volumes.

Displays or specifies whether automatic system checking is schedule to be run on a FAT16 or FAT32 volume when the computer is started.

For more information about Chkntfs, see Command Line References in the Tools and Settings Collection.

**Defrag.exe: Defragmentation**
**Category**
Operating system tool

**Version compatibility**
Windows Server 2003. Defrag.exe works on FAT and NTFS volumes.

Arranges clusters on a disk in an optimized order.

For more information about Defrag, see Command Line References in the Tools and Settings Collection.

**Diskpart.exe: Disk Partition**
**Category**
Operating system tool

**Version compatibility**
Windows Server 2003. Diskpart includes a few 64-bit parameters that are only available on Itanium-based computers. Diskpart.exe works on both FAT and NTFS volumes.

Command-line tool that allows you to manage disks and partitions by using scripts or direct input from a command prompt. Diskpart locates and consolidates fragmented boot files, data files, and folders on local or remote volumes.

For more information about Diskpart, see Command Line References in the Tools and Settings Collection.

**Format.exe: Format**
**Category**
Operating system tool

**Version compatibility**
Windows Server 2003. Format.exe works on FAT and NTFS volumes.

Prepares a volume on the specified disk to accept Windows files.

For more information about Format, see Command Line References in the Tools and Settings Collection.

**Fsutil.exe: File Systems Utilities**
**Category**
Operating System tool

**Version compatibility**
Windows Server 2003. Fsutil.exe works on FAT and NTFS volumes.

Performs file system tasks such as disabling long file names, checking whether a volume is flagged as dirty, viewing NTFS-related information about a volume, creating hard links, and managing quotas and sparse files.

For more information about Fsutil, see Command Line References in the Tools and Settings Collection.

**Recovery Console**
**Category**
Operating system tool

**Version compatibility**
Windows Server 2003. Recovery Console works on FAT and NTFS volumes.

The Recovery Console is a text-mode command-line interpreter that you can use for basic troubleshooting and maintenance. It is separate from the Windows Server 2003 command prompt and grants limited local hard disk access for FAT volumes.

**Vrfydsk.exe: Verify Disk**
**Category**
Resource Kit tool

**Version compatibility**
Windows Server 2003. Vrfydsk.exe works on FAT and NTFS volumes.

Command-line tool that checks the consistency and integrity of the file system on a specified volume.

For more information about Vrfydsk, see Resource Kit Tools in the Tools and Settings Collection.

**FAT Registry Entries**
The following registry entries are associated with the FAT file system.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**FileSystem**
The following registry entry is located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\FileSystem.

**Win95TruncatedExtensions**
**Registry Path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem

**Version**
Microsoft Windows NT 4.0 Server and Windows NT 4.0 Workstation and later.

Truncates extensions on FAT partitions, allowing you to work with 3-character extension files as well as 4-character extension files (for example, *.htm is treated identically to *.html).

For more information about this registry entry, see the Registry Reference in the Tools and Settings Collection.

**FAT WMI Classes**

The following table lists and describes the WMI classes that are associated with file systems.

**WMI Classes Associated with FAT**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_AutochkSetting | \root\cimv2 | Windows XP or later |
| Win32_DefragAnalysis | \root\cimv2 | Windows Server 2003 |
| Win32_DiskDriveToDiskPartition | \root\cimv2 | Windows 2000 and later |
| Win32_DiskPartition | \root\cimv2 | Windows 2000 and later |
| Win32_LogicalDisk | \root\cimv2 | Windows 2000 and later |
| Win32_LogicalDiskRootDirectory | \root\cimv2 | Windows 2000 and later |
| Win32_LogicalDiskToPartition | \root\cimv2 | Windows 2000 and later |
| Win32_DiskDrivePhyiscalMedia | \root\cimv2 | Windows 2000 and later |
| Win32_Volume | \root\cimv2 | Windows Server 2003 |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

# Disk Defragmenter Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Disk Defragmenter Technical Reference**
Defragmentation is the process of consolidating fragmented files and folders. Disk Defragmenter is a Microsoft Windows Server 2003 tool that analyzes storage areas on a disk, referred to as volumes, and consolidates fragmented files and folders so that each occupies a single, contiguous space on the volume. As a result, a system can access and save files and folders more efficiently. By consolidating files and folders, Disk Defragmenter also consolidates the free space on a volume, making it less likely that new files will be fragmented.

Disk Defragmenter can defragment volumes that are formatted with the FAT16, FAT32, and NTFS file systems. Windows Server 2003 offers two choices for defragmenting disks: the Disk Defragmenter snap-in and a new command-line version of the tool, Defrag.exe.

# What Is Disk Defragmenter?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Disk Defragmenter?**

**In this section**

- Common Scenarios for Disk Defragmenter
- Disk Defragmenter Interactions
- Related Information

When you create, copy, or move a file on your hard disk, the operating system looks for blocks of contiguous free disk space where it can write the file. When the operating system cannot find enough contiguous space, it looks for free space scattered throughout the hard disk to which the file can be written in pieces. As a result, pieces of the file may end up scattered over the hard disk rather than in one contiguous chunk. When a file is written to non-contiguous free space, it is known as a fragmented file.

All Windows file systems are susceptible to fragmentation, regardless of the type of file system or the type of disk. When a volume contains many fragmented files and folders, it requires several additional disk drive reads and more movement of the disk drive heads to collect the various pieces, resulting in Windows taking much longer to read a file. Similarly, creating new files and folders also takes longer when the free space available on the volume is scattered. If the free space is not consolidated, then subsequent files written to the volume will more likely be fragmented.

Disk Defragmenter is both a Microsoft Management Console (MMC) snap-in and a command-line utility that can be used to optimize NTFS- or FAT-formatted volumes. Disk Defragmenter rearranges files so that files and free space are consolidated. A reduction in fragmentation results in a reduction in the amount of mechanical movement required to locate all clusters of a file.

**Common Scenarios for Disk Defragmenter**

Disk Defragmenter is commonly used in the following scenarios.

**Installing new software**

Running Disk Defragmenter on a volume after installing software organizes the clusters on the volume.

**Rewriting, updating, and deleting files**

Running Disk Defragmenter on a regular basis consolidates space to create more contiguous free clusters on the volume, which allows disk heads to read files and write updates more quickly.

**Disk Defragmenter Interactions**

Disk Defragmenter interacts with the following technologies.

**NTFS and FAT file systems**

You can use Disk Defragmenter to reduce fragmentation and improve the overall performance of disk input and output (disk I/O) on either NTFS- or FAT-formatted volumes by performing online defragmentation of the master file table (MFT) on NTFS volumes or by working on volumes with any cluster size.

# How Disk Defragmenter Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Disk Defragmenter Works**

**In this section**

- Disk Defragmenter Architecture
- Physical Structure of a Volume Using Disk Defragmenter
- Disk Defragmenter Processes and Interactions
- Related Information

Fragmentation causes a disk subsystem to perform more data-seeking operations, slowing the rate at which data is transferred and resulting in sluggish disk performance. Fragmentation can occur under the following conditions.

- You create a file, but the volume does not have a group of contiguous clusters that is large enough to contain the entire file. Therefore, the file is broken into fragments rather than residing in contiguous clusters on the volume.
- You edit a file so that it outgrows its existing space on the volume. When a file uses all the clusters in a group of contiguous, free clusters, the file is then broken into fragments that are stored in free clusters elsewhere on the disk.

To achieve the best results from Disk Defragmenter, run Disk Defragmenter frequently. Do the following before running Disk Defragmenter.

- Verify that the volume has 15 percent of its space free for the utility to use. Windows Server 2003 uses this free space as a sorting area for file fragments.
- Delete any unwanted or temporary files.
- Terminate any file system backup processes before running the utility. Backup processes cause the disk defragmentation process to pause.

This section covers the architecture of Disk Defragmenter, the physical layout of a volume, the process and interactions of defragmentation, and files excluded by the utility.

**Disk Defragmenter Architecture**

Disk Defragmenter interacts with the local file system to move files and consolidate free space, resulting in improved I/O performance. When a fragmented file is requested through an I/O call, the disk heads must move to different tracks on the disk to read all of the fragments. A file that is spread across thousands of fragments may require thousands of I/O calls to the disk controller and extensive movement of the disk head to complete a read operation, resulting in slower performance of the server. To reduce both the I/O calls and the head movement required to read the file, Disk Defragmenter moves the fragments of the file to clusters that are contiguous.

The following diagram, Disk Defragmenter Architecture, shows how the Disk Defragmenter snap-in and command-line tool use the DeviceIOControl file system application programming interface (API) to locate fragments of a file and to move files. The file system API provides access to the layout of the files on the disk and the free space. After the fragments of the file are located, the file system control code is used to move the fragment to a new location.

**Disk Defragmenter Architecture**

In the previous illustration, a disk has three volumes: C, V, and F. Two volumes are formatted with the NTFS file system and one volume is formatted with the FAT file system. Windows Server 2003, the Disk Defragmenter snap-in, and the Disk Defragmenter command-line tool are installed on the C volume. The following occurs when you run the Disk Defragmenter snap-in on the V volume.

1. Disk Defragmenter analyzes the V volume and determines the extent to which the volume is fragmented.

2. Disk Defragmenter uses file system API calls to move and organize the files.

3. Disk Defragmenter writes the reorganized files back to the V volume.

**Physical Structure of a Volume Using Disk Defragmenter**

The physical structure of the volume determines how efficiently the space is used by the file system. The smaller the cluster size, the more efficiently a disk stores information; this is because unused space within a cluster cannot be used by other files. Because the file system has limits on the number of clusters it can support, it chooses the default cluster size of the volume.

### Note

- NTFS uses default cluster sizes unless another cluster size is specified by the user.

Cluster size does not determine where files are written to the volume. Disk Defragmenter organizes clusters, regardless of their size, to more efficiently use resources.

**Default Cluster Sizes**

A cluster (or allocation unit) is the smallest amount of disk space that can be allocated to hold a file. All file systems used by Windows Server 2003 organize hard disks based on cluster size, which is determined by the number of sectors (units of storage on a hard disk) that the cluster contains. For example, on a disk that uses 512-byte sectors, a 512-byte cluster contains one sector, whereas a 4-kilobyte (KB) cluster contains eight sectors.

The following tables give the default cluster sizes for NTFS and FAT file systems.

### Default NTFS Cluster Sizes

| Volume Size | NTFS Cluster Size |
|---|---|
| 7 MB – 512 MB | 512 bytes |
| 513 MB – 1,024 MB | 1 KB |
| 1,025 MB – 2 GB | 2 KB |
| 2 GB – 2 terabytes | 4 KB |

The FAT16 file system supports a maximum of 65,524 clusters per volume, in spite of the 4-GB maximum volume size. FAT32 volumes must have a minimum of 65,527 clusters on a 32-GB volume, which is the largest FAT32 volume that Windows Server 2003 can format.

**Default FAT Cluster Sizes**

| Volume Size | FAT16 Cluster Size | FAT32 Cluster Size |
|---|---|---|
| 7 MB – 16 MB | 2 KB | Not supported |
| 17 MB – 32 MB | 512 bytes | Not supported |
| 33 MB – 64 MB | 1 KB | 512 bytes |
| 65 MB – 128 MB | 2 KB | 1 KB |
| 129 MB – 256 MB | 4 KB | 2 KB |
| 257 MB – 512 MB | 8 KB | 4 KB |
| 513 MB – 1,024 MB | 16 KB | 4 KB |
| 1,025 MB – 2 GB | 32 KB | 4 KB |
| 2 GB – 4 GB | 64 KB | 4 KB |
| 4 GB – 8 GB | Not supported | 4 KB |
| 8 GB – 16 GB | Not supported | 8 KB |
| 16 GB – 32 GB | Not supported | 16 KB |
| 32 GB – 2 terabytes | Not supported | Not supported |

**Volume Structure Before and After Running Disk Defragmenter**

The following figure shows a general example of how Disk Defragmenter organizes file fragments to create contiguous clusters.

**Volume Structure Before and After Running Disk Defragmenter**

Two files, File01 and File02, are saved in nine clusters on a volume. Each cluster-sized part of a file contains an indicator to tell the disk head on which cluster the next part of the file is located. For example, File01 uses four clusters. Contained in cluster 1 with the first chunk of the file's data is a pointer that indicates that the next part of the file is located in cluster 3; cluster 3 indicates that the next part of the file is located in cluster 6; cluster 6 indicates that the next part of the file is located in cluster 8. Cluster 8 has an indicator, 0xFFFF, that marks that cluster as containing the last part of the file. Because the parts are spread out across four chunks on the volume, the disk head must move more to retrieve the parts of the file than if the file were consolidated in one chunk. This extra movement results in decreased performance.

After running Disk Defragmenter, file parts are organized such that more parts of each file are contiguous. Thus, File01 now uses clusters 0 – 3. Because the disk head has less distance to travel, it has less work to do, and performance is increased. In addition, the free space available in clusters 2, 4, 7, and 9 before disk defragmentation has been consolidated; there is now a larger free space in clusters 6 – 9.

**Disk Defragmenter Processes and Interactions**

The amount of time that defragmentation takes depends on several factors, including the size of the volume, the number and

size of files on the volume, the amount of fragmentation, and the available local system resources. You can find the fragmented files and folders before defragmenting them by analyzing the volume first. You can then see how fragmented the volume is and decide whether to defragment the volume.

The defragmentation process can run even when files are in use by another process. The movement of a file by Disk Defragmenter is invisible to the other process and is managed by the file system APIs. There will be some performance impact on the system if Disk Defragmenter is run while backups are in progress, but there is no risk of data loss due to the use of Disk Defragmenter.

This section covers the following topics.

- Process limitations
- Analyzing volumes
- Updating the master file table (MFT)
- Optimizing startup

**Process Limitations**

Disk Defragmenter cannot be used under the following circumstances.

- You cannot defragment volumes that the file system has marked as dirty, which indicates possible corruption. Running Chkdsk or Fsutil on a volume in advance of running Disk Defragmenter can help to determine whether a volume is dirty.
- You cannot run Disk Defragmenter from the command line and through the Disk Defragmenter snap-in simultaneously. If you run Disk Defragmenter from the command line and then open the Disk Defragmenter snap-in, the defragmentation options in the Disk Defragmenter snap-in are unavailable. Conversely, if you are using the snap-in to defragment a volume and then run Disk Defragmenter from the command line, the command-line tool fails.

**Files Excluded by Disk Defragmenter**

All Windows file systems have on-disk structures that are excluded by Disk Defragmenter. Files are excluded because it may not be possible to move the file after the operating system has started up or because the benefit of consolidating the file is negligible. The following table lists files excluded by Disk Defragmenter.

**Files Excluded by Disk Defragmenter**

| Component | Description |
|---|---|
| Bootsect.dos | Holds the contents of the boot sector, disk sector 0 from the bootable hard drive volume. |
| Safeboot.fs, Safeboot.csv, Safeboot.rsv | Contain an internal verification of data structures. |
| Hiberfil.sys | File to which the system's physical memory is written during hibernation. On resuming from hibernation, the BIOS reads Hiberfil.sys to restore the state of the computer to its pre-hibernation state. Because the location of the Hibernate file is determined very early in the startup process, it cannot be moved. It can, however, be defragmented safely at startup using an enterprise-level defragmenter. |
| Memory.dmp | Holds the contents of the kernel address space when a computer restarts due to an error. |
| Paging file | Used by the operating system as storage space when swapping data in and out of random access memory (RAM). When memory requirements exceed the amount of physical RAM, Virtual Memory Manager transfers the oldest data stored in RAM to the paging file. The paging file can be defragmented during the boot process only. |
| FAT directories | Lists the contents of a directory on FAT16 and FAT32 file systems. |

| | |
|---|---|
| Change journal | Provides a persistent log of changes made to files on an NTFS volume. NTFS maintains the change journal by tracking information about added, deleted, and modified files for each volume. |

**Note**

- Although Disk Defragmenter does not defragment FAT-formatted directories, it will defragment directories on NTFS-formatted volumes.

**Analyzing Volumes**

By using the Disk Defragmenter snap-in, you can analyze the volume before you defragment and view the fragmentation report to see how many files and folders are fragmented. If 10 percent or more of the files and folders are fragmented, it is recommended that you defragment the volume. If the volume is less than 10 percent fragmented, you can still defragment it.

The following figure shows the Disk Defragmenter snap-in.

**Disk Defragmenter snap-in**

The upper part of the screen lists the volumes on the local computer and allows you to select a volume to analyze and defragment. The lower part of the screen displays a graphical representation of the fragmentation on the volume. The colors indicate the condition of the volume:

- Red areas show fragmented files.
- Blue areas show contiguous (unfragmented) files.
- White areas show free space on the volume. White areas on an NTFS volume might also represent the MFT zone (the space set aside to keep as much of the MFT as possible contiguous).
- Green areas show files that cannot be moved. The green areas usually represent the paging file, but on NTFS volumes, green areas might also represent space used by the NTFS change journal and the NTFS log file.

By comparing the estimated disk usage before defragmentation to the estimated disk usage after defragmentation, you can see the improvement in your volume. The defragmentation report provides further details on the fragmentation state of the volume. Analyze volumes regularly and defragment them when Disk Defragmenter recommends it.

**Updating the Master File Table**

On NTFS volumes, the MFT represents an index for every file on the volume and contains an entry for every file, including the MFT itself. With the introduction of Windows Server 2003, the MFT can be defragmented while the server is online; it is no longer excluded by Disk Defragmenter. Although Disk Defragmenter attempts to defragment the MFT after it becomes

fragmented, it cannot move the first 16 KB of the file, which contains the metadata for the file system. If space is available, the remainder of the MFT can be moved as one fragment to a location on the volume. The NTFS file system reserves one-eighth of the disk space for the MFT to use. This area of the disk is known as the MFT zone and it is set aside to keep as much of the MFT as possible contiguous.

The following steps are the processes by which Disk Defragmenter and file system defragment an NTFS volume and update the MFT.

1. Locate the fragments of each file throughout the disk.
2. Copy the fragments to contiguous locations on the disk.
3. Verify that the copy is an exact duplicate of the original file.
4. Update the MFT in NTFS with the new location of the beginning of the file.
5. Free up the space previously used by the file.

### Note

- When file fragments are moved to contiguous clusters, the files within a folder are not necessarily grouped in contiguous clusters by the defragmentation process. It should not be assumed that a logical grouping of files in a folder translates into a physical grouping of files on the volume.

#### Optimizing Startup

The Boot Optimize functionality uses Disk Defragmenter to move startup files into a contiguous location at the start of the volume. Disk Defragmenter moves the files in a specified order to a location that affords the earliest full fit on the volume for all of the files. This placement reduces the number and distance of disk head movements required to read startup files into memory, allowing the computer to boot more quickly.

# Disk Defragmenter Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Disk Defragmenter Tools and Settings**

**In this section**

- Disk Defragmenter Tools
- Disk Defragmenter Registry Entries
- Disk Defragmenter Group Policy Settings
- Disk Defragmenter WMI Classes
- Related Information

**Disk Defragmenter Tools**

The following tools are associated with Disk Defragmenter.

**Defrag.exe: Disk Defragmenter**

**Category**

Operating system tool

**Version compatibility**

All versions of the Disk Defragmenter command-line tool in the Windows Server 2003 family are identical.

Disk Defragmenter displays a blinking cursor while it is analyzing and defragmenting a volume. When Disk Defragmenter finishes analyzing a volume, it displays the analysis report. When Disk Defragmenter finishes defragmenting a volume, it displays the defragmentation report. After the process completes, Disk Defragmenter exits to the command prompt. The command-line version of Disk Defragmenter will analyze a volume only if the **-a** option is used.

For more information about Defrag.exe, see "Command Line References" in the Tools and Settings Collection.

**Dfrg.msc: Disk Defragmenter snap-in**

**Category**

Operating system tool

**Version compatibility**

All versions of the Disk Defragmenter snap-in in the Windows Server 2003 family are identical.

The Disk Defragmenter snap-in is divided into two main areas. The upper part lists the volumes on the local computer and allows you to select a volume to analyze and defragment. The lower part displays a graphical representation of the fragmentation on the volume. The colors indicate the condition of the volume:

- Red areas show fragmented files.
- Blue areas show contiguous (unfragmented) files.
- White areas show free space on the volume. White areas on an NTFS volume might also represent the MFT zone. For more information about the MFT zone, see "NTFS Technical Reference".
- Green areas show files that cannot be moved. The green areas usually represent the paging file, but on NTFS volumes, green areas might also represent space used by the NTFS change journal and the NTFS log file.

**Disk Defragmenter Registry Entries**

The following registry entries are associated with Disk Defragmenter.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It

is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

For more information about registry entries, see "Registry Reference" in the Tools and Settings Collection.

**BootOptimizeFunction**
The following registry entries are located under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg\BootOptimizeFunction.

**Enable**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg\BootOptimizeFunction

**Version**
Windows Server 2003

Accepted values for this entry are Y or N. If the entry is set to Y, Windows automatically optimizes the file location for boot optimization. This optimization occurs automatically if the system is idle for 10 minutes. Boot optimization improves startup time by locating startup files in contiguous clusters on the volume, reducing the movement of the disk head when reading the volume.

**LcnEndLocation**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg\BootOptimizeFunction

**Version**
Windows Server 2003

Stores the logical cluster number (LCN) that specifies the end location of the files moved by Disk Defragmenter for boot optimization.

**LcnStartLocation**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg\BootOptimizeFunction

**Version**
Windows Server 2003

Stores the LCN that specifies the starting location of the files moved by Disk Defragmenter for boot optimization.

**OptimizeComplete**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg\BootOptimizeFunction

**Version**
Windows Server 2003

Stores the value that indicates whether the optimize operation is complete.

**OptimizeError**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg\BootOptimizeFunction

**Version**
Windows Server 2003

Stores an error message if an error was encountered during the optimization process.

**Dfrg**
The following registry entries are located under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg.

**FreeSpaceErrorLevel**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg

**Version**
Windows Server 2003

Sets the percentage of volume capacity that must be free space for Disk Defragmenter to use as a sorting area. The default value is 15.

**PathName**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg

**Version**
Windows Server 2003

Stores the path to the resource DLL for defragmentation, usually *systemroot*\system32.

**ResourceDllName**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dfrg

**Version**
Windows Server 2003

Stores the name of the resource DLL for defragmentation, usually *systemroot*\system32\DfrgRes.dll.

**Disk Defragmenter Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with Disk Defragmenter.

### Group Policy Settings Associated with Disk Defragmenter

| Group Policy Setting | Description |
|---|---|
| Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment\Back up files and directories | Allows the Administrator to bypass access control list (ACL) check when obtaining the file handle during the defragmentation procedure. |

For more information about Group Policy settings, see "Group Policy Settings Reference" in the Tools and Settings Collection.

**Disk Defragmenter WMI Classes**
The following table lists and describes the WMI classes that are associated with Disk Defragmenter. The Win32_Volume class contains the Defrag method, used to defragment a FAT or NTFS volume.

### WMI Classes Associated with Disk Defragmenter

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_Volume | \root\cimv2 | Windows Server 2003 |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

# Disks and Volumes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Disks and Volumes**

The Microsoft Windows Server 2003 operating system offers two types of disks for storing information on your server: basic and dynamic. Basic and dynamic disks offer flexibility in the types of volumes you use to store data. In x86-based computers, basic disks are the default type of storage and use the same disk structures as those used by the Microsoft MS-DOS operating system and all previous versions of Microsoft Windows. Dynamic disks provide features that basic disks do not, such as the ability to create volumes that span multiple disks, including fault-tolerant volumes. Dynamic disks were introduced in Microsoft Windows 2000, and use a database to track information about dynamic volumes on the disk and about other dynamic disks in the computer. Because each dynamic disk in a computer stores a replica of the dynamic disk database, Windows Server 2003 can repair a corrupted database on one dynamic disk by using the database on another dynamic disk.

When using basic disks in x86-based computers, you are limited to creating four primary partitions per disk, or three primary partitions and one extended partition with unlimited logical drives. Primary partitions and logical drives on basic disks are known as basic volumes. All volumes on dynamic disks are known as dynamic volumes. All dynamic disks in a computer automatically belong to the same disk group.

The term partition style refers to the method that Windows Server 2003 uses to organize partitions on the disk. All x86-based computers use the partition style known as the master boot record (MBR). The MBR contains a partition table that describes where the partitions are located on the disk. Because MBR is the only partition style available on x86-based computers, it is used automatically and you do not need to choose this style.

Itanium-based computers running the 64-bit versions of Windows Server 2003 use a new partition style called the globally unique identifier (GUID) partition table (GPT). The GPT partition style supports partitions up to 2 terabytes and 128 partitions per disk.

**Note**

- You can use the 64-bit versions of Windows Server 2003 to *manage* MBR disks and GPT disks. However, you cannot *start* the 64-bit versions of Windows Server 2003 from an MBR disk.

After you install a new disk, you must choose a partition style and storage type to use on the disk. Your choices vary according to which operating system you are running and whether the computer is an x86-based computer or an Itanium-based computer. The following table lists the storage types and partition styles that are available for each version of Windows Server 2003.

**Storage Types and Partition Styles Available in Windows Server 2003**

| Operating System | Basic Volumes | Dynamic Simple, Spanned, and Striped Volumes | Dynamic Mirrored and RAID-5 Volumes | MBR Partition Style | GPT Partition Style |
|---|---|---|---|---|---|
| Windows Server 2003, Standard Edition | ● | ● | ● | ● | |
| Windows Server 2003, Enterprise Edition | ● | ● | ● | ● | |
| Windows Server 2003, Datacenter Edition | ● | ● | ● | ● | |
| Windows Server 2003, Web Edition | ● | ● | ● | ● | |
| The 64-bit version of Windows Server 2003, Enterprise Edition | ● | ● | ● | ● | ● |
| The 64-bit version of Windows Server 2003, Datacenter Edition | ● | ● | ● | ● | ● |

The introduction of GPT makes understanding the partition styles a bit more challenging, but most disk-related tasks are unchanged. You can still use basic disks and dynamic disks as you did in Windows 2000, and these storage types are available on disks that use either partition style.

The Disk Management snap-in differentiates between partition styles by referring to disks that use the master boot record as MBR disks and disks that use the GUID partition table as GPT disks. The following figure shows how Disk Management displays GPT and MBR disks in an Itanium-based computer.

**How Disk Management Displays GPT and MBR Disks on an Itanium-based Computer**

# Basic Disks and Volumes Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Basic disks and basic volumes are the storage types most often used with Microsoft Windows operating systems. The term basic disk refers to a disk that contains basic volumes, such as primary partitions and logical drives. The term basic volume refers to a partition on a basic disk. Basic disks, which are found in both x86-based and Itanium-based computers, provide a simple storage solution that can accommodate changing storage requirements. Basic disks support clustered disks, Institute of Electrical and Electronics Engineers (IEEE) 1394 disks, and universal serial bus (USB) removable drives.

In x86-based computers running Windows Server 2003, basic disks use the same Master Boot Record (MBR) partition style as the disks used by the Microsoft MS-DOS operating system and all previous versions of Microsoft Windows.

Itanium-based computers also support basic disks, but you can choose from two partition styles (MBR or GPT) for each basic disk. You can create up to 128 volumes on an MBR or GPT disk. The partition style determines the operating systems that can access the disk.

The following topics within the Basic Disks and Volumes Technical Reference describe how basic disks and volumes work, their architecture, and the tools you can use to manipulate them.

**In this subject**

# What Are Basic Disks and Volumes?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Basic Disk and Volume Scenarios

Basic disks and basic volumes are the storage types most often used with Windows operating systems. The term basic disk refers to a disk that contains basic volumes, such as primary partitions and logical drives. The term basic volume refers to a partition on a basic disk. Basic disks, which are found in both x86-based and Itanium-based computers, provide a simple, elegant storage solution that can accommodate changing storage requirements. Basic disks support clustered disks, Institute of Electrical and Electronics Engineers (IEEE) 1394 disks, and universal serial bus (USB) removable drives.

In x86-based computers running Windows Server 2003, basic disks use the same Master Boot Record (MBR) partition style as the disks used by Microsoft MS-DOS, and all previous versions of Microsoft Windows.

Itanium-based computers also support basic disks, but you can choose from two partition styles (MBR or GPT) for each basic disk. You can create up to 128 volumes on an MBR or GPT disk. The partition style determines the operating systems that can access the disk.

Before you can create simple volumes, spanned volumes, or volumes that use redundant array of independent disks (RAID) technology (striped volumes, mirrored volumes, and RAID-5 volumes) you must convert a basic disk to a dynamic disk.

Windows Server 2003 supports the following types of basic volumes:

- Primary partitions (master boot record (MBR) and GUID partition table (GPT) disks)
- Logical drives within extended partitions (MBR disks only)

The number of basic volumes you can create on a basic disk depends on the partition style of the disk:

- On MBR disks, you can create up to four primary partitions, or you can create up to three primary partitions and one extended partition. Within the extended partition, you can create up to 128 logical drives.
- On GPT disks, you can create up to 128 partitions. Because GPT disks do not limit you to four partitions, extended partitions and logical drives are not available on GPT disks.
- If you want to add more space to existing primary partitions and logical drives, you can extend the volume using the **extend** command in DiskPart.

**Basic Disk and Volume Scenarios**

Basic disks and volumes can be scaled to match your storage needs. Basic disks and volumes are commonly used in the following scenarios.

**Home or business desktop computer with one disk**

Most home and business users require a basic disk and one basic volume for storage, and do not require a computer with volumes that span multiple disks or that provide fault-tolerance. This is the best choice for those who require simplicity and ease of use.

**Home or business desktop computer with one disk and more than one volume**

If a home or small business user wants to upgrade the operating system without losing their personal data, they should store the operating system in a separate location from their personal data. In this scenario, a basic disk with two or more basic volumes is required. The user can install the operating system on the first volume, creating a boot volume or system volume, and use the second volume to store data. When a new version of the operating system is released, the user can reformat the boot or system volume and install the new operating system. Their personal data, located on the second volume, remains untouched.

**Business server with one disk and multiple volumes and logical drives**

If a small business operates a file server and requires multiple volumes for file sharing and file security, the system administrator can create up to three primary partitions and one extended partition with up to 128 logical drives. In this scenario, each of the partitions and logical drives receives its own drive letter so that each of these volumes can be individually secured to limit access to specific, authorized users.

For example, perhaps each department within this business requires its own volume. The business could create individual volumes and grant permissions to members of those departments. Data shared by members of human resources, for example, could be kept separate from the data used by members of the accounting, sales, or marketing departments.

As storage needs and the importance of the data stored on disk increase, the logical next step for this business would be to add additional disks to the server, convert the disks to dynamic, and then create fault-tolerant mirrored- or RAID-5 volumes.

# How Basic Disks and Volumes Work
