- Basic Disks and Volumes Architecture
- Basic Disk and Volume Interfaces
- Basic Disks and Volumes Physical Structure
- Disk Sectors on GPT Disks
- Basic Disks and Volumes Processes and Interactions

Basic disks and basic volumes are the storage types most often used with Windows operating systems. The term basic disk refers to a disk that contains basic volumes, such as primary partitions and logical drives. The term basic volume refers to a partition on a basic disk. Basic disks, which are found in both x86-based and Itanium-based computers, provide a simple, elegant storage solution that can accommodate changing storage requirements. Basic disks support clustered disks, Institute of Electrical and Electronics Engineers (IEEE) 1394 disks, and universal serial bus (USB) removable drives. Before you can use a basic disk, it must have a disk signature and be formatted with either the File Allocation Table (FAT) or NT file system (NTFS) file systems.

An optimal environment for basic disks and volumes is defined as follows:

- Windows Server 2003 operating system is installed and functioning properly.
- The basic disk is functioning properly and displays the Healthy status in the Disk Management snap-in.

The following sections provide an in-depth view of how basic disks and volumes work in an optimal environment.

**Basic Disks and Volumes Architecture**

Basic disks and volumes rely on the Logical Disk Manager (LDM) and Virtual Disk Service (VDS) and their associated components. These components enable you to perform tasks such as converting basic disks into dynamic disks, and creating fault-tolerant volumes. The following diagram shows the LDM and VDS components.

**Logical Disk Manager and Virtual Disk Service Components**

The following table lists the LDM and VDS components and provides a brief description of each.

**Logical Disk Manager and Virtual Disk Service Components**

| Component | Description |
|---|---|
| Disk Management snap-in:<br><br>Dmdlgs.dll<br><br>Dmdskmgr.dll<br><br>Dmview.ocx<br><br>Diskmgmt.msc | Binaries that comprise the Disk Management snap-in user interface. |
| DiskPart command line utility:<br><br>Diskpart.exe | A scriptable alternative to the Disk Management snap-in. |
| Mount Manager command line:<br><br>Mountvol.exe | A command line utility that can be used to create, delete, or list volume mount points |

| | |
|---|---|
| Virtual Disk Service:<br><br>Vds.exe<br><br>Vdsutil.dll | A program used to configure and maintain volume and disk storage. |
| Virtual Disk Service provider for basic disks and volumes:<br><br>Vdsbas.dll | The Virtual Disk Service calls into the basic provider when configuring basic disks and volumes. |
| Virtual Disk Service provider for dynamic disks and volumes:<br><br>Vdsdyndr.dll | The Virtual Disk Service calls into the dynamic provider when configuring dynamic disks and volumes. |
| Dmboot.sys<br><br>Dmconfig.dll<br><br>Dmintf.dll<br><br>Dmio.sys<br><br>Dmload.sys<br><br>Dmremote.exe<br><br>Dmutil.dll | Drivers and user mode components used to configure dynamic disks and volumes and perform I/O. |
| Logical Disk Administrator service:<br><br>Dmadmin.exe | The VDS provider for dynamic disks and volumes uses the interfaces exposed by this service to configure dynamic disks. |
| Logical Disk Service:<br><br>Dmserver.dll | A service that detects and monitors new hard disk drives and sends disk volume information to Logical Disk Manager Administrative Service for configuration. If this service is stopped, dynamic disk status and configuration information might become outdated. If this service is disabled, any services that explicitly depend on it will fail to start. |
| Basic disk I/O driver:<br><br>Ftdisk.sys | A driver that manages all I/O for basic disks. Other system components, such as mount point manager, call into this driver to get information about basic disk volumes. |
| Mount point manager driver:<br><br>Mountmgr.sys | A binary that tracks drive letters, folder mount paths and other mount points for volumes. Assigns a unique volume mount point of the form \??\Volume<*GUID*> to each volume, in addition to any drive letters or folder paths that have been assigned by the user. Ensures that a volume will get the same drive letter each time the computer boots, and also tries to retain a volume's drive letter when the volume's disk is moved to a new computer. |
| Partition manager:<br><br>Partmgr.sys | A filter driver that sits on top of the disk driver. All disk driver requests pass through the partition manager driver. This driver creates partition devices and notifies the volume managers of partition arrivals and removals. Exposes IOCTLs that return information about partitions to other components, and allow partition configuration. |

**Basic Disk and Volume Interfaces**

Basic disks and volumes can be managed using the Disk Management snap-in. The following table lists the control codes used

by the Disk Management snap-in when managing disks and volumes.

For more information about the interfaces used by Disk Management when managing disks and volumes, see *Disk Management Reference* on MSDN.

**Disk Management Control Codes**

| Control Code | Operation |
|---|---|
| IOCTL_DISK_CREATE_DISK | Initializes the specified disk and disk partition table using the specified information. |
| IOCTL_DISK_DELETE_DRIVE_LAYOUT | Removes the boot signature from the master boot record. |
| IOCTL_DISK_GET_DRIVE_GEOMETRY_EX | Retrieves information about the physical disk's geometry. |
| IOCTL_DISK_GET_DRIVE_LAYOUT_EX | Retrieves information about the number of partitions on a disk and the features of each partition. |
| IOCTL_DISK_GET_LENGTH_INFO | Retrieves the length of the specified disk, volume, or partition. |
| IOCTL_DISK_GET_PARTITION_INFO_EX | Retrieves partition information for AT and EFI (Extensible Firmware Interface) partitions. |
| IOCTL_DISK_GROW_PARTITION | Enlarges the specified partition. |
| IOCTL_DISK_SET_DRIVE_LAYOUT_EX | Partitions a disk. |
| IOCTL_DISK_SET_PARTITION_INFO_EX | Sets the disk partition type. |

For more information about the Disk Management control codes, see *Disk Management Control Codes* on MSDN.

**Basic Disks and Volumes Physical Structure**

Basic disks can use either the master boot record (MBR) or GUID partition table (GPT) partitioning style. x86-based computers use disks with the MBR partitioning style and Itanium-based computers use disks with the GPT partitioning style.

The following figure compares a basic MBR disk to a basic GPT disk.

**Comparison of MBR and GPT Disks**

A comparison of MBR and GPT disks is listed in the following table.

**Comparison of MBR and GPT Disks**

| Characteristic | MBR Disk (x86-based Computer) | GPT Disk (Itanium-based Computer) |
|---|---|---|
| Number of partitions on basic disks | Supports up to:<br>• Four primary partitions per disk, or<br>• Three primary partitions and an extended partition with up to 128 logical drives | Supports up to 128 partitions |
| Compatible operating systems | Can be read by:<br>• Microsoft MS-DOS<br>• Microsoft Windows 95<br>• Microsoft Windows 98<br>• Microsoft Windows Millennium Edition<br>• Windows NT, all versions<br>• Windows 2000, all versions<br>• Windows XP<br>• Windows Server 2003, all versions for x86-based computers and Itanium-based computers | Can be read by:<br>• Windows XP 64-Bit Edition<br>• The 64-bit version of Windows Server 2003, Enterprise Edition<br>• The 64-bit version of Windows Server 2003, Datacenter Edition |
| Maximum size of basic volumes | 2 terabytes | 2 terabytes |
| Partition tables (copies) | Contains one copy of the partition table. | Contains primary and backup partition tables for redundancy and checksum fields for improved partition structure integrity. |
| Locations for data storage | Stores data in partitions and in unpartitioned space. Although most data is stored within partitions, some data might be stored in hidden or unpartitioned sectors created by OEMs or other operating systems. | Stores user and program data in partitions that are visible to the user. Stores data that is critical to platform operation in partitions that the 64-bit versions of Windows Server 2003 recognize but do not make visible to the user. Does not store data in unpartitioned space. |
| Troubleshooting methods | Uses the same methods and tools used in Windows 2000. | Uses tools designed for GPT disks. (Do not use MBR troubleshooting tools on GPT disks.) |

**Master Boot Record on Basic Disks**

The master boot record (MBR), the most important data structure on the disk, is created when the disk is partitioned. The MBR contains a small amount of executable code called the master boot code, the disk signature, and the partition table for the disk. At the end of the MBR is a 2-byte structure called a signature word or end of sector marker, which is always set to 0x55AA. A signature word also marks the end of an extended boot record (EBR) and the boot sector.

The disk signature, a unique number at offset 0x01B8, identifies the disk to the operating system. Windows Server 2003 uses the disk signature as an index to store and retrieve disk information, such as drive letters, in the registry.

**Master boot code**

The master boot code performs the following activities:

1. Scans the partition table for the active partition.
2. Finds the starting sector of the active partition.
3. Loads a copy of the boot sector from the active partition into memory.
4. Transfers control to the executable code in the boot sector.

If the master boot code cannot complete these functions, the system displays a message similar to one of the following:

```
Invalid partition table.
Error loading operating system.
Missing operating system.
```

**Note**

- Floppy disks and removable disks, such as Iomega Zip disks, do not contain an MBR. The first sector on these disks is the boot sector. Although every hard disk contains an MBR, the master boot code is used only if the disk contains the active primary partition.

**Partition Table on Basic Disks**

The partition table, which is a 64-byte data structure that is used to identify the type and location of partitions on a hard disk, conforms to a standard layout, independent of the operating system. Each partition table entry is 16 bytes long, with a maximum of four entries. Each entry starts at a predetermined offset from the beginning of the sector, as follows:

- Partition 1 0x01BE (446)
- Partition 2 0x01CE (462)
- Partition 3 0x01DE (478)
- Partition 4 0x01EE (494)

The following example shows a partial printout of an MBR revealing the partition table from a computer with three partitions. When there are fewer than four partitions on a disk, the remaining partition table fields are set to the value 0.

```
000001B0:                                                 80 01                  ..
000001C0: 01 00 07 FE BF 09 3F 00 - 00 00 4B F5 7F 00 00 00   ......?...K....
000001D0: 81 0A 07 FE FF FF 8A F5 - 7F 00 3D 26 9C 00 00 00   .........=&....
000001E0: C1 FF 05 FE FF FF C7 1B - 1C 01 D6 96 92 00 00 00   ................
000001F0: 00 00 00 00 00 00 00 00 - 00 00 00 00 00 00         ..............
```

The following figure provides an example of how to interpret the sector printout of the partition table. The Boot Indicator, System ID, Relative Sectors, and Total Sectors values correspond to the values described in the table titled "Partition Table Fields" later in this section.

**Interpreting Data in the Partition Table**

```
                    System ID
                                Relative Sectors
                                                Total Sectors
                                                              Boot Indicator
000001B0:                                                     80 01                  ..
000001C0: 01 00 07 FE BF 09 3F 00  - 00 00 4B F5 7F 00 00 00   ......?...K.▯...
000001D0: 81 0A 07 FE FF FF 8A F5  - 7F 00 3D 26 9C 00 00 00   ........▯.=&....
000001E0: C1 FF 05 FE FF FF C7 1B  - 1C 01 D6 96 92 00 00 00   ................
000001F0: 00 00 00 00 00 00 00 00  - 00 00 00 00 00 00         ..............
```

The following table describes the fields in each entry in the partition table. The Sample Values correspond to the first partition table entry shown in the previous example. The Byte Offset values correspond to the addresses of the first partition table entry. There are three additional entries whose values can be calculated by adding 10h to the byte offset value specific for each additional partition table entry (for example, add 20h for partition table entry 3 and 30h for partition table entry 4).

The following table and sections following the table provide additional detail about these fields.

**Partition Table Fields**

| Byte Offset | Field Length | Sample Value1 | Field Name and Definition |
|---|---|---|---|
| 0x01BE | 1 byte | 80 | **Boot Indicator**. Indicates whether the volume is the active partition. Legal values include:<br>• 00. Do not use for booting.<br>• 80. Active partition. |
| 0x01BF | 1 byte | 01 | **Starting Head**. |
| 0x01C0 | 6 bits | 01 *2 | **Starting Sector**. Only bits 0–5 are used. The upper two bits, 6 and 7, are used by the Starting Cylinder field. |
| 0x01C1 | 10 bits | 00 * | **Starting Cylinder**. Uses 1 byte in addition to the upper 2 bits from the Starting Sector field to make up the cylinder value. The Starting Cylinder is a 10-bit number that has a maximum value of 1023. |
| 0x01C2 | 1 byte | 07 | **System ID**. Defines the volume type. See the table titled "System ID Values" later in this section for sample values. |
| 0x01C3 | 1 byte | FE | **Ending Head**. |
| 0x01C4 | 6 bits | BF * | **Ending Sector**. Only bits 0–5 are used. The upper two bits, 6 and 7, are used by the Ending Cylinder field. |
| 0x01C5 | 10 bits | 09 * | **Ending Cylinder**. Uses 1 byte in addition to the upper 2 bits from the Ending Sector field to make up the cylinder value. The Ending Cylinder is a 10-bit number, with a maximum value of 1023. |
| 0x01C6 | 4 bytes | 3F 00 00 00 | **Relative Sectors**. The offset from the beginning of the disk to the beginning of the volume, counting by sectors. |
| 0x01CA | 4 bytes | 4B F5 7F 00 | **Total Sectors**. The total number of sectors in the volume. |

1. Numbers larger than one byte are stored in little endian format, or reverse-byte ordering. Little endian format is a method of storing a number so that the least significant byte appears first in the hexadecimal number notation. For example, the sample value for the Relative Sectors field in the previous table, 3F 00 00 00, is a little endian representation of 0x0000003F. The decimal equivalent of this little endian number is 63.

2. Sample values marked with an asterisk (*) do not accurately represent the value of the fields, because the fields are either 6 bits or 10 bits and the data is recorded in bytes.

**Boot Indicator Field**

The first element of the partition table, the Boot Indicator field, indicates whether the volume is the active partition. Only one primary partition on the disk can have this field set. See the previous table for the acceptable values.

It is possible to have different operating systems and different file systems on different volumes. By using disk configuration tools, such as the Windows Server 2003-based Disk Management and DiskPart, or the MS-DOS-based Fdisk, to designate a primary partition as active, the Boot Indicator field for that partition is set in the partition table.

**System ID Field**

Another element of the partition table is the System ID field. It defines which file system, such as FAT16, FAT32, or NTFS, was used to format the volume. The System ID field also identifies an extended partition, if one is defined. Windows Server 2003 uses the System ID field to determine which file system device drivers to load during startup. The following table identifies the values for the System ID field.

**System ID Values**

| Partition Type | ID Value |
|---|---|
| 0x01 | FAT12 primary partition or logical drive (fewer than 32,680 sectors in the volume) |

| | |
|---|---|
| 0x04 | FAT16 partition or logical drive (32,680–65,535 sectors or 16 MB–33 MB) |
| 0x05 | Extended partition |
| 0x06 | BIGDOS FAT16 partition or logical drive (33 MB–4 GB) |
| 0x07 | Installable File System (NTFS partition or logical drive) |
| 0x0B | FAT32 partition or logical drive |
| 0x0C | FAT32 partition or logical drive using BIOS INT 13h extensions |
| 0x0E | BIGDOS FAT16 partition or logical drive using BIOS INT 13h extensions |
| 0x0F | Extended partition using BIOS INT 13h extensions |
| 0x12 | EISA partition or OEM partition |
| 0x42 | Dynamic volume |
| 0x84 | Power management hibernation partition |
| 0x86 | Multidisk FAT16 volume created by using Windows NT 4.0 |
| 0x87 | Multidisk NTFS volume created by using Windows NT 4.0 |
| 0xA0 | Laptop hibernation partition |
| 0xDE | Dell OEM partition |
| 0xFE | IBM OEM partition |
| 0xEE | GPT partition |
| 0xEF | EFI System partition on an MBR disk |

Windows Server 2003 does not support multidisk volumes that are created by using Windows NT 4.0 or earlier, and that use System ID values 0x86, 0x87, 0x8B, or 0x8C.

Before you upgrade from Windows NT Server 4.0 to Windows Server 2003, you must first back up and then delete all multidisk volumes. After you complete the upgrade, create dynamic volumes and restore the data. If you do not delete the multidisk volumes before beginning Setup, you must use the Ftonline tool, which is part of Windows Support Tools, to access the volume after Setup completes.

If you are upgrading from Windows 2000 to Windows Server 2003, you must convert the multidisk volumes to dynamic before you begin Setup, or Setup does not continue.

MS-DOS can only access volumes that have a System ID value of 0x01, 0x04, 0x05, or 0x06. However, you can delete volumes that have the other values listed in the table titled "System ID Values" earlier in this section by using Disk Management, DiskPart, or the MS-DOS tool Fdisk.

**Starting and Ending Cylinder, Head, and Sector Fields**

The Starting and Ending Cylinder, Head, and Sector fields (collectively known as the CHS fields) are additional elements of the partition table. These fields are essential for starting the computer. The master boot code uses these fields to find and load the boot sector of the active partition. The Starting CHS fields for non-active partitions point to the boot sectors of the remaining primary partitions and the extended boot record (EBR) of the first logical drive in the extended partition, as shown in the figure titled "Interpreting Data in the Partition Table" earlier in this section.

Knowing the starting sector of an extended partition is very important for low-level disk troubleshooting. If your disk fails, you need to work with the partition starting point (among other factors) to retrieve stored data.

The Ending Cylinder field in the partition table is 10 bits long, which limits the number of cylinders that can be described in the partition table to a range of 0 through 1,023. The Starting Head and Ending Head fields are each one byte long, which limits the field range from 0 through 255. The Starting Sector and Ending Sector fields are each six bits long, which limits the range of these fields from 0 through 63. However, the enumeration of sectors starts at 1 (not 0, as for other fields), so the maximum number of sectors per track is 63.

Because Windows Server 2003 supports hard disks that are low-level formatted with a standard 512-byte sector, the maximum disk capacity described by the partition table is calculated as follows:

Maximum capacity = sector size cylinders (10 bits) heads (8 bits) sectors per track (6 bits).

Using the maximum possible values yields:

512 1024 256 63 (or 512 x $2^{24}$) = 8,455,716,864 bytes or 7.8 gigabytes (GB).

Windows Server 2003 and other Windows-based operating systems that support BIOS INT 13h extensions can access partitions that exceed the first 7.8 GB of the disk by ignoring the Starting and Ending CHS fields in favor of the Relative Sectors and Total Sectors fields.

Windows 2000 and Windows Server 2003 ignore the Starting and Ending CHS fields regardless of whether the partition exceeds the first 7.8 GB of the disk. However, Windows Server 2003 must place the appropriate values in the Starting and Ending CHS fields because Windows 95, Windows 98, and Windows Millennium Edition (which all support BIOS INT 13h extensions) use the Starting and Ending CHS fields if the partition does not exceed the first 7.8 GB of the disk. These fields are also required to maintain compatibility with the BIOS INT 13h for startup.

MS-DOS and other Windows operating systems that do not support BIOS INT 13h extensions ignore partitions that exceed the 7.8 GB boundary because these partitions use a System ID that is recognized only by operating systems that support BIOS INT 13h extensions.

Both the operating system and the computer must support BIOS INT 13h extensions if you want to create partitions that exceed the first 7.8 GB of the disk.

**Relative Sectors and Total Sectors Fields**

The Relative Sectors field represents the offset from the beginning of the disk to the beginning of the volume, counting by sectors, for the volume described by the partition table entry. The Total Sectors field represents the total number of sectors in the volume.

Using the Relative Sectors and Total Sectors fields (resulting in a 32-bit number) provides eight more bits than the CHS scheme to represent the total number of sectors. This allows you to create partitions that contain up to 232 sectors. With a standard sector size of 512 bytes, the 32 bits used to represent the Relative Sectors and Total Sectors fields translates into a maximum partition size of 2 terabytes (or 2,199,023,255,552 bytes).

**Note**

- For more information about the maximum partition size that each file system supports, see "NTFS Technical Reference."

The following figure shows the MBR, partition table, and boot sectors on a basic disk with four partitions. The definitions of the fields in the partition table and the extended partition tables are the same.

**Detail of a Basic Disk with Four Partitions**

**Extended Boot Record on Basic Disks**

An extended boot record (EBR), which consists of an extended partition table and the signature word for the sector, exists for each logical drive in the extended partition. It contains the only information on the first side of the first cylinder of each logical drive in the extended partition. The boot sector in a logical drive is usually located at either Relative Sector 32 or 63. However, if there is no extended partition on a disk, there are no EBRs and no logical drives.

The first entry in an extended partition table for the first logical drive points to its own boot sector. The second entry points to the EBR of the next logical drive. If no further logical drives exist, the second entry is not used and is recorded as a series of zeros. If there are additional logical drives, the first entry of the extended partition table for the second logical drive points to its own boot sector. The second entry of the extended partition table for the second logical drive points to the EBR of the next logical drive. The third and fourth entries of an extended partition table are never used.

As shown in the following figure, the EBRs of the logical drives in the extended partition are a linked list. The figure shows three logical drives on an extended partition, illustrating the difference in extended partition tables between preceding logical drives and the last logical drive.

**Detail of an Extended Partition on a Basic Disk**

With the exception of the last logical drive on the extended partition, the format of the extended partition table, which is described in the following table, is repeated for each logical drive: the first entry identifies the logical drive's own boot sector and the second entry identifies the next logical drive's EBR. The extended partition table for the last logical drive has only its own partition entry listed. The second through fourth entries of the last extended partition table are not used.

**Contents of Extended Partition Table Entries**

| Entry | Contents |
|---|---|
| First | Information about the current logical drive in the extended partition, including the starting address for the boot sector preceding the data. |
| Second | Information about the next logical drive in the extended partition, including the address of the sector that contains the EBR for the next logical drive. If no additional logical drives exist, this field is not used. |
| Third | Not used. |
| Fourth | Not used. |

The fields in each entry of the extended partition table are identical to the MBR partition table entries. For more information about partition table fields, see the table titled "Partition Table Fields" earlier in this section.

The Relative Sectors field in an extended partition table entry shows the number of bytes that are offset from the beginning of the extended partition to the first sector in the logical drive. The number in the Total Sectors field refers to the number of sectors that make up the logical drive. The value of the Total Sectors field equals the number of sectors from the boot sector defined by theextended partition table entry to the end of the logical drive.

Because of the importance of the MBR and EBR sectors, it is recommended that you run disk-scanning tools regularly and that you regularly back up all your data files to protect against losing access to a volume or an entire disk.

**Disk Sectors on GPT Disks**

GUID partition table (GPT) disks use primary and backup partition structures to provide redundancy. These structures are located at the beginning and the end of the disk. GPT identifies these structures by their logical block address (LBA) rather than by their relative sectors. Using this scheme, sectors on a disk are numbered from 0 to *n*-1, where *n* is the number of sectors on the disk.

As shown in the following figure, the first structure on a GPT disk is the Protective MBR in LBA 0, followed by the primary GPT header in LBA 1. The GPT header is followed by the primary GUID partition entry array, which includes a partition entry for each partition on the disk.

Partitions on the disk are located between the primary and backup GUID partition entry arrays. The partitions must be placed within the first usable and last usable LBAs, as specified in the GPT partition header.

**Partition Structures on a GPT Disk**

**Protective MBR**

The Extensible Firmware Interface (EFI) specification requires that LBA 0 be reserved for compatibility code and a Protective MBR. The Protective MBR has the same format as an existing MBR, and it contains one partition entry with a System ID value of 0xEE. This entry reserves the entire space of the disk, including the space used by the GPT header, as a single partition. The Protective MBR is included to prevent disk utilities that were designed for MBR disks from interpreting the disk as having available space and overwriting GPT partitions. The Protective MBR is ignored by EFI; no MBR code is run.

The following example shows a partial printout of a Protective MBR.

```
000001B0: 00 00 00 00 00 00 00 00 - 04 06 04 06 00 00 00 00   ................
000001C0: 02 00 EE FF FF FF 01 00 - 00 00 FF FF FF FF 00 00   ................
000001D0: 00 00 00 00 00 00 00 00 - 00 00 00 00 00 00 00 00   ................
000001E0: 00 00 00 00 00 00 00 00 - 00 00 00 00 00 00 00 00   ................
000001F0: 00 00 00 00 00 00 00 00 - 00 00 00 00 00 00 55 AA   ..............U.
```

The following table describes the fields in each entry in the Protective MBR.

**Protective MBR in GPT Disks**

| Byte Offset | Field Length | Sample Value1 | Field Name and Definition |
|---|---|---|---|
| 0x01BE | 1 byte | 00 | **Boot Indicator**. Must be set to 00 to indicate that this partition cannot be booted. |
| 0x01BF | 1 byte | 00 | **Starting Head**. Matches the Starting LBA of the single partition. |
| 0x01C0 | 1 byte | 02 | **Starting Sector**. Matches the Starting LBA of the single partition. |
| 0x01C1 | 1 byte | 00 | **Starting Cylinder**. Matches the Starting LBA of the GPT partition. |
| 0x01C2 | 1 byte | EE | **System ID**. Must be EE to specify that the single partition is a GPT partition. If you move a GPT disk to a computer running Windows 2000 with Service Pack 1 or greater or Windows Server 2003, the partition is displayed as a **GPT Protective Partition** and cannot be deleted. |

| | | | |
|---|---|---|---|
| 0x01C3 | 1 byte | FF | **Ending Head**. Matches the Ending LBA of the single partition. If the Ending LBA is too large to be represented here, this field is set to FF. |
| 0x01C4 | 1 byte | FF | **Ending Sector**. Matches the Ending LBA of the single partition. If the Ending LBA is too large to be represented here, this field is set to FF. |
| 0x01C5 | 1 byte | FF | **Ending Cylinder**. Matches the Ending LBA of the single partition. If the Ending LBA is too large to be represented here, this field is set to FF. |
| 0x01C6 | 4 bytes | 01 00 00 00 | **Starting LBA**. Always set to 1. The Starting LBA begins at the GPT partition table header, which is located at LBA 1. |
| 0x01CA | 4 bytes | FF FF FF FF | **Size in LBA**. The size of the single partition. Must be set to FF FF FF FF if this value is too large to be represented here. |

1. Numbers larger than one byte are stored in little endian format, or reverse-byte ordering. Little endian format is a method of storing a number so that the least significant byte appears first in the hexadecimal number notation.

**GPT Partition Table Header**

The GPT header defines the range of logical block addresses that are usable by partition entries. The GPT header also defines its location on the disk, its GUID, and a 32-bit cyclic redundancy check (CRC32) checksum that is used to verify the integrity of the GPT header.

GPT disks use a primary and a backup GUID partition table (GPT) header:

- The primary GPT header is located at LBA 1, directly after the Protective MBR.
- The backup GPT header is located in the last sector of the disk. No data follows the backup GPT header.

EFI verifies the integrity of the GPT headers by using a CRC32 checksum, which is a calculated value that is used to test data for the presence of errors. If the primary GPT header is corrupted, the system checks the backup GPT header checksum. If the backup checksum is valid, then the backup GPT header is used to restore the primary GPT header. This restoration process works in reverse if the primary GPT header is valid but the backup GPT header is corrupted. If both the primary and backup GPT headers are corrupted, then the 64-bit versions of Windows Server 2003 cannot access the disk.

**Note**

- Do not use disk editing tools such as DiskProbe to make changes to GPT disks because any change that you make renders the checksums invalid, which might cause the disk to become inaccessible. To make changes to GPT disks, do either of the following:
- Use Diskpart.efi in the firmware environment.
- Use Diskpart.exe or Disk Management in the 64-bit versions of Windows Server 2003.

The following example shows a partial printout of a GPT header.

```
00000000: 45 46 49 20 50 41 52 54 - 00 00 01 00 5C 00 00 00   EFI PART....\...
00000010: 27 6D 9F C9 00 00 00 00 - 01 00 00 00 00 00 00 00   'm..............
00000020: 37 C8 11 01 00 00 00 00 - 22 00 00 00 00 00 00 00   7.......".......
00000030: 17 C8 11 01 00 00 00 00 - 00 A2 DA 98 9F 79 C0 01   .............y..
00000040: A1 F4 04 62 2F D5 EC 6D - 02 00 00 00 00 00 00 00   ...b/..m........
00000050: 80 00 00 00 80 00 00 00 - 27 C3 F3 85 00 00 00 00   ........'.......
00000060: 00 00 00 00 00 00 00 00 - 00 00 00 00 00 00 00 00   ................
```

The following table describes the fields in the GPT header.

**GUID Partition Table Header**

| Byte Offset | Field Length | Sample Value1 | Field Name and Definition |
|---|---|---|---|

| | | | |
|---|---|---|---|
| 0x00 | 8 bytes | 45 46 49 20 50 41 52 54 | **Signature**. Used to identify all EFI-compatible GPT headers. The value must always be 45 46 49 20 50 41 52 54. |
| 0x08 | 4 bytes | 00 00 01 00 | **Revision**. The revision number of the EFI specification to which the GPT header complies. For version 1.0, the value is 00 00 01 00. |
| 0x0C | 4 bytes | 5C 00 00 00 | **Header Size**. The size, in bytes, of the GPT header. The size is always 5C 00 00 00 or 92 bytes. The remaining bytes in LBA 1 are reserved. |
| 0x10 | 4 bytes | 27 6D 9F C9 | **CRC32 Checksum**. Used to verify the integrity of the GPT header. The 32-bit cyclic redundancy check (CRC) algorithm is used to perform this calculation. |
| 0x14 | 4 bytes | 00 00 00 00 | **Reserved**. Must be 0. |
| 0x18 | 8 bytes | 01 00 00 00 00 00 00 00 | **Primary LBA**. The LBA that contains the primary GPT header. The value is always equal to LBA 1. |
| 0x20 | 8 bytes | 37 C8 11 01 00 00 00 00 | **Backup LBA**. The LBA address of the backup GPT header. This value is always equal to the last LBA on the disk. |
| 0x28 | 8 bytes | 22 00 00 00 00 00 00 00 | **First Usable LBA**. The first usable LBA that can be contained in a GUID partition entry. In other words, the first partition begins at this LBA. In the 64-bit versions of Windows Server 2003, this number is always LBA 34. |
| 0x30 | 8 bytes | 17 C8 11 01 00 00 00 00 | **Last Usable LBA**. The last usable LBA that can be contained in a GUID partition entry. |
| 0x38 | 16 bytes | 00 A2 DA 98 9F 79 C0 01 A1 F4 04 62 2F D5 EC 6D | **Disk GUID**. A unique number that identifies the partition table header and the disk itself. |
| 0x48 | 8 bytes | 02 00 00 00 00 00 00 00 | **Partition Entry LBA**. The starting LBA of the GUID partition entry array. This number is always LBA 2. |
| 0x50 | 4 bytes | 80 00 00 00 | **Number of Partition Entries**. The maximum number of partition entries that can be contained in the GUID partition entry array. In the 64-bit versions of Windows Server 2003, this number is equal to 128. |
| 0x54 | 4 bytes | 80 00 00 00 | **Size of Partition Entry**. The size, in bytes, of each partition entry in the GUID partition entry array. Each partition entry is 128 bytes. |
| 0x58 | 4 bytes | 27 C3 F3 85 | **Partition Entry Array CRC32**. Used to verify the integrity of the GUID partition entry array. The 32-bit CRC algorithm is used to perform this calculation. |
| 0x5C | 420 bytes | | **Reserved**. Must be 0. |

1. Numbers larger than one byte are stored in little endian format, or reverse-byte ordering. Little endian format is a method of storing a number so that the least significant byte appears first in the hexadecimal number notation.

**GUID Partition Entry Array**

Similar to the partition table on MBR disks, the GUID partition entry array contains partition entries that represent each partition on the disk. The 64-bit versions of Windows Server 2003 create an array that is 16,384 bytes, so the first usable block must start at an LBA greater than or equal to 34. (LBA 0 contains the protective MBR; LBA 1 contains the GPT header; and LBAs 2 through 33 are used by the GUID partition entry array.)

Each GPT disk contains two GUID partition entry arrays:

- The primary GUID partition entry array is located after the GUID partition table header and ends before the first usable LBA.

- The backup GUID partition entry array is located after the last usable LBA and ends before the backup GUID partition table header.

A CRC32 checksum of the GUID partition entry array is stored in the GPT header. When a new partition is added, this checksum is updated in the primary and backup GUID partition entries, and then the GPT header size checksum is updated.

**GUID Partition Entry**

A GUID partition entry defines a single partition and is 128 bytes long. Because the 64-bit versions of Windows Server 2003 create a GUID partition entry array that has 16,384 bytes, you can have a maximum of 128 partitions on a basic GPT disk.

Each GUID partition entry begins with a partition type GUID. The 16-byte partition type GUID, which is similar to a System ID in the partition table of an MBR disk, identifies the type of data that the partition contains and identifies how the partition is used. The 64-bit versions of Windows Server 2003 recognize only the partition type GUIDs described in the following table, and do not mount any other type of partition. However, original equipment manufacturers (OEMs) and independent software vendors (ISVs), as well as other operating systems might define additional partition type GUIDs.

**Partition Type GUIDs**

| Partition Type | GUID Value |
|---|---|
| Unused entry | {00000000–0000–0000–0000–000000000000} |
| EFI System partition | {28732AC1–1FF8–D211–BA4B–00A0C93EC93B} |
| Microsoft Reserved partition | {16E3C9E3–5C0B–B84D–817D–F92DF00215AE} |
| Primary partition on a basic disk | {A2A0D0EB–E5B9–3344–87C0–68B6B72699C7} |
| LDM Metadata partition on a dynamic disk | {AAC80858–8F7E–E042–85D2–E1E90434CFB3} |
| LDM Data partition on a dynamic disk | {A0609BAF–3114–624F–BC68–3311714A69AD} |

The following example illustrates a partial hexadecimal printout of the GUID partition entry array on a basic GPT disk. This printout shows three partition entries: an EFI System partition, a Microsoft Reserved partition, and a primary partition. The partition type GUIDs are bold and match the entries in the previous table.

```

```

The following table illustrates the layout of a GUID partition entry. The sample values correspond to the EFI System partition entry in the preceding example.

**GUID Partition Entry**

| Byte Offset | Field Length | Sample Value1 | Field Name and Definition |
|---|---|---|---|

| | | | |
|---|---|---|---|
| 0x00 | 16 bytes | 28 73 2A C1 1F F8 D2 11 BA 4B 00 A0 C9 3E C9 3B | **Partition Type GUID**. Identifies the type of partition. The partition type GUID in this example identifies Microsoft Reserved partitions. For a description of partition type GUIDs, see the table titled Partition Type GUIDs earlier in this section. |
| 0x 10 | 16 bytes | C0 94 77 FC 43 86 C0 01 92 E0 3C 77 2E 43 AC 40 | **Unique Partition GUID**. A unique ID created for each partition entry. |
| 0x 20 | 8 bytes | 3F 00 00 00 00 00 00 00 | **Starting LBA**. The starting LBA of the partition that is defined by this partition entry. |
| 0x 28 | 8 bytes | CC 2F 03 00 00 00 00 00 | **Ending LBA**. The ending LBA of the partition that is defined by this partition entry. |
| 0x 30 | 8 bytes | 00 00 00 00 00 00 00 00 | **Attribute Bits**. Describe how the partition is used. For a description of the attribute used by the 64-bit versions of Windows Server 2003, see the table titled "GUID Partition Entry Attributes Used by the 64-Bit Editions of Windows on Itanium-based Computers" later in this section. |
| 0x 38 | 72 bytes | EFI system partition | **Partition Name**. A 36-character Unicode string that can be used to name the partition. |

1. Numbers larger than one byte are stored in little endian format, or reverse-byte ordering. Little endian format is a method of storing a number so that the least significant byte appears first in the hexadecimal number notation.

#### GUID Partition Entry Attributes

GUID partition entry attributes are descriptors for how a partition is used. The attributes are specified within a 64-bit value, so EFI supports up to 64 different attributes. The 64-bit versions of Windows Server 2003 use two attributes as described in the following table.

**GUID Partition Entry Attributes Used by the 64-Bit Editions of Windows on Itanium-based Computers**

| Bits | Description |
|---|---|
| Bit 0 | Specifies that this partition is required for the platform to function. All original equipment manufacturer (OEM) partitions must have this bit set to protect the OEM partition from being overwritten by the disk tools supplied with Windows Server 2003. |
| Bit 60 | Marks the partition as read-only. Used only for primary basic partitions of type {EBD0A0A2-B9E5-4433-87C0-68B6B72699C7}. |
| Bit 62 | Marks the partition as hidden. Used only for primary basic partitions of type {EBD0A0A2-B9E5-4433-87C0-68B6B72699C7}. |
| Bit 63 | Prevents the system from assigning a default drive letter to the partition. Used only for primary basic partitions of type {EBD0A0A2-B9E5-4433-87C0-68B6B72699C7}. |

#### Boot Sectors on GPT Disks

Boot sectors on GPT disks are similar to boot sectors on MBR disks, except that EFI ignores all x86 code in the boot sector. Instead, EFI uses its own file system driver to read the BIOS parameter block (BPB) and then mount the volume.

#### Basic Disks and Volumes Processes and Interactions

The following basic disk and volume processes and interactions assume that your computer has at least one basic disk and that the basic disk is functioning properly.

#### Creating a Basic Volume

When you create a basic volume, the Virtual Disk Service (VDS) uses the IOCTL, IOCTL_DISK_SET_DRIVE_LAYOUT_EX, to set the drive layout, and add a new partition.

VDS calls the disk driver. Partition manager (Partmgr.sys), sits on top of the disk driver as a filter). Partition manager creates the partition device and notifies the volume manager that there is a new partition. The volume manager announces the volume device to Plug and Play and to the system. Plug and Play notifies the mount point manager (Mountmgr.sys) that a new volume

has arrived and the mount point manager sets up a drive letter as long as AutoMount is enabled.

**Note**

- AutoMount is disabled by default on Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition.

### What Happens When a Basic Volume Is Created

**Reading or Writing to a Basic Volume**

When you read or write data to basic disk or volume, the input/output (I/O) is sent through the file system to the volume manager. The volume manager creates a new I/O request packet (IRP) and sends it to the partition manager (Partmgr.sys) in the disk stack, which relays it to the disk driver. The volume manager waits for the completed IRP to return from the disk stack. Then, the volume manager completes and returns the file system IRP.

The following figure illustrates the processes involved when reading or writing to a basic volume.

**Basic Disk and Volume Input/Output (I/O) Processes**

**Converting a Basic Disk into a Dynamic Disk**

You can convert a basic disk to dynamic by using Disk Management or by using DiskPart, a command-line tool that provides the same functions as Disk Management.

When you convert a disk to dynamic, the following events occur:

- All existing primary partitions and logical drives become simple volumes.
- The disk joins the local disk group and receives a copy of the dynamic disk database.

**Note**

- For certain disks, the menu command to convert the disk to dynamic is unavailable in Disk Management.

You can convert basic disks to dynamic at any time. In most cases, you do not need to restart your computer to complete the conversion. However, you must restart the computer if the disks you are converting contain any of the following volumes:

- **System volume (x86-based computers only).** The system volume contains hardware-specific files such as Ntldr and Boot.ini. These files are needed to load Windows Server 2003 in x86-based computers.
- **Boot volume.** The boot volume contains the Windows Server 2003 operating system and its support files. In x86-based computers, the boot volume can be, but does not have to be, the same volume as the system volume. In Itanium-based computers, the boot volume is never the same volume as the EFI System partition.
- **Volumes that contain the paging file.** The paging file is a hidden file on the hard disk that Windows Server 2003 uses to hold parts of programs and data files that do not fit in memory.

**Note**

- When you convert MBR disks that contain the system, boot, or paging file volumes to dynamic, you are prompted to

restart the computer two times. You must restart the computer both times to complete the conversion.

As shown in the following figure the Disk Management snap-in identifies the system and boot volumes, as well as those that contain the paging file in the graphical and disk list views. If you have a combined system and boot volume that also contains the paging file (the most common scenario), then only **System** is shown.

**How Disk Management Identifies Separate System, Boot, and Paging File Volumes for an x86-based Computer**

The list volume command in DiskPart shows the system, boot, and paging file volumes as follows:

```
Volume ###   Ltr   Label        Fs     Type        Size        Status     Info
----------   ---   -----------  -----  ----------  ---------   ---------  --------
Volume 0      G                       DVD-ROM           0 B   Healthy
Volume 1      C                 NTFS  Partition      2048 MB   Healthy    System
Volume 2      E                 NTFS  Partition     17418 MB   Healthy
Volume 3      F                 NTFS  Partition      4003 MB   Healthy    Boot
Volume 4      H                 NTFS  Partition       751 MB   Healthy    Pagefile
```

Even after you convert a disk to dynamic, some types of primary partitions do not become dynamic volumes. These partitions retain their partition entries in the partition table and are shown as primary partitions in Disk Management. These partitions are:

- Known OEM partitions (usually displayed in Disk Management as EISA Configuration partitions).
- EFI System partitions on GPT disks.

**Before Converting Disks to Dynamic**

Converting a disk to dynamic changes the partition layout on the disk and creates the dynamic disk database. The result of these changes is increased flexibility for volume management in Windows Server 2003. However, these changes are not easily reversed, and the structure of dynamic disks is not compatible with some operating systems. Therefore, you must consider the following issues before you convert disks to dynamic.

**If the disk contains partitions displayed as Healthy (Unknown) in Disk Management**

Do not convert a disk to dynamic if it contains unknown partitions created by other operating systems. Windows Server 2003

converts unrecognized partitions to dynamic, making them unreadable to other operating systems.

**If a disk contains shadow copies**
If you use separate disks to store the source volume and the shadow copies, and you convert the disk that contains the source volume to dynamic, the shadow copies are lost. Shadow copies are retained only if the source files and the shadow copies are stored on the same volume.

**If the disk contains an OEM partition that is not at the beginning of the disk**
Do not convert a disk to dynamic if it contains an OEM partition that is not at the beginning of the disk. (In Disk Management, an OEM partition usually appears as an EISA Configuration partition.) When you convert a disk to dynamic, Windows Server 2003 preserves the OEM partition only if it is the first partition on the disk. Otherwise the partition is deleted during the conversion to dynamic.

**If you want to extend a dynamic volume**
You can extend dynamic volumes that do not retain their partition entries in the partition table. The following volumes retain their entries in the partition table and cannot be extended:

- The system volume and boot volume of the operating system that you used to convert the disk to dynamic.
- Any basic volume that was present on the disk when you converted the disk from basic to dynamic by using the version of Disk Management included with Windows 2000.
- Simple volumes on which you run the DiskPart command **retain**. This command adds a partition entry to the partition table. However, after you use this command, you can no longer extend the volume.

**Note**

- The **retain** command adds an entry to the partition table of an MBR disk only for simple volumes that are contiguous, start at cylinder-aligned offsets, and are an integral number of cylinders in size. If a volume does not meet these requirements, the **retain** command fails.
- The following examples describe volumes on which the **retain** command will succeed:
- The simple volume is contiguous and starts at the beginning of the disk.
- The simple volume was present on the disk when the disk was converted to dynamic.

The only way to add more space to the system or boot volume on a dynamic disk is to back up all data on the disk, repartition and reformat the disk, reinstall Windows Server 2003, convert the disks to dynamic, and then restore the data from backup.

The following volumes do not have partition entries and can be extended:

- Simple volumes and spanned volumes created from unallocated space on a dynamic disk.
- A basic volume that meets the following criteria:
    - The basic volume is not the system or boot volume.
    - The basic volume is on a disk that was converted from basic disk to dynamic disk by using Windows Server 2003.

Although striped, mirrored, or RAID-5 volumes do not have entries in the partition table, Windows Server 2003 does not support extending them. You can add more space to a striped, mirrored, or RAID-5 volume by backing up the data, deleting the volume, recreating the volume by using Windows Server 2003, and then restoring the data.

**If you want to install Windows Server 2003 on a dynamic volume**
You can install Windows Server 2003 only on dynamic volumes that retain their partition entries in the partition table. The only dynamic volumes listed in the partition table are the following:

- The system volume and boot volume of the operating system (Windows Server 2003 or Windows 2000) that you used to convert the disk to dynamic. The system volume and boot volume can be simple or mirrored volumes.

- Any basic volume that was present on the disk when you used Windows 2000 to convert the disk from basic to dynamic.

- Simple volumes on which you run the DiskPart command **retain**. This command adds a partition entry to the partition table so that you can install Windows Server 2003 on the simple volume.

- A basic mirror set that was converted to a dynamic mirrored volume by using Windows 2000. If you break this mirrored volume into two simple volumes, you can also install Windows Server 2003 on either simple volume because they both retain their partition entries.

Because these dynamic volumes retain their partition entries, you can install Windows Server 2003 on them. However, you cannot extend any of these volumes because you can only extend volumes that do not have entries in the partition table.

**If you want to access the disk by using Windows Millennium Edition or earlier, or Windows NT 4.0**
If you plan to move the disk after you convert it to dynamic, note that you can access dynamic disks only from computers that are running Windows 2000, Windows XP Professional, Windows XP 64-Bit Edition, or Windows Server 2003. You cannot access dynamic disks from computers running Windows NT 4.0 or earlier.

When moving disks, note that access to dynamic disks is further restricted by the partition style used on the dynamic disk:

- **Dynamic MBR disks**. Only computers running Windows 2000, Windows XP Professional, Windows XP 64-Bit Edition, or Windows Server 2003 can access dynamic MBR disks.

- **Dynamic GPT disks**. Only Itanium-based computers running Windows XP 64-Bit Edition or the 64-bit versions of Windows Server 2003 can access dynamic GPT disks.

### Note

- Volumes on dynamic MBR and GPT disks are available across a network to computers running MS-DOS, Windows 95, Windows 98, Windows Millennium Edition, Windows NT 4.0 or earlier, Windows XP, and Windows Server 2003.

**If a disk or computer contains multiple copies of Windows XP Professional, Windows Server 2003 or Windows 2000**
Do not convert a disk to dynamic if it contains multiple copies of Windows XP Professional, Windows Server 2003, or Windows 2000. Even though these operating systems support dynamic disks, they require certain registry entries that allow them to start from dynamic disks. If the operating systems are installed on the same disk and you use one of the operating systems to convert the disk to dynamic, the registry of the other operating system becomes out-of-date because the drivers required to start the operating system from a dynamic disk are not loaded. Therefore, you can no longer start the other operating system.

One way that you can use dynamic disks with Windows XP Professional, Windows Server 2003, and Windows 2000 in a multiple-boot configuration is to install each operating system to a different disk. However, startup problems can also occur if you boot from one of the operating systems and then convert the disks that contain the other operating systems to dynamic.

To ensure that each operating system can start, start each operating system and then convert only the disk that contains the current boot volume to dynamic. For example, install Windows XP Professional on disk 1 and Windows Server 2003 on disk 2. Use Windows XP Professional to convert disk 1 to dynamic, and then use Windows Server 2003 to convert disk 2 to dynamic. By using this method, you ensure that the registries are updated for each boot volume.

**Disks That Cannot Be Converted to Dynamic**
Windows Server 2003 Setup and Disk Management ensure that disks initialized by Windows Server 2003 can be converted to dynamic. However, on some disks the conversion fails or the **Convert to Dynamic Disk** command is not available when you right-click a basic disk. The following conditions prevent you from converting a basic disk to dynamic.

**Cluster disks**
You cannot convert cluster disks to dynamic if they are connected to shared SCSI or Fibre Channel buses. Windows Cluster service cannot read disks that are dynamic and makes dynamic disks unavailable to programs or services that are dependent on these disk resources in the server cluster. For this reason, the option to convert these disks to dynamic is unavailable.

You must use Veritas Volume Manager to use dynamic disks with Cluster service.

**Removable disks**

You cannot use dynamic disks on the following:

- Removable media, such as Iomega Zip or Jaz disks, CDs, DVDs, or floppy disks.
- Disks that use universal serial bus (USB) or IEEE 1394 (also called FireWire) interfaces.

**Disks with sectors larger than 512 bytes**
A sector is a unit of storage on a hard disk. The majority of hard disks use 512-byte sectors. Windows Server 2003 supports converting basic disks to dynamic only if the sector size of the basic disk is 512 bytes.

**GPT disks with non-contiguous partitions**
If an unknown partition lies between two known partitions on a GPT disk, you cannot convert the disk to dynamic. Unknown partitions are created by operating systems or utilities that use partition type GUIDs that the 64-bit versions of Windows Server 2003 do not recognize.

**MBR disks that do not have space for the dynamic disk database**
An MBR disk requires 1 MB of free space at the end of the disk to be used for the dynamic disk database. Windows Server 2003 and Windows 2000 automatically reserve 1 MB or one cylinder, whichever is greater, when creating partitions on a disk, but in rare cases, disks with partitions created by other operating systems might not have this space available. If this space is not available, you cannot convert the disk to dynamic.

To convert the disk to dynamic, you must back up or move the data, delete the partitions, recreate the partitions, restore the data, and then convert the disk to dynamic. By using Windows Server 2003 to create the partitions, you ensure that the necessary space is available for the dynamic disk database.

This limitation does not affect GPT disks because the database is created in its own partition with space borrowed from the Microsoft Reserved partition.

# Basic Disks and Volumes Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Basic Disk and Volume Tools
- Basic Disk and Volume Registry Entries
- Basic Disk and Volume WMI Classes

The following tools, registry settings, and Windows Management Instrumentation (WMI) classes are associated with basic disks and volumes.

**Basic Disk and Volume Tools**
The following tools are associated with basic disks and volumes.

**Bootcfg.exe: Boot Configuration Tool**
**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
All versions of the Boot Configuration Tool in the Windows Server 2003 family are identical.

You can use the Boot Configuration Tool to query, configure, or change settings in the Boot.ini file on your computer.

**Dmdiag.exe: Disk Manager Diagnostics**
**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
All versions of Dmdiag in the Windows Server 2003 family are identical.

Dmdiag displays the following information for the computer on which it is run:

- Computer name and operating system version
- Physical disk to disk type
- Mount points
- Logical Disk Manager (LDM) file versions
- Drive letter usage
- List of devices
- Symbolic links
- Disk partition information

**Dskmgmt.msc: Disk Management**
**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
All versions of the Disk Management snap-in in the Windows Server 2003 family are identical.

You can use the Disk Management snap-in to remotely manage disks and volumes on other computers running Windows 2000, Windows XP or Windows Server 2003

**DiskPart.exe: DiskPart**
**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
All versions of DiskPart in the Windows Server 2003 family are identical. DiskPart includes a few 64-bit parameters that are only available on Itanium-based computers.

DiskPart is a text-mode command interpreter that enables you to manage objects (disks, partitions, or volumes) by using scripts or direct input from a command prompt.

**Format.exe: Format**
**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
All versions of Format in the Windows Server 2003 family are identical.

Format prepares a volume on the specified disk to accept Windows files.

**FTonline.exe: Fault-tolerant Disk Mounter**
**Category**
Windows Server 2003 support tool.

**Version compatibility**
FTonline enables an administrator to mount and recover files from fault-tolerant disks created in previous versions of Windows. This tool is useful if you did not upgrade your disks to dynamic disks, or failed to back up your data before installing Windows Server 2003. You can install FTonline using the Support Tools setup program located in the \Support\Tools folder on the Windows XP Professional and the Windows Server 2003 family of operating systems CDs.

**Mountvol.exe: Mountvol**
**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
All versions of Mountvol in the Windows Server 2003 family are identical. Mountvol includes a few 64-bit parameters that are only available on Itanium-based computers.

Mountvol creates, deletes, or lists volume mount points. Mountvol enables you to link volumes without using drive letters.

**SecInspect.exe: Sector Inspector**
**Category**
Windows Server 2003 command-line tool.

**Version compatibility**
SecInspect is a command-line diagnostics tool that enables administrators to view the contents of master boot records, boot sectors, and IA64 GUID partition tables. Additional features include creating hexadecimal dumps of binary files and backup/restore of sector ranges. For more information about this tool, see the Help that comes with the tool. To find this tool, see Tool Updates in Tools and Settings Collection.

**Basic Disk and Volume Registry Entries**
The following registry entries are associated with basic disks and volumes. For more information about the registry, see the Registry Reference in Tools and Settings Collection.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following sections describe the basic disk and volume registry entries that are listed below \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\. The headings represent the next level in the path after \Services. For example, Vds\Debuglog is equal to \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Vds\Debuglog.

**Vds\Debuglog**
**Level**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Vds\Debuglog\Level

**Version**
Windows Server 2003 family.

Sets the level of logging for VDS.

Use Registry Editor to add a decimal value named Level. Stop and restart the service after changing.

### VDS Log Options

| Item Logged | Bitmask Number |
|---|---|
| Errors | 1 |
| Warnings | 2 |
| Trace | 4 |
| Information | 8 |

Set the value by adding the bitmask numbers of the values you want to log. For example, decimal 3 logs errors (1) and warnings (2). Decimal 9 logs errors (1) and information (8). The range for this value is 0-15. Set the value to 0xF (decimal 15) to log all items.

**Dmadmin\Parameters**
**EnableDynamicConversionFor1394**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\dmadmin\Parameters\EnableDynamicConversionFor1394

**Version**
Windows Server 2003 family.

Allows a user to convert an Institute of Electrical and Electronics Engineers, Inc. (IEEE) 1394 (FireWire) disk to a dynamic disk on Windows Server 2003 or earlier operating systems. Converting 1394 disks to dynamic is not a tested or supported scenario. This registry entry is provided for compatibility with a Windows 2000 beta that supported this functionality.

EnableDynamicConversionFor1394 is a DWORD Value, with a range of 0-1. Default is zero. To modify, use Registry Editor. Stop and restart the service after modifying.

**Basic Disk and Volume WMI Classes**
The following table lists and describes the WMI classes that are associated with basic disks and volumes.

### WMI Classes Associated with Basic Disks and Volumes

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_DiskDrive | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_DiskDrivePhyiscalMedia | \root\cimv2 | Windows Server 2003 family |
| Win32_DiskDriveToDiskPartition | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_DiskPartition | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_LogicalDisk | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_LogicalDiskToPartition | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_MappedLogicalDisk | \root\cimv2 | Windows Server 2003 family |
| Win32_PhysicalMedia | \root\cimv2 | Windows Server 2003 family |
| Win32_Volume | \root\cimv2 | Windows Server 2003 family |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

# Dynamic Disks and Volumes Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Like basic disks, which are the most commonly used storage type found on computers running Microsoft Windows, dynamic disks can use the master boot record (MBR) or GUID partition table (GPT) partitioning scheme. All volumes on dynamic disks are known as dynamic volumes. Dynamic disks were first introduced with Windows 2000 and provide features that basic disks do not, such as the ability to create volumes that span multiple disks (spanned and striped volumes), and the ability to create fault tolerant volumes (mirrored and RAID-5 volumes).

Dynamic disks offer greater flexibility for volume management because they use a database to track information about dynamic volumes on the disk and about other dynamic disks in the computer. Because each dynamic disk in a computer stores a replica of the dynamic disk database, Windows Server 2003can repair a corrupted database on one dynamic disk by using the database on another dynamic disk.

The following topics describe how dynamic disks and volumes work, their architecture, and the tools you can use when working with them:

**In this subject**

- What Are Dynamic Disks and Volumes?
- How Dynamic Disks and Volumes Work
- Dynamic Disks and Volumes Tools and Settings

# What Are Dynamic Disks and Volumes?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Are Dynamic Disks and Volumes?**

**In this section**

- Types of Dynamic Volumes
- Dynamic Disk and Volume Scenarios

Like basic disks, which are the most commonly used storage type found on computers running Microsoft Windows, dynamic disks can use the master boot record (MBR) or GUID partition table (GPT) partitioning scheme. All volumes on dynamic disks are known as dynamic volumes. Dynamic disks were first introduced with Windows 2000 and provide features that basic disks do not, such as the ability to create volumes that span multiple disks (spanned and striped volumes), and the ability to create fault tolerant volumes (mirrored and RAID-5 volumes).

Dynamic disks offer greater flexibility for volume management because they use a database to track information about dynamic volumes on the disk and about other dynamic disks in the computer. Because each dynamic disk in a computer stores a replica of the dynamic disk database, Windows Server 2003 can repair a corrupted database on one dynamic disk by using the database on another dynamic disk.

The location of the database is determined by the partition style of the disk.

- On MBR disks, the database is contained in the last 1 megabyte (MB) of the disk.
- On GPT disks, the database is contained in a 1-MB reserved (hidden) partition known as the Logical Disk Manager (LDM) Metadata partition.

All online dynamic disks in a computer must be members of the same disk group, which is a collection of dynamic disks. A computer can have only one dynamic disk group, also called the primary disk group. Each disk in a disk group stores a replica of the same dynamic disk database. A disk group uses a name consisting of the computer name plus a suffix of Dg0. The disk group name is stored in the registry.

When you move dynamic disks to a computer that has existing dynamic disks, you must import the dynamic disks to merge the databases on the moved disks with the databases on the existing dynamic disks.

The disk group name on a computer never changes, as long as the disk group contains dynamic disks. If you remove the last disk in the disk group or convert all dynamic disks to basic, the registry entry remains. However, if you create a dynamic disk again on that computer, a new disk group name is generated. The computer name in the disk group remains the same, but the suffix is Dg1 instead of Dg0.

When you move a dynamic disk to a computer that has no dynamic disks, the dynamic disk retains its disk group name and ID from the original computer and uses them on the local computer.

For more information about converting basic disks to dynamic disks, including the limitations of dynamic disks, see "Converting a Basic Disk into a Dynamic Disk" in How Basic Disks and Volumes Work.

**Types of Dynamic Volumes**

A dynamic volume is a volume that is created on a dynamic disk. Dynamic volume types include simple, spanned, and striped volumes. Windows Server 2003 also supports mirrored and RAID-5 volumes, which are fault tolerant. Fault tolerance is the ability of computer hardware or software to make sure that your data is still available, even if there is a hardware failure.

Regardless of the partition style used (MBR or GPT), you can create up to 1000 dynamic volumes per disk group, although boot time increases as the number of volumes increases. The recommended number of dynamic volumes is 32 or fewer per disk group.

The following sections describe the different types of dynamic volumes.

**Simple Volumes**

Simple volumes are the dynamic-disk equivalent of the primary partitions and logical drives found on basic disks. When creating simple volumes, keep these points in mind:

- If you have only one dynamic disk, you can create only simple volumes.
- You can increase the size of a simple volume to include unallocated space on the same disk or on a different disk. The volume must be unformatted or formatted by using NTFS. You can increase the size of a simple volume in two ways:
    - By extending the simple volume on the same disk. The volume remains a simple volume, and you can still mirror it.
    - By extending a simple volume to include unallocated space on other disks on the same computer. This creates a spanned volume.

    **Note**

If the simple volume is the system volume or the boot volume, you cannot extend it.

**Spanned Volumes**
Spanned volumes combine areas of unallocated space from multiple disks into one logical volume. The areas of unallocated space can be different sizes. Spanned volumes require two disks, and you can use up to 32 disks. When creating spanned volumes, keep these points in mind:

- You can extend only NTFS volumes or unformatted volumes.
- After you create or extend a spanned volume, you cannot delete any portion of it without deleting the entire spanned volume.
- You cannot stripe or mirror spanned volumes. For more information about striped or mirrored volumes, see “Striped Volumes” or “Mirrored Volumes” later in this section.
- Spanned volumes do not provide fault tolerance. If one of the disks containing a spanned volume fails, the entire volume fails, and all data on the spanned volume becomes inaccessible. The reliability for a spanned volume is less than the least reliable disk in the set.

**Striped Volumes**
Striped volumes improve disk input/output (I/O) performance by distributing I/O requests across disks. Striped volumes are composed of stripes of data of equal size written across each disk in the volume. They are created from equally sized, unallocated areas on two or more disks. In Windows Server 2003, the size of each stripe is 64 kilobytes (KB) and cannot be changed.

Striped volumes cannot be extended or mirrored and do not offer fault tolerance. If one of the disks containing a striped volume fails, the entire volume fails, and all data on the striped volume becomes inaccessible. The reliability for the striped volume is less than the least reliable disk in the set.

**Mirrored Volumes**
A mirrored volume is a fault-tolerant volume that provides a copy of a volume on another disk. Mirrored volumes provide data redundancy by duplicating the information contained on the volume. The two disks that make up a mirrored volume are known as mirrors. Each mirror is always located on a different disk. If one of the disks fails, the data on the failed disk becomes unavailable, but the system continues to operate by using the unaffected disk.

Mirrored volumes are available only on computers running the Windows 2000 Server family or Windows Server 2003.

**RAID-5 Volumes**
A RAID-5 volume is a fault-tolerant volume that stripes data and parity across three or more disks. Parity is a calculated value that is used to reconstruct data if one disk fails. When a disk fails, Windows Server 2003 continues to operate by recreating the data that was on the failed disk from the remaining data and parity. RAID-5 volumes are available only on computers running the Windows 2000 Server family or Windows Server 2003.

**Dynamic Disk and Volume Scenarios**
To gain the maximum benefit from dynamic disks and volumes, it is best to use them in computers with more than one disk,

which allows you to scale the storage to match your needs. Dynamic disks and volumes are commonly used in the following scenarios.

**Create a spanned volume to increase volume size**
Spanned volumes are typically created by a user who has at least two disks in their computer. If the user doesn't require the high read throughput of a striped volume or the fault tolerance offered by mirrored or RAID-5 volumes, the user can create a spanned volume.

If the data volume on a user's primary disk gets too full, the user can extend that volume onto a second disk in their computer. This enables the user to create a big volume that uses space on two disks. If necessary, they can extend the volume to cover up to 32 disks. If the user has some space left on their primary disk after performing configuration changes, they can use that space and combine it with space on the second disk, creating a spanned volume.

**Create a spanned volume to combine two or three small disks into a large volume**
If a user has two or more small disks in their computer, they can combine those disks into a single large volume by creating a spanned volume. To the user, the space spread across the disks would look and function like a single volume.

**Create a striped volume to accommodate high read/write throughput**
Striped volumes are typically created by the user who has at least two disks in their computer. If the user requires high read/write throughput but does not require the fault-tolerance offered by mirrored or RAID-5 volumes, the user can create a striped volume.

**Create a RAID-5 volume to protect critical data**
RAID-5 volumes are typically created by the user who requires fault-tolerance and who has at least three disks in their computer. If one of the disks in the RAID-5 volume fails, the data on the remaining disks, along with the parity information, can be used to recover the lost data. RAID-5 volumes are well-suited to storing data that will need to be read frequently but written to less frequently. Database applications that read randomly work well with the built-in load balancing of a RAID-5 volume.

**Create a mirrored volume to protect critical data**
Mirrored volumes are typically created by the user who requires fault-tolerance and who has two disks in their computer. If one disk fails, the user always has a copy of their data on the second disk. Mirrored volumes provide better write performance than RAID-5 volumes.

**Create a mirror to migrate data to a larger disk**
If a user has run out of room on the simple volume where they store data and there is no room left on the disk to extend the volume, they can move this data to a larger disk instead of creating a spanned volume. The user can create a mirrored volume using the simple volume containing their data and a larger disk. After creating the mirrored volume, the user can break the mirrored volume and extend the new volume to fill the larger disk, leaving a complete copy of the original volume with available space for new data. The space on the original volume can be reclaimed for other uses.

# How Dynamic Disks and Volumes Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Dynamic Disks and Volumes Work**

**In this section**

- Dynamic Disks and Volumes Architecture
- Dynamic Disk and Volume Physical Structure
- Dynamic Disk and Volume Processes and Interactions
- Types of RAID Volumes

Like basic disks which are the most commonly used storage type found on computers running Microsoft Windows, dynamic disks can use the master boot record (MBR) or GUID partition table (GPT) partitioning scheme. All volumes on dynamic disks are known as dynamic volumes. Dynamic disks were first introduced with Windows 2000 and provide features that basic disks do not, such as the ability to create volumes that span multiple disks (spanned and striped volumes), and the ability to create fault tolerant volumes (mirrored and RAID-5 volumes).

Dynamic disks offer greater flexibility for volume management because they use a database to track information about dynamic volumes on the disk and about other dynamic disks in the computer. Because each dynamic disk in a computer stores a replica of the dynamic disk database, Windows Server 2003 can repair a corrupted database on one dynamic disk by using the database on another dynamic disk.

An optimal environment for basic disks and volumes is defined as follows:

- Windows Server 2003 operating system is installed and functioning properly.
- The dynamic disks are functioning properly and they display the Online status in the Disk Management snap-in.
- The dynamic volumes display the Healthy status in the Disk Management snap-in.

The following sections provide an in-depth view of how basic disks and volumes work in an optimal environment.

**Dynamic Disk and Volume Architecture**

Dynamic disks and volumes rely on the Logical Disk Manager (LDM) and Virtual Disk Service (VDS) and their associated components. These components enable you to perform tasks such as converting basic disks into dynamic disks, and creating fault-tolerant volumes. The following diagram shows the LDM and VDS components.

**Logical Disk Manager and Virtual Disk Service Components**

The following table lists the LDM and VDS components and provides a brief description of each.

**Logical Disk Manager and Virtual Disk Service Components**

| Component | Description |
|---|---|
| Disk Management snap-in:<br><br>Dmdlgs.dll<br><br>Dmdskmgr.dll<br><br>Dmview.ocx<br><br>Diskmgmt.msc | Binaries that comprise the Disk Management snap-in user interface. |
| DiskPart command line utility:<br><br>Diskpart.exe | A scriptable alternative to the Disk Management snap-in. |
| Mount Manager command line:<br><br>Mountvol.exe | A command line utility that can be used to create, delete, or list volume mount points. |

| | |
|---|---|
| Virtual Disk Service:<br><br>Vds.exe<br><br>Vdsutil.dll | A program used to configure and maintain volume and disk storage. |
| Virtual Disk Service provider for basic disks and volumes:<br><br>Vdsbas.dll | The Virtual Disk Service calls into the basic provider when configuring basic disks and volumes. |
| Virtual Disk Service provider for dynamic disks and volumes:<br><br>Vdsdyndr.dll | The Virtual Disk Service calls into the dynamic provider when configuring dynamic disks and volumes. |
| Dmboot.sys<br><br>Dmconfig.dll<br><br>Dmintf.dll<br><br>Dmio.sys<br><br>Dmload.sys<br><br>Dmremote.exe<br><br>Dmutil.dll | Drivers and user mode components used to configure dynamic disks and volumes and perform I/O. |
| Logical Disk Administrator service:<br><br>Dmadmin.exe | The VDS provider for dynamic disks and volumes uses the interfaces exposed by this service to configure dynamic disks. |
| Logical Disk Service:<br><br>Dmserver.dll | A service that detects and monitors new hard disk drives and sends disk volume information to Logical Disk Manager Administrative Service for configuration. If this service is stopped, dynamic disk status and configuration information might become outdated. If this service is disabled, any services that explicitly depend on it will fail to start. |
| Basic disk I/O driver:<br><br>Ftdisk.sys | A driver that manages all I/O for basic disks. Other system components, such as mount point manager, call into this driver to get information about basic disk volumes. |
| Mount point manager driver:<br><br>Mountmgr.sys | A binary that tracks drive letters, folder mount paths and other mount points for volumes. Assigns a unique volume mount point of the form \??\Volume<*GUID*> to each volume, in addition to any drive letters or folder paths that have been assigned by the user. Ensures that a volume will get the same drive letter each time the computer boots, and also tries to retain a volume's drive letter when the volume's disk is moved to a new computer. |
| Partition manager:<br><br>Partmgr.sys | A filter driver that sits on top of the disk driver. All disk driver requests pass through the partition manager driver. This driver creates partition devices and notifies the volume managers of partition arrivals and removals. Exposes IOCTLs that return information about partitions to other components, and allow partition configuration. |

**Dynamic Disk and Volume Physical Structure**

Dynamic disks can use either the master boot record (MBR) or GUID partition table (GPT) partitioning style. x86-based

computers use disks with the MBR partitioning style and Itanium-based computers use disks with the GPT partitioning style.

The following diagram compares a dynamic MBR disk to a dynamic GPT disk.

**Comparison of Dynamic MBR and GPT Disks**

The following table compares dynamic MBR and GPT disks.

**Comparison of Dynamic MBR and GPT Disks**

| Characteristic | MBR Disk(x86-based Computer) | GPT Disk(Itanium-based Computer) |
|---|---|---|
| Number of volumes on dynamic disks | Supports up to 1000 volumes per disk group. | Supports up to 1000 volumes per disk group. |
| Compatible operating systems | Can be read by:<br>• Windows 2000, all versions<br>• Windows XP<br>• Windows Server 2003, all versions for x86-based computers and Itanium-based computers | Can be read by:<br>• Windows XP 64-Bit Edition<br>• The 64-bit version of Windows Server 2003, Enterprise Edition<br>• The 64-bit version of Windows Server 2003, Datacenter Edition |
| Maximum size of dynamic volumes | Supports the maximum volume size of the file system used to format the volume.<br>Up to 64 terabytes for a striped or spanned volume using 32 disks. | Supports the maximum volume size of the file system used to format the volume.<br>Up to 64 terabytes for a striped or spanned volume using 32 disks. |

| | | |
|---|---|---|
| Partition tables (copies) | Contains one copy of the partition table. | Contains primary and backup partition tables for redundancy and checksum fields for improved partition structure integrity. |
| Locations for data storage | Stores data in partitions and in unpartitioned space. Although most user and program data is stored within partitions, some system metadata might be stored in hidden or unpartitioned sectors created by OEMs or other operating systems. | Stores user and program data in partitions that are visible to the user. Stores system metadata that is critical to platform operation in partitions that the 64-bit versions of Windows Server 2003 recognize but do not make visible to the user. Does not store any data in unpartitioned space. |
| Troubleshooting methods | Uses the same methods and tools used in Windows 2000. | Uses tools designed for GPT disks. (Do not use MBR troubleshooting tools on GPT disks.) |

**Dynamic Disk and Volume Processes and Interactions**

The following section discusses the different processes that are used by dynamic disks and volumes and discusses the ways in which those processes interact. This section assumes that your computer has at least three dynamic disks and that the dynamic disk is functioning properly.

**Creating a simple volume**

Creating a simple volume involves the Virtual Disk Service (VDS) and Logical Disk Manager (LDM). A simple volume is a dynamic volume made up of disk space from a single dynamic disk. When you use Disk Management or DiskPart to create a simple volume, they call the VDS API, which sends an IOCTL to the Volume Manager to create the volume. Volume Manager creates the simple volume and documents it in the dynamic disk's database. Next, Volume Manager sends information about the new volume to Plug and Play. Plug and Play sends information about the new volume to the Mount Manager and to VDS. Mount Manager assigns a drive letter to the volume and after VDS sends the information to Disk Management or DiskPart, the volume is available and ready for use.

### What Happens When a Simple Volume Is Created

**Partition Entries on MBR Dynamic Disks**

Like basic disks, dynamic disks contain an MBR that includes the master boot code, the disk signature, and the partition table for the disk. However, the partition table on a dynamic disk does not contain an entry for each volume on the disk because volume information is stored in the dynamic disk database. Instead, the partition table contains entries for the system volume, boot volume (if it is not the same as the system volume), and one or more additional partitions that cover all the remaining unallocated space on the disk. All these partitions use System ID 0x42, which indicates that these partitions are on a dynamic disk. Placing these partitions in the partition table prevents MBR-based disk utilities from interpreting the space as available for new partitions.

### Note

- In Windows 2000, the partition entries for existing basic volumes were preserved in the partition table when the disk was

converted to dynamic. These entries prevented the converted dynamic volumes from being extended. This limitation has been removed from Windows Server 2003 for all converted volumes except the boot and system volumes. Partition entries for all other converted volumes are removed from the partition table, and therefore these volumes can be extended.

The following example shows a partial printout of an MBR on a dynamic disk that contains four simple volumes: the system volume, the boot volume, and two data volumes. Note, however, that the partition table contains entries for only three partitions. The first entry is the system volume, which is marked as active. The second entry is the boot volume, and the third entry is the container partition for the two data volumes on the disk. All entries are type 0x42, which specifies dynamic volumes.

```
000001B0:                                                 80 01   .....,Dc!.!.....
000001C0: 01 00 42 FE 7F 04 3F 00 - 00 00 86 FA 3F 00 00 00   ..B..?.....?...

```

**Partition Entries on Dynamic GPT Disks**

The following example illustrates a partial hexadecimal printout of a GUID partition entry array on a dynamic GPT disk. The GUID partition entry array shows the Microsoft Reserved partition plus additional entries that appear only on dynamic GPT disks:

- The LDM Metadata partition is a 1-megabyte hidden partition that stores the dynamic disk database, which contains information about all dynamic disks and volumes installed on the computer.
- The LDM Data partition acts as a container for dynamic volumes. Individual dynamic volumes do not contain entries in the GUID partition entry array.

The partition type GUIDs are bold and match the entries in the table titled “Partition Type GUIDs” later in this section.

**Partition Type GUIDs**

| Partition Type | GUID Value |
|---|---|
| Unused entry | {00000000–0000–0000–0000–000000000000} |
| EFI System partition | {28732AC1–1FF8–D211–BA4B–00A0C93EC93B} |

| | |
|---|---|
| Microsoft Reserved partition | {16E3C9E3–5C0B–B84D–817D–F92DF00215AE} |
| Primary partition on a basic disk | {A2A0D0EB–E5B9–3344–87C0–68B6B72699C7} |
| LDM Metadata partition on a dynamic disk | {AAC80858–8F7E–E042–85D2–E1E90434CFB3} |
| LDM Data partition on a dynamic disk | {A0609BAF–3114–624F–BC68–3311714A69AD} |

**GUID Partition Entry Attributes**

GUID partition entry attributes are descriptors for how a partition is used. The attributes are specified within a 64-bit value, so EFI supports up to 64 different attributes. The 64-bit versions of Windows Server 2003 use two attributes as described in the following table.

**GUID Partition Entry Attributes Used by the 64-Bit Editions of Windows on Itanium-based Computers**

| Bits | Description |
|---|---|
| Bit 0 | Specifies that this partition is required for the platform to function. All original equipment manufacturer (OEM) partitions must have this bit set to protect the OEM partition from being overwritten by the disk tools supplied with Windows Server 2003. |
| Bit 60 | Marks the partition as read-only. Used only for primary basic partitions of type {EBD0A0A2-B9E5-4433-87C0-68B6B72699C7}. |
| Bit 62 | Marks the partition as hidden. Used only for primary basic partitions of type {EBD0A0A2-B9E5-4433-87C0-68B6B72699C7}. |
| Bit 63 | Prevents the system from assigning a default drive letter to the partition. Used only for primary basic partitions of type {EBD0A0A2-B9E5-4433-87C0-68B6B72699C7}. |

**Types of RAID Volumes**

A redundant array of independent disks (RAID) is a fault-tolerant disk configuration in which part of the physical storage capacity contains redundant information about data stored on the disks. The redundant information is either parity information (in the case of a RAID-5 volume), or a complete, separate copy of the data (in the case of a mirrored volume). The redundant information enables regeneration of the data if one of the disks or the access path to it fails, or a sector on the disk cannot be read.

Windows Server 2003 supports three types of software RAID configurations:

- **Striped volumes** use RAID-0, which stripes data across multiple disks. RAID-0 does not offer fault tolerance, but it does offer increased performance.
- **Mirrored volumes** use RAID-1, which provides redundancy by creating two identical copies of a volume.
- **RAID-5 volumes** use RAID-5, which stripes parity information across multiple disks. This parity information can be used to recreate data stored on a failed disk.

**Note**

- Fault tolerance is never an alternative to performing regular backups.

Use DiskPart or Disk Management to configure and repair mirrored volumes and RAID-5 volumes. The following figure shows a mirrored and a RAID-5 volume with failed redundancy status. The mirrored and RAID-5 volumes are in failed redundancy because one of the disks that makes up the volumes is offline.

**Mirrored and RAID-5 Volumes That Have Failed Redundancy Status**

**Striped Volumes**

Striped volumes improve input/output (I/O) performance by distributing I/O requests across two or more disks. Striped volumes are composed of stripes of data of equal size written across each disk in the volume. They are created from equally sized, unallocated areas on two or more disks. For Windows Server 2003, the size of each stripe is 64 kilobytes (KB).

The disks in a striped volume do not need to be identical, but there must be unused space available on each disk that you want to include in the volume.

You cannot increase the size of a striped volume after it is created. To change the size of a striped volume, you must first complete the following steps:

1. Back up the data.
2. Delete the striped volume by using Disk Management or DiskPart.
3. Create a new, larger, striped volume by using Disk Management or DiskPart.
4. Restore the data to the new striped volume.

Striped volumes do not contain redundant information. Therefore, the cost per gigabyte on a striped volume is identical to that for the same amount of storage configured from a contiguous area on a single disk. If one disk fails, the entire striped volume fails and no data can be recovered. The reliability for the striped volume is less than the least reliable disk in the set.

Striped volumes are used for performance reasons. In general, striped volumes work well when you need to distribute disk I/O operations. Access to the data on a striped volume is usually faster than access to the same data would be on a single disk, because the I/O is spread across more than one disk. Therefore, Windows Server 2003 can be seeking on more than one disk at the same time and can have simultaneous read or write operations.

A striped volume works well in the following situations:

- When users need rapid read or write access to large databases or other data structures.
- When collecting data from external sources at very high transfer rates. This is especially useful when collection is done

asynchronously.

- When multiple independent applications require access to data stored on the striped volume. When the operating system supports asynchronous multithreading, which helps with load balancing of disk read and write operations.

**Mirrored Volumes**

A mirrored volume provides an identical twin of the selected volume. All data written to the mirrored volume is written to both volumes, which results in disk capacity of only 50 percent. Because dual-write operations can degrade system performance, many mirrored volume configurations use duplexing, which means that each disk in the mirrored volume resides on its own disk controller. The benefit of duplexing is that you reduce the risk of a single point of failure: if one disk controller fails, the other controller (and the disk on that controller) continues to operate normally. If you do not use two controllers, a failed controller makes both volumes in a mirrored volume inaccessible until the controller is replaced.

**Note**

- If one disk in a mirrored volume fails, the computer continues to run and the mirrored volume is still accessible. However, the mirrored volume is no longer fault-tolerant, so you need to replace the failed disk or controller as soon as possible. If your computer supports hot-swappable hard disks, you do not need to restart the computer to install a new disk and resynchronize the mirror.

Almost any volume can be mirrored, including the system and boot volumes. However, you cannot mirror the EFI System partition on GPT disks. In addition, you cannot add disk space to a mirrored volume to increase the size of the volume later.

**Advantages of Mirrored Volumes**

Random disk-read operations on a mirrored volume are more efficient than random disk-read operations on a single volume. Windows Server 2003 has the capacity to load balance read operations across the disks. With current SCSI and Fibre Channel technology, two disk read operations can be done simultaneously.

When one of the volumes that makes up a mirrored volume fails, the mirrored volume is said to have lost redundancy. A mirrored volume that loses redundancy impacts system performance the least, because the remaining disk contains all of the data. No data recomputation is needed to run the system. When you configure your boot volume on a mirrored volume, you do not have to reinstall Windows Server 2003 to restart the computer after a disk failure.

When compared to a RAID-5 volume, a mirrored volume:

- Has a lower entry cost because it requires only two disks, whereas a RAID-5 volume requires three or more disks.
- Requires less system memory.
- Provides good overall performance.
- Does not degrade performance during a failure except when high-volume read operations are performed. However, if a single write error occurs, redundancy is lost.

A mirrored volume works well in the following situations:

- When extremely high data reliability is required. A duplexed mirrored volume has the best data reliability because the entire I/O subsystem is duplicated.
- When you have heavy write loads that need fault tolerance. In this case, mirrored volumes perform better than RAID-5 volumes.
- When simplicity is important. Mirrored volumes are simple to understand and easy to set up.

**Disadvantages of Mirrored Volumes**

Disk-write operations on mirrored volumes are less efficient because data must be written to both disks. This performance penalty is minor, however, because writing to both disks usually takes place concurrently. In many situations, an end-user application is not affected by data being written do both disks.

Another performance penalty occurs when you resynchronize a mirrored volume. Resynchronization is the process by which a mirrored volume's mirrors are made to contain identical data. During resynchronization, performance is affected because the computer is performing many I/O operations to copy the data.

Mirrored volumes are the least efficient at maximizing storage space. Because the data is duplicated, the space requirements for a mirrored volume are higher than for a RAID-5 volume.

**Best Practices for Configuring Mirrored Volumes**
To a large extent, how you configure your mirrored volumes depends on the number of disks and controllers that you want to have on the computer running Windows Server 2003. The following are general guidelines for configuring mirrored volumes:

- Keep data volumes separate from boot volumes for better performance. Configuring your boot volume on a disk (and controller) that does not contain data sets gives you better performance.

- Do not put the paging file on a mirrored volume. The paging file does not need to be redundant and can decrease the mirrored volume's performance due to frequent disk-writing operations. Instead, put the paging file on a striped or simple volume.

- For additional protection, put each disk in a mirrored volume on its own disk controller. When you use a mirrored volume for your system or boot volumes, you can make the configuration more fault-tolerant by putting each disk member of the mirrored volume on a separate controller. This approach allows you to survive controller or disk failures. Putting each disk member of the mirrored volume on a separate channel of a multichannel controller does not make the controller fault tolerant. However, this approach might improve performance.

- Use identical disks when putting the system or boot volume on a mirrored volume. Although it is not necessary to use identical disks or to have the same volumes on each disk, it is strongly recommended that you use identical disks and controllers if you put your system and boot volume on a mirrored volume.

**Note**

- After you mirror your system volume, you must test your configuration by starting Windows Server 2003 from each volume to ensure that you can start Windows Server 2003 if one of the disks fails. Startup problems can occur if the disks use different geometries or if the system volumes are at different offsets on the disk.

**Creating Mirrored Volumes**
To create a mirrored volume, use the Disk Management snap-in or the DiskPart command-line tool. You can create a mirrored volume in two ways:

- Add a mirror to an existing simple volume on a dynamic disk. You must have an area of unused space on a different dynamic disk at least as large as the original simple volume. If you do not have a dynamic disk with enough unallocated space, the **Add Mirror** command is unavailable.

- Create a new mirrored volume from unallocated space on two dynamic disks. The amount of disk space used for each half of the mirrored volume must be equal. If you have less unallocated space on one disk than the other, the mirrored volume can be no larger than the smaller of the two unallocated spaces.

In either case, if you have unallocated space left over, you can use the space to create other volumes.

**Mirroring the System and Boot Volumes in x86-based Computers**
To ensure that your x86-based computer can load Windows Server 2003 if one of the disks or controllers fails, you can mirror the system and boot volumes.

- Mirroring the system volume makes an exact copy of the volume that contains the hardware-specific files needed to load Windows Server 2003.

- Mirroring the boot volume makes an exact copy of the volume that contains the Windows Server 2003 operating system.

The boot and system volumes can be separate volumes on the same disk, separate volumes on different disks, or they can be the same volume on the same disk. In addition, the system and boot volumes can be mirrored to a different disk on the same

controller or to a different disk on a different controller. The following figure illustrates some common configurations for mirroring system and boot volumes.

**Common Configurations of Mirrored System Volumes and Boot Volumes (x86-based Computers)**

**Guidelines for Mirroring System or Boot Volumes in x86-based Computers**

Before you mirror the system or boot volume in an x86-based computer, note the following guidelines:

- Use care when selecting Advanced Technology Attachment (ATA) disks for a mirrored system volume. Although using ATA disks is supported, the recovery procedure is more complicated when the master disk on the primary integrated device electronics (IDE) channel fails. In this case, you must move the disk with the remaining mirror to the primary IDE channel and set its jumper to master position.

- Do not mirror the system volume by using an ATA disk with a SCSI disk because startup problems can occur if one of the disks fails.

- If you use duplexed SCSI controllers, make sure to use identical controllers from the same manufacturer.

- You must test the mirrored system volume before a failure to ensure that the computer can start from the remaining mirror.

**Mirroring the Boot Volume and Replicating the EFI System Partition in Itanium-based Computers**

To ensure that your Itanium-based computer can load Windows Server 2003 if one of the disks or controllers fails, you can mirror the boot volume. Mirroring the boot volume makes an exact copy of the volume that contains the Windows Server 2003 operating system. In addition to mirroring the boot volume, you should also replicate the EFI system partition. If you do not replicate the EFI system partition, and the disk holding it fails, you will not be able to boot the computer, even if there is a good, remaining boot volume on another disk.

The process to replicate the EFI system partition involves creating a new EFI system partition on a second GUID partition table (GPT) disk. Because the second EFI system partition is empty, you must copy the contents from original EFI system partition into the second EFI system partition. After replicating the EFI system partition, you must use Bootcfg.exe to add the appropriate boot entries to the NVRAM to point to the copy of the EFI system partition you placed on the second disk. Later, if you make any changes to the original EFI system partition, you must manually replicate those changes in the second EFI system partition.

The boot volume and the EFI system partition can be on the same disk, or they can be the on different disks. The following figure illustrates the most common configuration.

**Common Configurations of Mirrored Boot Volumes and Replicated EFI System Partitions (Itanium-based Computers)**

**Prior to mirroring** **After mirroring the boot volume and replicating the EFI system partition**

**Guidelines for Mirroring the Boot Volume and Replicating the EFI System Partition in Itanium-based Computers**

Before you mirror the boot volume or replicate the EFI system partition in an Itanium-based computer, you must note the following guidelines:

- Use care when selecting Advanced Technology Attachment (ATA) disks for a replicated EFI sys partition. Although using ATA disks is supported, the recovery procedure is more complicated when the master disk on the primary integrated device electronics (IDE) channel fails. In this case, you must move the disk with the remaining EFI system partition to the primary IDE channel and set its jumper to master position.

- Do not replicate the EFI system partition by using an ATA disk with a SCSI disk, because startup problems can occur if one of the disks fails.

- If you use duplexed SCSI controllers, make sure to use identical controllers from the same manufacturer.

- You must test the mirrored boot volume and replicated EFI system partition before a failure, to ensure that the computer can start from the remaining boot volume and EFI system partition.

**RAID-5 Volumes**

Using three or more disks, a RAID-5 volume dedicates the equivalent of the space of one disk in the RAID-5 volume for storing parity stripes, but distributes the parity stripes across all the disks in the group. The data and parity information are arranged on the volume so that they are always on different disks.

Implementing a RAID-5 volume requires a minimum of three disks. The disks do not need to be identical, but there must be equally sized blocks of unallocated space available on each disk in the set. The disks can be on the same or different controllers. However, neither the system volume nor boot volume can be on a RAID-5 volume.

### Note

- As with striped volumes, you cannot add disks to a RAID-5 volume if you need to increase the size of the volume later.

If one of the disks in a RAID-5 volume fails, none of the data is lost. When a read operation requires data from the failed disk, the system reads all of the remaining good data stripes in the stripe and the parity stripe. Each data stripe is subtracted (by using **XOR**) from the parity stripe; the order is not important. The result is the missing data stripe.

When the system needs to write a data stripe to a disk that has failed, it reads the data stripes on the other disks. The system uses the data stripes on the remaining disks to calculate the parity. Because the data stripe on the failed disk is unavailable, it is not written; the system only updates the parity stripe.

**Advantages of RAID-5 Volumes**

RAID-5 volumes work well for storing data that will need to be read frequently but written to less frequently and also work well in the following situations:

- In large query or database mining applications where reads occur much more frequently than writes. Performance degrades as the percentage of write operations increases. Database applications that read randomly work well with the built-in load balancing of a RAID-5 volume.

- Where a high degree of fault tolerance is required without the expense (incurred by the additional disk space required) of a mirrored volume. A RAID-5 volume is significantly more efficient than a mirrored volume when larger numbers of disks are used. The space required for storing the parity information is equivalent to 1/Number of disks, so a 10-disk array uses 1/10 of its capacity for parity information. The disk space that is used for parity decreases as the number of disks in the array increases.

**Disadvantages of RAID-5 Volumes**
RAID-5 volumes are not well suited for most write-intensive workloads because a single write is likely to generate a two disk reads (one to read the old data and one to read the old parity information) and two writes (one to update the data and a second to update the parity information).

For example, a RAID-5 volume is not well suited for the following situations:

- For hosting applications that require high-speed data collection. This type of application requires continuous high-speed disk writes, which do not work well with the asymmetrical I/O balance inherent in RAID-5 volumes and the extra I/Os required to write the parity stripe.

- In transaction-processing database applications in which records are continually updated, such as in financial applications where balances are frequently updated.

If a disk that is part of a RAID-5 volume fails, read operations for data stripes on that disk are substantially slower than for a single disk. The software has to read all of the other disks in the set to calculate the data.

A RAID-5 volume requires more system memory than a mirrored volume. In addition, regenerating a RAID-5 volume negatively impacts performance more than regenerating a mirrored volume does.

**Guidelines for Configuring RAID-5 Volumes**
When configuring a RAID-5 volume, buy disks based on:

- **Performance**. RAID-5 performance improves for each disk that you use.

- **Percentage of usable storage**. The space lost to parity information decreases with each additional disk.

- **Cost per gigabyte**. A RAID-5 volume requires a minimum of three disks. Buying three large disks might cost less per gigabyte, but buying six smaller disks results in better performance and more available disk space because less space is used for parity.

The following table compares two RAID-5 configurations that provide the same disk capacities. The configuration that uses six disks is the more efficient storage solution in terms of capacity and performance.

**Comparison of Two RAID-5 Configurations**

| Comparative Feature | 3 Disks at 36.4 GB Each | 6 Disks at 18.2 GB Each |
|---|---|---|
| Total capacity | 109.2 GB | 109.2 GB |
| Spaced used for parity | 36.0 GB | 18.6 GB |
| Available disk space | 73.2 GB | 90.6 GB |

Follow these guidelines for configuring RAID-5 volumes:

- Do not configure your system volume or your boot volume on a RAID-5 volume. In addition, keep the RAID-5 volume on a different controller and disk than your system and boot volume. Using separate controllers improves performance and can accelerate recovery from hardware failures.

- Do not put the paging file on a RAID-5 volume. The paging file does not need to be redundant and can decrease the RAID-5 volume's performance due to frequent disk-writing operations. Instead, put the paging file on a striped or simple volume.

**Fault-Tolerant Hardware and Software**
You can create a RAID-5 volume using hardware- or software-based solutions. With hardware-based RAID, an intelligent disk controller handles the creation and regeneration of redundant information on the disks that make up the RAID-5 volume. The Windows Server 2003 family of operating systems provides software-based RAID, where the creation and regeneration of redundant information on the disks in the RAID-5 volume is handled by the Logical Disk Manager (LDM). In either case, data is stored across all members in the disk array.

In general, hardware-based RAID offers performance advantages over software-based RAID because hardware-based RAID incurs no overhead on the system processor. For example, you can improve data throughput significantly by implementing RAID-5 through hardware that does not use system software resources. Read and write performance and total storage size can be further improved by using multiple disk controllers.

Some hardware-based RAID arrays support hot swapping, which enables you to replace a failed disk or controller while the computer is still running Windows Server 2003. Consider the following points when you evaluate a fault-tolerant hardware or software solution:

- Hardware fault tolerance provides better performance.
- Hardware fault tolerance offers features such as hot sparing, in which additional disks are attached to the controller and left in standby mode. If a failure occurs, the controller uses one of the spare disks to replace the bad disk.
- Software fault tolerance is less expensive.

Regardless of whether you implement fault tolerance by using hardware, software, or both, implementing fault tolerance does not reduce the need for backups.

# Dynamic Disks and Volumes Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dynamic Disks and Volumes Tools and Settings**

**In this section**

- Dynamic Disk and Volume Tools
- Dynamic Disk and Volume Registry Entries
- Dynamic Disk and Volume WMI Classes

The following tools, registry settings, and Windows Management Instrumentation (WMI) classes are associated with dynamic disks and volumes.

**Dynamic Disk and Volume Tools**

The following tools are associated with dynamic disks and volumes.

**Bootcfg.exe: Boot Configuration Tool**

**Category**

Windows Server 2003 operating system tool.

**Version compatibility**

All versions of the Boot Configuration Tool in the Windows Server 2003 family are identical.

You can use the Boot Configuration Tool to query, configure, or change settings in the Boot.ini file on your computer.

**Dmdiag.exe: Disk Manager Diagnostics**

**Category**

Windows Server 2003 operating system tool.

**Version compatibility**

All versions of Dmdiag in the Windows Server 2003 family are identical.

Dmdiag displays the following information for the computer on which it is run:

- Computer name and operating system version
- Physical disk to disk type
- Mount points
- Logical Disk Manager (LDM) file versions
- Drive letter usage
- List of devices
- Symbolic links
- Disk partition information

**Dskmgmt.msc: Disk Management**

**Category**

Windows Server 2003 operating system tool.

**Version compatibility**

All versions of the Disk Management snap-in in the Windows Server 2003 family are identical.

You can use the Disk Management snap-in to remotely manage disks and volumes on other computers running Windows 2000, Windows XP or Windows Server 2003

**DiskPart.exe: DiskPart**
**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
All versions of DiskPart in the Windows Server 2003 family are identical. DiskPart includes a few 64-bit parameters that are only available on Itanium-based computers.

DiskPart is a text-mode command interpreter that enables you to manage objects (disks, partitions, or volumes) by using scripts or direct input from a command prompt.

**Format.exe: Format**
**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
All versions of Format in the Windows Server 2003 family are identical.

Format prepares a volume on the specified disk to accept Windows files.

**FTonline.exe: Fault-tolerant Disk Mounter**
**Category**
Windows Server 2003 support tool.

**Version compatibility**
FTonline enables an administrator to mount and recover files from fault-tolerant disks created in previous versions of Windows. This tool is useful if you did not upgrade your disks to dynamic disks, or failed to back up your data before installing Windows Server 2003. You can install FTonline using the Support Tools setup program located in the \Support\Tools folder on the Windows XP Professional and the Windows Server 2003 family of operating systems CDs.

**Mountvol.exe: Mountvol**
**Category**
Windows Server 2003 operating system tool.

**Version compatibility**
All versions of Mountvol in the Windows Server 2003 family are identical. Mountvol includes a few 64-bit parameters that are only available on Itanium-based computers.

Mountvol creates, deletes, or lists volume mount points. Mountvol enables you to link volumes without using drive letters.

**SecInspect.exe: Sector Inspector**
**Category**
Windows Server 2003 Resource Kit tool.

**Version compatibility**
SecInspect is a command-line diagnostics tool that enables administrators to view the contents of master boot records, boot sectors, and IA64 GUID partition tables. Additional features include creating hexadecimal dumps of binary files and backup/restore of sector ranges. For more information about this tool, see the Help that comes with the tool. To find this tool, see Resource Kit Tool Updates in Tools and Settings Collection.

**Dynamic Disk and Volume Registry Entries**
The following registry entries are associated with dynamic disks and volumes. For more information about the registry, see the Registry Reference in Tools and Settings Collection.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following sections describe the dynamic disk and volume registry entries that are listed below \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\. The headings represent the next level in the path after \Services. For example, Vds\Debuglog is equal to \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Vds\Debuglog.

**Vds\Debuglog**
**Level**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Vds\Debuglog\Level

**Version**
Windows Server 2003 family.

Sets the level of logging for VDS.

Use Registry Editor to add a decimal value named Level. Stop and restart the service after changing.

### VDS Log Options

| Item Logged | Bitmask Number |
|---|---|
| Errors | 1 |
| Warnings | 2 |
| Trace | 4 |
| Information | 8 |

Set the value by adding the bitmask numbers of the values you want to log. For example, decimal 3 logs errors (1) and warnings (2). Decimal 9 logs errors (1) and information (8). The range for this value is 0-15. Set the value to 0xF (decimal 15) to log all items.

**Dmadmin\Parameters**
**EnableDynamicConversionFor1394**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\dmadmin\Parameters\EnableDynamicConversionFor1394

**Version**
Windows Server 2003 family.

Allows a user to convert a Institute of Electrical and Electronics Engineers, Inc. (IEEE) 1394 (FireWire) disk to a dynamic disk on Windows Server 2003 or earlier operating systems. Converting 1394 disks to dynamic is not a tested or supported scenario. This registry entry is provided for compatibility with a Windows 2000 beta that did support this functionality.

EnableDynamicConversionFor1394 is a DWORD Value, with a range of 0-1. Default is zero. To modify, use Registry Editor. Stop and restart the service after modifying.

**Dynamic Disk and Volume WMI Classes**
The following table lists and describes the WMI classes that are associated with dynamic disks and volumes.

### WMI Classes Associated with Dynamic Disks and Volumes

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_DiskDrive | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_DiskDrivePhyiscalMedia | \root\cimv2 | Windows Server 2003 family |
| Win32_DiskDriveToDiskPartition | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_DiskPartition | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_LogicalDisk | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_LogicalDiskToPartition | \root\cimv2 | Windows NT Server 4.0 SP4 and later |
| Win32_MappedLogicalDisk | \root\cimv2 | Windows Server 2003 family |
| Win32_PhysicalMedia | \root\cimv2 | Windows Server 2003 family |
| Win32_Volume | \root\cimv2 | Windows Server 2003 family |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

# Storage Services Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Storage Services Technologies**
Much of the data stored on Microsoft Windows-based servers is critically important for the day-to-day activities in business organizations. Because it is important that employees are able to access and store data reliably, data storage and recovery are a concern for many IT managers. In response to the expanding needs for storage in distributed computing environments, Windows Server 2003 includes several storage technologies that are designed to help you store, access, and manage data on servers.

**In this overview**

- Storage Services Components
- Storage Services Scenarios

**Storage Services Components**
This section discusses the components that make up Storage Services:

- Virtual Disk Service
- Remote Storage
- Removable Storage

**Virtual Disk Service**
For Windows 2000, each company that made storage devices (for example, hard disks, Peripheral Component Interconnect (PCI) redundant array of independent disks (RAID) adapters, and storage arrays) provided its own application for installing and managing that storage device. As a result, users had to run separate applications for each type of storage device that they used on their computer system. This made it difficult to manage different types of storage devices. To address this issue, Windows Server 2003 introduced Virtual Disk Service (VDS). VDS is a set of application programming interfaces (APIs) that provides a single interface for managing disks. VDS provides an end-to-end solution for managing storage hardware and disks, and for creating volumes on those disks.

**Remote Storage**
Remote Storage is a component that you can use to extend disk space without adding more hard disks. Remote Storage automatically copies eligible files on your local volumes to a library of magnetic tapes or magneto-optical disks. Remote Storage then monitors the amount of space that is available on your local volumes. When the amount of available space on a local volume falls below the level that you designate, Remote Storage automatically removes the content from a sufficient number of eligible files and migrates this content to an attached storage device, which frees up disk space on the volume.

**Removable Storage**
Removable Storage is a component that you can use to track your removable storage media (tapes and optical disks) and manage the hardware libraries that contain them (changers and jukeboxes).

With Removable Storage, you can:

- Label, catalog, and track media.
- Control library drives, slots, and doors.
- Perform drive-cleaning operations.

Removable Storage works together with your data-management applications such as Backup. You use data-management applications to manage the actual data stored on the media. Removable Storage makes it possible for multiple applications to share the same storage media resources, which can reduce your costs. It also provides a common interface for managing those

resources, which makes resource management much more efficient.

**Storage Services Scenarios**
This section describes a few scenarios in which you can use Virtual Disk Service, Removable Storage, and Remote Storage to solve unique storage problems in your organization.

**Virtual Disk Service Scenarios**
VDS is commonly used in the following scenarios.

**Managing LUNs on Hardware Storage Devices**
VDS defines a set of features which provide a virtual view of any storage hardware. You can use the VDS APIs to write a storage management application that can manage any other storage hardware RAID arrays and logical unit numbers (LUNs) that have VDS providers. For example, you can use the VDS APIs to create or delete simple, spanned, striped, mirrored, or striped with parity LUNs.

**Managing Disks and Volumes**
The VDS APIs enable applications to manage disks and volumes. You can create your own application that uses the VDS APIs or use applications such as the Disk Management snap-in or the DiskPart command-line tool (both use the VDS APIs) to perform tasks such as creating or deleting simple, striped, spanned, mirrored or RAID-5 volumes, formatting volumes, assigning drive letters to volumes, and converting basic disks into dynamic disks.

**Managing End-To-End Storage Operations**
The VDS APIs enable applications to manage end-to-end storage operations. Using the VDS APIs, your application can create a LUN in the storage array, unmask the LUN to a host, create and format a volume on the LUN, and assign a drive letter to the volume.

**Remote Storage Scenarios**
Remote Storage is commonly used in the following scenarios.

**Conserving disk space on managed volumes**
You can use Remote Storage to ensure that disk space on the managed volume where your system files are located does not fall below a certain level. This is important if you want to make sure that operating system efficiency is not compromised because of decreased disk space.

**Extending disk space on managed volumes**
You can use Remote Storage to make additional space available for new, more frequently accessed files, while retaining older, less frequently accessed files that you might need to access some time in the future.

**Generating multiple media copies of removable media**
You can use Remote Storage to ensure that one or more copies of your migrated files exist on different media in case the original storage medium (disk or tape) becomes unusable.

**Replacing damaged removable media while Remote Storage is running**
You can use Remote Storage to ensure that when you replace a copy of your migrated files that has become damaged or unusable with another copy of the same files, Remote Storage will, at the same time, automatically generate additional copies on different media.

**Recovering from loss of Remote Storage metadata**
You can use Remote Storage to ensure that you can retrieve any metadata that is associated with your Remote Storage files.

**Removable Storage Scenarios**
Removable Storage is commonly used in the following scenarios.

**Managing stand-alone drive libraries**
You can use Removable Storage to manage multiple single-drive libraries, such as CD-ROM or DVD-ROM drives. A library consists of data-storage media and the device that is used to read from and write to the media – for example, tape and a stand-alone tape drive. You can also use Removable Storage to organize all the media in your libraries into different media pools, and move media between media pools in order to provide the appropriate amount of data storage that your applications require.

**Managing automated libraries**
You can use Removable Storage to manage automated libraries. Automated libraries are automated units that hold multiple tapes or disks, and some have multiple drives. These libraries are sometimes called *changers* or *jukeboxes*, and commonly use robotic subsystems to move media stored in the library's storage slots. You can also use Removable Storage to manage a combination of single-drive and automated libraries.

# Virtual Disk Service Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Virtual Disk Service Technical Reference**
For Microsoft Windows 2000, each company that made storage devices (for example, hard disks, PCI RAID adapters, storage arrays) provided its own application for installing and managing that storage device. As a result, users had to run separate applications for each type of storage device they used on their computer system. This made managing the different types of storage devices difficult. To address this issue, Microsoft Windows Server 2003 introduced Virtual Disk Service (VDS). VDS is a set of application programming interfaces (APIs) that provides a single interface for managing disks. VDS provides an end-to-end solution for managing storage hardware and disks, and for creating volumes on those disks.

VDS uses two sets of providers to manage your storage devices. The built-in VDS software providers enable you to manage disks and volumes at the operating system level. Hardware providers supplied by the hardware vendor enable you to manage hardware RAID arrays.

Each hardware vendor writes a VDS hardware provider that translates the general-purpose VDS APIs into specific instructions for their hardware. VDS simplifies storage management because storage applications no longer need to take into account the specific hardware being targeted. Because of VDS, you no longer need to use a different storage application to manage each different storage device. Instead, you can use one compatible storage application to manage any hardware that has a VDS hardware provider.

Windows Server 2003 components that work with VDS include the Disk Management snap-in, the DiskPart command-line tool, and the DiskRAID command-line tool (Diskraid.exe), which is available in the Windows Server 2003 Deployment Kit. DiskRAID requires at least one VDS provider supplied by a storage vendor.

# What Is Virtual Disk Service?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Common Virtual Disk Service Scenarios
- Technologies Related to Virtual Disk Service
- Virtual Disk Service Dependencies
- Related Information

For Windows 2000, each company that made storage devices (for example, hard disks, PCI RAID adapters, storage arrays) provided its own application for installing and managing that storage device. As a result, users had to run separate applications for each type of storage device they used on their computer system. This made managing the different types of storage devices difficult. To address this issue, Windows Server 2003 introduced Virtual Disk Service (VDS). VDS is a set of application programming interfaces (APIs) that provides a single interface for managing disks. VDS provides an end-to-end solution for managing storage hardware and disks, and for creating volumes on those disks.

VDS uses two sets of providers to manage your storage devices. The built-in VDS software providers enable you to manage disks and volumes at the operating system level. Hardware providers supplied by the hardware vendor enable you to manage hardware RAID arrays.

Each hardware vendor writes a VDS hardware provider that translates the general-purpose VDS APIs into specific instructions for their hardware. VDS simplifies storage management because storage applications no longer need to take into account the specific hardware being targeted. Because of VDS, you no longer need to use a different storage application to manage each different storage device. Instead, you can use one compatible storage application to manage any hardware that has a VDS hardware provider.

Windows Server 2003 components that work with VDS include the Disk Management snap-in, the DiskPart command-line tool, and the DiskRAID command-line tool (Diskraid.exe), which is available in the Windows Server 2003 Deployment Kit. DiskRAID requires at least one VDS provider supplied by a storage vendor.

Depending on the underlying disk subsystem, a disk can be a single physical hard disk (sometimes called a spindle), or it can be a group of hard disks bound together at the controller level and presented to the operating system as a single disk. This type of disk is often referred to as a virtual disk or logical unit number (LUN), and typically uses some form of hardware-based RAID to ensure data availability if one of the disks fails.

If your hardware vendor supplies a VDS hardware provider, you can use DiskRAID to manage individual physical disks, also called drives, in a LUN. The following example shows two DiskRAID printouts. The first printout shows information about the LUNs in a given disk subsystem. The second printout shows information about the physical disks that correspond to LUN 0.

**How DiskRAID Displays LUNs in a Disk Subsystem**

```
LUN ###  Status      Health        Type        Size    Sub  Dev
-------  ----------  ------------  --------  --------  ---  ---
LUN 0    Online      Healthy       Stripe     1064 GB    0    3
LUN 1    Online      Healthy       Parity      200 GB    0    4
```

**How DiskRAID Displays the Disks Associated With LUN 0**

```
Drive ###  Status      Health          Size      Free    Bus  Slot  Flags
---------  ----------  ------------  --------  --------  ---  ----  -----
Drive 0    Online      Healthy          66 GB     66 GB    0     5
Drive 1    Online      Healthy          66 GB     35 GB    0     0
Drive 2    Online      Healthy          66 GB     35 GB    1     0
Drive 3    Online      Healthy          66 GB     66 GB    1    11
Drive 4    Online      Healthy          66 GB     66 GB    0     7
Drive 5    Online      Healthy          66 GB     66 GB    0     8
Drive 6    Online      Healthy          66 GB     35 GB    1     3
```

```
Drive 7     Online       Healthy          66 GB      66 GB     1      7
Drive 8     Online       Healthy          66 GB      35 GB     0      2
Drive 9     Online       Healthy          66 GB      66 GB     1      9
```

Windows Server 2003 supplies VDS software providers for basic and dynamic disks and volumes so that you can use tools such as the Disk Management snap-in and DiskPart command-line tool to manage LUNs. However, the Disk Management snap-in and the DiskPart command-line tool display LUNs as disks, as shown in the following figure. Unlike DiskRAID, you cannot use these tools to view or manage the underlying physical disks in a LUN. However, using the Disk Management snap-in or DiskPart command-line tool, you can create partitions and volumes, convert disks to dynamic, and so forth. In the following figure, disk 2 (volume G:) and disk 3 (volume H:) are both on LUNs.

**How Disk Management Displays LUNs As Disks**

**Common Virtual Disk Service Scenarios**
VDS is commonly used in the following scenarios.

**Managing LUNs on Hardware Storage Devices**
VDS defines a set of features which provide a virtual view of any storage hardware. You can use the VDS APIs to write a storage management application that can manage any other storage hardware RAID arrays and LUNs that have VDS providers. For example, you can use the VDS APIs to create or delete simple, spanned, striped, mirrored, or striped with parity LUNs.

**Managing Disks and Volumes**
The VDS APIs enable applications to manage disks and volumes. You can create your own application that uses the VDS APIs or use applications such as the Disk Management snap-in or the DiskPart command-line tool (both use the VDS APIs) to perform tasks such as creating or deleting simple, striped, spanned, mirrored or RAID-5 volumes, formatting volumes, assigning drive letters to volumes, and converting basic disks into dynamic disks.

**Managing End-To-End Storage Operations**
The VDS APIs enable applications to manage end-to-end storage operations. Using the VDS APIs, your application can create a LUN in the storage array, unmask the LUN to a host, create and format a volume on the LUN, and assign a drive letter to the volume.

**Technologies Related to Virtual Disk Service**
VDS is closely related to the following technologies:

**Volume Shadow Copy Service (VSS)**

The Volume Shadow Copy service provides an infrastructure for creating consistent point-in-time copies known as shadow copies. The Volume Shadow Copy service can produce consistent shadow copies by coordinating with business applications, file-system services, backup applications, and storage hardware.

**Logical Disk Manager (LDM)**
The Logical Disk Manager (LDM) provides the drivers and user-mode components that are used to configure dynamic disks and volumes on computers running the Windows XP, Windows 2000, and Windows Server 2003 operating systems.

**Virtual Disk Service Dependencies**
VDS has the following dependencies:

- **OEM Hardware Providers**. VDS requires a hardware provider that is supplied by the hardware manufacturer in order to manage storage hardware.

**Related Information**
The following resources contain additional information that is relevant to this section.

- Disks and Volumes
- Basic Disks and Volumes Technical Reference
- Dynamic Disks and Volumes Technical Reference

# How Virtual Disk Service Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Virtual Disk Service Architecture**

VDS provides three interfaces: a single interface between the application layer and the service, and two interfaces between the service and provider programs in the data layer. The following illustration shows the application-to-service interface and the service-to-provider interface.

**Virtual Disk Service Architecture**

VDS coordinates with the file-system functions, synchronizes provider activities, and coordinates between applications. Being between the application and provider, VDS presents uniform functionality to applications even though some of the underlying providers might lack such uniformity.

VDS implements the following common functionality: formatting volumes, adding and removing mount points or drive letters, and managing unallocated disks (disks that have no partition information). VDS also returns event notifications to registered applications.

**Software and Hardware Providers**

VDS supplies two provider interfaces, one for a software provider and one for a hardware provider. Each provider implements a different portion of the VDS API.

- A *software provider* is a host-based program that is supported by a kernel-mode driver in the storage input/output (I/O) stack. The provider-kernel runtime interacts with the Plug and Play (PnP) Manager at discovery time to claim each disk. Software providers operate on volumes, disks, and disk partitions.

  VDS includes two software provider types: basic and dynamic. The basic software provider manages basic disks and offers no fault-tolerant binding. The dynamic software provider manages dynamic disks and offers fault management, where applicable. Software provider behavior is consistent with the behavior of basic and dynamic disks on the host. For example, if the operating system of a given host supports fault-tolerant dynamic disks, VDS also supports fault-tolerant dynamic disks on the host.

- A *hardware provider* is software that translates the VDS APIs into instructions that are specific to the storage hardware. Hardware providers implement the methods used to manage a storage subsystem—a hardware disk array or adapter card that enables the creation of logical disks configured to enhance performance, data availability, or data recovery. Many RAID cabinet manufacturers have produced hardware providers designed for use with VDS.

  The capabilities of a hardware provider depend on the capabilities of the underlying storage hardware. Therefore, the degree to which each manufacturer implements the VDS API can vary. For instance, manufacturers can implement as many of the features that are defined in the VDS API as are necessary to optimize hardware configurations, monitor and dynamically tune performance, or automate fault management.

Hardware providers offer several configuration options that are not available to the software providers. The most notable is the automagic configuration model, which presents an attribute-based view of storage to each application. Binding hints, such as “mostly reads” or “fast crash recovery required” replace the complexity of binding physical storage into virtual storage. Each hardware provider performs extent mapping, space allocation, and binding-type selection based on the hints submitted by an application. For the complete hardware provider description, including the available configuration options, see the documentation supplied by your hardware subsystem manufacturer.

**Virtual Disk Service Interfaces**

Storage management applications can use VDS methods to query and configure host-based disks and RAID storage. Typical storage management applications use VDS to solve configuration management and monitoring problems. These applications range from dedicated storage-management systems to applications that require better control over configuration or fault management. The following Windows Server 2003 applications use VDS:

- **The Disk Management snap-in**. This snap-in configures and manages disks controlled by a host computer. System administrators and end users can

use the snap-in to query and configure local (or remote) disks and volumes.

- **The DiskPart utility**. DiskPart is a scriptable command-line utility that configures and manages disks, volumes, and partitions. Although DiskPart is available for Windows XP and Windows 2000, these versions do not support VDS.

- **The DiskRAID utility**. DiskRAID is a scriptable command-line utility that configures and manages hardware RAID subsystems. This utility can interact with any storage hardware accompanied by a VDS hardware provider. DiskRAID ships with the Windows Server 2003 Technical Reference and the Windows Server 2003 Deployment Kit.

VDS objects provide interfaces that expose methods for querying, configuring, and maintaining storage devices, as shown in the following diagram.

**VDS Interfaces Architecture**

The following tables list the interfaces implemented by the VDS service, the VDS software providers, and the VDS hardware providers.

**VDS Interfaces Implemented by Applications**

| Interface | Description |
|---|---|
| IVdsAdviseSink | Receives VDS notifications. |

**Interfaces Implemented by VDS**

| Interface | Description |
|---|---|
| IVdsAdmin | Registers a provider with VDS. |
| IVdsService | Provides service-level methods for working with VDS. |
| IVdsServiceLoader | Launches VDS. |
| IVdsVolumeMF | Performs access path and file system operations on volume objects. |

**VDS Interfaces Implemented by Software Providers**

| Interface | Description |
|---|---|
| IEnumVdsObject | Enumerates through a set of VDS objects of a given type. |
| IVdsAdvancedDisk | Creates and deletes partitions, and modifies partition attributes, such as read-only, hidden, and so forth.<br><br>Used most often with OEM partitions.<br><br>For ordinary partitions, use IVdsVolume. |
| IVdsAsync | Manages asynchronous operations. |

| | |
|---|---|
| IVdsCreatePartitionEx | Creates a new partition on a basic disk.<br><br>Used most often with OEM partitions or for aligning partitions.<br><br>For ordinary partitions, use IVdsVolume. |
| IVdsDisk | Queries and configures basic and dynamic disks. |
| IVdsPack | Queries and configures packs containing disks, and creates volumes. |
| IVdsProvider | Returns a hardware or software provider's properties. |
| IVdsSwProvider | Performs software-provider operations. |
| IVdsRemovable | Queries and ejects removable disks, such as CD-ROMs. |
| IVdsVolume | Creates and deletes volume plexes, and modifies volume attributes. |
| IVdsVolumePlex | Queries the containing volume and repairs bad extents. |

**VDS Interfaces Implemented by Hardware Providers**

| Interface | Description |
|---|---|
| IEnumVdsObject | Enumerates through a set of VDS objects of a given type. |
| IVdsAsync | Manages asynchronous operations. |
| IVdsController | Exposes methods for performing query and configuration operations on a controller. |
| IVdsDrive | Provides methods for performing query and configuration operations on a drive. |
| IVdsHwProvider | Provides methods for performing query, re-enumeration, and refresh operations on a hardware provider. |
| IVdsLun | Provides methods for performing query and configuration operations on a LUN. |
| IVdsLunPlex | Provides methods for performing query and configuration operations on a LUN plex. A *LUN plex* is the collection of disks that make up the LUN. Except for mirrored LUNs, each LUN can have only one plex. Each plex contains a copy of the data on the LUN. New plexes can be added to a LUN, and, with the exception of the original plex, existing plexes can be removed. VDS supports four LUN plex types: simple, spanned, striped, and striped with parity. |
| IVdsMaintenance | Provides methods for performing maintenance operations on a subsystem, controller, drive, or LUN. |
| IVdsProvider | Returns a hardware or software provider's properties. |
| IVdsSubSystem | Provides methods for performing query and configuration operations on a subsystem. |

**Virtual Disk Service Processes and Interactions**

Some of the common VDS processes and interactions are discussed in the following sections:

- Managing Servers and Desktops
- Retrieving a List of Providers
- Determining the Number of Controllers on the Subsystem

**Managing Servers and Desktops**

VDS makes it easy for you to manage the storage on remote servers. Applications that are written for VDS, such as the Disk Management snap-in, use the appropriate services to connect to and manage the storage on those systems.

To remotely manage a computer running Windows Server 2003 from another computer running Windows Server 2003, the following process occurs. The VDS Loader on the first Windows Server 2003 computer loads VDS on the managed computer. VDS calls CoCreateInstance, which passes an interface pointer back to the Disk Management snap-in, which then allows remote management of the computer.

The following diagram illustrates the components that are used when you remotely manage the storage devices on computers that are running Windows Server 2003.

**Components Used When Managing Remote Servers**

**Retrieving a List of Providers**

When you manage storage on a server, it is often useful to retrieve the list of hardware and software providers. To get the list of providers, you can use an application, such as DiskRAID, to call CoCreateInstance with the class identifier of the VDS Loader and request the IVdsServiceLoader interface. Using the IVdsServiceLoader interface, the application makes a call to the LoadService() method which loads VDS.

The application then calls the WaitForServiceReady() method to wait for the service to fully load before making other calls. The LoadService() method loads the providers. VDS queries the registry and retrieves the list of registered software and hardware providers. VDS loads all providers listed in the registry. The LoadService() method returns the IVdsService interface, which contains the QueryProviders method. This method returns a COM enumerator interface.

The application then uses the COM enumerator interface to get an IUnknown interface on the provider object (call Next*() on the enumerator interface), and calls the QueryInterface method on the IUnknown interface to get specific provider interface, such as IVdsSwProvider or IVdsHwProvider. This provider interface can be used to query the software and hardware providers and retrieve the providers properties such as the name, type, and version. The following diagram summarizes the process of retrieving a list of providers.

**How an Application Gets the List of Providers**

**Determining the Number of Controllers on the Subsystem**

When managing storage on a server, it is often useful to determine how many controllers are on the storage subsystems attached to the server. To determine the number of controllers that are on the subsystem, an application, such as DiskRAID, uses the IVdsService interface to call the QueryProviders method and get a COM enumerator interface. Calling the Next() method on the COM enumerator interface provides an IUnknown pointer to a provider object. The application can call the QueryInterface() method on the IUnknown interface and request the appropriate provider interface, in this case, IVdsHwProvider.

With the hardware provider interface, the application can query the hardware subsystems by calling the QuerySubSystems() method to get a subsystem enumerator interface. Calling the Next() method on this interface returns an IUnknown interface on the subsystem object. The application can then call the QueryInterface() method to request a specific interface, such as the IVdsSubSystem interface. The application obtains the list of controllers for a subsystem by calling the QueryControllers method on the IVdsSubSystem interface. The following diagram summarizes the process of determining the number of

controllers on the subsystem.

**How an Application Determines the Number of Controllers on the Subsystem**

# Virtual Disk Service Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Virtual Disk Service Tools
- Virtual Disk Service Registry Entries

**Virtual Disk Service Tools**
The following tools are associated with Virtual Disk Service (VDS).

**DiskPart.exe: DiskPart**
**Category**
Windows Server 2003 operating system tool

**Version compatibility**
All versions of DiskPart in the Windows Server 2003 family are identical. DiskPart includes a few 64-bit parameters that are only available on Itanium-based computers.

DiskPart is a text-mode command interpreter that you can use to manage objects (disks, partitions, or volumes) by using automated scripts or commands from a command prompt.

**DiskRAID.exe: RAID configuration tool**
**Category**
Windows Server 2003 Resource Kit tool

**Version compatibility**
DiskRAID is not included in the Windows Server 2003 operating system. DiskRAID is included with the Windows Server 2003 Resource Kit tools.

DiskRAID is a text-mode command interpreter. You can use DiskRAID to manage hardware devices that have VDS hardware providers by using automated scripts or commands from a command prompt. You can use DiskRAID to configure and manage redundant array of independent disks (RAID) storage subsystems.

To find more information about DiskRAID, see Resource Kit Tools in Tools and Settings Collection.

**Dskmgmt.msc: Disk Management**
**Category**
Windows Server 2003 operating system tool

**Version compatibility**
All versions of the Disk Management snap-in in the Windows Server 2003 family are identical.

You can use the Disk Management snap-in to remotely manage disks and volumes on other computers running Windows 2000, Windows XP or Windows Server 2003.

**Mountvol.exe: Mountvol**
**Category**
Windows Server 2003 operating system tool

**Version compatibility**
All versions of the Mountvol command-line tool in the Windows Server 2003 family are identical. Mountvol includes a few 64-bit parameters that are only available on Itanium-based computers.

Mountvol creates, deletes, or lists volume mount points. You can use Mountvol to link volumes without using drive letters.

**Virtual Disk Service Registry Entries**
The following registry entries are associated with VDS. For more information about the registry, see the Registry Reference in Tools and Settings Collection.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are

not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following sections describe the VDS registry entries that are listed below \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Vds. The headings represent the next level in the path after \Vds. For example, Debuglog is equal to \HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Vds\Debuglog.

**Debuglog**
**Level**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Vds\Debuglog\Level

**Version**
Windows Server 2003 family

Sets the level of logging for VDS.

Use Registry Editor to add a decimal value named Level. Stop and restart the service after changing.

### VDS Log Options

| Item Logged | Bitmask Number |
|---|---|
| Errors | 1 |
| Warnings | 2 |
| Trace | 4 |
| Information | 8 |

Set the value by adding the bitmask numbers of the values you want to log. For example, decimal 3 logs errors (1) and warnings (2). Decimal 9 logs errors (1) and information (8). The range for this value is 0-15. Set the value to 0xF (decimal 15) to log all items.

**SoftwareProviders**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Vds\SoftwareProviders

**Version**
Windows Server 2003 family

Stores the globally unique identifiers (GUIDs) and attributes of the software providers that are registered with VDS.

VDS supplies a class identifier (Clsid) for the service loader and service objects, but only the service loader Clsid is public. The service is initialized when the providers, a calling application, and the service perform the following tasks:

- Each new provider invokes the IVdsAdmin::RegisterProvider method during installation to register with VDS. The call creates a registry key under either the SoftwareProviders or the HardwareProviders key (depending on the provider type), which is identified by the object GUID of the provider. The Clsid of the provider object is contained under this key. It includes the provider's name, version, and version GUID.

### Note

- Object GUIDs of the provider are persistent. Software and hardware object GUIDs are not.

- An application calls the CoCreateInstance function and passes the service loader Clsid as an argument. With a pointer to the service loader object, the application can start VDS locally or remotely by passing the desired computer name as a parameter to the IVdsServiceLoader::LoadService method.

- When the initial application attaches to the service, VDS first calls CoCreateInstance on each Clsid found under the SoftwareProviders and HardwareProviders registry keys, and then calls the IVdsProviderPrivate::OnLoad method on each provider to start the programs.

**HardwareProviders**
**Registry path**
\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Vds\HardwareProviders

**Version**
Windows Server 2003 family

Stores the globally unique identifiers (GUIDs) and attributes of the non-Microsoft hardware providers that are registered with VDS. VDS requires these GUIDs to be able to connect to and manage the storage hardware. When VDS starts, it loads all registered hardware providers.

VDS supplies a class identifier (Clsid) for the service loader and service objects, but only the service loader Clsid is public. The service is initialized when the providers, a calling application, and the service perform the following tasks:

- Each new provider invokes the IVdsAdmin::RegisterProvider method during installation to register with VDS. The call creates a registry key under either the SoftwareProviders or the HardwareProviders key (depending on the provider type), which is identified by the object GUID of the provider. The Clsid of the provider object is contained under this key. It includes the provider's name, version, and version GUID.

### Note

- Object GUIDs of the provider are persistent; software and hardware object GUIDs are not.

- An application calls the CoCreateInstance function, and passes the service loader Clsid as an argument. With a pointer to the service loader object, the application can start VDS locally or remotely by passing the desired computer name as a parameter to the IVdsServiceLoader::LoadService method.

- When the initial application attaches to the service, VDS first calls CoCreateInstance on each Clsid found under the SoftwareProviders and HardwareProviders registry keys, and then calls the IVdsProviderPrivate::OnLoad method on each provider to start the programs.

# Remote Storage Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote Storage Technical Reference**
You can use Remote Storage to extend disk space on your server without adding more hard disks. Remote Storage automatically copies eligible files on your local volumes to a library of magnetic tapes or magneto-optical disks. Remote Storage then monitors the amount of space that is available on your local volumes.

When the amount of available space on a local volume falls below the level that you designate, Remote Storage automatically removes the content (data) from a sufficient number of eligible files and migrates this content to an attached storage device, thus freeing up disk space on the volume. When data is removed from a file, the logical size of the file remains the same, and to the user, the file appears unchanged, but the physical size of the file is reduced to 1 KB. Content in other eligible files is not removed until more disk space is needed. When you need to open a file whose data has been removed, the data is automatically recalled from remote storage.

Remote Storage runs on Microsoft Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and the 64-bit versions of these operating systems. Remote Storage is also available on Microsoft Windows 2000 Server. However, Remote Storage is not installed by default. To install Remote Storage, you can select Remote Storage during Setup, or you can later manually install Remote Storage through **Add or Remove Programs** in Control Panel. You can only use Remote Storage to manage NTFS volumes.

# What Is Remote Storage?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Remote Storage?**

**In this section**

- Common Scenarios for Remote Storage
- Remote Storage Dependencies on or Interactions with Other Technologies
- Remote Storage Logical Diagrams
- Related Information

You can use Remote Storage to extend disk space on your server without adding more hard disks. Remote Storage automatically copies eligible files on your local volumes to a library of magnetic tapes or magneto-optical disks. Remote Storage then monitors the amount of space that is available on your local volumes.

When the amount of available space on a local volume falls below the level that you designate, Remote Storage automatically removes the content (data) from a sufficient number of eligible (or premigrated) files and migrates this content to an attached storage device, thus freeing up disk space on the volume. When data is removed from a file, the logical size of the file remains the same, and to the user, the file appears unchanged, but the physical size of the file is reduced to 1 KB. Content in other eligible files is not removed until more disk space is needed. When you need to open a file whose data has been removed, the data is automatically recalled from remote storage. To find more information about these processes, see "Remote Storage Logical Diagrams" in this section. See also "Remote Storage Terms and Definitions" and "Remote Storage Processes and Interactions" in "How Remote Storage Works."

Remote Storage runs on Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and the 64-bit versions of these operating systems. Remote Storage is also available on Windows 2000 Server. However, Remote Storage is not installed by default. To install Remote Storage, you can select Remote Storage during Setup, or you can later manually install Remote Storage through **Add or Remove Programs** in Control Panel. You can only use Remote Storage to manage NTFS volumes.

**Levels of data storage**

Remote Storage data storage is hierarchical, with two defined levels. The upper level, called local storage, includes the NTFS disk volumes of the computer running Remote Storage. The lower level, called remote storage, includes the automated media library or stand-alone tape or disk drive that is connected to the server.

Remote Storage supports all SCSI-class 4–mm tape, 8–mm tape, digital linear tape (DLT), and magneto-optical devices that are supported by Removable Storage. (To find more information about Removable Storage, see "What Is Removable Storage?." To find more information about the relationship between Remote Storage and Removable Storage, see "Remote Storage Processes and Interactions" in "How Remote Storage Works.") Remote Storage does not support quarter-inch cartridge (QIC) tape libraries, rewritable compact disks (CD-RWs), or rewritable DVDs (DVD-RWs).

**Retrieval of stored files**

When you need to access a file on a volume managed by Remote Storage, you simply open the file as usual. If the data for the file is no longer on your local volume, Remote Storage recalls the data from a media library. Because this can take more time than usual, Remote Storage removes the data only from those files on your local volumes that you are least likely to need, based on criteria that you set.

**Coordination with other tools**

Remote Storage uses Removable Storage to access the applicable tapes that are contained in libraries. Remote Storage also works with Backup for data recovery, and with Task Scheduler to schedule file copy operations. For information about Removable Storage, see "Removable Storage Technical Reference." For information about Backup, see "Backup Technical Reference."

Remote Storage also provides certain data-recovery features, including the ability to generate multiple copies of data in remote storage.

**Business Benefits**
Remote Storage provides several significant business benefits, including the following:

- A low-cost solution for archiving files that are seldom accessed, but should still be available.
- A low-cost solution that enables virtual expansion of local storage space.
- Transparent automatic access to data in remote storage.
- Automation of the labor-intensive overhead associated with daily manual data-management operations.
- Centralized sharing of remote storage devices for multiple volumes.

### Note

- Using Remote Storage to copy files to remote storage is not the same as backing up your files. You should follow a regular schedule of data backups, including backing up the contents of the local volumes that Remote Storage manages. You should also back up the Remote Storage database and other program files that are located in the System32\RemoteStorage folder.

### Note

- Do not create File Replication service (FRS) replica sets on a volume that is managed by Remote Storage. In addition, do not add a volume to Remote Storage that contains directories that are part of an FRS replica set. Otherwise, you might severely impact system performance and possibly cause data loss within your media library.
- FRS might need to periodically read every file in the replica set to send the file contents to another computer. This causes FRS to recall all files that Remote Storage has sent to secondary storage, which might take a long time (hours or days). If you use tape for your secondary storage, remember FRS recalls files in directory order rather than media order, so the excessive number of tape seeks performed by FRS will likely ruin the tapes and cause data loss.

**Common Scenarios for Remote Storage**
Remote Storage is especially useful in the following scenarios.

(To find more information about the terms used in these scenarios, see "Remote Storage Terms and Definitions" in "How Remote Storage Works." See also "Remote Storage Processes and Interactions" in the same topic.)

**Conserving disk space on managed volumes**
In this scenario, you want to ensure that disk space on the managed volume where your system files are located does not fall below a certain level because you are concerned that operating system efficiency will be severely compromised if this is allowed to happen.

Remote Storage initiates Automatic File Truncation whenever the level of free space on a managed volume becomes less than the specified Desired Free Space. Eligible premigrated files are truncated in order to create additional free space on this volume. The premigrated files are quickly identified and truncated, based on the last access date, and are moved to an attached storage device from which they can later be retrieved if necessary. Placeholders for these files are created and reside in local storage, and the files themselves appear unchanged to the user. Automatic File Truncation continues until the free space on the volume is greater than the Desired Free Space.

To find more information about this process, see "Remote Storage Logical Diagrams" later in this section.

**Extending disk space on managed volumes**
In this scenario, you want to make additional space available for new, more frequently accessed files, while retaining older, less frequently accessed files that you might need to access some time in the future.

By using Scheduled File Truncation, you can force the truncation of premigrated files. The premigrated files that meet the selection criteria are truncated, regardless of the available space on the managed volume. Premigrated files are checked to make sure that they have not been modified since they were premigrated. If a premigrated file has been modified, then the file is not considered premigrated and the file is returned to normal file status. Additionally, the data for the premigrated file in remote storage (called the "unnamed data attribute") is marked as "deleted" to facilitate the reclaiming of space on the device.

With Scheduled File Truncation, you can manage disk space proactively. The action can be scheduled to reduce volume usage before a known volume-intensive event, such as the installation of a very large application.

To find more information about this process, see "Remote Storage Logical Diagrams" later in this section.

**Generating multiple media copies of removable media**
In this scenario, you want ensure that there exists one or more copies of your migrated files on different media in case the original storage medium (disk or tape) becomes unusable.

Media in remote storage are copied to protect data. Copies are updated at the same time as the original media are updated to ensure that a current copy of data is available.

Media copies are replicas that can be substituted for the original media. Data is migrated only to the original media, but can be recalled from either an original or a copy.

Copies are made before the original media are completely filled and are updated as the original is updated. When a media copy is complete, it can be removed from the library located with other media in the copy set, and a new media copy is started.

Remote Storage creates media copies only if a library has two or more available drives. Other media, for which copies cannot be made, must be protected by different means, such as strict physical or environmental safeguards. To replace an original with a copy, you must manually perform the action. You should uniquely identify media copies in order to avoid confusion among different versions.

When a media copy is used to replace damaged or lost remote storage media, Remote Storage automatically copies the media again to ensure a complete set of copies.

**Replacing damaged removable media while Remote Storage is running**
In this scenario, you want to ensure that when you replace a copy of your migrated files with another copy of the same files, Remote Storage will, at the same time, automatically generate additional copies on different media.

When a media copy is used to replace damaged or lost remote storage media, Remote Storage automatically copies the media again to ensure a complete set of copies.

Remote Storage creates media copies only if a library has two or more available drives. Other media, for which copies cannot be made, must be protected by different means, such as strict physical or environmental security. To replace an original with a copy, you must manually perform the action. You should uniquely identify media copies in order to avoid confusion among different versions.

**Recovering from loss of Remote Storage metadata**
In this scenario, you want to ensure that you can retrieve any metadata associated with your Remote Storage files.

Remote Storage metadata exists in files that can be protected by the primary backup system (Backup) for Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition. Windows Server 2003 file security ensures that only the account used by Remote Storage has access to the metadata. Therefore, the administrator must assign appropriate user rights to this account so that only certain individuals (or groups) have access to this metadata. Otherwise, the metadata might be at risk, and if deleted, would no longer be retrievable.

**Selecting the Appropriate Storage Medium: Two Different Scenarios**
As part of deciding whether or not to use Remote Storage, it is important to select the appropriate storage medium. Remote Storage supports magnetic tape and optical discs as media.

The following section compares the advantages and disadvantages of using magnetic tape or optical discs for your remote storage media and then presents two different scenarios as examples of the decision-making process.

*Advantages of Using Magnetic Tape*

The advantages of using magnetic tape include:

- Magnetic tape drives and media are less expensive than optical disc changers and media.
- Magnetic tape drives and media take up less room per megabyte than optical changers and associated media.
- Magnetic tapes are available in several different sizes.

*Disadvantages of Using Magnetic Tape*

The disadvantages of using magnetic tape include:

- A magnetic tape changer takes longer to recall files that have been migrated to Remote Storage. (Magnetic tapes are sequential access media. Depending on the location of a file on the tape, it can take longer to recall a file.)
- The shelf life of magnetic tapes is substantially shorter than that of optical discs.
- Files in Remote Storage cannot be recalled while a media copy to magnetic tape is in progress.
- Magnetic tapes require the following special environmental considerations:
    - Backup media lasts longer in cool, humidity-controlled locations.
    - Backup media must be stored in an area free of magnetic fields, such as those near the backs of computer terminals and analog telephone equipment.

*Advantages of Using Optical Media*

The advantages of using optical media include:

- Optical disc changers recall files from Remote Storage faster than magnetic tape changers. (Optical discs are random access media. Regardless of where the files exist on a disc, discs enable faster seek times while recalling files.)
- Optical media has a longer shelf life than magnetic tape.
- Files in Remote Storage can be recalled while a media copy is in progress.
- Optical discs do not require special environmental considerations.

*Disadvantages of Using Optical Media*

The disadvantages of optical media include:

- Optical disc changers and media are more expensive than magnetic tape drives and media.
- Optical disc changers and media take up more room per megabyte than tape changers and associated media.
- Optical media are available in fewer different sizes.

The following scenarios provide examples of when tape or optical media might be appropriate for an organization.

**Magnetic Tape Scenario**
You are a network administrator at an urgent care medical facility. One of your responsibilities is to maintain the health records of patients who are treated in your facility. A typical patient is treated and released without the need for follow-up care. The patient files are not likely to be recalled from Remote Storage, and recalling these files quickly is not necessary. You decide to use magnetic tape as the most cost-effective storage solution for your organization.

**Optical Disc Scenario**
Your role in the IT department of a large insurance company is to archive vast amounts of customer information. It is extremely important that this information be readily accessible and that the media on which the information is stored have as long a shelf life as possible. You decide to use optical media as the most practical storage solution for your organization.

**Remote Storage Dependencies on or Interactions with Other Technologies**
Remote Storage depends on, or interacts with, the following technologies:

- Microsoft Management Console
- Removable Storage

- Backup (or similar, non-Microsoft data-management programs)
- Win32 tape and disk management APIs
- Media libraries
- The registry
- Event Viewer
- Windows Explorer
- Windows security
- NTFS
- Task Scheduler
- Microsoft Systems Management Server (SMS)
- Active Directory

To find more information about this topic, see "Remote Storage Architecture" in "How Remote Storage Works."

**Remote Storage Logical Diagrams**
The following figures show how files are migrated to, and later recalled from, remote storage.

In the first figure, files on a user's hard drive are premigrated when their unnamed data attributes are copied to an attached storage device. These files are now eligible for truncation.

**Remote Storage Logical Diagram - Files Are Premigrated**

**Step 1: Files Are Premigrated**

In the second figure, the files that have been premigrated are automatically truncated and then migrated to an attached storage device when the level of available space on the hard drive falls below the Desired Free Space.

**Remote Storage Logical Diagram - Files Are Truncated and Migrated**

**Step 2: Premigrated Files Are Truncated and Migrated**

In the third figure, the files are recalled from the attached storage device when the user accesses the files on the hard drive. The files on the hard drive appear unchanged to the user, even though the data was removed during Step 2.

**Step 3: User Recalls Migrated Files**

**Related Information**

- Command-Line References in the Tools and Settings Collection.

# How Remote Storage Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Remote Storage Works**

**In this section**

- Remote Storage Terms and Definitions
- Remote Storage Architecture
- Remote Storage Protocols
- Remote Storage Interfaces
- Remote Storage Processes and Interactions
- Network Ports Used by Remote Storage
- Related Information

You can use Remote Storage to extend disk space on your server without adding more hard disks. Remote Storage automatically copies eligible files on your local volumes to a library of magnetic tapes or magneto-optical disks. Remote Storage then monitors the amount of space that is available on your local volumes.

When the amount of available space on a local volume falls below the level that you designate, Remote Storage automatically removes the content (data) from a sufficient number of eligible (or premigrated) files and migrates this content to an attached storage device, thus freeing up disk space on the volume. When data is removed from a file, the logical size of the file remains the same, and to the user, the file appears unchanged, but the physical size of the file is reduced to 1 KB. Content in other eligible files is not removed until more disk space is needed. When you need to open a file whose data has been removed, the data is automatically recalled from remote storage. To find more information about these processes, see "What Is Remote Storage?" in "What is Remote Storage?" See also "Remote Storage Terms and Definitions" and "Remote Storage Processes and Interactions" in this section.

Remote Storage runs on Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and the 64-bit versions of these operating systems. Remote Storage is also available on Windows?2000 Server., However, Remote Storage is not installed by default. To install Remote Storage, you can select Remote Storage during Setup, or you can later manually install Remote Storage through **Add or Remove Programs** in Control Panel. You can only manage Remote Server on NTFS volumes.

**Levels of data storage**

Remote Storage data storage is hierarchical, with two defined levels. The upper level, called local storage, includes the NTFS disk volumes of the computer running Remote Storage. The lower level, called remote storage, includes the automated media library or stand-alone tape or disk drive that is connected to the server.

Remote Storage supports all SCSI-class 4–mm tape, 8–mm tape, digital linear tape (DLT), and magneto-optical devices that are supported by Removable Storage. (To find more information about Removable Storage, see "What Is Removable Storage? To find more information about the relationship between Remote Storage and Removable Storage, see "Remote Storage Processes and Interactions" in this section.) Remote Storage does not support quarter-inch cartridge (QIC) tape libraries, rewritable compact disks (CD-RWs), or rewritable DVDs (DVD-RWs).

**Retrieval of stored files**

When you need to access a file on a volume managed by Remote Storage, you simply open the file as usual. If the data for the file is no longer on your local volume, Remote Storage recalls the data from a media library. Because this can take more time than usual, Remote Storage removes the data only from those files on your local volumes that you are least likely to need, based on criteria that you set.

**Coordination with other tools**

Remote Storage uses Removable Storage to access the applicable tapes contained in libraries. Remote Storage also works with

Backup for data recovery, and with Task Scheduler to schedule file copy operations. For information about Removable Storage, see "Removable Storage Technical Reference". For information about Backup, see "Backup Technical Reference."

Remote Storage also provides certain data-recovery features, including the ability to generate multiple copies of data in remote storage.

**Business Benefits**
Remote Storage provides several significant business benefits, including the following:

- A low-cost solution for archiving files that are seldom accessed, but should still be available.
- A low-cost solution that enables virtual expansion of local storage space.
- Transparent automatic access to data in remote storage.
- Automation of the labor-intensive overhead associated with daily manual data-management operations.
- Centralized sharing of remote storage for multiple volumes.

### Note

- Using Remote Storage to copy files to remote storage is not the same as backing up your files. You should follow a regular schedule of data backups, including backing up the contents of the local volumes that Remote Storage manages. You should also back up the Remote Storage database and other program files located in the System32\RemoteStorage folder.

### Notes

- Do not create File Replication service (FRS) replica sets on a volume that is managed by Remote Storage. In addition, do not add a volume to Remote Storage that contains directories that are part of an FRS replica set. Otherwise, you might severely impact system performance and possibly cause data loss within your media library.
- FRS might need to periodically read every file in the replica set to send the file contents to another computer. This causes FRS to recall all files that Remote Storage has sent to secondary storage, which might take a long time (hours or days). If you use tape for your secondary storage, remember FRS recalls files in directory order rather than media order, so the excessive number of tape seeks performed by FRS will likely ruin the tapes and cause data loss.

The following sections provide an in-depth view of how Remote Storage works in an optimal environment. An optimal environment for Remote Storage is defined as follows:

- Windows Server 2003 is correctly installed and Remote Storage is enabled.
- All other dependencies are in place, properly designed and deployed, and functioning normally.
- Server hardware is sized appropriately and there are no disk, CPU, memory, or network bottlenecks that affect the performance of the technology.

**Remote Storage Terms and Definitions**
The following terms are associated with Remote Storage.

**Managed volume**
A local volume formatted with NTFS file system 5.0 whose disk space is managed by Remote Storage. Remote Storage frees up disk space by automatically moving infrequently accessed files to a remote storage device.

**Desired Free Space**
The amount of free space that you specify a volume should have at all times during normal use.

**Eligible file**
A file that has been premigrated, and is therefore ready to be truncated.

**File selection criteria**
User-defined criteria that determine which files Remote Storage will premigrate. One such criterion might be that all files that are .doc files should be premigrated.

**Unnamed data attribute**
The default data stream of an NTFS file, sometimes referred to as $DATA. The unnamed data attribute is copied to remote storage during premigration.

**Premigrated file**
A file whose unnamed data attribute has been copied to a remote storage device in preparation for truncation. Until truncation and migration take place, this file remains unchanged on the managed volume.

**Truncated file**
A file on a managed volume from which Remote Storage has removed data so that the physical file size is reduced to 1 KB. This file appears unchanged to the user.

**Migrated file**
A file that Remote Storage has copied from local storage to remote storage. The resulting file in remote storage is not visible to users. The file remaining in local storage is truncated.

**Automatic File Truncation**
The process in which data is removed from a sufficient number of premigrated files when available disk space on a managed volume falls below the required level. This process occurs without user intervention.

**Scheduled File Truncation**
The process in which a user forces data to be removed from premigrated files even if available disk space has not fallen below the required level.

**Placeholder**
An identifier for a file that has been migrated from local storage to remote storage. Placeholders are not visible to users.

**Remote storage**
The term "remote storage" (lower case) refers to infrequently accessed data and the media on which it is stored until the data is needed again.

**Removable Storage**
A service that you can use to manage removable media (such as tapes and discs) and storage devices (libraries). Removable Storage enables applications to access and share the same media resources. For a complete listing of Removable Storage terms and definitions, see MSDN and type Removable Storage Glossary in the "Search for" text box.

**Remote Storage Architecture**
From an architectural standpoint, Remote Storage is divided into three areas:

- **Remote Storage components:** The Remote Storage Microsoft Management Console (MMC) snap-in and the Remote Storage service.
- **Windows components and services:** Win32 tape and disk APIs, tape and disk drivers, changer drivers, Event Viewer, and the registry.
- **Libraries:** A robotic or automated library, stand-alone tape drive, and stand-alone disk driver, for example.

The following figure shows the components within these three areas and how the areas and components interact.

**Remote Storage Architectural Diagram**

The following table lists the components that are included in Remote Storage.

**Remote Storage Components**

| Component | Description |
|---|---|
| Remote Storage MMC snap-in | Administrative interface to Remote Storage. The Remote Storage snap-in enables you to:<br>• Set the device type while running the Remote Storage Setup Wizard the first time you start the snap-in, and subsequently view media state and utilization.<br>• Set Remote Storage system-wide feature options.<br>• View information about Remote Storage activity.<br>• Recover from media disasters. |
| Remote Storage service | Two system services that implement Remote Storage functionality.<br>The primary service starts automatically. The second service is used for recall notifications. |

The following table lists the items that are included in Windows components and services.

**Windows Components and Services**

| Service | Description |
|---|---|
| Win32 tape and disk management APIs | Comprises four different APIs: CreateFile, DeleteFile, GetDiskFreeSpace, and GetDiskFreeSpaceEx.<br>To find more information about these APIs, see "How Removable Storage Works" in "How Removable Storage Works." |

| | |
|---|---|
| Tape and disk driver | Enables a specific device, such as a stand-alone tape or disk drive, to communicate with the operating system. Although a device might be installed on your system, Windows cannot use the device until you have installed and configured the appropriate driver. If a device is listed in the Windows Catalog, a driver is usually included with Windows. Device drivers load automatically (for all enabled devices) when a computer is started, and thereafter run in a manner transparent to users.<br><br>(The Windows Catalog website has hardware and software compatibility information for the Windows 2000 Server family, Windows XP, and the Windows Server 2003 family.) |
| Changer driver | Enables a specific device, such as an automated or robotic library, to communicate with the operating system. Although a device might be installed on your system, Windows cannot use the device until you have installed and configured the appropriate driver. If a device is listed in the Windows Catalog, a driver is usually included with Windows. Device drivers load automatically (for all enabled devices) when a computer is started, and thereafter run in a manner transparent to users. |
| Event Viewer | A component that you can use to view and manage event logs, gather information about hardware and software problems, and monitor security events. Event Viewer maintains logs about program, security, and system events.<br><br>Recalls of files from Remote Storage are logged in the Windows event log. |
| The registry | A database repository for information about the configuration of a computer. The registry contains information that Windows continually references during operation, such as:<br><br>• Profiles for each user.<br>• Programs that are installed on the computer and the types of documents each can create.<br>• Property settings for folders and program icons.<br>• Hardware that exists on the system.<br>• Ports that are being used.<br><br>The registry is organized hierarchically as a tree and is made up of keys and their subkeys, hives, and entries. |

The following table lists the components that are included in libraries.

**Libraries**

| Library | Description |
|---|---|
| Robotic or automated library | Automated units that hold multiple tapes or disks. Some have multiple drives. These libraries are sometimes called *changers* or *jukeboxes*, and commonly use robotic subsystems to move media stored in the library's storage slots. Automated libraries can also consist of other hardware components that are managed by Removable Storage, such as doors, inject/eject ports, cleaner cartridges, and bar-code readers. |
| Stand-alone tape drive | A single-drive, nonautomated unit that holds a single tape. With this device, you manually insert a tape into the unit. |
| Stand-alone magneto-optical disk drive | A single-drive, nonautomated unit that holds a single disk. With this device, you manually insert a disk into the unit. |

**Remote Storage Protocols**

Remote Storage does not utilize any networking protocols.

**Remote Storage Interfaces**

There are no Remote Storage interfaces available.

**Remote Storage Processes and Interactions**

The following is a general description of how Remote Storage functions at a basic level. (To find more information about the terms used in this section, see "Remote Storage Terms and Definitions" earlier in this section.)

Remote Storage is a hierarchical storage management application that migrates data from *upper-level storage* to *lower-level storage*. Upper-level storage is commonly known as local storage: frequently accessed data that is stored locally on high-performance disks. Lower-level storage is also known as remote storage: infrequently accessed data that is stored on less expensive media until it is needed again. Hierarchical storage management reduces the costs of storing large quantities of data, while ensuring that the data is still accessible. The following table outlines when to use the two levels of Remote Storage.

**Levels of Remote Storage**

| Considerations | Upper-level Storage | Lower-level Storage |
|---|---|---|
| **Storage type** | Local or primary | Remote storage |
| **How often is data needed?** | Frequently | Less frequently |
| **Media type** | High-performance disks | CD-ROMs<br>DVD-ROMs<br>Magnetic tape, which includes:<br>• Digital audio tape (DAT)<br>• Digital linear tape (DLT)<br>Magneto-optical disk drive |
| **Storage cost** | More expensive | Less expensive |

Regardless of where you store the data, the file system namespace continues to provide users with access to the file. For example, when a user double-clicks a file in My Documents, Remote Storage retrieves the file from its storage location and restores it to the file system.

For users to access files that are stored on offline media, the media must be placed back online before the files are accessible. Therefore, these files require more time to access than files that are stored on online media.

The following is a more in-depth examination of how Remote Storage works at a basic level.

To prepare for the need to free storage space on a local server, Remote Storage regularly premigrates (copies) the unnamed data attribute of all eligible NTFS files on local storage to remote storage. After this is done, the files on local storage are considered to be premigrated. The unnamed data attribute of an NTFS file contains information that is tracked by NTFS. This information is needed to manage the data. To find more information about this process, see "What Is Remote Storage?" in "What Is Remote Storage?"

When the amount of available space on a local volume falls below the Desired Free Space, Remote Storage automatically removes the content (data) from a sufficient number of eligible files and migrates this content to an attached storage device, thus freeing up disk space on the volume. This process is referred to as truncation. When data is removed from a file, the disk space used by the file is reduced to 1 KB, although the file itself appears unchanged. At the same time, a "placeholder" is generated for each such file and this placeholder serves as an identifier for its newly-created counterpart on the attached storage device. Remote Storage marks the placeholder with the flag, FILE_ATTRIBUTE_OFFLINE. Content in other eligible files is not removed until more disk space is needed. When you need to open a file whose data has been removed, the data is automatically recalled from remote storage.

Even though Remote Storage changes the physical size of the file on local storage, the logical size and the date and time (created, last modified, last accessed) of the file remain unchanged. Users or applications (for example, disk quotas) that use file size as a determinant of a particular action are not affected by Remote Storage data migration.

For these processes and interactions to work as described, Removable Storage should reside in an optimal environment. An optimal environment for Removable Storage is defined as follows:

- Windows Server 2003 is correctly installed and the Removable Storage service is running.

- All other dependencies are in place, properly designed and deployed, and functioning normally.
- Server hardware is sized appropriately and there are no disk, CPU, memory, or network bottlenecks that affect the performance of the technology.

**Remote Storage Technologies**
The following is a more detailed description of specific technologies, features or attributes that either form a part of, or are closely identified with, Remote Storage.

**Removable Storage**
Remote Storage uses Removable Storage for copying data to online libraries that contain removable media. For example, if a volume that is being managed by Remote Storage meets the requirements for migrating data to secondary storage, Removable Storage moves media into a slot so that Remote Storage can migrate data to that media. To find more information about this topic, see "How Removable Storage Works" in "How Removable Storage Works."

**Disk Management Attribute**
In Remote Storage, you can define a single, system-wide, disk management attribute that can be applied to each managed volume. This attribute is referred to as the Desired Free Space setting and establishes a threshold that triggers Automatic File Truncation. The purpose of Automatic File Truncation is to free up disk space on a managed volume when the amount of space falls below a certain percentage. The default setting is five percent, but this can be adjusted to any percentage that you specify. In addition, you can set the level of Desired Free Space for several different managed volumes all at the same time.

### Notes

- It is important to realize that although the Desired Free Space setting is used to determine when files that have already been premigrated should be truncated, it is not used to determine how many files should be premigrated before the need for truncation occurs.
- In addition, by default, Remote Storage does not premigrate the Windows system files (or any files marked with the system attribute).

**Premigration**
Files are selected for premigration based on the following criteria:

- Path name
- File names, including wildcard characters in names
- Inclusion or exclusion of premigration specifications

The following criteria can be applied to an entire volume, but not to an individual file:

- Last access date or inactivity period
- Owner
- File size
- System and hidden files

You use these criteria to specify which files will be premigrated and, consequently, become eligible files. Eligible files are files that are truncated as the need for additional disk space arises. Remote Storage premigrates all files that meet the criteria and tracks these files to allow rapid file truncation. Even though Remote Storage changes the physical size of the file in local storage, the logical size and the dates and times (created, last modified, last accessed) of the file remain unchanged.

Remote Storage applies the inclusion and exclusion rules in such a manner that the more specific a rule, the higher its priority. For example, the rules of "Exclude *.*" and "Include \PROG*.EXE" causes the file "\Prog\Test.exe" to be included and "\Test.exe" to be excluded.

**Automatic File Truncation**
Remote Storage initiates Automatic File Truncation whenever the level of free space in a managed volume becomes less than the Desired Free Space. Eligible premigrated files are truncated to free space on local storage. The premigrated files are quickly identified and truncated, based on the last access date. The file truncation process continues until the free space on the volume is greater than the Desired Free Space.

If the premigrated file has not been modified, then the file is truncated and a placeholder for the file is created. If the premigrated file has been modified, the file is no longer considered premigrated and is returned to "normal file" status. In addition, the capacity flow meter is decremented and the data for the premigrated file in remote storage is marked as deleted to facilitate space reclamation. Reclamation is the process of deleting from the Remote Storage media pool any files that are no longer necessary, thereby freeing up additional storage space.

### Note

- Storage maintains a flow meter capacity metric that monitors the amount of data that is contained in remote storage, including overflowed and shelved data. Copying data from local storage to remote storage increases the value of the capacity metric. Removing local storage references to data in remote storage decreases the value of the capacity metric.

**Scheduled File Truncation**
Scheduled File Truncation is the process in which a user forces data to be removed from premigrated files even if available disk space has not fallen below the required level. Premigrated files are checked to make sure that they have not been modified since they were premigrated. If the premigrated file has been modified, then the file is not considered premigrated and the file is returned to normal file status. Additionally, the data for the premigrated file in remote storage is marked as deleted to facilitate space reclamation.

You can use Scheduled File Truncation to manage disk space proactively. The action can be scheduled to reduce volume usage in advance of a known volume-intensive event, such as the installation of a very large application.

**Validation of Managed Files**
You can use Validate Managed Files to validate premigrated files and placeholders, thus making sure that all the files on your managed volumes point to valid and correct data in remote storage. Validation includes detecting placeholders moved between volumes, disconnected placeholders, and modified premigrated files. Corrective actions are taken immediately to synchronize the placeholders and premigrated files with remote storage. Validation also recalculates volume statistics. Validation is automatically performed two hours after a backup program is used to restore a remote storage file, but can also be scheduled manually.

You should perform validation a regular basis to validate all files on a given volume and to correct any inconsistencies. You should also perform validation after restoring files on a local volume or after disk errors have occurred on a volume.

**File Recall**
The file is recalled on the first read, write, or memory map request. If the data is on tape or disk in remote storage, but the tape or disk is not in the library (storage device), the recall does not succeed and returns the message STATUS_FILE_IS_OFFLINE. In order to successfully recall the file, you need to manually insert the tape or disk into the library and then try the recall again.

### Notes

- Remote Storage does not affect a request that is made against a premigrated file. The data for the file exists locally on the NTFS volume and can be accessed normally. However, the client making the request on the server might time out. Client computers have their own configured time-out that is independent of Remote Storage, and if accessing the data takes longer than the time-out, the input/output request is unsuccessful for the client.

- Changing attributes, access control lists (ACLs), or named streams in a file does not recall the file.

**Runaway Recall Detection and Prevention**
*Runaway recalls* can be prevented by specifying that no more than a certain number of files can be recalled by a user from a volume in an hour. An administrator defines this setting, both in terms of enabling or disabling the feature, and in specifying the number of recall requests that are handled in a particular period of time.

**Renaming, Moving, or Copying Placeholders and Premigrated Files**
Migrated files (and their associated placeholders) and premigrated files can only be renamed on the same volume. Files cannot be renamed across volume boundaries. It is important to note that renaming a file does not cause the data in remote storage to be recalled.

However, it is possible to copy or move placeholders across volume boundaries. When this occurs, the data in remote storage is recalled. At the end of a *move* operation between volumes, the original placeholder is deleted and the file information that has been recalled and is now present on the other volume once again assumes a premigrated status. At the end of a *copy* operation between volumes, the original placeholder is also deleted, but there now exist two files, the first on the original volume and the second on the other. The same process applies when copying a placeholder to a different location on the same volume: the data in remote storage is recalled, the original placeholder is deleted, and there now exist two identical files, both on the same volume.

### Note

- In order to prevent file information from being recalled when moving or copying a file to a different volume on the same computer, you should use Backup to back up and restore the file to its new location, rather than moving or copying the file directly. Despite being moved or copied, the file will continue to point to the correct location in remote storage.

**Discontinuing Volume Management**
If necessary or desirable, you can specify that Remote Management no longer manage a volume. In doing this, you are given two choices:

- Remote Storage discontinues managing the local volume, but leaves data in remote storage. Data that is already in remote storage can be recalled as before. No automatic freeing of disk space takes place.

- Remote Storage recalls data from remote storage, and then discontinues managing the local volume. You should only select this option if your local volume has adequate disk space for the recalled data.

If you have adequate disk space to recall data from remote storage, but the option of recalling all data is disabled, click the **Refresh** button in order to update volume statistics. After you have updated the volume statistics, the option should be enabled.

**Restoring Placeholders from Backup and Disconnected Placeholders**
The data in remote storage is accessible only through a placeholder. If the placeholder is deleted, that data is inaccessible. An upper-level storage backup application, such as Backup, protects placeholders. If the placeholder is deleted, lost, or destroyed, the only recourse is to retrieve a copy from the backup media. If a placeholder is restored from backup, the placeholder is reconnected to that data. This is the same mechanism that you must use if any other file on the volume is deleted, lost, or destroyed.

Disconnected placeholders are placeholders whose file contents have been removed from remote storage. These placeholders might have been restored from backup after the space in remote storage was reclaimed, or the data within remote storage might be physically unavailable because of media failures. Disconnected placeholders do not point to valid locations in remote storage. By validating placeholders, you remove disconnected placeholders from the system and synchronize the remaining placeholders with remote storage.

**Interaction with Other Reparse Point Types**
Volume mount points and symbolic links cannot be changed into placeholders. The system explicitly ignores these types of files. Any file system scan that encounters a mount point or symbolic link does not follow the link.

**Placeholders Binding to a Specific Remote Storage Engine**
Placeholders identify the specific remote storage system that contains the managed data, binding a placeholder to a specific Remote Storage engine. Placeholders cannot be moved between multiple remote storage systems.

**Windows Server 2003 Family Security Integration**
Remote Storage supports NTFS security features. Remote Storage recalls files only if the user has valid access to a placeholder. Because a placeholder is identified as a special remote storage reparse point, the security of the reparse point mechanism determines the security of the placeholder.

Administrators and users undergo the normal security checks for Windows users. The Remote Storage Administrative user interface uses Windows permissions to grant or deny access to the interface. Only user accounts in the Administrators group are allowed access to the UI functions.

**Grouping of Files**
Files are grouped together by their volume and by the time at which they were originally premigrated. The files remain grouped during all remote storage operations. No other grouping of files is supported.

**Replication**

By using the file selection criteria, the administrator can exclude from the Manage Files action any files that are being replicated.

**Remote Storage Engine**
Remote storage is the part of the system that holds the copies of the data. The Remote Storage engine consists of libraries, drives, and the media used to store the data.

The Remote Storage engine service runs only on computers that are running Windows Server 2003, Datacenter Edition; Windows Server 2003, Enterprise Edition; or Windows 2000 Server. Only one Remote Storage engine can exist on a server.

**Flow meter capacity metric**
Remote Storage maintains a flow meter capacity metric that monitors the amount of data that is contained in remote storage, including data that has overflowed onto other media or is located on media that are no longer in the device and have been shelved. Copying data from local storage to remote storage increases the value of the capacity metric. Removing local storage references to data in remote storage decreases the value of the capacity metric.

Remote Storage increases the value of the flow meter capacity metric whenever one of the following occurs:

- A new file is managed.
- A previously deleted placeholder is restored to a volume and reconnected to remote storage.

Remote Storage decreases the value of the flow meter capacity metric whenever one of the following occurs:

- A premigrated file is modified.
- A placeholder or premigrated file is deleted.
- A file is unmanaged.

There might be a delay in changing the value of the flow meter capacity metric because detection of these conditions can happen at a later time.

**Media pool for remote storage**
All remote storage in Remote Storage exists in a single storage or media pool. A media pool is defined as a unit of storage that is administered by Removable Storage and composed of homogeneous storage media. A media pool is a self-contained storage area with homogeneous characteristics — for example, random access, sequential access, read/write, and write-once. To find more information about media pools, see "How Removable Storage Works" in "How Removable Storage Works."

Remote Storage supports one storage library within the single storage pool. The library must have at least one drive. To support media copies, it must have two or more drives. When multiple drives exist within a library, all drives must be identical in type.

### Note

- Relocation is the movement of data from one remote storage pool to another. Because Remote Storage only supports a single remote storage pool, relocation is not supported in Remote Storage.

**Handling remote storage that is full**
Remote Storage provides the following options for handling situations in which remote storage is physically full:

- **Stop managing new files.** Remote Storage becomes a recall-only system. This mode is invoked only after any possible space reclamation is performed.
- **Shelf storage.** Remote Storage cycles removable media to shelf (offline storage). Recalls of files stored on shelved media require physical intervention.

Remote storage is considered full either when there is not enough space on the media or when the media are not online. In either case, you must physically intervene to allow Remote Storage to continue migrating files. A notice is issued when physical remote storage use reaches the warning level that is defined by the administrator.

**Shelf media for Remote Storage**
Shelf media for Remote Storage are media that are not currently accessible by the system. The medium with the data on it can be removed from the device and the media management subsystem tracks its location. Shelf media allow a system to have more data in remote storage than the device can physically contain.

For removable media, you can remove media and optionally replace them with blank media. Remote Storage continues to premigrate data by using the new media. The removed media are considered shelf media. If a user needs access to data that is on shelf media, you must place the shelf media in the library, and the new media become shelf media. Media do not need to be full to be shelf media.

**Upgrading Remote Storage libraries**
Removable Storage provides Remote Storage with the ability to replace a library with another library that contains identical media and data read/write mechanisms. You must physically move the media from the old library to the new library, that is, physically replace the library, and then use the Remote Storage snap-in to register configuration changes within Remote Storage.

**Remote Storage Device Support**
Remote Storage supports all of the same 4-mm, 8-mm, and digital linear tape (DLT) and magneto-optical disc devices that Removable Storage supports. Because Remote Storage supports only a single media type, a device cannot be a mixed media device.

Removable Storage uses Windows kernel-mode drivers to support the management of tape and optical disc devices. These device drivers provide the backbone of device support for both Removable Storage and Remote Storage. The Windows Logo program identifies device drivers that have been approved for use with the Windows Server 2003 family.

Remote Storage cooperatively shares storage libraries with external applications by using a common media management facility, such as Removable Storage.

### Note

- Remote Storage does not support using small-capacity removable disk devices such as the Iomega Zip drive.

**Remote Storage Integration in Windows Server 2003**
Remote Storage is integrated closely with the NTFS file system in Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition. The following table provides details of this integration and describes the interfaces between Remote Storage and these operating systems.

### Remote Storage and Windows Server 2003 Integration

| Interface | Description |
|---|---|
| Placeholder format and reparse points | A placeholder has the system-defined $REPARSE_POINT attribute set with information that can identify and retrieve the unnamed data attribute from remote storage. The unnamed data attribute is in remote storage and its length is zero bytes. The reparse point type is “Remote Storage”.<br><br>The recall mechanism is based on the reparse point being identified by NTFS and is an efficient mechanism that uses this information when recalling a file. |
| File size of a placeholder | The logical file size of the unnamed data attribute of a placeholder is the same size as it was before it was truncated. The physical size of the unnamed data attribute of a placeholder is zero bytes. |
| Disk quotas and remote storage | Disk quotas do not change. Disk quotas are based on the logical file size that is not changed by Remote Storage. Therefore, the amount of space in use on a volume is not reduced or changed by having data in remote storage. |
| Remote Storage stage change | Remote Storage supports a Distributed Component Object Model (DCOM) interface–based mechanism that can change the system status. |

| | |
|---|---|
| Event log usage | Major Remote Storage system events are logged in the Windows event log. You can use the Windows Event Viewer to see the logged events.<br><br>The following events are optionally logged in the Windows event log:<br><br>• Recalled files<br>• Managed files<br>• Truncated files<br>• Mounted media<br>• Run jobs<br>• Scanned files |
| Windows Server 2003 Job Scheduler | Remote Storage uses the Windows Server 2003 Job Scheduler to schedule Remote Storage jobs. Job status can be monitored from within the Remote Storage snap-in.<br><br>Depending on the Job Scheduler, a job window can be specified that limits the amount of time spent in a single scan. This is useful because the system might have a large amount of data to manage and the scan might initially take too much time. A bookmark is kept where the scan stopped so the scan can continue from that point the next time it is run. |
| Windows Server 2003 registry usage | Remote Storage uses the registry to keep persistent information about startup, including the programs needed to initialize Setup. |
| Windows Server 2003 client time-out on recall | The registry entry HKEY_LOCAL_MACHINE\SYSTEM \CurrentControlSet\Services\LanmanWorkstation\parameters \OfflineFileTimeOutIntervalInSeconds controls the time-out period that the client uses when sending requests to a server. The default is value is 900 (or 15 minutes). You can increase this value on all Windows clients that open files on the volumes managed by Remote Storage. |

**Multiple Remote Storage Interactions**
A Remote Storage installation is limited to a single system running Windows Server 2003, Enterprise Edition or Windows Sever 2003, Datacenter Edition. There is no limit, however, to the number of stand-alone Remote Storage instances that can run on a homogeneous Windows network.

**Moving data from one Remote Storage installation to another**
To move managed data from one Remote Storage installation to another, you recall managed data and move the data to another volume managed by Remote Storage.

**Choosing Products That Work with Remote Storage**
Because it manages data transparently for applications and users, Remote Storage does not require that the other applications running on NTFS be completely compatible with it, nor does it require that the applications contain specific code to recognize that Remote Storage is running. However, products that regularly open many files might cause a great deal of data recall, thus reducing the benefits provided by Remote Storage. Thus, for best results, use applications that are compatible with Remote Storage.

### Note

- Although the features included with Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition are compatible with Remote Storage, many other applications are not and can result in time-outs or runaway recalls. In all cases, check with your independent software vendor (ISV) in order to determine if they provide a version that is compatible with Remote Storage.

**Backup Programs and Remote Storage**
A backup product that is compatible with Remote Storage must perform the following actions:

- Guarantee that a full backup of the file is kept. The backup product must recognize the difference between backing up the

placeholder and backing up the full data of the file, and must keep the full backup copy.

- Back up a placeholder (reparse point) correctly.
- Use the FILE_FLAG_OPEN_BACKUP_SEMANTICS parameter when opening a file to back it up.
- Properly use FILE_FLAG_OPEN_NO_RECALL.

Backup applications that are compatible with Remote Storage protect placeholder data and do not cause recalls.

Remote Storage relies on the primary backup to protect placeholder data. You must be aware of when placeholder backups occur. Specifically, if backup rotations are used, you must know when the primary backup databases contain a complete copy of the data and when they contain placeholder data.

Backup applications that open placeholders to read and copy without using the FILE_FLAG_OPEN_BACKUP_SEMANTICS parameter cause the data for the file to be recalled. If these products are performing a full system backup, all placeholders are replaced with recalled data.

**Antivirus Programs and Remote Storage**
Antivirus programs typically open files to check for infection by viruses. These products sometimes cause migrated data to be recalled. Antivirus programs that are compatible with Remote Storage can operate in one of the following ways:

- Detect placeholders and skip the check on such files. This assumes that the scanner checked the data before premigrating it. This might be somewhat hazardous because Remote Storage manages the unnamed data stream and does not manage named data streams. Because data in remote storage remains unchanged, an additional check for viruses is unnecessary.
- Open the file with the FILE_OPEN_NO_RECALL parameter. This allows the scanner to check the unnamed data stream by using local storage without recalling the data. This assumes a linear search of the file data, which might not always be the case.
- Do not update the last access date and time.

**Document Management Programs**
Many document management products open the data that they are managing, scan for key data, and then store references in additional files or alternate data streams, leaving the original data unchanged. A document management product that is compatible with Remote Storage can open placeholders with the FILE_OPEN_NO_RECALL parameter, which allow the migrated unnamed data to be read but not recalled.

In addition, after the index files are generated, some document management products provide a file viewer much like Windows Explorer. If the product is compatible with Remote Storage, when it opens each file, it experiences synchronous recalls of each file and any associated delay. The product also indicates which files are migrated and allows the user to issue asynchronous recalls of the data, while exhibiting improved performance.

Policies for managing files of the document management system exclude index files and other special files so that they are quickly accessible to the document management system.

### Note

- The Indexing service that is included with the Windows Server 2003 family is compatible with Remote Storage.

**Remote Storage Protection and Recovery**
Media in remote storage are copied to protect data. Copies are updated as the original media are updated to ensure that a current copy of data is available.

**Media copies**
Media copies are replicas that can be substituted for the original media. Data is migrated only to the original media, but can be recalled from either an original or a copy.

Copies are made before the original media are completely filled and are updated as the original is updated. When a media copy is complete, it can be removed from the library that is located with other media in the copy set, and a new media copy is

started.

Remote Storage creates media copies only if a library has two or more available drives. Other media, for which copies cannot be made, must be protected by different means, such as strict physical or environmental safeguards. To replace an original with a copy, you must manually perform the action. You should uniquely identify media copies in order to avoid confusion among different versions.

When a media copy is used to replace damaged or lost remote storage media, Remote Storage automatically copies the media again to ensure a complete set of copies.

Partial media copies are made by the system to protect the data. These partial copies can be removed from the library and are updated when they are reinserted in the library. If the source of the media copy is on the shelf, the source media must be reinserted in the library for the completion of the media copy.

**Copy sets and set rotation**
Remote Storage supports up to three copy sets of remote storage media. Media for the additional sets can be moved to shelf storage when they are synchronized. You can view the status of media copies.

**Media for media copies**
If a tape library has two or more available drives, Remote Storage uses scratch media for making a media copy. You can remove the updated media copies after several new media copies have been made. This is especially useful on weekends, during vacations, or following initial startup. After a copy is made, it must be returned to the library to be updated.

**Metadata Protection**
Remote Storage metadata exists in files that can be protected by the primary backup system (Backup) for Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition. Windows Server 2003 file security ensures that only the account used by Remote Storage has access to the metadata. It is therefore necessary for the administrator to assign appropriate user rights to this account so that only certain individuals (or groups) have access to this metadata. Otherwise, the metadata might be at risk, and if deleted, would no longer be retrievable.

**Network Ports Used by Remote Storage**
Remote Storage does not utilize any network ports.

**Related Information**
The following resources contain additional information that is relevant to this section.

Remote Storage enables you to extend disk space on your server without adding more hard disks. Remote Storage automatically copies eligible files on your local volumes to a library of magnetic tapes or magneto-optical disks. Remote Storage then monitors the amount of space available on your local volumes.

When the amount of available space on a local volume falls below the level that you designate, Remote Storage automatically removes the content (data) from a sufficient number of eligible (or premigrated) files and migrates this content to an attached storage device, thus freeing up disk space on the volume. When data is removed from a file, the logical size of the file remains the same, and to the user, the file appears unchanged, but the physical size of the file is reduced to 1 KB. Content in other premigrated files is not removed until more disk space is needed. When you need to open a file whose data has been removed, the data is automatically recalled from remote storage. To find more information about these processes, see What Is Remote Storage? in "What is Remote Storage?" See also How Remote Storage Works and How Remote Storage Works in "How Remote Storage Works."

Remote Storage runs on Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and the 64-bit versions of these operating systems. Remote Storage is also available on Windows 2000 Server. However, Remote Storage is not installed by default. To install Remote Storage, you can select Remote Storage during Setup, or you can later manually install Remote Storage through **Add or Remove Programs** in Control Panel. You can only use Remote Storage to manage NTFS volumes.

**Levels of data storage**

Remote Storage data storage is hierarchical, with two defined levels. The upper level, called local storage, includes the NTFS disk volumes of the computer running Remote Storage. The lower level, called remote storage, includes the automated media library or stand-alone tape or disk drive that is connected to the server.

Remote Storage supports all SCSI-class 4–mm tape, 8–mm tape, digital linear tape (DLT), and magneto-optical devices that are supported by Removable Storage. (To find more information about Removable Storage, see What Is Removable Storage? To find more information about the relationship between Remote Storage and Removable Storage, see How Remote Storage Works in "How Remote Storage Works.") Remote Storage does not support quarter-inch cartridge (QIC) tape libraries, rewritable compact disks (CD-RWs), or rewritable DVDs (DVD-RWs).

**Retrieval of stored files**

When you need to access a file on a volume managed by Remote Storage, you simply open the file as usual. If the data for the file is no longer on your local volume, Remote Storage recalls the data from a media library. Because this can take more time than usual, Remote Storage removes the data only from those files on your local volumes that you are least likely to need, based on criteria that you set.

**Coordination with other tools**

Remote Storage uses Removable Storage to access the applicable tapes that are contained in libraries. Remote Storage also works with Backup for data recovery, and with Task Scheduler to schedule file copy operations. For information about Removable Storage, see Removable Storage Technical Reference For information about Backup, see Backup Technical

## Reference

Remote Storage also provides certain data-recovery features, including the ability to generate multiple copies of data in remote storage.

**Business benefits**
Remote Storage provides several significant business benefits, including the following:

- A low-cost solution for archiving files that are seldom accessed, but should still be available.
- A low-cost solution that enables virtual expansion of local storage space.
- Transparent automatic access to data in remote storage.
- Automation of the labor-intensive overhead that is associated with daily manual data-management operations.
- Centralized sharing of remote storage devices for multiple volumes.

### Note

- Using Remote Storage to copy files to remote storage is not the same as backing up your files. You should follow a regular schedule of data backups, which includes backing up the contents of the local volumes that Remote Storage manages. You should also back up the Remote Storage database and other program files located in the System32\RemoteStorage folder.

### Note

- Do not create File Replication service (FRS) replica sets on a volume that is managed by Remote Storage. In addition, do not add a volume to Remote Storage that contains directories that are part of an FRS replica set. Otherwise, you might severely impact system performance and possibly cause data loss within your media library.
- FRS might need to periodically read every file in the replica set to send the file contents to another computer. This causes FRS to recall all files that Remote Storage has sent to secondary storage, which might take a long time (hours or days). If you use tape for your secondary storage, remember FRS recalls files in directory order rather than media order, so the excessive number of tape seeks performed by FRS will likely ruin the tapes and cause data loss.

**Remote Storage Tools**
The following tools are associated with Remote Storage.

**Remote Storage Microsoft Management Console (MMC) Snap-in**
**Category**
Part of Windows Server 2003.

**Version compatibility**
Runs on Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and the 64-bit versions of these operating systems. It is also available on Windows 2000 Server.

The Remote Storage MMC snap-in is an administrative interface to Remote Storage. With the Remote Storage snap-in, you can:

- Set the device type while running the Remote Storage Setup Wizard the first time you start the snap-in, and subsequently view media state and utilization.
- Set Remote Storage system-wide feature options.
- View information about Remote Storage activity.
- Recover from media disasters.
- Create and submit jobs.

**Rss.exe: Rss**
**Category**
Part of Windows Server 2003.

**Version compatibility**
Runs on Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and the 64-bit versions of these operating systems. It is also available on Windows 2000 Server.

You can use Rss.exe to manage Remote Storage from the command line. Using the **rss** command, you can run batch scripts for applications that will allow them to access Remote Storage directly.

To find more information about Remote Storage command-line parameters, see Command-Line References in the Tools and Settings Collection.

**Rsdiag.exe: Remote Storage Diagnostic Tool**
**Category**
Part of Windows Server 2003. However, it is not installed by default. You must install Rsdiag.exe separately from the Support\Reskit\Stormgmt\Rstool folder on the Windows Server 2003 operating system disc.

**Version compatibility**
Runs on Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and the 64-bit versions of these operating systems. It is also available on Windows 2000 Server.

You can use Rsdiag.exe to examine remote storage databases and display diagnostic information. Rsdiag.exe can output the contents of remote storage databases and property files to text files. You can use Rsdiag.exe and Rsdir.exe together to diagnose problems in the databases and to recover lost data.

To find more information about Rsdiag.exe, see Resource Kit Tools Help in the Tools and Settings Collection.

**Rsdir.exe: File Information Tool**
**Category**
Part of Windows Server 2003. However, it is not installed by default. You must install Rsdir.exe separately from the Support\Reskit\Stormgmt\Rstool folder on the Windows Server 2003 operating system disc.

**Version Compatibility**
Runs on Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and the 64-bit versions of these operating systems. It is also available on Windows 2000 Server.

You can use Rsdir.exe to examine reparse points and display information for managed files.

To find more information about Rsdir.exe, see Resource Kit Tools Help in the Tools and Settings Collection.

**Remote Storage Registry Entries**
The following registry entry is associated with Remote Storage.

The information provided here is a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**TapeTypesToSupport**
**Registry path**
HKEY_LOCAL_MACHINE\CurrentControlSet\Services\Remote_Storage_Server\Parameters\

**Version**
Windows Server 2003

**Data Type**
REG_MULTI_SZ

Each string in this multi-string value corresponds to an additional tape device that you want to support (in addition to those that are supported by default: 4-mm, 8-mm and DLT). Each string contains a number that corresponds to the tape device serial number as it appears in STORAGE_MEDIA_TYPE enumeration. For more information about STORAGE_MEDIA_TYPE enumeration, see http://go.microsoft.com/fwlink/?linkid=99314.

The only currently supported value is "86", which represents the LTO Ultrium tape device. Add this value if you want to use an LTO Ultrium tape device with Remote Storage. You need to add the value prior to completing the Remote Storage Setup Wizard, which starts the first time that you run the Remote Storage MMC snap-in.

**Remote Storage Group Policy Settings**
There are no Group Policy settings associated with Remote Storage.

**Remote Storage WMI Classes**
There are no WMI classes associated with Remote Storage.

**Network Ports Used by Remote Storage**
Remote Storage does not utilize any network ports.

**Related Information**
The following resources contain additional information that is relevant to this section.

- Command-Line References in the Tools and Settings Collection.

# Removable Storage Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Removable Storage Technical Reference**
The data storage and management features in the Microsoft Windows Server 2003 operating system provide you with various ways to manage and store data. With Removable Storage, a primary component of this feature set, you can track your removable storage media (tapes and optical disks) and manage the hardware libraries, such as changers and jukeboxes, which contain them.

With Removable Storage, you can:

- Label, catalog, and track media.
- Control library drives, slots, and doors.
- Perform drive-cleaning operations.

Removable Storage works together with your data-management applications such as Backup. You use data-management applications to manage the actual data stored on the media. Removable Storage makes it possible for multiple applications to share the same storage media resources, which can reduce your costs. It also provides a common interface for managing those resources, so that you can manage your storage media more efficiently.

# What Is Removable Storage?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Removable Storage?**

**In this section**

- Common Scenarios for Removable Storage
- Removable Storage Dependencies on or Interactions with Other Technologies
- Removable Storage Logical Diagram
- Related Information

The data storage and management features in the Windows Server 2003 operating system provide you with various ways to manage and store data. With Removable Storage, a primary component of this feature set, you can track your removable storage media (tapes and optical disks) and manage the hardware libraries, such as changers and jukeboxes, which contain them.

With Removable Storage, you can:

- Label, catalog, and track media.
- Control library drives, slots, and doors.
- Perform drive-cleaning operations.

Removable Storage works together with your data-management applications such as Backup. You use data-management applications to manage the actual data stored on the media. Removable Storage makes it possible for multiple applications to share the same storage media resources, which can reduce your costs. It also provides a common interface for managing those resources, so that you can manage your storage media more efficiently.

Removable Storage organizes all the media in your libraries into different media pools. A media pool is a logical collection of removable media that have the same management policies. Media pools are used by applications to control access to specific tapes or discs within libraries that are managed by Removable Storage. Removable Storage also moves media between media pools in order to provide the amount of data storage that your applications require. To find more information about media pools, see "How Removable Storage Works" in "How Removable Storage Works."

You cannot use Removable Storage to manage volumes, such as for media siding or striping. Also, you cannot use Removable Storage to manage files, such as for data backup or disk-extender operations. These services are performed by data-management applications such as Backup or Remote Storage. Remote Storage is not available on computers running Windows XP Professional; Windows Server 2003, Web Edition; or Windows Server 2003, Standard Edition.

You must run all your data-management applications on the same computer that connects to your library. Removable Storage does not support multiple data-management applications running on different computers that are connected to the same library.

Removable Storage is configured to start automatically when you start your computer. It is possible to change the service so that you can start it manually, but this is highly discouraged. Disabling the service causes several applications that are included in Windows Server 2003 (such as Backup and Remote Storage) to become inoperative.

**Common Scenarios for Removable Storage**

Removable Storage is commonly used in the following scenarios:

- Managing stand-alone drive libraries
- Managing automated libraries

**Managing stand-alone drive libraries**
In this scenario, you use Removable Storage to manage multiple single-drive libraries, such as CD-ROM or DVD-ROM drives.

In its simplest form, a library consists of data-storage media and the device that is used to read from and write to the media – for example, tape and a stand-alone tape drive. The group of libraries and associated media that you manage with a Removable Storage installation is called a *Removable Storage system*.

The main benefit to using Removable Storage is its efficiency: it is much easier to manage multiple libraries with a single tool, the Removable Management MMC snap-in, on behalf of different data-management applications, than it is to individually manage the same libraries with different sets of tools from those applications.

A further benefit of Removable Storage is that it organizes all the media in your libraries into different media pools, and also moves media between media pools in order to provide the appropriate amount of data storage your applications require.

To find more information about media pools, see "How Removable Storage Works" in "How Removable Storage Works."

**Managing automated libraries**
In this scenario, you use Removable Storage to manage one or more automated libraries.

Automated libraries are automated units that hold multiple tapes or disks, and some have multiple drives. These libraries are sometimes called *changers* or *jukeboxes*, and commonly use robotic subsystems to move media stored in the library's storage slots.

You can also use Removable Storage to manage a combination of single-drive and automated libraries.

The benefits are the same as the ones described in the previous scenario.

**Administrative Interface**
The Removable Storage Microsoft Management Console (MMC) snap-in is an administrative interface that you can use to manage both stand-alone drive libraries and automated libraries.

Using the Removable Storage snap-in, you can:

- Create media pools and set media pool properties.
- Insert and eject media in an automated library.
- Mount and dismount media.
- Clean tape drives.
- View the state of media and libraries.
- Enable and disable drives and libraries.
- Perform library inventories
- Set security permissions for users.
- Complete or refuse operator requests
- Cancel work queue items.

To find more information about these tasks, see "How Removable Storage Works" in "How Removable Storage Works."

**Removable Storage Dependencies on or Interactions with Other Technologies**
Removable Storage depends on, or interacts with, the following technologies:

- Microsoft Management Console (MMC)
- Backup (or similar, non-Microsoft data-management programs)

- Win32 tape and disk management application programming interfaces (APIs)
- The registry
- Event Viewer
- Group Policy
- Media libraries

To find more information about this topic, see "How Removable Storage Works" in "How Removable Storage Works."

**Removable Storage Logical Diagram**
The first part of the following figure shows the inherent complexity in using multiple applications to manage multiple devices (each containing a different media-type) without the aid of Removable Storage.

The second part shows how you can reduce this complexity by using Removable Storage as the common interface for managing multiple devices.

### Removable Storage Logical Diagram

- To find more information about Removable Storage interfaces, see MSDN and type "Disk Management Functions" in the "Search For" text box.

# How Removable Storage Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Removable Storage Works**

**In this section**

- Removable Storage Terms and Definitions
- Removable Storage Architecture
- Removable Storage Protocols
- Removable Storage Interfaces
- Removable Storage Processes and Interactions
- Network Ports Used by Removable Storage
- Related Information

The data storage and management features in the Windows Server 2003 operating system provide you with various ways to manage and store data. With Removable Storage, a primary component of this feature set, you can track your removable storage media (tapes and optical disks) and manage the hardware libraries, such as changers and jukeboxes, which contain them.

With Removable Storage, you can:

- Label, catalog, and track media.
- Control library drives, slots, and doors.
- Perform drive-cleaning operations.

Removable Storage works together with your data-management applications such as Backup. You use data-management applications to manage the actual data stored on the media. Removable Storage makes it possible for multiple applications to share the same storage media resources, which can reduce your costs. It also provides a common interface for managing those resources, so that you can manage your storage media more efficiently.

For these processes and interactions to work as described, Removable Storage should reside in an optimal environment. An optimal environment for Removable Storage is defined as follows:

- Windows Server 2003 is correctly installed and the Removable Storage service is running.
- All other dependencies are in place, properly designed and deployed, and functioning normally.
- Server hardware is sized appropriately and there are no disk, CPU, memory, or network bottlenecks that affect the performance of the technology.

**Removable Storage Terms and Definitions**

For a complete listing of Removable Storage Terms and Definitions, see MSDN and type **Removable Storage Glossary** in the **Search for** text box.

**Removable Storage Architecture**

From an architectural standpoint, Removable Storage is divided into three areas:

- **Removable Storage components:** The Removable Storage Microsoft Management Console (MMC) snap-in, the Removable Storage Application Programming Interface (API) and service, the Removable Storage database, and a data-management application (such as Backup).

- **Windows components and services:** Win32 tape and disk APIs, tape and disk drivers, changer drivers, Event Viewer, the registry, and Group Policy.

- **Libraries:** A robotic or automated library, a stand-alone tape drive, or a stand-alone DVD-RW drive, for example.

The following figure shows the components within these three areas and how the areas and components interact.

**Removable Storage Architectural Diagram**

The following table lists the components that are included in Removable Storage.

**Removable Storage Components**

| Component | Description |
|---|---|

| | |
|---|---|
| Removable Storage MMC snap-in | Provides an administrative interface to Removable Storage. Administrators can use the snap-in to insert and eject media, perform inventories, mount and dismount media, clean drives and check status information. Removable Storage objects can be physical objects (such as libraries, drives, and media) or groups of media (called media pools).<br><br>If only one removable storage device is being utilized, it is unlikely that you will ever be required to use the snap-in because each removable storage client application can take care of routine tasks by itself. For example, a simple backup application should not require a user to go to the snap-in to place media in a drive. In general, you will only need to use the snap-in if a system is running more than one removable-storage client application (for example, Backup and a document management system), or if the system has a sophisticated robotic library that requires administrative management.<br><br>The MMC snap-in can help administrators perform the following tasks:<br><br>● Complete or refuse operator requests.<br><br>● Point and click operations such as inserting media, ejecting media, drive cleaning, and dismounting media, moving media from one pool to another.<br><br>● Cancel work queue items.<br><br>● Enable and disable drives and libraries. |
| Removable Storage API | Provides a programmatic interface for applications to use to access the services and media in a Removable Storage system. It is a dynamic-link library (DLL) that contains a group of functions that you can use to build your data management application. These functions perform the following operations:<br><br>● Mount and dismount media.<br><br>● Clean drives.<br><br>● Insert and eject media.<br><br>● Inventory libraries.<br><br>● Enable and disable libraries, drives, and media.<br><br>● Access information in the Removable Storage database.<br><br>When you develop your media management application using the Removable Storage API, you gain the following benefits:<br><br>● Multiple applications can share the same library, drive, and media resources.<br><br>● Code written to the Removable Storage API for a specific library can execute on a wide range of libraries, both those that exist now and those that are introduced in the future.<br><br>● A single computer can track multiple types of media.<br><br>● A single computer can track media that are inside or outside a media library unit. |
| Removable Storage service | Manages and catalogs removable media and operates automated removable media services. If this service is stopped, programs that are dependent on Removable Storage, such as Backup and Remote Storage, will operate more slowly. If this service is disabled, any services that explicitly depend on it will fail to start.<br><br>The Removable Storage service depends on the Remote Procedure Call (RPC) service to function correctly. |

| | |
|---|---|
| Removable Storage database | Contains information about the objects in a Removable Storage system. Removable Storage maintains the data in the database and updates it whenever the administrator, an application, or a device makes a change in a Removable Storage system. For example, if the administrator wants to mount a piece of media in a library, Removable Storage mounts the media and updates the database to reflect the change. The database includes the following information:<br>• Library, drive, and media configuration and state.<br>• Media pool configuration and contents.<br>• Library requests.<br>• Library worklists.<br>• Operator requests. |
| Backup (storage management application) | Helps you protect data from accidental loss if your system's hardware or storage media fails. For example, you can use Backup to create a duplicate copy of the data on your hard disk and then archive the data on another storage device. The backup storage medium can be a logical drive such as your hard disk, a separate storage device such as a removable disk, or an entire library of disks or tapes organized and controlled by a robotic changer. If the original data on your hard disk is accidentally erased or overwritten, or becomes inaccessible because of a hard disk malfunction, you can easily restore the data from the archived copy. |

The following table lists the items that are included in Windows components and services.

**Windows Components and Services**

| Service | Description |
|---|---|
| Win32 tape and disk management APIs | Comprises four separate APIs: CreateFile, DeleteFile, GetDiskFreeSpace, and GetDiskFreeSpaceEx.<br>To find more information about these APIs, see "Removable Storage Interfaces" later in this section. |
| Tape and disk drivers | Enables a specific device, such as a stand-alone tape or disk drive, to communicate with the operating system. Although a device might be installed on your system, Windows cannot use the device until you have installed and configured the appropriate driver. If a device is listed in the Windows Catalog, a driver is usually included with Windows. Device drivers load automatically (for all enabled devices) when a computer is started, and then run in a manner that is transparent to users.<br>(The Windows Catalog website has hardware and software compatibility information for the Windows 2000 Server family, Windows XP, and the Windows Server 2003 family.) |
| Changer driver | Enables a specific device, such as an automated or robotic library, to communicate with the operating system. Although a device might be installed on your system, Windows cannot use the device until you have installed and configured the appropriate driver. If a device is listed in the Windows Catalog, a driver is usually included with Windows. Device drivers load automatically (for all enabled devices) when a computer is started, and thereafter run in a manner transparent to users. |
| Event Viewer | Provides a user interface for you to view and manage event logs, gather information about hardware and software problems, and monitor security events. Event Viewer maintains logs about program, security, and system events. |

| | |
|---|---|
| Registry | Contains information about the configuration of a computer. The registry database contains information that Windows continually references during operation, such as:<br>• Profiles for each user.<br>• Programs installed on the computer and the types of documents each can create.<br>• Property settings for folders and program icons.<br>• Hardware that exists on the system.<br>• Ports that are being used.<br><br>The registry is organized hierarchically as a tree and is made up of keys and their subkeys, hives, and entries. |
| Group Policy | Specifies settings for groups of users and computers. These groups include software policies, scripts, user documents and configurations, application deployment, and security configurations.<br><br>To find more information about how Removable Storage uses Group Policy, see Removable Storage Tools and Settings in "Removable Storage Tools and Settings." See also, Group Policy Settings Reference in the Tools and Settings Collection. |

The following table lists the components that are included in Libraries.

**Libraries**

| Library | Description |
|---|---|
| Robotic or automated library | Automated units that hold multiple tapes or disks. Some have multiple drives. These libraries are sometimes called *changers* or *jukeboxes*, and commonly use robotic subsystems to move media stored in the library's storage slots. Automated libraries can also consist of other hardware components that are managed by Removable Storage, such as doors, inject/eject ports, cleaner cartridges, and bar-code readers. |
| Stand-alone tape drive | A single-drive, nonautomated unit that holds a single tape. With this device, you manually insert a tape into the unit. |
| Stand-alone disk drive | A single-drive, nonautomated unit that holds a single disk. With this device, you manually insert a disk into the unit. |

**Removable Storage Protocols**
Removable Storage does not utilize any networking protocols.

**Removable Storage Interfaces**
The following APIs are associated with Removable Storage.

(To find more information about Removable Storage interfaces, see MSDN and type **Removable Storage Manager Functions** in the **Search for** text box.)

**Note**

- The Removable Storage functions were defined when the technology was previously named NTMS. As a result, many function names contain the prefix "Ntms". Similarly, the "scratch" pool was renamed "free", and the "foreign" pool was renamed "unrecognized". The term "partition" was replaced with the term "side".

Removable Storage can automatically clean tape drives that become dirty through use. You can use the following functions to control drive cleaning.

**Cleaner Management Functions**

| API Name | Description |
| --- | --- |
| CleanNtmsDrive | Queues a cleaning request for the specified drive for cleaning. |
| EjectNtmsCleaner | Ejects the cleaning cartridge from the currently reserved cleaner slot. |
| InjectNtmsCleaner | Allows a cleaner cartridge to be inserted into the specified library unit. |
| ReleaseNtmsCleanerSlot | Removes an existing slot reservation for a cleaning cartridge. The slot can then be used for data cartridges. |
| ReserveNtmsCleanerSlot | Reserves a single slot in a library unit for a drive cleaner cartridge. |

Removable Storage uses a database to store information about the removable media devices and cartridges in a system. Like any system resource, this database should be backed up in case it becomes lost or corrupted. You can use the following functions to backup and recover the Removable Storage database.

**Database Backup and Recovery Functions**

| API Name | Description |
| --- | --- |
| ExportNtmsDatabase | Creates a consistent set of database files in the Removable Storage database directory. |
| ImportNtmsDatabase | Causes Removable Storage to import the database files from the database Export directory at the next restart of the Removable Storage. |

You can use the following functions to get notifications when Removable Storage database objects change.

**Database Notification Functions**

| API Name | Description |
| --- | --- |
| CloseNtmsNotification | Closes the specified open notification channel. |
| OpenNtmsNotification | Opens a channel to receive Removable Storage object change notifications for objects of the specified type. |
| WaitForNtmsNotification | Waits for the next object change notification. |

Library control functions control injecting, ejecting, and moving media. They also enable and disable drive and changer resources. You can use the following library control functions.

**Library Control Functions**

| API Name | Description |
| --- | --- |
| AccessNtmsLibraryDoor | Unlocks the door of the specified library. If the library is busy, Removable Storage queues the request and returns successfully. |
| CancelNtmsLibraryRequest | Cancels outstanding Removable Storage requests, such as calls to the **CleanNtmsDrive** function. If the library is busy, Removable Storage queues the cancellation and returns success. |
| DeleteNtmsDrive | Deletes a drive from the Removable Storage database. The drive must have a **dwOperationalState** of NTMS_NOT_PRESENT. |
| DeleteNtmsLibrary | Deletes a library, and all the devices contained in the library, from the Removable Storage database. All media in the library is moved to the offline library. |
| DeleteNtmsRequests | Deletes a request or a list of requests from the Removable Storage database. Library or operator requests that are in a completed, failed, refused, or canceled state are removed. Submitted requests, queued requests, waiting requests, and in-progress requests cannot be deleted. |
| DismountNtmsDrive | Queues a command to move the media in the specified drive to its storage slot. This function should be paired with the **MountNtmsMedia** function. |

| | |
|---|---|
| EjectDiskFromSADrive | Ejects the media that is in a stand-alone removable drive. |
| EjectNtmsMedia | Ejects the specified medium from the port of the current library. If the library is busy, Removable Storage queues **EjectNtmsMedia** and returns a state of success. |
| GetNtmsRequestOrder | Gets the order that the specified request will be processed in the library queue. |
| GetNtmsUIOptions | Obtains the list of computer names to which the specified type of user interface is being directed for the given object. A call to **GetNtmsUIOptions** returns the list of destinations for the instance determined by the *lpObjectId* and *dwType* parameters.<br><br>If there are no destinations in the list for the specified instance, the function returns ERROR_SUCCESS along with a list length of zero. |
| GetVolumesFromDrive | Retrieves the volume and drive letter for a given Removable Storage media drive. |
| IdentifyNtmsSlot | Identifies the media in the specified slot in a library. The command returns a state of success when the identification is complete. |
| InjectNtmsMedia | Allows media to be inserted into the port of the specified library. If the library is busy, Removable Storage queues **InjectNtmsMedia** and returns a state of success. |
| InventoryNtmsLibrary | Queues an inventory of the specified library. If the library is busy, Removable Storage queues **InventoryNtmsLibrary** and returns success. |
| SetNtmsUIOptions | Modifies the list of computer names to which the specified type of UI is being directed for the given object. |
| SetNtmsRequestOrder | Sets the order that the specified request will be processed in the library queue. |

Your media label library must support the following functions. Removable Storage uses these functions to communicate with media label libraries.

**Media Label Library Functions**

| API Name | Description |
|---|---|
| ClaimMediaLabel | Determines whether a specified media label was created by the media's associated application. |
| MaxMediaLabel | Determines the maximum size of the media label for the applications that are supported by the media label library. |

Media services functions are used for mounting and dismounting media and managing media pools. You can use the following media services functions.

**Media Services Functions**

| API Name | Description |
|---|---|
| AddNtmsMediaType | Adds the specified media type to the specified library if there is not currently a relation in the library object. The function then creates the system media pools if they do not exist. |
| AllocateNtmsMedia | Allocates a piece of available media. |
| ChangeNtmsMediaType | Moves the specified Physical Media Identifier (PMID) to the specified target media pool and sets the PMID's media type identifier to the media type of the target media pool.<br><br>(A PMID is defined as a representation of media.) |
| CreateNtmsMedia | Creates a PMID and side (or sides) for a new piece of offline media. The media is placed in the media pool that is specified for the *lpPhysicalMedia* parameter.<br><br>A tape or disk side is where actual information is stored. |

| | |
|---|---|
| CreateNtmsMediaPool | Creates a new application media pool. |
| DeallocateNtmsMedia | Deallocates the side that is associated with the specified logical media. |
| DecommissionNtmsMedia | Moves a side from the Available state to the Decommissioned state. |
| DeleteNtmsMedia | Deletes a physical piece of offline media from Removable Storage by removing all references to the specified media from the database. |
| DeleteNtmsMediaPool | Deletes the specified application media pool. |
| DeleteNtmsMediaType | Deletes the specified media type relation from the specified library, provided that the library does not contain any physical media objects of the specified media type. |
| DismountNtmsMedia | Queues a command to move the specified media in a drive to its storage. This function should be paired with the **MountNtmsMedia** function. |
| GetNtmsMediaPoolName | Retrieves the specified media pool's full name hierarchy. |
| MountNtmsMedia | Synchronously mounts one or more pieces of media. |
| MoveToNtmsMediaPool | Moves the specified medium from its current media pool to the specified media pool. |
| SetNtmsMediaComplete | Marks a piece of logical media as complete. |
| SwapNtmsMedia | Swaps the sides associated with the two specified Logical Media Identifiers (LMIDs). The specified LMIDs must be in the same media pool.<br><br>(An LMID is defined as a logical representation of a physical storage location. The Media Service generally defines sides of the logical media for use by the application. The intent of logical media is to allow the underlying physical medium of the data to change without affecting the application.) |

You can use the following functions to enumerate, get, and set information about Removable Storage objects.

**Object Management Functions**

| API Name | Description |
|---|---|
| DisableNtmsObject | Disables the specified Removable Storage object. |
| EnableNtmsObject | Enables the specified object. |
| EnumerateNtmsObject | Enumerates the Removable Storage objects contained in the *lpContainerId* parameter. |
| GetNtmsObjectAttribute | Retrieves the extended attribute (named Private Data) from the specified Removable Storage object. |
| GetNtmsObjectInformation | Returns the information structure for the specified object. |
| GetNtmsObjectSecurity | Reads the security descriptor for the specified Removable Storage object. |
| SetNtmsObjectAttribute | Creates an extended attribute (named Private Data) in the specified Removable Storage object. |
| SetNtmsObjectInformation | Changes the information structure of the specified object. |
| SetNtmsObjectSecurity | Writes the security descriptor for the specified Removable Storage object. |

Removable Storage identifies media in a system by reading an on-media identifier (OMID). You can use the following function to update the RSM database when a new OMID is written.

**On-Media-Identifier Management Functions**

| API Name | Description |
|---|---|

| | |
|---|---|
| UpdateNtmsOmidInfo | Updates the Removable Storage database with label information immediately after writing to the newly allocated medium. |

You can use the following functions to manage and control requests to system operators.

**Operator Request Functions**

| API Name | Description |
|---|---|
| CancelNtmsOperatorRequest | Cancels the specified Removable Storage operator request. |
| SatisfyNtmsOperatorRequest | Completes the specified Removable Storage operator request. |
| SubmitNtmsOperatorRequest | Submits a Removable Storage operator request. |
| WaitForNtmsOperatorRequest | Waits for the specified Removable Storage operator request. |

Before calling any other functions, an application must open a Removable Storage session, and the session must be closed before the application exits. You can use the following session management functions to open and close Removable Storage sessions.

**Session Management Functions**

| API Name | Description |
|---|---|
| CloseNtmsSession | Closes the specified Removable Storage session. |
| OpenNtmsSession | Sets up a session with a Removable Storage server. |

**Removable Storage Processes and Interactions**

The following is a general description of how Removable Storage functions at a basic level.

As noted earlier, Removable Storage works together with your data-management applications, such as Backup. You use data-management applications to manage the actual data stored on the media. Removable Storage makes it possible for multiple programs to share the same storage media resources, which can reduce your costs.

The Removable Storage MMC snap-in is an administrative interface to Removable Storage and is used to perform a number of important tasks. With the Removable Storage MMC snap-in, you can:

- Create media pools and set media pool properties.
- Insert and eject media in an automated library.
- Mount and dismount media.
- Clean tape drives.
- View the state of media and libraries.
- Enable and disable drives and libraries.
- Perform library inventories
- Set security permissions for users.
- Complete or refuse operator requests
- Cancel work queue items.

Removable Storage organizes all the media in your libraries into different media pools. Removable Storage also moves media between media pools in order to provide the amount of data storage that your applications require.

You cannot use Removable Storage to manage volumes, such as for media siding or striping. Also, you cannot use Removable Storage to manage files, such as for data backup or disk-extender operations. These services are performed by data-management applications such as Backup or Remote Storage. Remote Storage is not available on computers running Windows XP Professional, Windows Server 2003, Web Edition; or Windows Server 2003, Standard Edition.

You must run all your data-management programs on the same computer that connects to your library. Removable Storage does not support multiple data-management programs running on different computers that are connected to the same library.

For these processes and interactions to work as described, Removable Storage should reside in an optimal environment. An optimal environment for Removable Storage is defined as follows:

- Windows Server 2003 is correctly installed and the Removable Storage service is running.
- All other dependencies are in place, properly designed and deployed, and functioning normally.
- Server hardware is sized appropriately and there are no disk, CPU, memory, or network bottlenecks that affect the performance of the technology.

**Removable Storage Technologies**

The following is a more detailed description of specific technologies, features or attributes that either form a part of, or are closely identified with, Removable Storage.

**Libraries**

In its simplest form, a library consists of data storage media and the device used to read from and write to the media. The group of libraries and associated media that are managed by a Removable Storage installation is called a *Removable Storage system*. There are two major types of libraries:

- **Automated libraries** are automated units that hold multiple tapes or disks, and some have multiple drives. These libraries are sometimes called *changers* or *jukeboxes*, and commonly use robotic subsystems to move media stored in the library's storage slots. Automated libraries can also consist of other hardware components that are managed by Removable Storage, such as doors, inject/eject ports, cleaner cartridges, and bar-code readers.
- **Stand-alone drive libraries**, or *stand-alone drives*, are single-drive, nonautomated units, such as tape or CD-ROM drives, that hold a single tape or disk. With these, you manually insert a tape or disk into the unit.

Not only can Removable Storage manage multiple libraries, but it can also track offline media that are not currently contained in a library. These media might be on a shelf or in a drawer, for example. Every tape or disk that is offline can belong to a library.

**Managing libraries**

Removable Storage provides comprehensive control and management of libraries. You can enable or disable entire libraries or only specific drives within a library. You can change the media type for a library. You can also open the door on an automated library and set various time-out values.

Removable Storage attempts to automatically configure all libraries, including automated libraries, when you first start Removable Storage and when you add or remove a library from a computer that is running Removable Storage.

Removable Storage can always automatically configure stand-alone drives, but you can use the automatic configuration feature of Removable Storage for automated libraries only if you connect all drives on the same SCSI bus as the associated media changer, or if all drives have unique serial numbers. Also, you must use automated libraries that support drive-element address reporting. For information on whether your library supports this feature, consult the library manufacturer.

### Note

- Because not all library configurations support the automatic configuration feature, Removable Storage provides a method for manually configuring libraries. However, do not use this method unless it is absolutely necessary because manually configured libraries do not recognize system configuration changes. Manually configured libraries also involve registry changes.
- Removable Storage numbers slots and drives starting from either 0 or 1. However, the device (firmware) has its own addresses that it uses. The Mcd.sys driver maps these addresses to the more user-friendly numbers (starting from 0 or 1) used by Removable Storage.

**Inventorying libraries**
You can create an inventory of all media in a library. Removable Storage supports two inventory methods:

- **Fast inventory.** Removable Storage checks the storage slots and reads the on-media identifier on media in slots that were previously empty.

- **Full inventory.** Removable Storage mounts each tape or disk in your library and reads the on-media identifier.

**Media Pools**
A media pool is a collection of tapes or disks that have the same management properties. All media in a Removable Storage system belong to a media pool, and each media pool holds only one type of media. Data management programs use media pools to gain access to specific tapes or disks within a library.

Using media pools, you can define properties that apply to a set of media. This is useful because Removable Storage allows multiple programs to share the same media within a single library. A library can include media from different media pools, each with different properties. A single media pool can span multiple libraries. You can also create hierarchies of media pools, or media pools that contain other media pools. For example, you can create a media pool for each specific media type required by a program, and then create another media pool that contains this collection of media pools. Media pools can contain either media or other media pools, but not both.

A Removable Storage system provides two classes of media pools: system and application.

System media pools include free media pools, unrecognized media pools, and import media pools. Removable Storage creates one free, one unrecognized, and one import media pool for each media type in your Removable Storage system. The system media pools are used to hold media that are not currently being used by an application.

Application media pools are created by data-management applications such as Backup and Remote Storage, the latter for computers running Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; the 64-bit version of Windows Server 2003, Enterprise Edition; or the 64-bit version of Windows Server 2003, Datacenter Edition.

The different media pools are defined as follows:

- **Unrecognized media pools** contain blank (new) media and media that Removable Storage does not recognize. You should immediately move a new tape or disk from an unrecognized media pool to a free media pool so that the tape or disk can be used by applications, or remove it from the library.

Unrecognized media are automatically deleted from the Removable Storage database when they are ejected from a library.

- **Import media pools** contain media that Removable Storage recognizes in the database, but that have not been used before in a particular Removable Storage system. For example, media in an import media pool could be media from one office location that are introduced into a Removable Storage system at another office location.

You can move media from import media pools to free media pools or application media pools so applications can use them.

- **Free media pools** contain media that are not currently in use by applications and do not contain useful data. Media in free media pools are available for use by applications.

You can configure application media pools to automatically draw media from free media pools when there are not sufficient media available in a particular application media pool. If you do not implement this configuration, you must manually move media from a free media pool when needed.

- **Application media pools** determine which media can be accessed by which applications. You or data management applications create them.

Media in an application media pool are controlled by that application or by an administrator. An application can use more than one media pool, and more than one application can share a single media pool. For example, Backup might use one media pool for a full backup and another media pool for an incremental backup, each containing a different media type.

There can be any number of application media pools in a Removable Storage system. Media that are currently reserved for use

by an application, called *allocated media*, cannot be moved between media pools. Allocation controls how the media are used by applications.

The following figure shows how media can move from one media pool to another.

**How Media Can Move From One Media Pool To Another**

**Managing media pools**

After configuring your libraries, you can configure your media pools. Before creating a new media pool, you should answer the following questions:

- What media types are available in your Removable Storage system?
- Should media be automatically drawn from a free media pool when there are not sufficient media in an application media pool? (It is recommended that you implement this configuration.)
- Should media be automatically returned to a free media pool when they are no longer needed by an application?

**Note**

- You cannot delete system media pools.

**Managing tapes and disks in a media pool**

After you create and configure your media pools, you can move media to a specific media pool. It is important that you have a sufficient amount of media in a free media pool so that applications can use media in this pool when needed.

Next, you can use a data management application such as Backup to allocate media to the application media pool created for (or by) that application. Allocating media to an application media pool reserves all media in that media pool for exclusive use by that application. See the documentation for your particular data management application for information on how to reserve media for that application.

Removable Storage provides comprehensive control of tapes or disks in your library. You can enable or disable specific media in your library, insert and eject media, and mount and dismount media.

A tape or disk can be inserted in or ejected from an automated library using either a library door or an inject/eject port. A library door allows unrestricted access to the media inside. You can add or remove media directly from a storage slot using a door access. An inject/eject port allows controlled access to the media inside. You insert a tape or disk in the port and then the library uses the drive bay to move the media to a storage slot.

A tape or disk can be mounted on or dismounted from a particular drive in a library. You can use the same media many times before dismounting them. You can also mount and dismount the same media many times before deallocating them.

**Note**

- Removable Storage requires that CDs are formatted with the CD-ROM file system and that rewritable optical media (such as magneto-optical disks) are formatted with the FAT, FAT32, or NTFS file system.
- Windows does not directly support the use of media that can be written to only once, such as write once, read-many (WORM), CD-R, and DVD-R disks. If you plan to use these, you must acquire other software that supports these

technologies.

**Media Identification**
Removable Storage uses two identification methods to track media and perform inventories: on-media identifiers and bar codes.

**On-media identifiers**
On-media identifiers are electronically recorded on media the first time a tape or disk is inserted into a library. The next time the medium is inserted into the library, Removable Storage uses the on-media identifier to recognize and track the tape or disk.

An on-media identifier has two parts: a label type and a label ID. The label type identifies the specific format used to record information on the tape or disk, such as Microsoft Tape Format (MTF). The label ID is a unique identifier for the tape or disk in the Removable Storage system. If Removable Storage does not recognize the label type, it adds the medium to an unrecognized media pool. If Removable Storage recognizes the label type, but does not recognize the label ID, it puts the media in an import media pool. If Removable Storage recognizes the label type and the label ID, it updates the Removable Storage database to reflect that the medium is online and available for use.

### Note

- Removable Storage does not record on-media identifiers for read-only or write-once optical media, such as CD-ROM, DVD-ROM, CD-R, DVD-R, or WORM disks. Instead, Removable Storage uses the volume and serial number information that is already associated with the disk.

**Bar codes**
If your library supports bar codes, Removable Storage can use them to identify media. Media with bar codes also have on-media identifiers. Removable Storage can use either the bar codes or the on-media identifiers. Using bar codes to track media is generally much faster because each tape or disk does not have to be mounted to read the on-media identifier.

**Media States**
Each tape or disk in a Removable Storage system has a state associated with it that determines what operations can be performed with the media. When media are inserted into a library, Removable Storage uses the on-media identifier or bar code to determine its state.

There are two sets of media states that govern media movement and usage by Removable Storage: physical states and side states.

**Physical states**
The physical states identify operations performed that involve media location or movement. The following table lists and describes the five possible physical states.

### Physical States

| Physical State | Description |
|---|---|
| Idle | Tape or disk is currently in a storage slot in an automated library or is shelved offline. |
| In-use | Tape or disk is in the process of being moved. |
| Loaded | Tape or disk is mounted in a drive and data is available to be read or written. |
| Mounted | Tape or disk is mounted in a drive, but data is not yet available to be read or written. |
| Unloaded | Tape or disk has been dismounted and is ready to be removed from a drive. |

**Side states**
A tape or disk side is where actual information is stored. Side states identify operations that are performed that involve media usage rather than location or movement. The following table lists and describes the nine possible side states.

### Side States

| Side State | Description |
|---|---|

| | |
|---|---|
| Allocated | Side is reserved for use by an application. The side is not available to any other application. |
| Available | Side is currently available for use by an application. |
| Completed | Side is in use, but cannot be used for write operations. The side is full. |
| Decommissioned | Side is no longer available for use because it has reached its allocation maximum. |
| Imported | Side's label type is recognized, but its label ID is not recognized by Removable Storage. |
| Incompatible | The media type of the side is not compatible with the library. The tape or disk should be removed from the library. |
| Reserved | Side is unavailable for allocation except by a single application. This applies only to two-sided media where one side has already been allocated. |
| Unprepared | Side has been placed in a free media pool, but does not yet have a free media label. This is a temporary state. |
| Unrecognized | Side's label type and label ID are not recognized by Removable Storage. |

The relationship between the various media pools and side states is as follows: Import media pools can only hold media sides in the Imported state. Unrecognized media pools can only hold media sides that are in the Unrecognized state. Free media pools can only hold media sides that are in the Available (and transitional unprepared) state.

**Managing Operator Requests and Queued Work**

The work queue lists all library requests, or work items that are initiated by an application or by Removable Storage. A request to mount a tape in a library, for example, results in a mount work item listed in the work queue.

The following table describes the states that a work item can have.

**Work Item States**

| Work State | Description |
|---|---|
| Completed | The work item has been completed successfully. |
| Failed | Removable Storage was unable to complete the work item. |
| In Process | Removable Storage is actively operating on the work item. |
| Queued | The work item is ready to be carried out, but Removable Storage has not yet begun to operate on it. |
| Waiting | One or more resources needed to satisfy the request are currently in use. |
| Cancelled | A user has cancelled the work item. |

An operator request is a message that asks you to perform a specific task. Operator requests can be issued by Removable Storage or by a program that is aware of Removable Storage, such as Backup. Removable Storage can generate an operator request when any of the following occur:

- An application initiates a mount request for a tape or disk that is offline.
- There are no available media online. That is, a program requires media and none exist in the appropriate application media pool or in a free media pool.
- A library has failed and requires servicing.
- A drive needs cleaning and no usable cleaner cartridges are available in the library.

You can respond to operator requests by either completing or refusing the operator request. When you refuse an operator request, Removable Storage notifies the application that generated the request. By default, Removable Storage stores an operator request in the work queue for 72 hours after you respond to the request.

The following table describes the states that an operator request can have.

**Operator Request States**

| Operator request state | Description |
|---|---|
| Completed | You have indicated, or Removable Storage has detected, that the operator request was completed. |
| Refused | You have indicated that the operator request will not be performed. |
| Submitted | Removable Storage or an application has submitted an operator request for action. |

You can change how operator requests are displayed on your computer, delete operator requests, cancel any pending operation listed in the work queue, and change the order of mount requests in the work queue.

**Network Ports Used by Removable Storage**

Removable Storage does not utilize any network ports.

**Related Information**

The following resources contain additional information that is relevant to this section.

- "Resource Kit Tools Help" in the Tools and Settings Collection.

# Removable Storage Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Removable Storage Tools and Settings**

**In this section**

- Removable Storage Tools
- Removable Storage Registry Entries
- Removable Storage Group Policy Settings
- Removable Storage WMI Classes
- Network Ports Used by Removable Storage
- Related Information

The data storage and management features in the Windows Server 2003 operating system provide you with various ways to manage and store data. With Removable Storage, a primary component of this feature set, you can track your removable storage media (tapes and optical disks) and manage the hardware libraries, such as changers and jukeboxes, which contain them.

With Removable Storage, you can:

- Label, catalog, and track media.
- Control library drives, slots, and doors.
- Perform drive-cleaning operations.

Removable Storage works together with your data-management applications such as Backup. You use data-management applications to manage the actual data stored on the media. Removable Storage makes it possible for multiple applications to share the same storage media resources, which can reduce your costs. It also provides a common interface for managing those resources, so that you can manage your storage media more efficiently.

Removable Storage organizes all the media in your libraries into different media pools. A media pool is a logical collection of removable media that have the same management policies. Media pools are used by applications to control access to specific tapes or discs within libraries that are managed by Removable Storage. Removable Storage also moves media between media pools in order to provide the amount of data storage that your applications require. To find more information about media pools, see "How Removable Storage Works" in "How Removable Storage Works."

You cannot use Removable Storage to manage volumes, such as for media siding or striping. Also, you cannot use Removable Storage to manage files, such as for data backup or disk-extender operations. These services are performed by data-management applications such as Backup or Remote Storage. Remote Storage is not available on computers running Windows XP Professional; Windows Server 2003, Web Edition; or Windows Server 2003, Standard Edition.

You must run all your data-management applications on the same computer that connects to your library. Removable Storage does not support multiple data-management applications running on different computers that are connected to the same library.

Removable Storage is configured to start automatically when you start your computer. It is possible to change the service so that you can start it manually, but this is highly discouraged. Disabling the service causes several applications that are included in Windows Server 2003 (such as Backup and Remote Storage) to become inoperative.

**Removable Storage Tools**

The following tool is associated with Removable Storage.

**Removable Storage Microsoft Management Console (MMC) Snap-in**
**Category**
Part of Windows Server 2003.

**Version compatibility**
Also part of Windows XP and can be used to perform administrative tasks on locally attached storage devices.

The Removable Storage MMC snap-in is an administrative interface to Removable Storage. Administrators can use the snap-in to insert and eject media, perform inventories, mount and dismount media, clean drives and check status information. Removable Storage objects can be physical objects (such as libraries, drives, and media) or logical groups of media (called media pools).

### Note

- If only one removable storage device is being utilized, it is unlikely that you will ever be required to use the snap-in because each removable storage client application can take care of routine tasks by itself. For example, a simple backup application should not require a user to go to the snap-in to place media in a drive. In general, you will only need to use the snap-in if a system is running more than one removable storage client application (for example, Backup and a document management system), or if the system has a sophisticated robotic library that requires administrative management.

The MMC snap-in can help administrators perform the following tasks:

- Create media pools and set media pool properties.
- Insert and eject media in an automated library.
- Mount and dismount media.
- Clean tape drives.
- View the state of media and libraries.
- Enable and disable drives and libraries.
- Perform library inventories.
- Set security permissions for users.
- Complete or refuse operator requests.
- Cancel work queue items.

To find more information about Microsoft Management Console, see “Resource Kit Tools Help” in the Tools and Settings Collection.

**Removable Storage Registry Entries**
The following registry entries are associated with Removable Storage.

The information provided here is a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

To find more information about the Removable Storage registry entries, see “Registry Reference” in the Tools and Settings Collection.

**AutoCfg**
**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Config\Changer%d\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_DWORD

This entry specifies whether the changer has been manually configured by an administrator.

**Changer**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Config\

**Version**
Windows 2000, Windows XP, Windows Server 2003

The Config key contains a subkey for each changer (for example, Changer0) and a subkey for each stand-alone drive. Each changer subkey contains an entry for each drive bay in the changer (for example, DriveBay0). For each drive bay entry that has the value "???", replace that value with the device name of the drive in that bay, such as "Tape3". Do not use an initial "\" or "." (period) character"."

**CurrentConfigPassed**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Config\Changer%d\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_DWORD

This entry is set when configuration is complete.

**Description**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\NTMS\OMID\Tape*\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_SZ

This entry contains the description for the media label library (MLL). A media label library is defined as a dynamic-link library (DLL) that can interpret the format of a media label written by a Removable Storage application.

**DriveBay%d**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Config\Changer%d\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_SZ

This entry contains information about a drive in a specific drive bay (for example, CdRom0, Tape1, and so on).

**EventMessageFile**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\EventLog\System\Removable Storage Service\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_EXPAND_SZ

This entry stores the location of the file that contains event identifiers for the events generated by the source program, and text

describing each event. Typically, event identifiers are included in the dynamic-link library (DLL) or executable file for the source program.

**NumDrives**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Config\Changer%d\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_DWORD

This entry shows the number of drives in the changer.

**Path**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\NTMS\OMID\Tape*\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_EXPAND_SZ

This entry contains the path and DLL for the media label library (MLL).

**ServiceDll**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Parameters\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_EXPAND_SZ

This entry informs Service Control Manager of the service DLL (along with its path).

**ShutdownTime**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Parameters\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_DWORD

This entry determines the amount of inactive time that can pass before the Removable Storage service shuts down.

**TypesSupported**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\EventLog\System\Removable Storage Service\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_DWORD

This entry indicates newly introduced media types. These are in addition to the standard media types that the operating system recognizes by default.

**HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NtmsSvc\Config**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Config\.

**DriveList**
**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Config\Changer%d\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_SZ

This entry lists the drives in the changer.

**DriveList**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtmsSvc\Config\Standalone\

**Version**
Windows 2000, Windows XP, Windows Server 2003

**Data Type**
REG_SZ

This entry lists the stand-alone drives that are connected to the computer.

**Removable Storage Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with Removable Storage. These settings permit or prohibit the use of the Removable Storage MMC snap-in.

**Group Policy Settings Associated with Removable Storage Management**

| Group Policy Setting | Description |
|---|---|
| Not Configured | If this policy is not configured, the setting of the **Restrict users to the explicitly permitted list of snap-ins** policy determines whether this snap-in is permitted or prohibited. |
| Enabled | The snap-in is permitted. |
| Disabled | The snap-in is prohibited. |

**Note**

- The path to Removable Storage Management is User Configuration\Administrative Templates\Windows Components\Microsoft Management Console\Restricted/Permitted snap-ins. (Restricted/Permitted snap-ins is the full name for the folder.)

To find more information about Removable Storage Group Policy settings, see "Group Policy Settings Reference" in the Tools and Settings Collection.

**Removable Storage WMI Classes**
There are no WMI Classes associated with Removable Storage.

**Network Ports Used by Removable Storage**
Removable Storage does not utilize any network ports.

**Related Information**
The following resources contain additional information that is relevant to this section.

- Resource Kit Tools Help in the Tools and Settings Collection.
- Registry Reference in the Tools and Settings Collection.
- "Command-Line References" in the Tools and Settings Collection.
- Group Policy Settings Reference in Tools and Settings Collection.

“Search For” text box.

# Windows Security Collection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windows Security Collection**

As organizations expand the availability of network data, applications, and systems, it becomes more challenging to ensure the security of the network infrastructure. Security technologies in the Microsoft Windows Server 2003 operating system enable organizations to better protect their network resources and organizational assets in increasingly complex environments and business scenarios.

**Fundamental Security Principles**

Windows Server 2003 security technologies address fundamental security requirements that help meet the complex security needs of organizations of all types and sizes. Windows Server 2003 security is based on the following fundamental principles:

- **Identification.** To help ensure that only the appropriate users and computers have access to resources, it is first necessary to identify users and computers on the network. This involves setting up and maintaining account information for users and computers, preferably in a single, easy-to-access location so that it is easy to set up, modify, and maintain. The user name generally is a unique identifier.

- **Authentication.** The authentication process validates the authentication data of a user or computer against the information in a database. This authentication data can include the user name, logon domain, password, and other credentials. After a user or computer has been authenticated, the operating system examines the privileges that are assigned to the user account. The information relating to the user in the account database is used to create an access token, which is then used to determine the access rights of a user or computer during the current session.

- **Authorization and access control.** Access rights to a given resource are validated based on access control lists (ACLs) associated with the resource. The contents of the access token are compared to the contents of the ACL in order to determine the rights of the user in regard to the resource.

- **Confidentiality.** Confidentiality helps prevent the intentional or unintentional disclosure of data or of the actions that a user is performing on the data — for example, a withdrawal from a bank account. Confidentiality is typically accomplished by means of encryption as data crosses exposed portions of a network.

- **Integrity**. Integrity services help to ensure that the content of a message or data file has not been modified when it travels over a network.

- **Nonrepudiation.** Nonrepudiation, an extension of authentication and integrity, prevents a user from denying, after the fact, that they sent a message or signed a document. It can also be used to prove that the message was sent, that it was delivered, and that it was received.

- **Trusts.** Logical relationships are established between domains, by means of trusts, to allow pass-through authentication, in which one domain accepts the logon authentications of the other domain. A trust either allows or disallows authentication traffic to flow between two or more domains.

- **Audit entries.** Audit entries represent data that is recorded in the security event log of a server or workstation when specified system, application, and security-related events take place. Audit entries provide valuable data about system operations, which can be used to identify system use and misuse, and to diagnose system behavior.

**Security Architecture**

The Windows Server 2003 security infrastructure consists of the following components:

- **Logon and authentication technologies.** Logon and authentication technologies include a variety of protocols, including Kerberos version 5 authentication, NTLM, Secure Sockets Layer/Transport Layer Security (SSL/TLS), and Digest; as well as features such as Stored User Names and Passwords that enable single sign-on (SSO) and reduced sign-on (RSO).

- **Authorization and access control technologies.** The ACL-based impersonation model and a new roles-based protected subsystem model enable extremely flexible and manageable authorization and access control strategies.

- **Data security technologies.** Encrypting File System (EFS), Internet Protocol security (IPSec), system key utility (Syskey), and Routing and Remote Access Services (RRAS) provide additional security for data under a variety of special circumstances.

- **Group Policy technologies.** Group Policy options that can enhance security management include security policy and software restriction policies.

- **Trust technologies.** Trusts can be established between domains and across forests to improve security and business processes for complex organizations.

- **Public key infrastructure (PKI) technologies.** Certificates, Certificate Services, and certificate policy-enabled qualified subordination can be used to support a variety of application-specific security solutions.

Each of these sets of technologies can be used in conjunction with the other sets of technologies — such as networking and storage — to enable secure network-enabled business processes.

**Logon and Authentication Technologies**

Applications integrated with Windows Server 2003 and Active Directory directory service use the built-in features of the operating system to perform authentication. Authentication mechanisms are fundamental to system security.

Authentication mechanisms verify the identity of users who attempt to log on to a domain or to access network resources. Authentication, the act of proving the identity of a user to an application or resource, is typically done by cryptographically signing data with a key only the user knows.

The server side of the authentication exchange compares the signed data with a known cryptographic key to validate the authentication attempt. Because the cryptographic keys are stored in a secure central location, the authentication process is scalable and maintainable. In the Windows operating system, the recommended locations for storing identity information, including the cryptographic keys that are the credentials of the users, is the Local Security Authority (LSA) of a client computer or Active Directory on a network.

Windows Server 2003 implements a number of authentication protocols, including Kerberos v 5 authentication, NTLM, secure channel, Passport, and Digest. These protocols enable authentication of users, computers, and services in a variety of network scenarios, including private networks based on Active Directory, networks based on Microsoft Windows NT 4.0 domains, and clients and servers based on non-Windows operating systems, and also across the public Internet.

Windows makes it possible to use a single user identity across a local network by locally caching user credentials in the Local Security Authority (LSA) of a client computer. When a user logs on to a domain, Windows authentication packages transparently use the credentials to provide single sign-on when authenticating to network resources on servers that trust the user's account domain.

However, as more companies deploy Internet applications that are used by partners and customers, the authentication mechanisms they currently use to provide single sign-on to their intranets are not always adequate. In fact, the technologies required for Internet-facing Web application single sign-on are significantly different. For this reason, the authentication process they provide is referred to by a different term, Web single sign-on.

Sometimes it is not possible to achieve single sign-on. In these cases, reduced sign-on (RSO) is preferred. This reduces the number of times a user must enter their credentials to access resources and applications.

Stored User Names and Passwords improves the SSO and RSO experience by simplifying the management and use of multiple sets of logon credentials, including X.509 certificates used with smart cards and Passport credentials. The credentials — part of the user's profile — are stored until needed as an encrypted part of a user's local profile and can even roam with the user if the user's network policy supports Roaming Profiles.

Authentication in Windows Server 2003 also includes two-factor authentication, such as smart cards, which are a tamper-resistant and portable way to provide security solutions for tasks such as client authentication, logging on to a Windows Server 2003 domain, code signing, and helping to secure e-mail.

**Authorization and Access Control Technologies**

How you choose to give and manage appropriate access to individual users and groups of users is the key to your resource authorization and access control strategy. Users must be authorized to access specific resources, but only at the level of access

they need.

Authorization and access control in Windows are based on user rights and permissions. User rights grant specific privileges and logon rights to users and groups in your computing environment. Permissions define the type of access granted to a user or group for an object or object property.

Windows Server 2003 manages user rights and permissions based on the following two primary authorization models:

- The ACL-based impersonation model
- A new roles-based protected subsystem model

Logging on does not automatically give users access to the resources that they require. With the impersonation model, an authentication package authenticates the user and then builds an access token that represents the security context for that user. The security context represents the identity and groups that a user is a member of, as well as the privileges or rights that are granted to that user to perform specific tasks that affect an entire computer system.

Many users and computers have identical needs for access to a network resource. For this reason, the ACL-based impersonation model allows you to place users and computers in security groups in order to manage the rights and permissions of many users and computers at the same time.

If your organization has Active Directory, it can serve as the focal point for managing and administering user accounts, security group memberships, security policies, and organizational resources such as computers, printers, and servers. Organizations that use Active Directory as the authoritative store for identity, authentication, and authorization information can extend this access control framework to other applications, systems, and, by means of Lightweight Directory Access Protocol (LDAP) compliance, to other platforms.

After the authentication package generates the security context, an application or service can be given the security context to use for accessing resources. In other words, the service can use the user's security context to obtain access to resources instead of using the service's own context.

Another component of the impersonation model is the object-based ACL. The ACL for an object indicates what level of access any number of security principals have to the object. For example, the ACL on a file might define that one user has the ability to read the file while another user has the ability to both read and delete the file.

The operating system, specifically the Windows Object Manager, is the final arbitrator of access to objects that are using the impersonation model. The Object Manager does this by comparing the security context of the user against the ACL on the object. Because the operating system is the final arbitrator, the ACL-based impersonation model has security characteristics that are good for scenarios in which multiple applications can access a system resource.

Windows Server 2003, Enterprise Edition introduces a new roles-based protected subsystem authorization model, a feature called Authorization Manager. In the roles-based protected subsystem model, users are assigned to roles and the security settings that authorize users for specific sets of tasks are based on authorization rules that allow you to apply fine-grained control over the mapping between access control and the structure and tasks performed in your organization. For example, under the roles-based protected subsystem model, a bank teller is allowed to enter account deposits and withdrawals for a customer. If this employee suddenly becomes a loan officer, the application rules can dynamically allow him or her to view a customer's bank balances and record new loans, but prevent him or her from making deposits or withdrawals on behalf of a customer.

Windows Server 2003 provides complete authorization auditing support. For the ACL-based impersonation model, the Object Manager reports audits for resource access according to the audit configuration. This configuration can be enforced by means of Group Policy or manually on each server. The roles-based protected subsystem model supports both run-time auditing and policy change auditing. Run-time auditing uses either fail or success audits to report application initialization, context creation and deletion, and object access.

**Data Security Technologies**

Applications consume authentication and authorization data to allow or deny access to a user. However, the business requirements of an organization — for example, the need to support mobile users who travel with sensitive corporate data or the need to communicate sensitive data securely over the public Internet — make additional data protection strategies necessary.

IT professionals can use the data security technologies in Windows Server 2003 to complement the data security features that are coded into an application. Windows Server 2003 includes the following disk-based encryption features:

- **Encrypting File System (EFS).** Stored data (stored online or offline) can be protected by means of EFS and digital signatures. By using EFS, you can encrypt data as it is stored on disk. EFS uses public key encryption to encrypt local NTFS file system data.

- **The system key utility (Syskey).** Syskey provides additional protection against password-cracking software. It uses strong encryption techniques to secure account password information that is stored in the Security Accounts Manager (SAM) database or in directory services.

Additional Windows Server 2003 features can protect network data as it passes in and out of your site (across intranets, extranets, or an Internet gateway). These features include:

- **Internet Protocol Security (IPSec).** IPSec is a suite of industry-standard cryptography-based protection services and security protocols that are used to protect local area network (LAN) traffic. IPSec provides computer-level authentication, as well as data encryption, for virtual private network (VPN) connections that use the Layer 2 Tunneling Protocol (L2TP).

- **Routing and Remote Access.** The Routing and Remote Access service for the Windows Server family is a full-featured software router and an open platform for routing and internetworking. It offers routing services to businesses in LAN and wide area network (WAN) environments, or over the Internet, by using secure VPN connections.

- **Internet Authentication Service (IAS).** Internet Authentication Service (IAS) in Windows Server 2003 provides security and authentication for dial-in users and for local networks by means of 802.1x.

**Group Policy Technologies**

Windows Server 2003 Group Policy technologies enable you to efficiently manage groups of users and computers by configuring Group Policy objects (GPOs) and linking them to an organizational unit, domain, or site.

Group Policy allows an organization to more effectively manage its applications and operating environments on a per-computer or per-user basis.

Group Policy in Windows Server 2003 includes extensions for the following:

- Administrative templates

- Software installation

- Security settings

- Software restrictions

- IPSec policy

- Scripts

- Wireless network policies

- Folder redirection

- Internet Explorer maintenance

- Disk quotas

- Quality of service

- Remote installation services

You can use security settings policies as part of your overall security implementation to help secure domain controllers, servers, clients, and other resources in your organization. Security settings policies are used to manage the following aspects of

security:

- User authentication to a network or computer
- Resources that users are permitted to access
- Whether to record a user's or group's actions in the Event log
- Membership in a group

This assists administrators in the following tasks:

- Ensuring that corporate security policies are enforced across desktops and servers.
- Keeping desktops and servers up-to-date with the latest security patches.
- Monitoring systems for potential security compromises.

Software restriction policies further enhance an organization's ability to enforce security policy on its computers and network by limiting the opportunities for malicious code to enter an operating system and impact an organization.

Users can receive hostile code in many forms, ranging from native Windows executable files (.exe), to macros in documents (such as .doc files), to scripts (such as .vbs files). Attackers often use social engineering methods, such as viruses and worms, to cause users to activate their code. If such code is activated, it can generate denial-of-service attacks on the network, send sensitive or private data to the Internet, put the security of the computer at risk, or damage the contents of the hard disk drive.

To help protect network computers from both hostile code and unknown or unsupported software, administrators can use software restriction policies to define which applications are allowed or not allowed to run on a target computer. To help organizations address the problem of unknown code, administrators can use software restriction policies to perform the following tasks:

- Counteract computer viruses.
- Regulate which ActiveX controls can be downloaded.
- Run only digitally signed scripts.
- Enforce the policy that only approved software is installed on system computers.
- Lock down a computer.

For more information about Group Policy, see the Group Policy Collection.

**Trust Technologies**

The goals of SSO and RSO are largely based on trusts establish between domains and forests. However, SSO and RSO can be difficult to establish and maintain when organizations are continuously evolving with mergers, acquisitions, and divestitures, as well as a wide variety of partnerships with business partners.

The trust technologies in Windows Server 2003 help organizations address these business requirements and enhance their ability to offer and maintain SSO and RSO. When a trust exists between two domains, the authentication mechanisms for each domain trust the authentication data coming from the other domain. Trusts help provide for controlled access to shared resources in a resource domain (the trusting domain) by verifying that incoming authentication requests come from a trusted authority (the trusted domain).

Applications integrated with Windows Server 2003 and Active Directory use the built-in features of the operating system to establish and maintain trust for a wide variety of business requirements and scenarios, including forest trusts and cross forest trusts.

Windows Server 2003 fully audits trust configuration at a detailed level. Auditable events include the creation, deletion, and modification of trusts.

**PKI Technologies**

A different form of trust can be implemented by using a public key infrastructure (PKI). A PKI is a system of digital certificates, certification authorities (CAs) and registration authorities (RAs) that verify and authenticate the validity of each party involved in an electronic transaction by means of the use of public key cryptography. For this to occur, however, each party must trust the issuer of the certificate, most often a CA.

For Windows Server 2003 users, computers, and services, trust in a CA is established when a copy of the root certificate, as well as a valid certification path, exists in the trusted root certification authorities store. A valid certification path means that none of the certificates in the certification path has been revoked or has expired. The process of importing a root certificate into the trusted root certification authorities store is the most straightforward way to establish a PKI trust for a computer and the applications hosted by that computer.

While the root store certification authority mechanism is fairly easy to deploy, it might not meet the security requirements of complex scenarios for establishing a federated trust between two organizations. One solution is to use qualified subordination.

Qualified subordination allows you to place certificate issuance constraints on subordinate CAs and to place usage constraints on the certificates they issue. By using qualified subordination, you can focus subordinate CAs according to specific certification needs and administer your PKI more efficiently. Qualified subordination also allows you to establish trust between CAs in separate trust hierarchies. This type of trust relationship is also called cross-certification. With this trust relationship, qualified subordination is not limited to subordinate CAs. Trust between hierarchies can be established using a subordinate CA in one hierarchy and the root CA in another hierarchy.

**Security Scenarios**

As organizations grow and evolve, the need for security technologies that help to protect system resources becomes more critical. For example:

- A growing number of users have laptop computers which they are just as likely to use away from the office as at a network-connected desktop.
- Many organizations are making business processes more efficient by eliminating paper documents and replacing them with electronic documents that may be more difficult to track or control.
- Many organizations are increasing their use of contractors and consultants, and entering partnerships that require a high level of information sharing.

These types of scenarios require organizations to conduct in-depth security audits and evaluations on a regular basis to ensure that existing and potential security threats are addressed to the extent possible.

It is important to evaluate the potential security implications for every network application and technology that you deploy. It is also important to consider the security technologies in Windows Server 2003 any time that you plan to introduce new capabilities in your organization. Security technologies in Windows Server 2003 provide many enhanced security advantages, including the following:

- Enhanced single sign on by means of Kerberos authentication and domain trusts.
- Greater control over access control by means of applications that apply roles-based authorization.
- Increased flexibility and security for employees who are traveling and accessing the network remotely, by means of the use of EFS and Routing and Remote Access connectivity.
- Improved password protection by means of PKI-enabled smart card authentication or security policy settings that require users to set complex passwords and change them regularly.
- The ability to create security groups and GPOs that allow contractors and business partners limited access to set ACLs on carefully defined sets of resources.

# Logon and Authentication Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Logon and Authentication Technologies**
The Microsoft Windows Server 2003 operating system implements a default set of authentication protocols, including Negotiate, Kerberos, NTLM, Schannel (secure channel), and Digest, as part of an extensible architecture. These protocols enable authentication of users, computers, and services; the authentication process, in turn, enables authorized users and services to access resources in a secure manner.

**Authentication Concepts**
Authentication is a process for verifying the identity of an object or person. When you authenticate an object, the goal is to verify that the object is genuine. When you authenticate a person, the goal is to verify that you are not dealing with an imposter.

Similarly, in a networking context, authentication is the act of proving identity to a network application or resource. Typically, identity is proven by a cryptographic operation that uses either a key only the user knows — as with public key cryptography — or a shared key. The server side of the authentication exchange compares the signed data with a known cryptographic key to validate the authentication attempt.

Storing the cryptographic keys in a secure central location makes the authentication process scalable and maintainable. Active Directory directory service is the recommended and default technology for storing identity information (including the cryptographic keys that are the user's' credentials). Active Directory is required for default NTLM and Kerberos implementations.

Authentication techniques range from a simple logon, which identifies users based on something that only the user knows — like a password, to more powerful security mechanisms that use something that the user has — like tokens, public key certificates, and biometrics. In a business environment, users might access multiple applications on many types of servers within a single location or across multiple locations. For these reasons, authentication must support environments for other platforms, for Windows Server 2003, and for other Windows operating systems.

**Authentication and Authorization: A Travel Analogy**
A travel analogy can help explain how authentication works. For example, when you cross an international border, a border guard asks for credentials and you present a passport. The process is two-fold:

- The guard authenticates the passport by verifying that it was issued by a security authority that the local government trusts — trusts, at least, to issue passports — and by verifying that the passport has not been modified.
- The guard authenticates you by verifying that your face matches the face of the person pictured on the passport.

If the passport proves to be valid and you prove to be its owner, you are who you say you are.

Transitive trust between security authorities is the foundation of authentication; the type of authentication that takes place at an international border is based on trust. The local government does not know you, but it trusts that your government does. When your government issued your passport, it did not know you either. It trusted the agency that issued your birth certificate. The agency that issued your birth certificate, in turn, trusted the physician who signed the certificate. The physician witnessed your birth and stamped the certificate with your footprint, direct proof of your identity. Trust that is transferred in this way, through trusted intermediaries, is transitive.

Similarly, transitive trust is the foundation for network security in Windows Server 2003. A trust relationship flows throughout a set of domains, such as a domain tree, and forms a relationship between a domain and all domains that trust that domain. For example, if domain A has a transitive trust with domain B, and if domain B trusts domain C, then domain A trusts domain C.

There is a difference between authentication and authorization. With authentication, the system proves that you are who you say you are; however with authorization, the system verifies that you have rights to do what you want to do. To take the border analogy to the next step, merely authenticating that you are the proper owner of a valid passport does not necessarily authorize you to enter a country. Residents of a particular country are allowed to enter another country by simply presenting a passport only in situations where the country being entered grants blanket permission for all citizens of that particular country to enter.

Similarly, you can grant all users from a certain domain permissions to access a resource. Any user who belongs to that

domain has access to the resource, just as Canada allows U.S. citizens to enter Canada. However, U.S. citizens attempting to enter Brazil or India would find that they cannot enter those countries merely by presenting a passport because both of those countries require visiting U.S. citizens to have a valid visa. Thus, authentication does not guarantee access (or authorization).

**Single Sign-On**

Single sign-on (SSO) makes it possible for users to access resources over the network without having to repeatedly supply their credentials. Forcing users to enter multiple passwords — or to enter a single password multiple times — to access system resources is inefficient and provides an unpleasant user experience.

Users of the Windows Server 2003 operating systems must supply their credentials only once to access network resources; subsequent authentication is transparent to users. SSO allows users to authenticate once with the system in order to access all applications and data sources that they are authorized to use without entering another account ID or password. The Microsoft Windows platform capitalizes on the ability to use a single user identity (maintained by Active Directory) across the network by locally caching user credentials in the operating system's Local Security Authority (LSA). When a user logs on to the domain, Windows authentication packages transparently use the credentials to provide SSO when authenticating to network resources.

**Authentication Architecture**

**Windows Server 2003 Authentication Services**

Windows Server 2003 provides a method for applications to authenticate users by using the Security Support Provider Interface (SSPI) to abstract calls to authentication. Thus, developers do not need to understand the complexities of specific authentication protocols or build authentication protocols into their applications.

For best results, however, before starting the application design process, developers should understand the different types of authentication, the effects of using different protocols, and the interfaces they support. Then they can specify their preferred authentication protocol and use the authentication protocols provided by the Windows platform.

If the preferred protocol is not in Windows Server 2003, developers can use a custom Security Support Provider (SSP). Implementing authentication protocols on an application-by-application basis is inefficient and can introduce security flaws across the organization.

**Security Subsystem Architecture**

Windows Server 2003 operating systems include a set of security components that make up the Windows security model. These components ensure that applications cannot gain access to resources without authentication and authorization.

The Local Security Authority (LSA) is a protected subsystem that authenticates and logs users on to the local computer. In addition, LSA maintains information about all aspects of local security on a computer (these aspects are collectively known as the local security policy), and it provides various services for translation between names and security identifiers (SIDs).

The security subsystem keeps track of the security policies and the accounts that are in effect on a computer system. In the case of a domain controller, these policies and accounts are the ones that are in effect for the domain in which the domain controller is located. These policies and accounts are stored in Active Directory.

The local security policy identifies the following:

- Which domains are trusted to authenticate logon attempts.
- Who can have access to the system and in what way (for example, interactively, over the network, or as a service).
- Who is assigned what rights.
- What security auditing is performed.
- What the default memory quotas are for paged and non-paged memory pool usage.

**LSA Architecture**

The LSA security subsystem provides services for validating access to objects, checking user rights, and generating audit messages. A local procedure call (LPC) occurs between components on the same system. A remote procedure call (RPC) occurs between components on different systems, as do LDAP communications.

In general, the LSA performs the following functions:

- Manages local security policy.
- Provides interactive user authentication services.
- Generates access tokens.
- Manages the audit policy and settings.

### LSA Components for All Systems

| Component | Description |
|---|---|
| Winlogon.exe | The executable file responsible for managing secure user interactions. Winlogon initiates the logon process for Windows Server 2003, Microsoft Windows 2000, Microsoft Windows XP, and Microsoft Windows NT 4.0 operating systems. |
| Msgina.dll | The default dynamic-link library (DLL) module that operates in the security context of Winlogon. The Graphical Identification and Authentication (GINA) is responsible for processing secure attention sequence (SAS) events and activating the user's shell. The GINA can generate SAS events in some instances. |

| | |
|---|---|
| Netlogon.dll | Some of the services that Net Logon performs include:<br>• Net Logon maintains the computer's secure channel (not to be confused with Schannel) to a domain controller.<br>• Net Logon passes the user's credentials through a secure channel to the domain controller and returns the domain SIDs and user rights for the user.<br>• In the Windows 2000 Server and Windows Server 2003 operating systems, the Net Logon service publishes service resource records in the Domain Name System (DNS) and uses DNS to resolve names to the Internet Protocol (IP) addresses of domain controllers.<br>• Net Logon also implements the replication protocol based on RPC for synchronizing Windows NT 4.0 primary domain controllers (PDCs) and backup domain controllers (BDCs). |
| Msv1_0.dll | The NTLM authentication protocol. This protocol authenticates clients that do not use Kerberos authentication. |
| Schannel.dll | The Secure Sockets Layer (SSL) and Transport Layer Security (TLS) authentication protocol. This protocol provides authentication over an encrypted channel instead of a less-secure clear channel. |
| Kerberos.dll | The Kerberos V5 authentication protocol. This protocol provides authentication using Kerberos protocol instead of plaintext, NTLM, or digest method. |
| Wdigest.dll | Simple challenge-and-response protocol that provides increased security over basic authentication. |
| Lsasrv.dll | The LSA Server service, which both enforces security policies and acts as the security package manager for the LSA. |
| Samsrv.dll | The Security Accounts Manager (SAM), which stores local security accounts, enforces locally stored policies, and supports APIs. |
| Secur32.dll | The multiple authentication provider that holds all of the components together. |

**LSA Components Unique to Domain Controllers**

| Component | Description |
|---|---|
| Kdcsvc.dll | The Kerberos Key Distribution Center (KDC) service, which is responsible for providing ticket-granting tickets to clients. |
| Ntdsa.dll | The directory service module, which supports the Windows Server 2003 and Windows 2000 replication protocol and LDAP, and manages partitions of data. |

**Security Support Provider Interface**

The Security Support Provider Interface (SSPI) is the foundation for authentication in Windows Server 2003. SSPI is the implementation of the Generic Security Service API (GSSAPI) in Windows Server 2003. For more information about GSSAPI, see RFCs 2743 and 2744 in the IETF RFC Database.

The default Security Support Providers in Windows Server 2003 — Negotiate (SPNEGO), Kerberos, NTLM, Schannel, and Digest authentication protocols — are plugged into the SSPI in the form of DLLs. Additional SSPs can be plugged in if they are interoperable with the SSPI.

**SSPI in Authentication**

The SSPI in Windows Server 2003 provides a mechanism that carries authentication tokens over the existing protocol, thus eliminating the need for communicating parties to specify a network protocol for use during authentication. When two parties need to be authenticated so that they can communicate, the requests for authentication are routed to the SSPI, which completes the authentication process, regardless of the network protocol currently in use.

**SSPI Architecture**

Any application can make a request of the SSPI. Each of these requests goes through the SSPI, for example:

- Winlogon sends requests to the Local Security Authority (LSA), which obtains tickets to access the local computer.
- Internet Explorer obtains tickets to access information about a Web site.
- An LDAP client obtains tickets to enable access to information in an x500 directory, such as Active Directory.

Some applications integrate use of the SSPI into their authentication designs. When such applications need to authenticate a user, they ask the SSPI to complete the authentication by using specific parameters, such as the user's name and secret key (if they were not cached from a previous logon), and the service that the user wants to access. The SSPI receives the request, examines its contents, and passes the request to the SSP specified in the request. The SSP handles the details of the authentication and sends a success or failure message back to the SSPI, which relays the message back to the application that initially requested authentication. SSPI enables an application to use various security models available on a computer or network without changing the interface to the security system.

For example, if a client has a service ticket for a server for which the preferred authentication protocol is Kerberos, and the client wants to issue that server a remote procedure call (RPC), the client's Kerberos SSP generates a request message based on standard GSS-API (RFC 1964) calls, which the application sends to the server. When the server receives the request, the server passes the ticket to the Kerberos SSP. The client routes the reply token to its SSP, which then evaluates and manages the contents of the reply. The server and the client know nothing about the contents of the token that is used to enable secure communication, because this information is handled by the SSP. The details of authentication are handled behind the scenes, and the results of the authentication process are passed back to the applications.

**Security Support Provider Selection**

The SSPI in Windows Server 2003 can use any of the five protocols — Negotiate, Kerberos, NTLM, Schannel, and Digest — that it supports. However, because not all operating systems support the same SSP packages that Windows Server 2003 supports; clients and servers must negotiate to use a protocol that they both support. Windows Server 2003 prefers clients to use Kerberos, a strong standards-based protocol, when possible, but continues to allow clients that do not support Kerberos, such as Windows NT 4.0 clients, to authenticate.

Before authentication can take place, however, the two communicating computers must agree on a protocol that they both can support. For any protocol to be usable through the SSPI, each party must have the appropriate SSP. For example, in order for a client and server to use the Kerberos authentication protocol, they must both support Kerberos V5. Windows Server 2003 uses the function **EnumerateSecurityPackages** to identify which SSPs are supported on a computer and what the capabilities of those SSPs are.

The selection of an authentication protocol can be handled in one of two ways, each of which is described in more detail below:

- A single authentication protocol can be specified.
- The negotiate option can be used to allow the parties to attempt to find an acceptable protocol. This is based on the Simple and Protected GSS-API Negotiation Mechanism (SPNEGO, RFC 2478).

**Single Authentication Protocol Specified**

When a single acceptable protocol is specified, the server allows only one acceptable authentication method for the exchange. If the client does not support the protocol specified, the communication fails. When a single acceptable protocol is specified, the authentication exchange takes place as follows:

1. The client requests access to a service.

2. The server replies with an authentication challenge in which it specifies the protocol that be used.

3. The client examines the contents of the reply and checks to determine whether it supports the specified protocol. If the client does support the specified protocol, the authentication continues. If the client does not support the protocol, the authentication fails, regardless of whether the client is authorized to access the resource.

For example, if a Windows Server 2003 client received a reply that specified the Kerberos protocol, the authentication exchange could proceed. On the other hand, if a Windows NT 4.0 client received the same reply, the authentication exchange would fail, because computers running versions of Windows earlier than Windows 2000 do not support Kerberos authentication. If the specified protocol fails, then negotiation is needed.

**Negotiate Option Is Used**
When the authentication begins with the option to negotiate for an authentication protocol, the SPNEGO exchange takes place as follows:

1. The client requests access to a service.

2. The server replies with a list of authentication protocols that it can support and an authentication challenge based on the protocol that is its first choice. For example, the server might list Kerberos and NTLM, and send a Kerberos challenge.

3. The client examines the contents of the reply and checks to determine whether it supports any of the specified protocols.

    - If the client supports the preferred protocol, authentication proceeds.

    - If the client does not support the preferred protocol, but does support one of the other protocols listed by the server, the client lets the server know which authentication protocol it supports, and the authentication proceeds.

    - If the client does not support any of the listed protocols, the authentication exchange fails.

For example, if the server specified Kerberos and NTLM, and returned a Kerberos challenge, a Windows Server 2003 client could immediately authenticate by using Kerberos. A Windows NT 4.0 client could negotiate to complete the authentication exchange by using NTLM.

**Kerberos SSP**
The Kerberos SSP (Kerberos.dll) is the first choice for authentication in Windows Server 2003. The Kerberos SSP uses the Kerberos V5 authentication protocol (RFC 1510).

Because Kerberos is the default authentication protocol for Windows Server 2003, all domain services support the Kerberos SSP, which includes:

- Active Directory queries using the Lightweight Directory Access Protocol (LDAP).

- Remote server or workstation management using RPC calls.

- Print services.

- Client-server authentication.

- Remote file access using Common Internet File System/server message block (CIFS/SMB).

- Distributed file system management and referrals.

- Intranet authentication to Internet Information Services (IIS).

- Security authority authentication for Internet Protocol security (IPSec).

- Certificate requests to Certificate Services for domain users and computers.

**NTLM SSP**
Windows Server 2003 supports the NTLM SSP, Msv1_0.dll, to enable clients running versions of Windows earlier than Windows 2000 to authenticate. NTLM is the default authentication protocol for Windows NT 4.0. The NTLM SSP includes the NTLM and NTLMv2 authentication protocols.

Windows Server 2003 can use the NTLM SSP for the following:

- Client/server authentication
- Print services
- File access using CIFS/SMB
- Secure RPC/DCOM-based services

**Negotiate SSP**
Microsoft Negotiate is a security support provider (SSP) that acts as an application layer between the Security Support Provider Interface (SSPI) and the other SSPs. When an application calls in to the SSPI to log on to a network, it can specify an SSP to process the request. If the application specifies Negotiate, Negotiate analyzes the request and picks the best SSP to handle the request based on customer-configured security policy.

Negotiate implements RFC 2478, "The Simple and Protected GSS-API Negotiation Mechanism."

Currently, the Negotiate security package selects between Kerberos and NTLM. Negotiate selects Kerberos by default unless Kerberos cannot be used by one of the systems involved in the authentication or the calling application did not provide sufficient information to use Kerberos.

**Secure Channel (Schannel) SSP**
The Schannel SSP is used for access to Web-enabled services, such as mail or personal information served on Web pages.

The Schannel SSP, which includes a suite of four authentication protocols, uses public key certificates to authenticate parties. When authenticating parties, Schannel SSP selects one of the four protocols in the following order of preference:

- Transport Layer Security (TLS).
- Secure Socket Layer (SSL) version 3.0.
- Private Communications Technology (PCT). PCT is disabled by default in Windows Server 2003.
- SSL version 2.0.

The protocol that is selected is the preferred authentication protocol that both parties can support. For example, if a server supports all four Schannel protocols and the client supports only SSL 3.0 and SSL 2.0, the authentication process uses SSL 3.0.

**Digest SSP**
Digest SSP (Wdigest.dll) is the preferred authentication protocol for certain applications, such as LDAP and HTTP. Digest SSP is used for the following:

- Internet Explorer (IE) and Internet Information Services (IIS) access.
- LDAP queries.

**Passport SSP**
Windows Server 2003 contains no specific Passport SSP. Instead, passport authentication is enabled by an Internet Server Application Programming Interface (ISAPI) DLL called Passport.dll that captures and processes any cookie information that contains passport credentials.

**Authentication Protocols**
Each authentication protocol is composed of a series of steps, used by two or more parties, that verifies the identity of one or more of the parties.

The authentication process is vulnerable to numerous types of security attacks. For example, an attacker who has access to authentication information can steal keys to the network, modify messages, or replay old messages.

The authentication protocols in Windows Server 2003, which include Kerberos, NTLM, Schannel, Digest, and Passport, are designed to address potential security threats by verifying the identities of one or more of the communicating parties.

**Windows Server 2003 Authentication Protocols**

| Authentication Protocol | Description |
|---|---|
| Kerberos V5 authentication | An industry standard protocol that is used with either a password or a smart card for interactive logon. It is also the default method of network authentication for services in Windows 2000, Windows XP, and Windows Server 2003. |
| Digest authentication | An industry standard that is used in Windows Server 2003 for Lightweight Directory Access Protocol (LDAP) and Web authentication that transmits credentials across the network as an MD5 hash or message digest. |
| Negotiate | Negotiate implements RFC 2478, "The Simple and Protected GSS-API Negotiation Mechanism."<br><br>Currently, the Negotiate security package selects between Kerberos and NTLM. By default, Negotiate selects Kerberos unless Kerberos cannot be used by one of the systems involved in the authentication, or the calling application did not provide sufficient information to use Kerberos. |
| NTLM authentication | A challenge response protocol that is used to provide compatibility with versions of Windows earlier than Windows 2000. |
| Passport authentication | A user-authentication service that provides a Web-based authentication mechanism enabling Web-services to offer a single sign-in service. |
| Secure Sockets Layer/Transport Layer Security (SSL/TLS) authentication | A protocol that is used for Web-based server authentication, such as when a user attempts to access a secure Web server. |

Each of these protocols is used in different ways in Windows Server 2003 to promote secure communication in a network environment that is not secure.

**Logon Authentication Scenarios**

It is not possible to use a computer that is running Windows Server 2003 without using at least some system services. To use a system service, the account must be a client of the service, and all clients must first be authenticated by the service. Authentication requires the service to know the user's credentials.

On computers running Windows Server 2003, system services can run under various accounts depending on the way that the applications are written. For example, a computer can access domain resources by using the network service, local system, or domain user accounts. Domain users who log on interactively must also be assigned the appropriate permissions before they can access the computer's services.

**Interactive Logon**

The logon process begins when a user enters credentials into the Log On to Windows dialog box or when the user inserts a smart card into the smart card reader. Credentials consist of a user's user name and password for local logons and the user's user name, password, and domain for domain logons. The process confirms the user's identification to the security database on the user's local computer or to an Active Directory domain. This mandatory logon process cannot be turned off for users in a domain.

Users can perform an interactive logon to a computer in either of two ways:

- Locally, when the user has direct physical access to the computer.
- Remotely, through Terminal Services, in which case the logon is further qualified as remote interactive.

After an interactive logon, Windows runs applications on the user's behalf and the user can interact with those applications.

Users can perform an interactive logon by using a local user account or a domain account to log on to a computer.

**Local Logon**
A local logon grants a user access to Windows resources on the local computer. A local logon requires that the user have a user account in the Security Accounts Manager (SAM) on the local computer. The SAM protects and manages user and group information in the form of security accounts stored in the local computer registry. The computer can have network access, but it is not required. Local user account and group membership information is used to manage access to local resources.

**Domain Logon**
A domain logon grants a user access to local and domain resources. A domain logon requires that the user have a user account in Active Directory. The computer must have an account in the Active Directory domain and be physically connected to the network. Users must also have the user rights to log on to a local computer or a domain. Domain user account information and group membership information is used to manage access to domain and local resources.

**Smart Card Logon**
Logging on to a domain with a smart card provides a strong form of authentication because smart cards use cryptography-based identification and proof of possession when authenticating a user to a domain.

To log on to a domain with a smart card, a user does not need to press CTRL+ALT+DEL and enter credentials into the Log On to Windows dialog box. The user merely inserts the smart card into the smart card reader and the computer prompts for the user's personal identification number (PIN) instead of the user name and password.

Smart cards are a tamper-resistant, portable way to provide security solutions for tasks such as client authentication, code signing, securing e-mail, and logging on to a Windows Server operating systems domain.

Smart cards provide:

- Tamper-resistant storage for protecting private keys and other forms of personal information.
- Isolation of security-critical computations involving authentication, digital signatures, and key exchange from other parts of the computer that do not have a "need to know." The security critical operations are all performed on the smart card.
- Portability of credentials and other private information between computers at work, home, or on the road.

**Network Logon**
A network logon can only be used after a user, service, or computer authentication has taken place. During network logon, the process does not use the logon dialog boxes, such as the Log On to Windows dialog box, to collect data. Instead, previously established credentials or another method to collect credentials is used. This process confirms the users identification to any network service that the user is attempting to access. This process is typically invisible to the user unless alternate credentials need to be provided.

To provide this type of authentication, the security system includes these authentication mechanisms:

- Kerberos V5
- Public key certificates
- Secure Sockets Layer/Transport Layer Security (SSL/TLS)
- Digest
- NTLM (for compatibility with Windows NT 4.0-based systems)

# Digest Authentication Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Digest Authentication Technical Reference**
Digest Authentication is a standards-based authentication protocol, implemented through wdigest.dll, that provides for authentication, between Microsoft Windows operating environments and operating environments other than Windows, over the Internet. It is described in RFC 2617: HTTP Authentication: Basic and Digest Access Authentication. Wdigest.dll was first included as an authentication package in the Microsoft Windows XP operating system. The Digest security support provider (SSP) implements both RFC 2617 and RFC 2831: Using Digest Authentication as a SASL Mechanism. Digest Authentication, as a simple authentication and security layer (SASL) mechanism, is used primarily for Lightweight Directory Access Protocol (LDAP) authentication.

Digest Authentication works in situations where the Kerberos protocol does not. Digest Authentication offers single sign-on only to a single Web URL protection space. If users navigate to a different Web site, or even to a different server in the same site, they will usually be prompted to enter credentials again.

This section explains what Digest Authentication is and how it works, and it explains which tools are available for configuring Digest Authentication. This technology is also referred to in Internet Information Services (IIS) 6.0 documentation as Advanced Digest Authentication.

# What is Digest Authentication?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Digest Authentication?**

**In This Section**

- Common Digest Authentication Scenarios
- Technologies Related to Digest
- Digest Authentication Dependencies

WDigest.dll was introduced in the Windows XP operating system The Digest Authentication protocol is designed for use with Hypertext Transfer Protocol (HTTP) and Simple Authentication Security Layer (SASL) exchanges, as documented in RFCs 2617 and 2831. These exchanges require that parties that seek to authenticate must demonstrate their knowledge of secret keys. This process improves upon earlier versions of HTTP authentication, in which users provide passwords that are not encrypted when they are sent to a server, leaving them vulnerable to capture by attackers, or that are encrypted but sent in an expensive, ongoing, Secure Sockets Layer (SSL) session.

Digest Authentication has similar security characteristics to the proprietary NTLM protocol. Both Digest Authentication and NTLM are challenge/response protocols. Challenge/response protocols require an authenticating server to generate a challenge containing some amount of unpredictable data. A client then uses a key derived from the user's password to encrypt the challenge and forms a response. The server, or a trusted service such as Active Directory, can verify that the user possesses the correct password by comparing the client's encrypted response to a stored response based on the credential associated with the user in Active Directory or in the server account database for local users. If the responses match, the user is authenticated.

**Limitations of Digest Authentication**

SSL and Transport Layer Security (TLS) are often used to protect Digest Authentication from an offline attack against the Digest Authentication challenge/response.

Digest Authentication offers single sign-on only to a single Web URL protection space. If users navigate to a different Web site, or even to a different server in the same site, they will usually be prompted to enter credentials again.

**Digest Authentication Protocol Standards**

Digest Authentication is a standards-based authentication protocol that provides for authentication, between Windows operating environments and operating environments other than Windows, over the Internet. It is described in RFC 2617. Windows Server 2003 implements Digest Authentication as a simple authentication and security layer (SASL) mechanism that is used primarily for LDAP authentication, as described in RFC 2831. SASL is method for adding authentication support to connection-based protocols.

**Common Digest Authentication Scenarios**

Many people think of Digest Authentication as a protocol that is used with Web browsers for authenticating users browsing the Internet. However, Digest Authentication is also a general purpose protocol that can be used for authentication, and by using SASL, it can provide integrity protection. For example, you can use Digest Authentication for:

- Authenticated client access to a Web site
- Authenticated client access using SASL
- Authenticated client access with integrity protection to a directory service using LDAP

**Authenticated client access to a Web site**

Digest Authentication can be used to provide user authentication when users access pages on a Web server.

**Authenticated client access to a directory service using LDAP**

Digest Authentication can be used as a SASL mechanism for any protocol that has a SASL profile. Using it as a SASL mechanism is a convenient way to support a single authentication mechanism for Web, e-mail, LDAP, and other protocols.

**Authenticated client access with integrity protection to a directory service using LDAP**
When using SASL, integrity protection can be added.

This is not an exhaustive list. The ability to access Digest through the SSPI interface means that developers can take advantage of Digest Authentication for just about any application. Because Digest Authentication uses a *message digest* function to enable authentication, it works well with devices such as personal digital assistants (PDAs) that have little processor power and that need to have authenticated access to resources to read e-mail, access appointment information on an Exchange server, or view Web pages on a server running services such as Internet Information Services (IIS).

The Windows Server 2003 implementation of Digest Authentication is integrated with Active Directory. This integration enables you to centrally manage accounts, but you must consider how accounts for employees, partners, and customers are provisioned and maintained. Because Digest Authentication is user name- and password-based, you must think about how you manage user accounts, password changes, password resets, and entitlements for your employees, partners, and customers.

**Technologies Related to Digest Authentication**
The following diagram shows how Digest Authentication fits with other technologies in Windows Server 2003. Depending on whether the client application or server application are user-mode or kernel-mode applications, they will use either Secur32.dll or Ksecdd.sys respectively via SSPI calls to communicate with the Local Security Authority Subsystem (LSASS).

### Digest Authentication Architecture

Below is a description of the components that participate in Digest Authentication.

### Security Subsystem Components used in Digest Authentication

| Component | Description |
|---|---|
| Wdigest.dll | The SSP that implements an industry standard and that is used in Windows Server 2003 for LDAP and Web authentication. Digest Authentication transmits credentials across the network as an MD5 hash or message digest and thus provides increased security over basic authentication. |
| Ksecdd.sys | The Kernel Security Device Driver is used to communicate with LSASS in user mode. |
| Lsasrv.dll | The LSA Server service, which both enforces security policies and acts as the security package manager for the LSA. |

| | |
|---|---|
| Netlogon.dll | The Net Logon service performs Digest Authentication- relevant services:<br>• Net Logon passes the user's credentials through a secure channel to the domain controller and returns the domain SIDs and user rights for the user. |
| Secur32.dll | The Secur32.dll component is the multiple authentication provider that implements SSPI for user mode applications. |
| Samsrv.dll | The Security Accounts Manager (SAM) stores local security accounts, enforces locally stored policies, and supports APIs. |

SSPI is an application interface that provides the security services for Windows Server 2003. SSPI supports the Digest Authentication SSP, wdigest.dll, which is the preferred authentication protocol for some applications and which uses protocols such as LDAP and HTTP.

The Digest SSP is used for the following:

- Internet Explorer (IE) and IIS access
- LDAP queries

**Digest Authentication Dependencies**
Digest Authentication depends on several related technologies and resources to function properly. The following section describes these technologies and resources and summarizes how they relate to Digest Authentication.

**Active Directory Domains**
Digest Authentication is not supported in earlier operating systems, such as Windows NT.

- Users and services must have a valid Active Directory domain account.
- The Web server must be a member of the same forest as the user accounts.

For more information about Active Directory, see the Active Directory Technical Reference.

**Operating Systems**
Wdigest.dll is built into Windows Server 2003 and Windows XP. If a client or server is running an earlier operating system, it will not use the Digest Authentication described in How Digest Authentication Works, but the older implementation of Digest.

**Windows Server 2003 Domain Controllers**
All domain controllers for the domains of the users and services using Digest Authentication must be running on Windows Server 2003 to use the latest implementation of Digest Authentication. This requirement is because of password hash storage in Active Directory. The domains do not need to be configured for the Windows Server 2003 domain functional level.

If any of the domain controllers in the account domains are running Windows 2000 Server, then subauthentication, which requires reversible encryption, is required for Digest Authentication to work.

# How Digest Authentication Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Digest Authentication Works**

**In This Section**

- Digest SSP Architecture
- Digest Authentication Processes and Interactions
- Network Ports Used by Digest Authentication
- Related Information

**Digest SSP Architecture**

The Windows Server 2003 operating system implements the Digest Authentication protocol as a security support provider (SSP), a dynamic-link library (DLL) that is supplied with the operating system. Which SSP is used depends on the capabilities of the computer on the other side of the connection and the preferences of the individual application that is being used.

The Microsoft Security Support Provider Interface (SSPI) is the foundation for authentication in Windows Server 2003. Applications and infrastructure services that require authentication use SSPI to provide it.

SSPI is the implementation of the Generic Security Service API (GSSAPI) in Windows Server 2003. For more information about GSSAPI, see RFC 2743 and RFC 2744 in the IETF RFC Database.

The default SSPs in Windows Server 2003 — Negotiate (SPNEGO), Kerberos, NTLM, Schannel, and Digest Authentication protocols — are incorporated into the SSPI as DLLs. Additional SSPs can be incorporated if they can operate with the SSPI.

**SSPI Architecture**

The SSPI in Windows Server 2003 provides a mechanism that carries authentication tokens over the existing communication channel between the client and server. When two parties need to be authenticated so that they can communicate securely, the requests for authentication are routed to the SSPI, which completes the authentication process, regardless of the network protocol currently in use. The SSPI returns transparent binary large objects, these are passed between the applications, at which point they can be passed to the SSPI layer on that side. Thus, the SSPI enables an application to use various security models available on a computer or network without changing the interface to the security system.

The following table describes the SSP components that are plugged into the SSPI. Each of the protocols in the table is used in different ways in Windows Server 2003 to promote secure communication in an unsecure network environment.

**SSP Layer Components**

| Component | Description |
|---|---|
| Kerberos V5 Authentication | An industry-standard protocol that is used with either a password or a smart card for interactive logon. It is also the preferred authentication method for services in Windows 2000 Server, Windows 2000 Professional, and Windows Server 2003. |

| | |
|---|---|
| NTLM Authentication | A challenge-response protocol that is used to provide compatibility with versions of Windows earlier than the Windows 2000 operating systems. |
| Digest Authentication | An industry standard that is used in Windows Server 2003 for Lightweight Directory Access Protocol (LDAP) and Web authentication. Digest Authentication transmits credentials across the network as an MD5 hash or message digest. |
| Schannel | An SSP that implements the Secure Sockets Layer (SSL) and Transport Layer Security (TLS) Internet standard authentication protocols. Schannel is used for Web-based server authentication such as when a user attempts to access a secure Web server. |
| Negotiate | An SSP that can be used to negotiate a specific authentication protocol. When an application calls into SSPI to log on to a network, it can specify an SSP to process the request. If the application specifies Negotiate, Negotiate analyzes the request and picks the best SSP to handle the request based on customer-configured security policies. |

**Digest SSP**

The Digest SSP, which is implemented through wdigest.dll, is one of the authentication protocols for some applications such as LDAP and HTTP. Depending on your deployment scenario, it might be the preferred protocol.

The Digest SSP is used for the following:

- Internet Explorer (IE) and Internet Information Services (IIS) access
- LDAP queries

**Digest Authentication Processes and Interactions**

**Digest Authentication Scheme**

### Overview of a Digest Authentication Scheme That Is Using HTTP

The Digest Authentication process involves the following steps:

1. The client sends the server a request for an access-protected resource.
2. The server receives the request from the client and recognizes that the request is for information or a service that requires authentication. The server checks whether the client has provided authentication information. Because this is the client's first request, it does not find any. The server responds by returning an HTTP WWW-Authenticate header to the client. This header includes the following:
    - The domain for which the server must supply credentials.
    - Information about whether authentication is required. If the exchange is Secure Authentication Socket Layer (SASL)-based, integrity and confidentiality might also be specified.
    - Server-side data, which often includes items such as a timestamp, nonce and an HTML tag that references the Uniform Resource Indicator (URI) requested, and is protected in the server's private key.
    - Hints about the security context.
    - A list of ciphers that the server supports.

- Specification of the encryption algorithm that is used in this authentication protocol. If the authentication is SASL-based, rather than HTTP-based, RC4 is the algorithm that is used in Windows Server 2003, although this is extensible and could be designed to use other algorithms.

The header is returned with a 401 message code, indicating that the client's request has generated an unauthorized access error.

3. The client receives the server's challenge and gathers the required credentials, either by accessing information in existing credentials or by prompting the user. The client's challenge response is then hashed with the user's secret key. This response includes the following parts:

   - The original nonce protected with the user's secret key, proving the client's knowledge of the user's password.
   - The user name and domain.
   - The original nonce and timestamp sent by the server, the number of times this number has been used, and a new random number, called a nonce number, which is unique and is used only once. To prevent replay attacks nonce counts are used.
   - The URI, which is the location of the resource that the client initially requested.
   - Information about whether authentication, integrity, and confidentiality is used.
   - Specification of the algorithms that are used.

4. The server receives the message and, as part of the authentication of the challenge response, the following checks are made:

   - That the challenge response is to a challenge issued by the server, and not another source.
   - That the challenge response message is properly formatted and the server-enforced options are valid.
   - That the nonce number has not been used before in challenge responses, to ensure that this is not a replay attack.

   If any of these checks fail, the server fails the authentication of the request.

   If the response meets the server's criteria, it relays the client's response to a domain controller, which completes the authentication. The Digest SSP checks whether the Digest Authentication response is valid and ensure that access restrictions, such as an expired password, do not apply.

   If the check is successful, the domain controller notifies the server that the client is authentic. A Digest Authentication session key is also returned to the originating server. If the check is not successful, the originating server sends the client an error message. After a successful authentication, the originating server allows the client to access the resource indicated by the URI.

   The Digest Authentication session key returned by the authenticating domain controller is cached by the originating server for use in authenticating future requests.

**Authentication of Subsequent Requests**

**Example Subsequent Request Using HTTP**

For subsequent requests, the client simply needs to send an authorization header with the security context reference to the server, because the security context has already been established with the server.

**Digest Authentication Headers**

Because Digest Authentication is accomplished through other protocols such as HTTP and LDAP, what is defined next is the challenge and challenge response that applications will transport to the Digest SSP.

**WWW-Authenticate Response Header**

When the server receives a request for an access-protected resource, the server replies with a "401 Unauthorized" status code and a WWW-Authenticate header with the digest scheme below. This section describes the directives that make up a Digest Authentication challenge.

RFC 2831 requires the size of a Digest Authentication challenge must be less than 2048 bytes. The Digest SSP enforces this for all Digest Authentication challenges. Following digest scheme is used:

Challenge = "Digest" digest-challenge

HTTP Authentication Digest-challenge = 1# (realm=*realm* | [domain="*domainname*"] | nonce="*nonce-value*" | [opaque="*opaque-value*"] | [stale=("true" | "false")] | [algorithm=("MD5" | "MD5-sess" | token] | [qop=1#("auth" | "auth-int" | token)] | [auth-parm]

SASL Digest-challenge = 1# ("*realm*" | nonce="*nonce-value*" | [qop=1#("auth" | "auth-int" | "auth-conf" | token")] | [stale=(true | false)] | [maxbuf=*maxbuf*] | [charset=*charset*] | [algorithm=("MD5" | "MD5-sess" | token] | [cipher=("3des" | "des" | "rc4-40" | "rc4" | "rc4-56" | token) | [auth-parm]

**Note**

- RFC 2617-compliant Digest Authentication challenges and responses must also comply with RFC 2616: Hypertext Transfer Protocol -- HTTP/1.1 quoted string requirements. This requirement particularly affects the use of backslash (\) and embedded double quotes. Both must be preceded (escaped) with a backslash.

- For example, *domain\username* according to RFC 2616 is read as *domainusername*. This reading is important because if an application sends information in this format rather than as *domain\\username,* authentication fails.

- However, because this is a known issue with *domain\username* , if authenticating with backslash encoding fails, Digest SSP attempts to authenticate the response and assumes that the backslash is part of the string. This behavior can be turned off by setting the ServerCompat registry key.

A Digest Authentication challenge can contain the following directives, which are defined in the relevant RFCs.

**Realm**

An implementation-defined string that is displayed to users if Digest Authentication is prompting users for credentials. This string helps users know which user name and password is required.

**Domainname (optional, not used in-SASL)**

A space-separated list of URIs that are contained in quotation marks and that define the protection space.

**Nonce-value**

A unique, encoded value that is generated by the server for each challenge. This value must not be altered by the client.

**Opaque-value (optional, not used in-SASL)**

A string of data specified by the server that contains a reference for the security context that is being established.

**Stale (optional)**

A flag that when set to TRUE indicates that the previous request from the client was rejected because the nonce value was stale, but the digest was valid. When not set to TRUE or not present then the user name and/or password are invalid and new values must be obtained.

**Algorithm (optional)**
A string indicating that the pair of algorithms used to produce the digest and checksum. If MD5 is not present, it is assumed. Digest SSP supports MD5 and MD5-Sess. For optimal performance, use MD5-Sess.

**QOP-(optional)**
Should be used by all RFC 2617-compliant implementations. The quality of protection (QOP) determines the level of security that is used when sending and receiving messages. The possible values for the QOP directive are described in the following table.

**QOP Options**

| Value | Description |
|---|---|
| "auth" | Authentication only. |
| "auth-int" | Authentication and integrity checking by using signatures. |
| "auth-conf" | (SASL only) Authentication, integrity and confidentiality checking by using signatures and encryption. See Ciphers. |

**Auth-parm (optional)**
Allows for future extensions of the RFC. Unrecognized directives must be ignored.

- **Maxbuf (optional, SASL only)**

  Number indicating the size of the largest buffer the server is able to receive when using "auth-int" or "auth-conf." The default is 65536.

- **Charset (optional)**

  Specified in RFC 2831, the charset directive can be set to UTF-8 if the server can process UTF-8–encoded user names and realms.

  **Note**

  - Digest SSP uses the charset directive for both HTTP and SASL mode. This directive allows the use of UTF-8 in HTTP mode. To maintain backwards compatibility with clients that do not understand the charset directive, the realm in the challenge is encoded in the standard ISO 8859-1 (Latin-1) character set. If the client understands the charset directive, then the username and realm (and password) can be encoded in UTF-8 in the challenge response sent back to the server. If the client does not understand the charset directive, then the standard ISO 8859-1 (Latin-1) must be used.

- **Cipher (SASL only)**

  The list of ciphers that the server supports. This element can be present in a Digest SASL challenge only if the QOP directive specifies auth-conf.

**Authorization Request Header**
The client must send the server a Digest Authentication challenge response when it receives a Digest Authentication challenge in response to a request for a resource. The client must send the request again and supply an Authorization Request header with the challenge response. This section describes the directives that make up a Digest Authentication challenge response.

RFC 2831 requires that the size of a Digest Authentication challenge response must be less than 4096 bytes. The Digest SSP enforces this for all Digest Authentication challenge responses. The following digest scheme is used:

Credentials = "Digest" digest-response

HTTP Authentication Digest-response = 1# (username="*username*"| realm | nonce | uri=digest-uri | response="*response* "| [algorithm] | [cnonce=*cnonce*] | [opaque] | [qop=*message-qop*] | [nc=*nonce-count*] | [auth-param])

SASL Digest-response = 1# (username="*username*"| realm | nonce | [cnonce=*cnonce*] | [nc=*nonce-count*] | [qop=*message-qop*] | uri=digest-uri | response="*response*" | [maxbuf=*maxbuf*] | [charset=*charset*] | cipher=*cipher* | [authzid=*authzid*] | [auth-param])

**Username**
The account name of the security principal requesting the resource.

**Realm**
The name of the domain that contains the account indicated by the user name.

**Nonce**
The nonce received in the Digest Authentication challenge.

**Digest-URI**
The URI of the requested resource.

**Response**
A value computed according to RFC 2617. An accurate response is conclusive proof that the user's password is known on the client side.

**Algorithm (Optional, not used in-SASL)**
The algorithm received in the Digest Authentication challenge.

**Cnonce (Optional)**
A unique, encoded value that is generated by the client for each challenge response, and that is used to avoid chosen plaintext attacks, provides some message integrity protection, and provides mutual authentication. This authentication is provided mutually in that the server proves it knows the user's secret information and not in that the server proves its identity. The nonce must be specified if a QOP directive is sent.

**Opaque (Optional, not used in-SASL)**
The opaque value received in the Digest Authentication challenge.

**Message-QOP (Optional)**
The quality of protection.

**Nonce-count (optional)**
The nonce count. The number of times the client has sent a challenge response by using the nonce. The nonce must be specified if a QOP directive is sent.

**Auth-parm (optional)**
Allows for future extensions of RFC. Unrecognized directives must be ignored.

- **Maxbuf (optional, SASL only)**

  Number indicating the size of the largest buffer that the client is able to receive. The default is 65536.

- **Charset (optional)**

  If the client understands the charset directive, it can respond by using UTF-8–encoded values.

  **Note**

  - Digest SSP uses the charset directive for both HTTP and SASL mode. This allows the use of UTF-8 in HTTP mode. To maintain backwards compatibility with clients that do not understand charset directive, the realm in the challenge is encoded in the standard ISO 8859-1 (Latin-1) character set. If the client understands the charset directive, then the username and realm (and password) can be encoded in UTF-8 in the challenge response sent back to the server. If the client does not understand the charset directive, then the standard ISO 8859-1 (Latin-1) must be used.

- **Cipher (SASL only)**

  The cipher selected by the client. This element must be present in a Digest SASL challenge if the QOP directive specifies auth-conf.

- **Authzid (optional, SASL only)**

  The authorization ID is specified in RFC 2222 and encoded in UTF-8. If the authenticating user has sufficient privilege and the server supports it, the server uses this ID after authentication for making all accesses and access checks. If the server

does not support authorization ID, then authentication fails if the client specifies it.

**Authentication-Info Header**
The server sends an HTTP response with an Authentication-Info Header with Security Context Reference back to the client. This section describes the directives that make up an Authentication-Info Header.

AuthenticationInfo = "Authentication-Info" : auth-info

Auth-info = 1# (nextnonce=*noncevalue* | [qop=*message-qop*] | [rspauth=*response-digest*] | [cnonce=*cnonce*] | [nc=*nonce-count*])

**Noncevalue**
The nonce that the server requires the client to use for future authentication responses. This nonce is not supported by Digest SSP (wdigest.dll).

**Message-QOP (Optional)**
The quality of protection applied by the server.

**Response-digest (Optional)**
Supports mutual authentication. This authentication is provided mutually in that the server proves it knows the user's secret information and not in that the server proves its identity.

**Cnonce (Optional)**
A unique, encoded value generated by the client for each challenge response and that is used to avoid chosen plaintext attacks, provide mutual authentication, and provide some message integrity protection. The nonce must be specified if a QOP directive is sent.

**Nonce-count (optional)**
The nonce count. The number of times the client has sent a challenge response by using the nonce. The nonce must be specified if a QOP directive is sent.

**SASL**
The Digest SASL mechanism defined in RFC 2831 describes the use of Digest Authentication as a SASL mechanism. Integrity protection on the application protocol messages is added as a new feature after the authentication exchange.

**Quality of Protection and Ciphers**
The quality of protection determines the level of security that is used when sending and receiving messages. The Digest SSP selects a level of integrity or confidentiality based on the requirements of the client and server.

When using Digest Authentication as a SASL mechanism, applications can specify that messages be kept confidential by using encryption. The server specifies the ciphers that it supports for encrypted messages, and the client selects a cipher from this list.

**Quality of Protection**
The quality of protection, identified by the QOP directive, is first specified by the server in the Digest Authentication challenge, and then confirmed by the client in the challenge response. If the client requires a quality of protection that the server does not support, the client must terminate the authentication.

The possible values for the QOP directive are described in the following table.

### QOP Options

| Value | Description |
|---|---|
| "auth" | Authentication only. |
| "auth-int" | Authentication and integrity checking by using signatures. |
| "auth-conf" | (SASL only) Authentication, integrity and confidentiality checking by using signatures and encryption. |

**Ciphers**
The following material is valid only when Digest is used as a SASL mechanism. Ciphers and encryption are not available for HTTP authentication by using Digest Authentication.

A Digest SASL challenge's cipher directive contains a list of the ciphers supported by a server that requires confidential communications. The cipher directive can only be included if the QOP directive is set to "auth-conf." The ciphers recognized by Digest Authentication are listed in the following table, from strongest to weakest.

**Ciphers That Are Supported by Digest Authentication**

| Cipher Value | Description |
|---|---|
| “rc4” | The RC4 cipher with a 128-bit key. |
| “3des” | The triple DES cipher in CBC mode with EDE with the same key for each E stage (two keys mode). Total key length is 112 bits. |
| “rc4-56” | The RC4 cipher with a 56-bit key. |
| ““rc4-40““ | The RC4 cipher with a 40-bit key. |
| “des” | The Data Encryption Standard (DES) cipher in cipher block chaining (CBC) mode with a 56-bit key. |

When a server application requests confidentiality (qop=auth-conf) the Digest SSP generates a challenge that offers the client all of the ciphers that are installed on the server and supported by Digest Authentication. The Digest client selects the strongest available cipher.

**Password Hashes**

The use of precalculated hashes is a new feature that allows system operators to skip the use of reversible encrypted passwords on the domain controller. A precalculated hash is formed for a user when the user’s password is changed.

Active Directory stores the following password-related materials:

- NTLM hash created by the NTLM SSP
- Kerberos key created by the Kerberos SSP
- Digest hashes created by the Digest SSP

When account passwords are modified (during either account creation or password reset/change), Security Account Manager (SAM) requests the authentication packages so that it can provide updated credential information based on the new password.

When passwords are changed, credential update notifications are sent to the authentication packages that have registered for credential updates.

**Digest Hashes**

Digest Authentication verifies passwords by computing a hash of the account name, realm property, and password. The specific format is H(username:realm:password) where H() is the MD5 hash operation. As this form shows, the plaintext password is required to compute the MD5 hash. To use Digest Authentication in previous versions of Windows Server, reversible encryption has to be set on an account. This setting allows the security provider to compute the digest hash when it is authenticating a server request by using Digest Authentication. In Windows Server 2003, a new digest hash is created and stored in Active Directory when a password is modified on an account. This digest hash contains several pre-computed versions of the H(username:realm:password) hash and permits these hashes to be authenticated without requiring reversible encryption to be enabled on an account.

The specific, precomputed forms are:

**Digest Hashes**

| Username | Realm | Password |
|---|---|---|
| SamAccountName | FlatDomainName for Account’s Domain | password |
| SamAccountName | DNSDomainName for Account’s Domain | password |
| User Principal Name (UPN) | NULL string | password |
| NetBiosName | NULL string | password |
| SamAccountName | “Digest” | password |

| | | |
|---|---|---|
| User Principal Name (UPN) | "Digest" | password |
| NetBiosName | "Digest" | password |

Where NetBiosName is FlatDomainName\SamAccountName.

Because the SamAccountName, UPN, and NetBiosName can have mixed cases, additional hashes are computed with these in lower case, upper case, and the original case used when account created.

**Note**

- Because only three versions of the user name are hashed, other variants of the user name do not work. For example, user, USER, and User might be created, but if presented with UsEr authentication would fail.

During the authentication of a request from a server, the challenge response sent from the client is compared to the pre-computed hashes stored on the user account. If a match is found, the server is notified by the domain controller that the challenge response is valid. If no match is found, a check is made by the domain controller to see if Reversible Encryption is enabled for the user account; if it is enabled, the domain controller computes the Digest hash with the plaintext version of the account's password, and a final validity test is performed by the domain controller on the challenge response.

**Network Ports Used by Digest Authentication**

Digest Authentication is not a network protocol. It uses the application protocol, so the port that Digest Authentication challenges and responses are sent by varies based on which application requests Digest Authentication and what port that application uses to communicate.

# Digest Authentication Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Digest Authentication Tools and Settings**

**In this section**

- Digest Authentication Tools
- Digest Authentication Registry Entries
- Digest Group Policy Settings
- Network Ports Used by Digest Authentication

**Digest Authentication Tools**

You can use the following tools to administer and troubleshoot Digest Authentication.

**Dsa.msc: Active Directory Users and Computers**

**Category**

Active Directory Users and Computers is a Microsoft Management Console (MMC) snap-in that automatically installs when you install Active Directory. This tool also ships with the Administration Tools Pack (Adminpak.msi).

You can access the tool from the **Start** menu: Click **Start**, then click **Programs**,then click **Administrative Tools,** and then click **Active Directory Users and Computers**.

**Version compatibility**

Active Directory Users and Computers runs on domain controllers that are running the Windows Server 2003 or Windows 2000 operating systems. In both of these operating systems, MMC provides a window in the user interface (UI) where you can add, configure, and control items. Active Directory Users and Computers is the snap-in that you can use to administer and publish information in Active Directory.

The Windows Server 2003 version of Active Directory Users and Computers can target domain controllers that are running Windows Server 2003 or Windows 2000 Server.

On administrative workstations that are running Windows XP Professional or Windows 2000, you can install the Windows Server 2003 Administration Tools Pack (Adminpak.msi) from the i386 directory on the Windows Server 2003 CD. This version of the Administration Tools Pack encrypts and signs Lightweight Directory Access Protocol (LDAP) traffic between the administrative tool clients and domain controllers.

**Note**

- You cannot run the Windows Server 2003 Administration Tools Pack (Adminpak.msi) on a computer that is running Windows XP Professional, Windows XP Home Edition, or Windows XP 64-Bit Edition Version 2003 without Windows XP Service Pack 1 (SP1).

You can use Active Directory Users and Computers to manage the properties that are listed in the following table, which are associated with objects in Active Directory. Your management of the properties affects the digest hashes for these objects.

**Active Directory Users and Computers Object Management**

| Property | Changes That Affect Digest Authentication |
|---|---|
| **User Objects Account Tab:**<br><br>Store passwords by using reversible encryption | An optional account property that can be set to keep an encrypted version of the user account's password on the domain controller. It is encrypted so that only the LSA can decrypt to access the Plaintext password for the account. |

You can find more information about Active Directory Users and Computers on Microsoft TechNet.

**Eventvwr.msc: Event Viewer**
**Category**
Event Viewer is included in Windows Server?2003, Windows XP, and Windows 2000.

**Version compatibility**
Event Viewer is supported by Windows Server 2003, Windows XP, and Windows 2000.

All account logons that occur on computers that are using Digest Authentication might be present in the security log. To find these events you need to enable auditing of account logon and logon events for user authentication. The following table lists event IDs and information potentially associated with Digest Authentication. Only relevant event information is present in the event log.

### Digest Authentication Security Log Events

| Event ID | Event Type | Description |
|---|---|---|
| 537 | Logon/Logoff<br>• Failure Audit | Logon Failure:<br>• Reason: An error occurred during logon<br>• User Name:<br>• Domain:<br>• Logon Type:<br>• Logon Process: WDIGEST<br>• Authentication Package: WDigest<br>• Workstation Name: |

| | | |
|---|---|---|
| 540 | Logon/Logoff<br>• Success Audit | Successful Network Logon:<br>• User Name:<br>• Domain:<br>• Logon ID:<br>• Logon Type:<br>• Logon Process: WDIGEST<br>• Authentication Package: WDigest<br>• Workstation Name:<br>• Logon GUID:<br>• Caller User Name:<br>• Caller Domain:<br>• Caller Logon ID:<br>• Caller Process ID:<br>• Transited Services:<br>• Source Network Address:<br>• Source Port: |
| 576 | Logon/Logoff<br>• Success Audit | Special privileges assigned to new logon:<br>• User Name:<br>• Domain:<br>• Logon ID:<br>• Privileges: |
| 680 | Account Logon<br>• Success Audit<br>• Failure Audit | Logon attempt by: WDigest<br>• Logon account:<br>• Source Workstation:<br>• Error Code: |

For more information about "Event Viewer", see "Event Viewer" on Microsoft TechNet.

**Netmon.exe: Network Monitor**
**Category**
A limited version of Network Monitor is included in Windows Server 2003, Windows XP, and Windows 2000. The full version

of Network Monitor is included with Microsoft Systems Management Server.

**Version compatibility**
Network Monitor is supported for Windows Server 2003, Windows XP, and Windows 2000.

Network Monitor enables you to capture network traces, which can be used in troubleshooting most network issues.

**Digest Authentication Registry Entries**
The following registry entries are associated with Digest Authentication:

- ClientCompat
- Negotiate
- ServerCompat
- UTF8HTTP
- UTF8SASL

The information here is provided as a reference for you to use when troubleshooting or verifying that the required settings are applied. We recommend that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. Modifications to the registry can result in irrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**ClientCompat**
**Registry path**
HKLM System\CurrentControlSet\Control\SecurityProviders\WDigest\

**Version**
Windows Server 2003, Windows XP

This entry controls the client option to quote the QOP directive because some servers require the client to quote the QOP directive. This entry does not exist in the registry by default. The default value is 1. The client will quote the QOP directive value in the challenge response that is sent over to the server. This behavior can be turned off by setting this value to 0.

**Negotiate**
**Registry path**
HKLM System\CurrentControlSet\Control\SecurityProviders\WDigest\

**Version**
Windows Server 2003, Windows XP

This entry controls adding Digest Authentication to the list of negotiable SSPs. The default value is 0.

**ServerCompat**
**Registry path**
HKLM System\CurrentControlSet\Control\SecurityProviders\WDigest\

**Version**
Windows Server 2003, Windows XP

This entry controls server to accept client challenge responses that do not encode backslash. This entry does not exist in the registry by default. The default value is 1. If authentication with backslash encoding fails, Digest SSP attempts to authenticate the response and assumes that the backslash is part of the string. This behavior can be turned off by setting this value to 0.

**UTF8HTTP**
**Registry path**
HKLM System\CurrentControlSet\Control\SecurityProviders\WDigest\

**Version**
Windows Server 2003, Windows XP

This entry controls UTF-8 encoding for HTTP mode. ISO 8859-1 Latin is used but does not support non US languages. This is a

port of SASL option to allow use of UTF-8 encoding to the HTTP mode. The default value is 1.

**UTF8SASL**
**Registry path**
HKLM System\CurrentControlSet\Control\SecurityProviders\WDigest\

**Version**
Windows Server 2003, Windows XP

This entry controls UTF-8 encoding for SASL mode. The default value is 1.

**Digest Authentication Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with Digest Authentication.

### Group Policy Settings Associated with Digest Authentication

| Group Policy Setting | Description |
|---|---|
| Account Policies:<br><br>Password Policy: Store passwords by using reversible encryption for all users in the domain | An optional account property that can be set to keep an encrypted version of the user account's password on the domain controller. It is encrypted so that only the LSA can decrypt to access the Plaintext password for the account. |

For more information about Group Policy settings, see the "Group Policy Settings Reference for Windows Server 2003" in Tools and Settings Collection.

**Network Ports Used by Digest Authentication**
Digest Authentication is not a network protocol. It uses the application protocol, so the port that Digest Authentication challenges and responses are sent by varies based on which application requests Digest Authentication and what port that application uses to communicate.

# Interactive Logon Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Interactive Logon Technical Reference**
The Microsoft Windows Server 2003 operating system requires all users to log on to access local and network resources. Windows secures resources by implementing the interactive logon process, which provides authentication of users.

# What is Interactive Logon?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Interactive Logon Scenarios
- Related Information

Windows Server 2003 requires that all users must validate their identities to successfully log on to the computer. The process of validating a user's identity is called authentication.

Security in the Windows Server 2003 operating system controls the use of local and network resources through the interrelated mechanisms of authentication and authorization. After a user is authenticated, Windows Server 2003 uses the authorization and access control technologies to implement the second phase of protecting resources: determining if an authenticated user is authorized to access a resource.

Windows Server 2003 can authenticate users and computers that have accounts either in the Security Accounts Manager (SAM) or the Active Directory directory service.

**Interactive Logon Scenarios**

An interactive logon to a computer can be performed either locally, when the user has direct physical access, or remotely, through Terminal Services, in which case the logon is further qualified as remote interactive. After an interactive logon, Windows runs applications on the user's behalf and the user can interact with those applications.

Users can perform an interactive logon by logging on to a computer using a local user account or by using their domain account.

The following figure shows local and domain logons.

**Interactive Logon Types**

**Local Logon**

A local logon requires that the user have a user account in the SAM on the local computer. The SAM protects and manages user and group information in the form of security accounts stored in the local computer registry. The computer can have network access, but it is not required. Local user account and group membership information is used to manage access to local resources.

**Domain Logon**

A domain logon requires that the user have a user account in the domain's Active Directory. The computer must be joined to the domain and have a network connection to the domain. Users must also have rights to log on to a local computer or a domain. Domain user account and group membership information is used to manage access to domain and local resources.

**Smart Card Logon**

Windows Server 2003 can also be configured to support special domain logon processes that require the use of a hardware token, such as a smart card. A smart card logon is a form of enhanced-security logon that requires both a physical identifier (the smart card) and a personal identification number (PIN).

# How Interactive Logon Works

Updated: March 31, 2015

Applies To: Windows 7, Windows 8, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2, Windows Vista

**In this section**

- Interactive Logon Architecture
- Interactive Logon Components
- Interactive Logon Protocols
- Interactive Logon Processes and Interactions
- Network Ports Used by Interactive Logon
- Related Information

The interactive logon process is the first step in user authentication and authorization. Interactive logon is mandatory in the Windows Server 2003, Windows XP, Microsoft Windows 2000, and Windows NT 4.0 operating systems. Interactive logon provides a way to identify authorized users and determine whether they are allowed to log on and access the system.

This section describes the interactive logon architecture, the process of an interactive logon, and the way in which the Windows Server 2003 interactive logon process locks the workstation and helps to keep it secure.

**Interactive Logon Architecture**

The Windows Server 2003 interactive logon architecture includes the following components:

- Winlogon
- Graphical Identification and Authentication (GINA) dynamic-link library (DLL)
- Local Security Authority (LSA)
- Authentication packages (NTLM and Kerberos)

For more information about these components, see Interactive Logon Components later in this section.

Windows Server 2003 interactive logons begin with the user pressing CTRL+ALT+DEL to initiate the logon process. The CTRL+ALT+DEL keystroke is called a secure attention sequence (SAS); Winlogon registers this sequence during the boot process to keep other programs and processes from using it. The GINA DLL generates the logon dialog box. The following figure shows the Windows Server 2003 logon dialog box.

**Windows Server 2003 Logon Dialog Box**

A user who logs on to a computer using either a local or domain account must enter a user name and password, which form the user's credentials and are used to verify the user's identity. For smart card logons, a user's credentials are contained on the card's security chip, which is read by an external device, a smart card reader. During a smart card logon, a user enters a personal identification number (PIN) instead of a user name, domain, and password.

**Local Logon**

Local logons give users access to local computer applications and resources but not to domain applications and resources. When users log on locally, their identities are validated by authentication packages to local account information stored in the Security Accounts Manager (SAM) database. The SAM operates in the security context of the LSA; it protects and manages user and group information in the form of security accounts stored in the local computer registry. Because user accounts are stored on the local computer, network access is not required for local logons. However, if a computer has a network connection and a user logs on to a local account, there is no interaction with the network.

Local logons can be performed on Windows client operating systems, such as Windows XP and Windows 2000 Professional. Windows server operating systems, such as Windows NT Server, Windows 2000 Server, and Windows Server 2003, also permit local logons.

The following figure shows the local logon architecture.

**Interactive Local Logon**

A successful local logon begins when a user presses CTRL+ALT+DEL. Winlogon and the GINA DLL collect the user's credentials and then send the credentials to the LSA. The LSA verifies the user's identity and then returns a logon success and the user's access token to Winlogon and the GINA DLL. Winlogon and the GINA DLL then activate the user's shell by creating a new process, such as Explorer.exe.

**Domain Logon**

Domain logons give users access to resources throughout the domain. Domain user accounts are stored in an Active Directory domain. Active Directory is deployed on each domain controller, and domain user accounts are replicated throughout a domain.

Before a user can log on to a computer by using a domain account, the computer must be joined to a domain. If the computer has access to a network connection, the user can log on to a domain if the user has an account in the domain's Active Directory.

The computer must transparently authenticate to the domain's Active Directory. This form of logon is called a computer logon. Both users and computers are considered equal security principals in Active Directory; to be granted access to network

resources, both must be able to verify their identities.

Users can use a domain account to log on to Windows client operating systems, such as Windows 8. Windows server operating systems, such as Windows Server 2012 R2, also permit domain logons. Only server operating systems can function as domain controllers and deploy Active Directory.

On a domain-joined computer, Windows is hard-coded to show only the last logged on user or **Other user**. Additional tiles for other users to log on are available only for computers joined to a workgroup.

The following figure shows the domain logon architecture.

**Interactive Domain Logon**

Unlike a local logon in which the local LSA validates the user, during a domain logon, the LSA on a domain controller validates the user. The LSA evaluates the user's credentials to determine if the logon should be processed as a logon to a local account or a logon to a domain account. After determining the logon type, either the NTLM or Kerberos authentication package validates the user. If the authenticating domain controller is a computer running Windows 2000 or Windows Server 2003, the LSA will use Kerberos, the default authentication package for domain and network logons. The LSA uses NTLM to process domain logons in Windows NT 4.0 mixed environments.

**Single Sign On**

Single sign-on (SSO) uses credentials collected during an interactive domain logon to allow the user to authenticate to a network one time and, thereafter, to have access to all authorized network resources without additional authentication. The network resources can range from hardware devices, such as printers, to applications, files, and other types of data, all of which may be located throughout an enterprise on servers of various types, possibly in different domains and running different operating systems.

**Cached Credentials**

After a successful domain logon, information is cached; this means that later a user can log on to the computer with the domain account even if the domain controller that authenticated the user is not available. Because the user has already been authenticated, Windows uses the cached credentials to log the user on locally. For example, if a mobile user logs on to a portable computer that is a domain member with a domain account and then takes the portable computer to a location where the domain is unavailable, Windows will attempt to use the cached credentials from the last successful logon with a domain account to locally log on the user and allocate access to local computer resources.

**Interactive Logon Components**

The components of the interactive logon process are responsible for helping to establish secure user authentication. This section describes the roles and functions of the user logon components.

**Winlogon**

Winlogon (%windir%\System32\Winlogon.exe) is the executable file responsible for managing secure user interactions. Winlogon initiates the logon process for Windows Server 2003, Windows 2000, Windows XP, and Windows NT 4.0.

Winlogon is responsible for the following tasks.

- Desktop lockdown
- Standard SAS recognition
- SAS routine dispatching
- User profile loading
- Screen saver control
- Multiple network provider support

**Desktop Lockdown**

Winlogon helps prevent unauthorized users from gaining access to system resources by locking the computer desktop. At any time, Winlogon is in one of three possible states: logged on, logged off, or workstation locked, as shown in the following figure.

**Winlogon States**

Winlogon switches between three desktops—Winlogon, screen saver, and default—depending on its state and user activity. The following table lists and describes each of these desktops.

**Winlogon Desktops**

| Desktop | Description |
|---|---|
| Winlogon | Also called the secure desktop. There are five dialog boxes in the Winlogon desktop, which are described in the following table. |
| Screen saver | Used when a screen saver is running. |
| Default | Displayed when a user has successfully logged on to Windows Server 2003 and the user's shell has been activated. The user's applications run in this desktop. |

The following table lists and describes the five dialog boxes in the Winlogon desktop.

**Winlogon Desktop Dialog Boxes**

| Desktop | Description |
|---|---|
| Welcome to Windows | Displayed when a computer has initially booted and no user has entered a SAS or when a user has logged off. |

| | |
|---|---|
| Log On to Windows | Displayed after a user presses CTRL+ALT+DEL when no user is currently logged on. |
| Windows Security and Change Password | Displayed when:<br>• A logged-on user presses CTRL+ALT+DEL when the workstation is not locked.<br>OR<br>• When the workstation is not locked, after a user presses CTRL+ALT+DEL and clicks **Change Password**. |
| Computer Locked | Displayed when the workstation is locked either explicitly by the user or when a screen saver is set as secure and is dismissed. |
| Unlock Computer | Displayed when a user presses CTRL+ALT+DEL when the workstation is locked. |

By switching between the desktops for different logon tasks, Winlogon ensures that its processes will be invisible to applications not involved in the logon process, preventing logon data from being compromised.

**Standard SAS Recognition**
Winlogon registers the default SAS during the boot process, which ensures that no other program can access the same key sequence and compromise the logon process by impersonating Winlogon and its logon dialog boxes.

**SAS Routine Dispatching**
When Winlogon recognizes a SAS event or the GINA delivers a SAS, Winlogon calls one of the SAS processing functions of the GINA.

**User Profile Loading**
After a successful logon, Winlogon loads user profiles into the HKEY_CURRENT_USER registry key.

**Screen Saver Control**
Winlogon monitors keyboard and mouse activity to determine when to activate screen savers. When a screen saver that is set as secure is dismissed, Winlogon treats the workstation as locked and the GINA displays the **Computer Locked** dialog box. When a screen saver not set as secure is dismissed, the user is able to access the application desktop without being prompted to reenter credentials.

**Multiple Network Provider Support**
If there are multiple network providers installed on a Windows-based system, they can be included in the authentication process and in password-updating operations. This inclusion lets additional network providers gather identification and authentication information during a logon, using the secure desktop.

**GINA**
The GINA is a DLL module that operates in the security context of Winlogon. Winlogon loads the GINA early in the boot process. The GINA is responsible for processing SAS events and activating the user's shell. The GINA can generate SAS events in some instances.

In Windows Server 2003, Windows XP, and Windows 2000, Msgina.dll (%windir%\System32\Msgina.dll) is the default GINA; it can be replaced to support specific and unique authentication methods. GINA customization is enabled to accommodate the use of authentication hardware tokens, such as retinal scanners and proprietary smart card solutions.

**LSA**
The LSA (%windir%\System32\lsass.exe) is a protected security subsystem that helps create secure user interactions in Windows Server 2003. Winlogon and the GINA call the LSA to process logon credentials.

The following components involved in user logon run in the security context of the LSA:

- Authentication packages
- SAM
- Active Directory

## LSA Responsibilities

| Role | Description |
| --- | --- |
| Application programming interfaces (APIs) | The LSA provides APIs for:<br>• Packages to create a user's logon token after authentication.<br>• Applications to call directly for user logon.<br>• Microsoft Security Support Provider Interface (SSPI) requests and the routing of requests to the appropriate authentication package.<br>• Applications to enumerate available authentication packages and query package capabilities.<br>• Applications to resolve Security Identifier-to-Name and Name-to-Security Identifier.<br>• Applications to store secret information in the system. |
| Logon session state | Manages the state of the logon session for any user authenticated by the authentication packages. |
| Notification to installed authentication packages | Notifies installed authentication packages of user logon, logoff, and credential updates. |
| Authentication packages | Loads and unloads authentication packages. |
| Encryption assistance | Includes subcomponents that provide encryption services to users of the local computer. |

The following figure shows the LSA architecture. Winlogon, which runs as a separate process from lsass.exe, is shown here to illustrate the way in which the logon process interacts with the LSA.

**LSA Architecture**

| Note |
| --- |
| Some components shown in this figure run only on domain controllers or non-domain controllers. The SAM runs only on non-domain controllers and Windows NT computers; Directory Services runs only on domain controllers. |

As the figure shows, all calls from Winlogon are sent by using the Secur32.dll LsaLogonUser call. LsaLogonUser returns the call through local procedure call (LPC) to the LSA Server service. The LSA Server service then determines which authentication package to use to process the logon.

You can set user rights for local computers by using the Local Security Policy snap-in of the Microsoft Management Console (MMC). On Windows Server 2003 non-domain controllers, the Group Policy User Rights Assignment contains information about which users are authorized to perform different tasks, including logging on to the system locally. Domain controllers use the Domain Security Policy snap-in of the MMC to set user rights for domain computers. The User Rights Assignment on domain controllers contains information that applies to the entire domain.

**Authentication Packages**

Authentication packages on the user's local computer communicate with server authentication packages to authenticate users. Windows Server 2003 applies default authentication packages for user authentication and also supports custom authentication packages.

The following table lists the Windows Server 2003 authentication packages used for interactive logons.

**Interactive Logon Authentication Packages**

| Name | Associated Protocol | Environment |
|---|---|---|
| Kerberos version 5 (V5) | Kerberos.dll | Windows 2000, Windows XP, and Windows Server 2003 |
| NTLM | MSV1_0.dll | Windows NT 4.0 and mixed environments |

**SAM**

The SAM stores information about local user accounts in the Windows registry. Passwords are encrypted by the NTLM authentication package. The outcome of the encryption is a hashed password transformed into ciphertext, a string of numbers and letters that appears meaningless. The hashing process occurs by means of a hashing algorithm. NTLM uses the same algorithm to encrypt and decrypt a user's password.

**Active Directory**

Domain account information is stored in Active Directory on the domain controllers. Within a particular domain, each domain controller has an identical copy of the domain's Active Directory. Users can therefore authenticate to any domain controller and their logon information will be recognized throughout the domain.

**Interactive Logon Protocols**

In network environments, authentication protocols are used to authenticate users, computers, and groups. For local logons, Windows Server 2003 supports the NTLM authentication protocol. For domain logons, Windows Server 2003 supports the Kerberos V5 and NTLM authentication protocols. Windows Server 2003 also supports custom authentication packages.

**Logon Protocols**

| Component | Description |
|---|---|
| Kerberos.dll | • Kerberos V5 authentication package authentication protocol.<br>• Standard Internet protocol and default network authentication protocol in Windows Server 2003.<br>• Performs authentication of users and computers in Windows 2000, Windows XP, and Windows Server 2003. |
| MSV1_0.dll | • NTLM authentication package authentication protocol.<br>• Default network authentication protocol in Windows NT 4.0.<br>• Performs authentication of users and computers in Windows NT 4.0 mixed environments.<br>• Included in Windows Server 2003 for compatibility with Windows NT 4.0 mixed environments. |

For more information about how the Kerberos V5 protocol implements user authentication, see Kerberos Authentication Technical Reference.

**Interactive Logon Processes and Interactions**
This section describes the events that occur during an interactive logon.

**Local Logon**
The following figure shows the local logon process.

### Local Logon Process

The GINA specifies the Negotiate authentication package when it calls into the LSA. Negotiate must then choose an authentication package to process the logon. Negotiate sends the credentials to Kerberos, the default authentication package beginning with Windows Server 2003. However, the Kerberos authentication package cannot process local logons, so it returns an error to Negotiate. Negotiate then calls NTLM to authenticate the user by comparing the received credentials with those hashed in the SAM.

If the credentials are valid, the LSA generates an access token for the user based upon user rights assigned to the user's account and LsaLogonUser returns the logon success and the user's access token to Winlogon and the GINA. The GINA then activates the user's shell and Winlogon switches to the default desktop. If the credentials are invalid, the LSA returns a logon failure, the GINA displays an error message and prompts the user to present valid credentials, and Winlogon remains in the Winlogon desktop.

**Domain Logon**
Domain logons can only be performed from computers that are joined to a domain. Domain credentials consist of a user's domain account user name, password, and the name of the domain. The local computer's LSA chooses the appropriate authentication package to use based on the domain's environment.

The following figure shows the process that occurs when the local computer can reach a domain controller to authenticate the user. If a domain controller is not available, a cached logon occurs.

### Domain Logon Process

As with the local logon process, the Negotiate authentication package routes the authentication request to the default authentication package, Kerberos.

The domain client chooses Kerberos, and Kerberos validates the user's credentials by contacting the domain controller. The LSA on the domain controller returns the logon success or failure to the local computer's LSA. If the domain logon succeeds, the local LSA generates an access token for the user based upon user rights assigned to the user's account, and LsaLogonUser returns the logon success and the user's access token to Winlogon and the GINA. The GINA then activates the user's shell, and Winlogon switches to the default desktop. If the credentials are invalid, the LSA returns a logon failure, the GINA displays an error message and prompts the user to present valid credentials, and Winlogon remains in the Winlogon desktop.

| **Note** |
| --- |
| In Windows NT 4.0 mixed environments, the NTLM authentication package validates the user's credentials by contacting the domain controller. Windows NT 4.0 stores user accounts in the SAM. |

**Smart Card Logons**

Windows Server 2003 can be configured to support smart card logons. All smart card logons are processed by the Kerberos authentication package. During a smart card logon, the local computer checks to ensure the user's PIN is valid. The domain controller then authenticates the user based on the user's credentials in the smart card.

**Cached Logons**

Windows Server 2003 supports cached logons. The cached credentials of the last 10 users who have successfully logged on to a domain account can be used to log a user on locally if the authenticating domain controller becomes unavailable.

**Network Ports Used by Interactive Logon**

Because the logon process can be deployed across various network boundaries, it can span one or more firewalls. The following table lists the three main configurable ports used by interactive logon.

**Port Assignments for Interactive Logon**

| Service Name | UDP | TCP |
| --- | --- | --- |
| LSA RPC port | Dynamic RPC | Dynamic RPC |

| | | |
|---|---|---|
| Kerberos V5 port | 88 | 88 |
| NTLM port | Dynamic | Dynamic |

You can use the Registry Editor to modify the registry to apply fixed ports for NTLM and the LSA.

**Related Information**

The following resources contain additional information that is relevant to this section.

# Interactive Logon Tools and Settings

Updated: November 10, 2008

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Interactive Logon Tools**
The following tools are associated with interactive logon.

**EventViewer.msc: Event Viewer**
**Category**

Event Viewer is included as part of the Windows Server 2003, Windows 2000, and Windows XP operating systems.

**Version compatibility**

Event Viewer is supported for Windows Server 2003, Windows XP, and Windows 2000.

The Event Log service starts automatically when you start Windows. The Event Log is a compilation of system events. There are three Event Logs: an application log, a system log, and a security log. All users can view application and system logs. Only administrators can gain access to security logs.

By default, security logging is turned off. You can use Group Policy to enable security logging. The administrator can also set auditing policies in the registry that cause the system to halt when the security log is full.

The system and security logs will contain logon error codes and other events related to interactive logon and network authentication.

The following table lists the event IDs that relate to interactive logon.

**Interactive Logon Events**

| Event ID | Description |
|---|---|
| 528 | Successful logon. |
| 529 | Logon failure. Unknown user name or bad password. |
| 530 | Logon failure. Account logon time restriction violation. |
| 531 | Logon failure. The account is currently disabled. |
| 532 | Logon failure. The specified user account has expired. |
| 533 | Logon failure. The user is not allowed to log on at this computer. |
| 534 | Logon failure. The user has not been granted the requested logon type at this computer. |
| 535 | Logon failure. The specified account's password has expired. |
| 536 | Logon failure. The NetLogon component is not active. |
| 537 | Logon failure. An unexpected error occurred during logon. |
| 538 | User logoff. This event is generated when the logoff process is complete. A logoff is considered complete when the associated logon session object is deleted, which occurs after all tokens associated with the logon session are closed. This can take an arbitrarily long time; this event should not be used to calculate the total logon duration. Instead, use event 551. |
| 539 | Logon failure. Account locked out. |
| 540 | Successful network logon. |
| 541 | IPSec security association established. |

| | |
|---|---|
| 542 | IPSec security association ended. Mode: Data Protection (Quick mode). |
| 543 | IPSec security association ended. Mode: Key Exchange (Main mode). |
| 544 | IPSec security association establishment failed because peer could not authenticate. The certificate trust could not be established. |
| 545 | IPSec peer authentication failed. |
| 546 | IPSec security association establishment failed because peer sent invalid proposal. |
| 547 | IPSec security association negotiation failed. |
| 548 | Logon failure. Domain security identifier (SID) is inconsistent. This event is generated when a user account from a trusted domain attempts to authenticate, but the domain SID does not match the SID stored in the Trusted Domain Object (TDO). |
| 549 | Logon failure. All SIDs were filtered out. During authentication across forests, SIDs corresponding to untrusted namespaces are filtered out. This event is generated when all SIDs are filtered. This event is generated on the Kerberos Key Distribution Center (KDC).<br><br>This event is not generated on Windows Server 2003. |
| 550 | Notification message that can indicate a possible denial-of-service attack. |
| 551 | User-initiated logoff. This event is generated when the user initiates the logoff process. When the logoff process is complete, event 538 is logged. |
| 552 | Successful logon. This event is generated when a user logs on with explicit credentials while already logged on as another user. This event is logged when using the RunAs tool. |
| 553 | Logon failure. This event is generated when an authentication package detects a replay attack. |

**Lusrmgr.msc: Local Users and Groups**

### Category

Local Users and Groups is included as part of the Windows Server 2003, Windows XP Professional, and Windows 2000 operating systems and is available in the Windows Server 2003 Administration Tools Pack (Adminpak.msi).

### Version compatibility

Local Users and Groups is supported for administering local groups on Windows Server 2003, Windows XP Professional, and Windows 2000.

Local Users and Groups manages users and groups of users for your computer. You can create new users and groups, add users to groups, remove users from groups, disable user and group accounts, and reset passwords.

You might need to be logged on as an administrator or a member of the Administrators group to perform some tasks.

**Secpol.msc: Local Security Policy**

### Category

Local Security Policy is included as part of the Windows Server 2003, Windows XP, and Windows 2000 operating system tools and is available in the Windows Server 2003 Administration Tools Pack.

### Version compatibility

Local Security Policy is supported for Windows Server 2003 and Windows 2000.

You can set security settings for the local computer in Local Security Policy.

For more information about security policy settings specific to interactive logons, see the “Interactive Logon Group Policy Settings” section later in this topic.

**Whoami**

### Category

Whoami is a command-line tool in Windows Server 2003. This tool is also included in the Windows 2000 Resource Kit.

### Version compatibility

Whoami is supported for Windows Server 2003 and Windows 2000.

You can use whoami to display the complete contents of a user's access token in the command window.

Whoami displays:

- User name and SID.
- Groups and their SIDs.
- Privileges and their status (for example, enabled or disabled).
- Logon ID.

For more information about whoami, see "Command Line References" in Tools and Settings Collection.

**Interactive Logon Registry Entries**
The following registry entries are associated with interactive logon.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_LOCAL_MACHINE\SYSTEM**
The following registry entries are located under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\.

**Bounds**
Registry Path

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

Version

The Bounds registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The Bounds entry specifies thresholds for managing the length of the kernel-mode Local Security Authority (LSA) audit queue. The audit queue stores kernel-mode events destined for the security log in Event Viewer.

The value of this entry is an 8-byte binary field. The value of the first four bytes specifies the maximum number of items that can be held in the audit queue (the upper bound). When the number of audits exceeds this value, the LSA discards all new audits until the number of audits remaining in the queue reaches the lower bound, as specified by the value of the last four bytes.

**CrashOnAuditFall**
### Registry Path

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

### Version

The CrashOnAuditFall registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The CrashOnAuditFall entry directs the system to halt when it cannot record new events in the security log in Event Viewer. This feature prevents unauthorized activities from occurring when they cannot be recorded in the security log.

The system also uses this entry to indicate that this feature has been triggered (a value of 2). When the value of this entry is 2, only members of the Administrators group can log on to the computer. This restricted state lets an Administrator log on to resolve the problem and to reset the value of this entry to 1.

Typically, the system cannot record security events because the security log in Event Viewer is full or because the internal queue to the log has reached the maximum established by the Bounds value.

This entry does not exist in the registry by default. You can add it by using the registry editor, Regedit.exe.

**Everyoneincludesanonymous**

### Registry Path

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

### Version

The Everyoneincludesanonymous registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The Everyoneincludesanonymous entry specifies whether the local Everyonegroup of users includes anonymous users. (The Everyone group is a generic group of users that includes all users.) Specifically, this entry determines whether the LSA includes the SID of the Everyone group in the security token of an anonymous user.

**Kerberos**

### Registry Path

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

### Version

The Kerberos registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The Kerberos subkey stores configuration data for the Kerberos version 5 (V5) authentication protocol in Windows Server 2003. The Kerberos V5 protocol is the primary security protocol for authentication within a domain. It verifies the identity of the user and the system.

**MSV1_0**

### Registry Path

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

### Version

The MSV1_0 registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The MSV1_0 subkey stores information about the computer’s security settings.

**NoLMHash**

### Registry Path

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

### Version

The NoLMHash registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The NoLMHash value specifies whether Security Accounts Manager (SAM) stores the LAN Manager (LM) hash of the user’s password. The LM hash of the user's password is required to authenticate down-level clients that cannot use NTLM or NTLM version 2 (NTLMv2) authentication.

The following table lists the possible settings for the NoLMHash value.

### NoLMHash Settings

| Value | Meaning |
|---|---|
| 0 | SAM stores the message digest of the user's password. |
| 1 | SAM does not store the message digest of the user’s password. |

**NotificationPackages**

### Registry Path

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

### Version

The NotificationPackages registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The NotificationPackages value specifies the dynamic-link libraries (DLLs) that are loaded or called when passwords are set or changed. This entry is often used to load libraries for services such as File and Print Services for NetWare.

You can use this entry to implement custom DLLs that specify alternate criteria for valid passwords, such as complex password rules. Notification packages that implement password verification are recommended for all primary and backup domain controllers (relevant for Windows NT 4.0 environments). You can also write a custom password filter to fulfill special security requirements.

**RestrictAnonymous**

**Registry Path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

**Version**

The RestrictAnonymous registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The RestrictAnonymous value restricts anonymous users from displaying lists of users and from viewing security permissions.

The following table lists the possible settings for the RestrictAnonymous value.

**RestrictAnonymous Settings**

| Value | Meaning |
|---|---|
| 0 | Disabled. Anonymous users are not restricted. |
| 1 | Enabled. Users who log on anonymously (a logon referred to as a null session connection) cannot display lists of domain user names or share names. Also, these users cannot view security permissions; they cannot use all of the features of Windows Explorer, Local Users and Groups, and other programs that enumerate users or shares. |
| 2 | Anonymous users have no access without explicit anonymous permissions. |

This entry does not exist in the registry by default. You can add it by using the registry editor, Regedit.exe.

**HKEY_LOCAL_MACHINE\SAM**

The following registry entry is located under HKEY_LOCAL_MACHINE\SAM.

**SAM**

**Registry Path**

HKEY_LOCAL_MACHINE\

**Version**

The SAM registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The SAM key contains information used by the SAM (Security Accounts Manager). Servers that are running Windows Server 2003 and are acting as domain controllers use this key to store user and group information pertaining to the directory service restore mode.

Domain controllers maintain user and group information in Active Directory to manage user security. However, Windows NT 4.0 and earlier, as well as Windows Server 2003-based computers that are not part of a Windows Server 2003 domain, use SAM. All of the data in this key is in binary form.

| **Note** |
|---|
| The HKEY_LOCAL_MACHINE\Security\SAM subkey stores a duplicate of the information in this key. The information in the SAM subkey cannot be viewed by users of Windows XP Professional and should not be edited directly in Windows Server 2003. Do not alter or add entries in the SAM subkey. Doing so could prevent users from logging on to their computers or the domain, and it could require you to restore the entire system. |

**HKEY_CURRENT_USER\Software**

The following registry entries are located under HKEY_CURRENT_USER\Software\Windows NT\CurrentVersion\Winlogon\.

**ReportDC**

**Registry path**

HKEY_USERS\.DEFAULT\Software\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The ReportDC registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The ReportDC value stores the user setting for the domain controller message. (The computer setting is stored in the value of HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WindowsNT\CurrentVersion\Winlogon\ReportControllerMissing.)

This entry determines, in part, whether the system displays the following message when it cannot contact the domain controller that stores a user's roaming user profile:

"A domain controller for your domain could not be contacted. You have been logged on using cached account information. Changes made to your profile since you last logged on might not be available."

This entry stores the setting of the **Do not display this message again** check box on the domain controller message dialog box. When the check box is selected, the system sets the value of this entry to 0.

The following table lists the possible settings for the ReportDC value.

**ReportDC Settings**

| Value | Meaning |
|---|---|
| 0 | Do not display the domain controller message. (The check box is selected.) |
| 1 (or not in the registry) | Display the domain controller message. (The check box is cleared.) |

Two registry entries manage the display of the domain controller message: ReportDC and ReportControllerMissing. The message is displayed only when both entries are set to their display setting, that is, when ReportDC is either set to 1 or does not appear in the registry and when ReportDomainControllerMissing appears in the registry with a value of TRUE. By default, the message is not displayed.

**RunLogonScriptSync**

**Registry Path**

HKEY_CURRENT_USER\SOFTWARE\Microsoft\WindowsNT\CurrentVersion\Winlogon\

**Version**

The RunLogonScriptSync registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The RunLogonScriptSync value specifies whether the system waits for the logon script to finish running before it starts Windows Explorer and creates the desktop.

The following table lists the possible settings for the RunLogonScriptSync value.

**RunLogonScriptSync Settings**

| Value | Meaning |
|---|---|
| 0 | The logon script and Windows Explorer can run simultaneously. |
| 1 | Windows Explorer does not start until the logon script has finished running. |

This entry can be superceded by Group Policy settings included in Windows Server 2003. When the **Run logon scripts synchronously** Group Policy setting is enabled (in the Computer Configuration or User Configuration policy folders), the system ignores this entry. The configuration of the **Run logon scripts synchronously** policy setting is stored in the values of RunLogonScriptSync in HKEY_LOCAL_MACHINE and of RunLogonScriptSync in HKEY_CURRENT_USER.

**HKEY_LOCAL_MACHINE\SOFTWARE**

The following registry entries are located under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\.

**AutoRestartShell**

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The AutoRestartShell registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The AutoRestartShell entry specifies whether the Windows user interface (typically, Explorer.exe) restarts automatically if it stops unexpectedly.

#### CachePrimary

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The CachePrimary registry setting appears in Windows Server 2003, Windows 2000, and Windows XP.

Windows Server 2003 does not use this entry. The entry remains in the registry to support programs designed for Windows NT 4.0 and earlier.

| **Note** |
| --- |
| Do not delete this entry from the registry or change its value. These changes can cause serious, unexpected results. |

#### DCacheUpdate

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The DCacheUpdate registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The DCacheUpdate entry stores domain names in binary form for internal Winlogon programming code to use.

| **Note** |
| --- |
| Winlogon stores the value of this entry for its own use. Do not delete this entry or change its value. If you do, Windows Server 2003 might not operate properly. |

#### DefaultDomainName

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The DefaultDomainName registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The DefaultDomainName entry stores the name of the domain to which the user most recently logged on successfully. The value of this entry appears in the **Log On to Windows** dialog box generated by the Graphical Identification and Authentication (GINA) DLL the next time the dialog box is displayed.

#### DefaultUserName

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The DefaultUserName registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The DefaultUserName entry stores the last user name entered in the **Log On to Windows** dialog box generated by the GINA. The value of this entry appears in the dialog box the next time it is displayed. It is also used in automated logons and unattended setup.

#### DontDisplayLastUserName

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The DontDisplayLastUserName registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The DontDisplayLastUserName entry specifies whether a user name appears in the **Log On to Windows**dialog box generated by the GINA.

By default, Windows Server 2003 displays the user name of the last user who logged on successfully (as stored in the value of DefaultUserName) in the dialog box. If the value of this entry is 1, then the **User name** box in the **Log On to Windows** dialog box is blank.

**RunLogonScriptSync**

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The RunLogonScriptSync registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The RunLogonScriptSync entry specifies whether the system waits for the logon script to finish running before it starts Windows Explorer and creates the desktop.

This entry does not exist in the registry by default. You can add it by using the registry editor, Regedit.exe.

**ScreenSaverGracePeriod**

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The ScreenSaverGracePeriod registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The ScreenSaverGracePeriod entry specifies when password protection of a screen saver becomes effective. This entry specifies the delay between the appearance of a password-protected screen saver and the enforcement of the password requirement.

Password protection of a screen saver is not effective immediately. By default, a brief period elapses within which the user can use the mouse or the keyboard to stop the screen saver without entering the password. This delay is designed to minimize the disruption that results when the screen saver starts while the user is working.

You can add this entry to the registry to adjust the length of the delay. To make password protection effective immediately, set the value of this entry to 0x0.

This entry does not exist in the registry by default. You can add it by using the registry editor, Regedit.exe.

**Shell**

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The Shell registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The Shell entry specifies the programs that provide the user interface to the operating system.

By default, Winlogon starts the programs specified in the value of Userinit, including Userinit.exe. Userinit.exe starts the user interface program. However, if Winlogon cannot start the programs specified in the value of Userinit, then Winlogon directly runs the programs specified in the value of this entry.

**ShowLogonOptions**

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The ShowLogonOptions registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The ShowLogonOptions specifies whether logon options are displayed in the **Log on to Windows** dialog box when the dialog box opens.

The **Log on to Windows** dialog box has an **Options** button that alternately hides and displays the **Domain** box and the **Log on using dial-up connection** options.

#### Welcome

**Registry Path**

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\

**Version**

The Welcome registry setting is available in Windows Server 2003, Windows 2000, and Windows XP.

The Welcome entry specifies the text that appears in the caption bar beside the title of the **Log On to Windows**, **Windows Security**, **Computer Locked**, and **Unlock Computer** dialog boxes.

This entry does not exist in the registry by default. You can add it by using the registry editor, Regedit.exe.

#### Interactive Logon Group Policy Settings

The following table lists and describes the Group Policy settings that are associated with Logon.

**Group Policy Settings Associated with Interactive Logon**

| Group Policy Setting | Description |
|---|---|
| Password Policy:<br>• Enforce password history<br>• Maximum password age<br>• Minimum password age<br>• Minimum password length<br>• Password must meet complexity requirements<br>• Store password using reversible encryption for all users in the domain | Changes to the Password Policy settings control:<br>The strength and complexity required of every user's password |
| Audit Policy:<br>• Audit account logon events<br>• Audit account management<br>• Audit logon events | Changes to the Audit Policy settings control:<br>• Auditing of logons and logoffs<br>• Auditing of password and permissions changes |

| | |
|---|---|
| User Rights Assignment:<br>• Access the computer from the network<br>• Deny logon as a batch job<br>• Deny logon as a service<br>• Deny logon locally<br>• Deny logon through terminal services<br>• Logon as a batch job<br>• Logon as a service<br>• Logon locally | Changes to the User Rights Assignment settings control:<br>• Which users are allowed or disallowed to log on to perform different tasks, including logging on as a batch job and a service<br>• Which users are allowed or disallowed to log on locally or through Terminal Services, as well as who can access the computer from the network |

| Security Options: | Changes to the Security Options settings control: |
|---|---|
| • Accounts: Limit local accounts use of blank passwords to console logon only<br>• Domain member: Maximum machine account password age<br>• Domain member: Require strong (in Windows 2000 or later) session key<br>• Interactive logon: Do not display last user name<br>• Interactive logon: Do not require CTRL+ALT+DEL<br>• Interactive logon: Message Text for users attempting to log on<br>• Interactive logon: Message title for users attempting to log on<br>• Interactive logon: Number of previous logons to cache (in case the domain controller is not available)<br>• Interactive logon: Require domain controller authentication to unlock workstation<br>• Interactive logon: Smart card removal behavior<br>• Recovery console: Allow automatic administrative logon<br>• Shutdown: Allow system to be shut down without having to log on | • Message text and title displayed by the GINA during an interactive logon<br>• Domain member settings<br>• Authentication settings, including allowing or disallowing blank passwords and password age |

For more information about Group Policy settings, see the "Group Policy Settings Reference for Windows Server 2003" in Tools and Settings Collection.

**Interactive Logon WMI Classes**

The following table lists the WMI classes that are associated with interactive logon.

**WMI Classes Associated with Interactive Logon**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_LogonSession | \root\cimv2 | Windows Server 2003<br>Windows XP |
| Win32_LogonSessionMappedDisk | \root\cimv2 | Windows Server 2003<br>Windows XP |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by Interactive Logon**

Because the logon process can be deployed across various network boundaries, it can span one or more firewalls. The following table lists the three main configurable ports used by interactive logon.

**Port Assignments for Interactive Logon**

| Service Name | UDP | TCP |
|---|---|---|
| LSA RPC port | Dynamic RPC | Dynamic RPC |
| Kerberos V5 port | 88 | 88 |
| NTLM port | Dynamic | Dynamic |

You can use the Registry Editor tool to modify the registry to apply fixed ports for NTLM and the LSA.

# Kerberos Authentication Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Kerberos Authentication Technical Reference**
The Microsoft Windows Server 2003 operating system implements the Kerberos version 5 authentication protocol. Windows Server 2003 also implements extensions for public key authentication. The Kerberos authentication client is implemented as a security support provider (SSP) and can be accessed through the Security Support Provider Interface (SSPI). Initial user authentication is integrated with the Winlogon single sign-on architecture. The Kerberos Key Distribution Center (KDC) is integrated with other Windows Server 2003 security services running on the domain controller. The KDC uses the domain's Active Directory directory service database as its security account database. Active Directory is required for default Kerberos implementations.

This subject will explain what Kerberos authentication is and how the Kerberos V5 protocol and extensions supported by Windows Server 2003 work.

# What Is Kerberos Authentication?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Kerberos Authentication?**

**In this section**

- Kerberos Authentication Benefits
- Kerberos V5 Protocol Standards
- Supported Extensions to the Kerberos V5 Protocol
- Technologies Related to Kerberos Authentication
- Kerberos Authentication Dependencies

The Kerberos version 5 authentication protocol provides a mechanism for authentication — and mutual authentication — between a client and a server, or between one server and another server.

Windows Server 2003 implements the Kerberos V5 protocol as a security support provider (SSP), which can be accessed through the Security Support Provider Interface (SSPI). In addition, Windows Server 2003 implements extensions to the protocol that permit initial authentication by using public key certificates on smart cards.

The Kerberos Key Distribution Center (KDC) uses the domain's Active Directory directory service database as its security account database. Active Directory is required for default NTLM and Kerberos implementations.

The Kerberos V5 protocol assumes that initial transactions between clients and servers take place on an open network in which packets transmitted along the network can be monitored and modified at will. The assumed environment, in other words, is very much like today's Internet, where an attacker can easily pose as either a client or a server, and can readily eavesdrop on or tamper with communications between legitimate clients and servers.

Microsoft's implementation of the Kerberos V5 protocol is:

**The default authentication package for Windows Server 2003.**
The Kerberos V5 protocol became the default authentication package with Windows 2000. Windows Server 2003 still supports NTLM for non-Kerberos clients such as the Windows NT Server 4.0 operating system.

**Based on RFC 1510 and draft revisions.**
The Kerberos protocol is a mature, widely used, open standard. Microsoft's implementation of the Kerberos V5 protocol adheres to the defined RFC standards, and thus provides interoperability with other implementations.

**Extensible.**
Kerberos architecture allows you to specify additional or alternate security methods. Also, the default shared secret key process can be supplemented with private/public key pairs by using smart cards.

**Kerberos Authentication Benefits**
The Kerberos V5 protocol is more secure, more flexible, and more efficient than NTLM. The benefits gained by using Kerberos authentication are:

**Delegated authentication.**
Windows services impersonate a client when accessing resources on the client's behalf. In many cases, a service can complete its work for the client by accessing resources on the local computer. Both NTLM and the Kerberos V5 protocol provide the information that a service needs to impersonate its client locally. However, some distributed applications are designed so that a front-end service must impersonate clients when connecting to back-end services on other computers. The Kerberos V5 protocol includes a proxy mechanism that enables a service to impersonate its client when connecting to other services. No equivalent is available with NTLM.

**Interoperability.**
Microsoft's implementation of the Kerberos V5 protocol is based on standards-track specifications that are recommended to the Internet Engineering Task Force (IETF). As a result, the implementation of the Kerberos V5 protocol in Windows

Server 2003 lays a foundation for interoperability with other networks in which the Kerberos V5 protocol is used for authentication.

**More efficient authentication to servers.**
With NTLM authentication, an application server must connect to a domain controller in order to authenticate each client. With the Kerberos V5 authentication protocol, on the other hand, the server is not required to go to a domain controller. Instead, the server can authenticate the client by examining credentials presented by the client. Clients can obtain credentials for a particular server once and then reuse those credentials throughout a network logon session. Renewable session tickets replace pass-through authentication. For more information about what renewable session tickets are and how they work, please see "How the Kerberos Version 5 Authentication Protocol Works."

**Mutual authentication.**
By using the Kerberos protocol, a party at either end of a network connection can verify that the party on the other end is the entity it claims to be. Although NTLM enables servers to verify the identities of their clients, NTLM does not enable clients to verify a server's identity, nor does NTLM enable one server to verify the identity of another. NTLM authentication was designed for a network environment in which servers were assumed to be genuine. The Kerberos V5 protocol makes no such assumption.

**Kerberos V5 Protocol Standards**
The Kerberos authentication protocol originated at MIT more than a decade ago, where it was developed by engineers working on Project Athena. The first public release was the Kerberos version 4 authentication protocol. After extensive industry review of that protocol, the protocol's authors developed and released the Kerberos version 5 authentication protocol.

The Kerberos V5 protocol is now on a standards track with the IETF. The implementation of the protocol in Windows Server 2003 closely follows the specification defined in Internet RFC 1510. In addition, the mechanism and format for passing security tokens in Kerberos messages follows the specification defined in Internet RFC 1964.

The Kerberos V5 protocol specifies mechanisms to:

- **Authenticate user identity.** When a user wants to gain access to a server, the server needs to verify the user's identity. Consider a situation in which the user claims to be, for example, Alice@tailspintoys.com. Because access to resources are based on identity and associated permissions, the server must be sure the user really has the identity it claims.

- **Securely package the user's name.** The user's name — that is, the User Principal Name (UPN): Alice@tailspintoys.com, for example — and the user's credentials are packaged in a data structure called a ticket.

- **Securely deliver user credentials.** After the ticket is encrypted, messages are used to transport user credentials along the network.

### Note

- Although the Kerberos protocol authenticates the user's identity, it does not authorize access. This is an important distinction. Tickets in other contexts, such as drivers' licenses, often both prove identity and authorize actions or access. A Kerberos ticket only proves that the user is who the user claims to be. After the user's identity is verified, the Local Security Authority will authorize or deny resource access.

**Keys: Privacy Through Encryption**
Kerberos messages are encrypted with various encryption keys to ensure that no one can tamper with the client's ticket or with other data in a Kerberos message.

Possible Kerberos keys include:

**Long-term key.**
A key — known only to the target server and the KDC — with which the client's ticket is encrypted.

**Client/server session key.**
A short-term, single-session key that is created by the KDC and used to encrypt the client-to-server and server-to-client messages after identity and authorization have been confirmed.

**KDC/user session key.**
The KDC and the user share a secret encryption key as well, which is used, for example, to encrypt the message to the client containing a session key.

**The Kerberos V5 protocol can use both symmetric and asymmetric encryption**
Because most Kerberos encryption methods are based on keys that can be created only by the KDC and the client, or by the KDC and a network service, the Kerberos V5 protocol is said to use symmetric encryption. That is, the same key is used to encrypt and decrypt messages.

Microsoft's implementation of the Kerberos protocol can also make limited use of asymmetric encryption. A private/public key pair can be used to encrypt or decrypt initial authentication messages from a network client or a network service.

**Kerberos Authenticator Prevents Packet Replay**
The Kerberos authentication mechanism creates and securely delivers an authenticator — usually based on unique timestamps — along with the client's ticket. The authenticator is unique and valid for only one use. This limited use minimizes the possibility of someone obtaining and re-using (replaying) the client ticket, perhaps in an attempt to steal and use the client's identity.

**Supported Extensions to the Kerberos V5 Protocol**
Windows Server 2003 implements extensions to the Kerberos V5 protocol. The extensions enable initial authentication by using public key certificates instead of conventional shared secret keys. This enhancement enables the protocol to support interactive logon with a smart card. The extensions for public key authentication are based on a draft specification being worked on by the IETF working group.

**Technologies Related to Kerberos Authentication**
The following diagram shows how Kerberos authentication fits with other technologies in Windows Server 2003. Depending on whether the client or server applications are user-mode or kernel-mode applications, they use either Secur32.dll or Ksecdd.sys, respectively, by means of SSPI calls to communicate with the Local Security Authority Subsystem (LSASS).

### Kerberos Architecture

The following table is a description of the components that participate in Kerberos Authentication.

### Security Subsystem Components Used in Digest Authentication

| Component | Description |
|---|---|
| Kerberos.dll | The SSP that implements an industry-standard protocol that is used with either a password or a smart card for interactive logon. It is also the preferred authentication method for services in Windows 2000 and Windows Server 2003. |
| Kdcsvc.dll | The Kerberos Key Distribution Center (KDC) service, which is responsible for providing ticket-granting tickets to clients. |

| | |
|---|---|
| Ksecdd.sys | The Kernel Security Device Driver is used to communicate with LSASS in user mode. |
| Lsasrv.dll | The LSA Server service, which both enforces security policies and acts as the security package manager for the LSA. |
| Secur32.dll | The Secur32.dll component is the multiple authentication provider that implements SSPI for user mode applications. |

Windows Server 2003 implements the Kerberos V5 authentication protocol as an SSP, which is a dynamic-link library (DLL) supplied with the operating system. The system uses the Kerberos SSP, Kerberos.dll, as its first choice for authentication. After the LSA establishes a security context for an interactive user, another instance of the Kerberos SSP can be loaded by a process running in the user's security context in order to support the signing and sealing of messages.

Because the Kerberos protocol is the preferred authentication protocol for Windows Server 2003, all domain services support the Kerberos SSP, including:

- Active Directory queries that use the Lightweight Directory Access Protocol (LDAP).
- Remote server or workstation management using RPC calls.
- Print services.
- Client-server authentication.
- Remote file access that uses Common Internet File System/server message block (CIFS/SMB).
- Distributed file system management and referrals.
- Intranet authentication to Internet Information Services (IIS).
- Security authority authentication for Internet Protocol security (IPSec).
- Certificate requests to Certificate Services for domain users and computers.

**Kerberos Authentication Dependencies**
This section reviews dependencies and summarizes how each dependency relates to Kerberos authentication.

**Operating System**
Kerberos authentication relies on client functionality that is built in to the Windows Server 2003 operating system, the Microsoft Windows XP operating system, and the Windows 2000 operating system. If a client, domain controller, or target server is running an earlier operating system, it cannot natively use Kerberos authentication.

**TCP/IP Network Connectivity**
For Kerberos authentication to occur, TCP/IP network connectivity must exist between the client, the domain controller, and the target server. For more information about TCP/IP, see "TCP/IP Technical Reference."

**Domain Name System**
The client uses the fully qualified domain name (FQDN) to access the domain controller. DNS must be functioning for the client to obtain the FQDN.

For best results, do not use Hosts files with DNS. For more information about DNS, see "DNS Technical Reference."

**Active Directory Domain**
Kerberos authentication is not supported in earlier operating systems, such as the Microsoft Windows NT 4.0 operating system. You must be using user and computer accounts in the Active Directory directory service to use Kerberos authentication. Local accounts and Windows NT domain accounts cannot be used for Kerberos authentication.

**Time Service**
For Kerberos authentication to function correctly, all domains and forests in a network should use the same time source so that the time on all network computers is synchronized. An Active Directory domain controller acts as an authoritative source of time for its domain, which guarantees that an entire domain has the same time. For more information, see "Windows Time Service Technical Reference."

**Service Principal Names**

Service principal names (SPNs) are unique identifiers for services running on servers. Every service that uses Kerberos authentication needs to have an SPN set for it so that clients can identify the service on the network. If an SPN is not set for a service, clients have no way of locating that service. Without correctly set SPNs, Kerberos authentication is not possible. For more information about user-to-user authentication, see "How the Kerberos Version 5 Authentication Protocol Works," and search for "The User-to-User Authentication Process."

# How the Kerberos Version 5 Authentication Protocol Works

Updated: October 7, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How the Kerberos Version 5 Authentication Protocol Works**

**In this section**

- Kerberos SSP Architecture
- Kerberos Physical Structure
- Kerberos Processes and Interactions
- Network Ports Used by the Kerberos V5 Protocol
- Related Information

The Kerberos Network Authentication Service version 5, defined in RFC 1510, provides a means of verifying the identities of principals on an open, potentially insecure network. This section discusses how the RFC standard Kerberos version 5 authentication protocol is used in Windows Server 2003.

This section is divided into four subsections:

- **Kerberos SSP Architecture** illustrates how the Microsoft Security Support Provider Interface (SSPI) in Windows Server 2003 provides a mechanism of generic routines that can access the Kerberos Security Support Provider (SSP).
- **Kerberos Physical Structure** discusses components of the Windows Server 2003 implementation of Kerberos authentication. These components include keys, tickets, and the Key Distribution Center (KDC).
- **Kerberos V5 Authentication Protocol Processes and Interactions** illustrates how the Kerberos protocol is used in different situations, details what is included in Kerberos messages, and discusses other related technologies. The examples will show the complete process, including related components and processes that are not defined by the Kerberos Network Authentication Service. Some processes—such as how to find an authentication service, what credentials information is passed, and where credentials information is stored—are specific to Windows systems and might or might not differ in other implementations of the Kerberos protocol.
- **Network Ports Used by the Kerberos V5 Protocol** tabulates networks ports used during Kerberos authentication.

**Kerberos SSP Architecture**

Windows Server 2003 implements the Kerberos V5 authentication protocol as a Security Support Provider (SSP), a dynamic-link library (DLL) supplied with the operating system. Windows Server 2003 includes an SSP for NTLM authentication as well. By default, both SSPs are loaded by the Local Security Authority (LSA) on a Windows Server 2003 computer when the system boots. The system can use either SSP to authenticate network logons and client/server connections. Which SSP is used depends on the capabilities of the computer on the other side of the connection and the preferences of the individual application that is being used.

The Microsoft SSPI is the foundation for authentication in Windows Server 2003. That is, applications and infrastructure services that require authentication use SSPI to provide it.

The SSPI is the implementation of the Generic Security Service API (GSSAPI) in Windows Server 2003. For more information about GSSAPI, see RFC 2743 and RFC 2744 in the IETF RFC Database.

The default SSPs in Windows Server 2003—Negotiate (SPNEGO), Kerberos, NTLM, Schannel, and Digest authentication protocols—are plugged into the SSPI in the form of DLLs. Additional SSPs can be plugged in if they can interoperate with the SSPI.

**SSPI Architecture graphic**

The SSPI in Windows Server 2003 provides a mechanism that carries authentication tokens over the existing communication channel between the client and server. When two parties need to be authenticated so that they can communicate securely, the requests for authentication are routed to the SSPI, which completes the authentication process, regardless of the network protocol currently in use. The SSPI returns transparent binary large objects, which are then passed to the other side of the connection by the application, at which point they can be passed to the SSPI layer on that side. Thus, the SSPI enables an application to use various security models available on a computer or network without changing the interface to the security system.

The following table describes the SSP components that are plugged into the SSPI. Each of the protocols in the table is used in different ways in Windows Server 2003 to promote secure communication in an insecure network environment.

**SSP Layer Components**

| Component | Description |
|---|---|
| Kerberos V5 authentication | An industry-standard protocol that is used with either a password or a smart card for interactive logon. It is also the preferred authentication method for services in Windows 2000 and Windows Server 2003. |
| NTLM authentication | A challenge-response protocol that is used to provide compatibility with versions of Windows earlier than Windows 2000. |
| Digest authentication | An industry standard that is used in Windows Server 2003 for Lightweight Directory Access Protocol (LDAP) and Web authentication. Digest transmits credentials across the network as an MD5 hash or message digest. |
| Schannel | An SSP that implements the Secure Sockets Layer (SSL) and Transport Layer Security (TLS) Internet standard authentication protocols. Schannel is used for Web-based server authentication such as when a user attempts to access a secure Web server. |
| Negotiate | An SSP that can be used to negotiate a specific authentication protocol. When an application calls into SSPI to log on to a network, it can specify an SSP to process the request. If the application specifies Negotiate, Negotiate analyzes the request and picks the best SSP to handle the request based on customer-configured security policy. |

**Kerberos SSP**

Windows Server 2003 implements the Kerberos V5 authentication protocol as an SSP, a DLL supplied with the operating system. The system uses the Kerberos SSP, Kerberos.dll, as its first choice for authentication. After the LSA establishes a security context for an interactive user, another instance of the Kerberos SSP can be loaded by a process running in the user's security context to support the signing and sealing of messages.

Because the Kerberos protocol is the preferred authentication protocol for Windows Server 2003, all domain services support the Kerberos SSP, including:

- Active Directory queries using the Lightweight Directory Access Protocol (LDAP)
- Remote server or workstation management using RPC calls
- Print services
- Client-server authentication
- Remote file access using the Common Internet File System/Server Message Block (CIFS/SMB)
- Distributed file system management and referrals

- Intranet authentication to Internet Information Services (IIS)
- Security authority authentication for Internet Protocol Security (IPSec)
- Certificate requests to Certificate Services for domain users and computers

**Kerberos Physical Structure**
Kerberos authentication provides a mechanism for mutual authentication between a client and a server on an open network—a network in which packets transmitted along the network could be monitored and modified at will. In order to provide secure authentication, Kerberos authentication uses symmetric keys, encrypted objects, and Kerberos services.

This subsection will cover the following topics:

- Keys Used in Kerberos Authentication
- Kerberos Tickets
- The Authenticator
- Credentials Cache
- Key Distribution Center
- The Kerberos Realm

**Kerberos Components**

**Keys Used in Authentication**
**Why are keys needed?**
The Kerberos protocol relies heavily on an authentication technique involving shared-secret keys. The basic shared-secret concept is quite simple: If a secret is known by only two people, then either person can verify the identity of the other by confirming that the other person knows the secret.

For example, suppose that Alice often sends messages to Bob, and that Bob needs to ensure that a message from Alice really has come from Alice before he acts on its information. They decide to solve their problem by selecting a password and agreeing to share the secret password between the two of them, but not with anyone else. If a message purported to be from

Alice can somehow demonstrate that the sender knows the password, Bob can verify that the sender is indeed Alice.

The only question left for Alice and Bob to resolve is how Alice will show that she knows the password. She could include it somewhere in her messages, perhaps in a signature block at the end—Alice, Our$ecret. This would be simple and efficient and would be effective if Alice and Bob could be sure that no one else is reading their mail. Unfortunately, their messages pass over a network used by people like Carol, who uses a network analyzer to scan traffic in hope that one day she might spot a password. Thus, Alice must not prove that she knows the secret by including it in her message. To keep the password secret, she must show that she knows it without revealing it.

The Kerberos protocol solves this problem with secret key cryptography. Instead of sharing a password, communication partners share a cryptographic key, and they use knowledge of this key to verify one another's identity. In order for the technique to work, the shared key must be symmetric—that is, a single key must be capable of both encryption and decryption. One party proves knowledge of the key by encrypting a piece of information; the other proves knowledge of the key by decrypting the information.

Kerberos authentication relies on several keys and key types for encryption. Key types can include long-term symmetric keys, long-term asymmetric keys, and short-term symmetric keys. The authentication protocol was designed to use symmetric encryption, meaning that the same shared key is used by the sender and the recipient for encryption and decryption.

**Long-Term Symmetric Keys: User, System, Service, and Inter-realm Keys**
The long-term symmetric keys are derived from a password. The plaintext password is transformed into a cryptographic key by passing the text of the password through a cryptographic function. (All implementations of the Kerberos version 5 authentication protocol must support DES-CBC-MD5. Other algorithms are permissible.) The result of the cryptographic function is the key.

**User keys**
When a user is created, the password is used to create the user key. In Active Directory domains, the user key is stored with the user's object in the Active Directory. At the workstation, the user key is created when the user logs on.

**System keys**
When a workstation or a server joins a Windows domain, it receives a password. In the same manner as a user account, the system account's password is used to create the system key.

**Service keys**
Services use a key based on the account password they use to log on.

All KDCs in the same realm use the same service key. This key is based on the password assigned to the krbtgt account. Every Active Directory domain will have this built-in account.

**Inter-realm keys**
In order for cross-realm authentication to occur, the KDCs must share an inter-realm key. The realms can then trust each other because they share the key.

Active Directory domains that have a parent-child relationship share an inter-realm key. This inter-realm key is the basis of transitive trusts in Windows 2000 and Windows Server 2003. If a shortcut trust is created, the two domains will exchange a key specifically for their trust.

**Kerberos SSP encryption key lengths**
Kerberos SSP supports different encryption types and key lengths depending on the task to be completed and the options specified. Although the size of the key determines the degree of protection the key provides, key size does not significantly impact the size of the ticket. The following table lists the key lengths that Kerberos SSP supports for the various types of encryption.

### Key Lengths for Encryption Types

| Encryption Algorithm | Key Length |
|---|---|
| RC4-HMAC | 128 |
| DES-CBC-CRC | 56 |
| DES-CBC-MD5 | 56 |

**Long-Term Asymmetric Keys: Public Key**
Currently, public-key certificates stored on smart cards are the only long-term asymmetric keys in the Microsoft implementation of Kerberos authentication.

**Short-Term Symmetric Keys: Session Keys**
The session keys used for ticket-granting tickets (TGTs) and service tickets are short-lived and used only as long as that session or service ticket is valid.

**Kerberos Tickets**
The main component of Kerberos authentication is the ticket. The Kerberos messages are used to request and deliver tickets. There are two types of tickets used in Kerberos authentication, TGTs and service tickets.

**Kerberos Ticket Requests**
The Kerberos client sends ticket requests to the KDC:

| Requested Ticket Type | KDC Service That Receives Request |
|---|---|
| TGT | Authentication service |
| Service ticket | Ticket-granting service |

The ticket requests include:

- Requested properties (flags), such as whether the ticket is renewable.
- Requested encryption method.

**Ticket-Granting Tickets**
The KDC responds to a client's authentication service request by returning a service ticket for itself. This special service ticket is called a ticket-granting ticket (TGT). A TGT enables the authentication service to safely transport the requester's credentials to the ticket-granting service.

A TGT is:

- A user's initial ticket from the authentication service.
- Used to request service tickets.
- Meant only for use by the ticket-granting service.

TGTs are encrypted with a key shared by the KDCs. The client cannot read tickets. Only KDC servers can read TGTs to secure access to user credentials, session keys, and other information. Like an ordinary service ticket, a TGT contains a copy of the session key that the service (in this case the KDC) will use in communicating with the client. The TGT is encrypted with the KDC's long-term key.

From the client's point of view, a TGT is just another ticket. Before it attempts to connect to any service, the client first checks its credentials cache for a service ticket to that service. If it does not have one, it checks the cache again for a TGT. If it finds a TGT, the client fetches the corresponding TGS session key from the cache, uses this key to prepare an authenticator (described later in this document), and sends both the authenticator and the TGT to the KDC, along with a request for a service ticket for the service. In other words, gaining admission to the KDC is no different from gaining admission to any other service in the domain—it requires a session key, an authenticator, and a ticket.

From the KDC's point of view, TGTs enable it to avoid the performance penalties of looking up a user's long term key every time the user requests a service. The KDC looks up the user's long-term key only once, when it grants an initial TGT. For all other exchanges with this client, the KDC can decrypt the TGT with its own long-term key, extract the session key, and use that to validate the client's authenticator.

**Service tickets**
A service ticket enables the ticket-granting service (TGS) to safely transport the requester's credentials to the target server or service.

The KDC responds to the client's request to connect to a service by sending both copies of the session key to the client. The client's copy of the session key is encrypted with the key that the KDC shares with the client. The service's copy of the session key is embedded, along with information about the client, in a data structure called a service ticket. The entire structure is then encrypted with the key that the KDC shares with the service. The ticket—with the service's copy of the session key safely inside—becomes the client's responsibility to manage until it contacts the service.

A service ticket is used to authenticate with services other than the TGS and is meant only for the target service.

A service ticket is encrypted with a service key, which is a long-term key shared by the KDC and the target service. Thus, although the client manages the service ticket, the client cannot read it. Only the KDC and the target service can read tickets, enabling secure access to user credentials, the session key, and other information.

**Note**

- The KDC is simply providing a ticket-granting service. It does not keep track of its messages to make sure they reach the intended address. No harm will be done if the KDC's messages fall into the wrong hands. Only someone who knows the client's secret key can decrypt the client's copy of the session key. Only someone who knows the server's secret key can read what is inside the ticket.

When the client receives the KDC's reply, it extracts the ticket and the client's copy of the session key, putting both aside in a secure cache (located in volatile memory, not on disk). When the client wants admission to the server, it sends the server a message that consists of the ticket, which is still encrypted with the server's secret key, and an authenticator, which is encrypted with the session key. The ticket and authenticator together are the client's credentials to the server.

**Benefits of service tickets**

The server does not have to store the session key that it uses in communicating with clients. It is the client's responsibility to hold a ticket for the server in its credentials cache and present the ticket each time it wants access to the server. Whenever the server receives a service ticket from a client, the server can use its secret key to decrypt the ticket and extract the session key. When the server no longer needs the session key, it can discard it.

The client does not need to go back to the KDC each time it wants access to this particular server. Service tickets can be reused. To guard against the possibility that someone might steal a copy of a ticket, service tickets have an expiration time that is specified by the KDC in the ticket's data structure.

How long a ticket is valid depends on the policy for the realm. Although the RFC recommends a maximum ticket lifetime of one day, in both MIT Kerberos 5 Release 1.3.1 and the Windows 2000 or Windows Server 2003 implementations of the Kerberos protocol, tickets are good for no longer than 10 hours by default, about the length of a normal logon session. When the user logs off, the credentials cache is flushed and all service tickets—as well as all session keys—are destroyed.

**What Is in a Ticket?**

For our purpose here, it is enough to list the fields in a ticket and to describe the information they contain. The exact data structures for tickets as well as messages can be found in RFC 1510.

The first three fields in a ticket are not encrypted. The information is in plaintext so that the client can use the information to manage tickets in its cache.

**Ticket Contents**

| Field Name | Description |
|---|---|
| Ticket Version Number | 5 |
| Realm | Name of the realm (domain) that issued the ticket. A KDC can issue tickets only for servers in its own realm, so this is also the name of the server's realm. |
| Server Name | Name of the server. |
| | The following fields are encrypted with the server's secret key. |
| Flags | Options that specify how and when the ticket can be used. See table below for details about ticket flags. |
| Key | The session key used to encrypt and decrypt client and target server messages. |
| Client Realm | Name of the requester's realm. |
| Client Name | Requester's name. |
| Transited | Lists the Kerberos realms that took part in the authentication of the client during cross-realm authentication. |

| | |
|---|---|
| Authentication Time | Time of initial authentication by the client.<br><br>The KDC places a timestamp in this field when it issues a TGT. When it issues tickets based on a TGT, the KDC copies the authentication time of the TGT to the authentication time of the ticket.<br><br>An application could have a policy to reject tickets that were based on "old" TGTs, requiring the client to obtain a new TGT and then a new service ticket. |
| Start Time | Time after which the ticket is valid. |
| End Time | Ticket's expiration time. |
| Renew Till | (Optional) Maximum end time that can be set in a ticket with a RENEWABLE ticket flag. |
| Client Address | (Optional) One or more addresses from which the ticket can be used. If omitted, the ticket can be used from any address. |
| Authorization-Data | (Optional) This field contains authorization data for the client.<br><br>In MIT's implementation of the Kerberos protocol, this field normally contains access restrictions. For example, if this were a ticket for a print server sent by a client wishing to print a file, the file name could be included here, restricting the print server's access on behalf of the client to only this file.<br><br>In the Microsoft implementation, this field is significant because it contains the user's SID and the SIDs of groups the client belongs to—data which is used to build the client's access token (the privilege attributes for the client).<br><br>The Kerberos service does not interpret the contents of this field. Interpretation is left up to the service requesting credentials. |

The following table lists and describes the Kerberos ticket Flag field. The Flag field is a bit-field in which options are set by turning a particular bit on (1) or off (0). Although the field is 32 bits long, only 11 ticket flags are of interest to Kerberos administrators.

**Ticket Flags**

| Flag | Description |
|---|---|
| FORWARDABLE | (TGT only). Tells the ticket-granting service that it can issue a new TGT—based on the presented TGT—with a different network address based on the presented TGT. |
| FORWARDED | Indicates either that a TGT has been forwarded or that a ticket was issued from a forwarded TGT. |
| PROXIABLE | (TGT only). Tells the ticket-granting service that it can issue tickets with a network address that differs from the one in the TGT. |
| PROXY | Indicates that the network address in the ticket is different from the one in the TGT used to obtain the ticket. |
| MAY-POSTDATE | (TGT only). Tells the ticket-granting service (TGS) that a postdated ticket can be issued. |
| POSTDATED | Indicates that the ticket has been postdated. |
| INVALID | Indicates that the ticket is invalid and must be validated by the KDC before use. A postdated ticket is flagged as invalid until its valid start time. |
| RENEWABLE | Used in combination with the End Time and Renew Till fields to cause tickets with long life spans to be renewed at the KDC periodically. |
| INITIAL | Indicates that a ticket was issued using the authentication service (AS) exchange and not issued based on a TGT. |
| PRE-AUTHENT | Indicates that the client was authenticated by the KDC before a ticket was issued. This flag usually indicates the presence of an authenticator in the ticket. It can also flag the presence of credentials taken from a smart card logon. |

| | |
|---|---|
| HW-AUTHENT | Indicates that the initial authentication required the use of hardware. |

**What information clients have about tickets**

A client needs to have some information about what is inside tickets and TGTs in order to manage its credentials cache. When the KDC returns a ticket and session key as the result of an authentication service (AS) or ticket-granting service (TGS) exchange, it packages the client's copy of the session key in a data structure that includes the information in the following ticket fields: Authentication Time, Start Time, End Time, and Renew Till. The entire structure is encrypted in the client's key and returned with the KRB_AS_REP or KRB_TGS_REP messages.

**Kerberos authorization data for Windows accounts**

The Kerberos protocol describes a number of fields to be used in the authentication exchange. One of these, the optional authorization data field, is intended to be specific to the end service, in this case, Microsoft authorization. The Microsoft implementation follows the Kerberos specification (RFC 1510) by using the authorization field to store information about user identity and group membership. This information is stored in Microsoft authorization data that is generated by a domain controller during an AS or TGS request. The Microsoft authorization data includes the following groups of information:

- **Credential information.** Information about the ticket and the client, such as Group IDs, which list relative IDs (RIDs) that belong to the client for his or her domain and groups.
- **Client information.** Ensures that the ticket belongs to the client who is submitting it.
- **Supplemental credentials.** Returned by the KDC service to enable PKINIT.
- **Signatures.** The Microsoft authorization data contains two digital signatures, one for the domain controller and one for the server offering the service. These signatures are used to prevent clients or untrusted services from generating their own forged Microsoft authorization data.
- **PAC-request pre-authentication data.** Normally, the Microsoft authorization data is included in every pre-authenticated ticket received from an AS request. However, a client can also explicitly request — with the privilege attribute certificate (PAC)-request pre-authentication data field — to include or not include SIDs. If the field is present, the account SIDs will be included. If the field is not present, SIDs will not be included.

For more information about Microsoft authorization data present in Kerberos tickets issued by Windows domain controllers, see "Utilizing the Windows 2000 Authorization Data in Kerberos Tickets for Access Control to Resources," a Windows Development (General) topic on MSDN.

**How the KDC limits a ticket's lifetime**

Each ticket has a start time and an expiration time. At any time after the start time but before the expiration time, a client holding a ticket for a service can present the ticket and gain access to the service, no matter how many times the client has used the ticket before. In order to reduce the risk that a ticket or the corresponding session key might be compromised, administrators can set the maximum lifetime for tickets. The maximum lifetime for tickets setting is an element of Kerberos policy.

When a client asks the KDC for a ticket to a service, the client can request a specific start time. If this time is missing from the request or is a time in the past, the KDC sets the ticket's start time field to the current time.

Whether or not a client specifies a start time, its request must include a desired expiration time. The KDC determines the value in a ticket's End Time field by adding the maximum ticket life fixed by Kerberos policy to the value in the ticket's Start Time field. It then compares the result with the requested expiration time. Whichever time is sooner becomes the ticket's end time.

**What happens when tickets expire**

The KDC does not notify clients when service tickets or TGTs are about to expire. Furthermore, other than keeping short-term records needed to prevent replay attacks, it does not keep track of transactions with clients.

If a client presents an expired service ticket when requesting a connection to a server, the server returns an error message. The client must request a new service ticket from the KDC. After a connection is authenticated, however, it no longer matters whether the service ticket remains valid. Service tickets are used only to authenticate new connections with servers. Ongoing operations are not interrupted if the service ticket used to authenticate the connection expires during the connection.

If a client presents an expired TGT when requesting a service ticket from the KDC, the KDC responds with an error message. The client must request a new TGT, and to do that it needs the user's long-term key. If the client did not cache the user's long-term key during the initial logon process, the client might have to ask the user for a password and derive the long-term key.

**Renewable TGTs**
When tickets are renewable, session keys are refreshed periodically without issuing a completely new ticket. If Kerberos policy permits renewable tickets, the KDC sets a RENEWABLE flag in every ticket it issues and sets two expiration times in the ticket. One expiration time limits the life of the current instance of the ticket; the second expiration time sets a limit on the cumulative lifetime of all instances of the ticket.

The expiration time for the current instance of the ticket is held in the End Time field. As with non-renewable tickets, the value in the End Time field equals the value in the Start Time field plus the value of the maximum ticket life specified by Kerberos policy. A client holding a renewable ticket must send it—presenting a fresh authenticator as well—to the KDC for renewal before the end time is reached. When the KDC receives a ticket for renewal, it checks the value of a second expiration time held in the Renew Till field. This value is set when the ticket is first issued. It equals the value in the tickets Start Time field plus the value of the maximum cumulative ticket life specified by Kerberos policy. When the KDC renews the ticket, it checks to determine if the renew-till time has not yet arrived. If it has not, the KDC issues a new instance of the ticket with a later end time and a new session key.

This means that administrators can set Kerberos policy so that tickets must be renewed at relatively short intervals—every day, for example. When tickets are renewed, a new session key is issued, minimizing the value of a compromised key. Administrators can also set cumulative ticket life for a relatively long period—one week or one month, for example. At the end of that time, the ticket expires and is no longer valid for renewal.

**The Authenticator**
Whenever a client sends a ticket to a target server—whether the server is the TGS or some other network server or resource—the client also includes an authenticator in the message. The authenticator verifies that the client listed as the sender in the ticket really is the ticket's source.

**Why is an authenticator necessary?**
The target server can trust the contents of the ticket because the ticket is encrypted with the target server's secret key. However, the target server cannot trust that the ticket was really sent by the client specified in the ticket. The ticket could have been stolen and is now being included in an imposter's message.

**How does the authenticator work?**

- The authenticator is encrypted with the session key created by the KDC to be used between the client and the target server. Only the client and the target server can access the session key.
- The target server uses its secret key to decrypt the ticket, finds the session key inside the ticket, and uses it to decrypt the authenticator.
- If the target server can successfully decrypt the authenticator and if the authenticator's data is accurate, then the target server will trust the source of the ticket.

**The authenticator's timestamp**
The timestamp is perhaps the most important piece of data in the authenticator. A domain's Kerberos policy and policies established by applications typically require that the timestamp be within minutes of the time on the target server. Otherwise, the authenticator and the ticket will be rejected. This helps prevent message replay.

Although no authenticator is included in the initial authentication service request message (explained later in this document), the message does include the client's timestamp in the pre-authentication field.

**What is in an authenticator?**
The following table lists and describes authenticator fields. The exact data structures for authenticators as well as messages can be found in RFC 1510.

### Authenticator Fields

| Field | Description |
|---|---|
| Checksum | A checksum of the data from the ticket-granting service request (KRB_TGS_REQ) or application server request (KRB_AP_REQ) message that the authenticator was a part of. This helps validate that the message sender was really the client. |
| Subkey | In a KRB_AP_REQ, this field specifies a subkey that the target server and the client will use to encrypt further communications, instead of using the TGS-supplied session key. |

| | |
|---|---|
| Sequence Number | An optional field that could be used to prevent replays. This sequence number might be based on the client nonce, for example. |
| Authorization Data | This optional field can include authorization data for specific applications. This is not the same as the Authorization Data field that carries the user's privilege attribute certificate (PAC). |

**Credentials Cache**

On computers running Windows 2000, Windows XP, or Windows Server 2003, tickets and keys obtained from the KDC are stored in a credentials cache, an area of volatile memory protected by the LSA. The credentials cache is never paged to disk. All objects stored there are destroyed when a security principal logs off or when the system is shut down.

The credentials cache is managed by the Kerberos SSP, which runs in the LSA's security context. Whenever tickets and keys need to be obtained or renewed, the LSA calls the Kerberos SSP to accomplish the task.

### Note

- In Windows XP and Windows 2000 with Service Pack 2 or later, TGT renewal is triggered when the TGT is used within 5 minutes of its expiration.
- In Windows Server 2003, periodically the system will automatically renew expiring TGTs.

The LSA also keeps a copy of an interactive user's hashed password. If the user's TGT expires during a logon session, the Kerberos SSP uses the LSA's copy of the hashed password to obtain a new TGT without interrupting the user's logon session. The password is not stored permanently on the computer, and the local copy of the hashed password is destroyed when the user's logon session is destroyed.

Hashed passwords for services and computers are handled differently than above. As in Windows NT, hashed passwords are stored in a secure area of the computer's registry. The registry is also used to store hashed passwords for user accounts on the local system, but local accounts are used only for access to computers in standalone mode, never for network access.

**Key Distribution Center**

The Key Distribution Center (KDC) is a service that runs on a physically secure server. The KDC maintains a database with account information for all security principals in its realm (the Kerberos equivalent of a Windows Server 2003 domain). Along with other information about each security principal, the KDC stores a cryptographic key known only to the security principal and the KDC. This key—also called the long-term key—is used in exchanges between the security principal and the KDC. In most implementations of the protocol, the long-term key is derived from a user's logon password.

As in other implementations of the Kerberos protocol, Microsoft implements the KDC as a single process that provides two services:

**Authentication service (AS)**

The AS issues TGTs good for admission to the ticket-granting service in its domain. Before network clients can get tickets for services, each client must get an initial TGT from the authentication service in the user's account domain.

**Ticket-granting service (TGS)**

The TGS issues tickets good for admission to other services in the TGS's domain or to the ticket-granting service of a trusted domain. When a client wants access to a service, it must contact the ticket-granting service in the service's account domain, present a TGT, and ask for a ticket. If the client does not have a TGT valid for admission to that ticket-granting service, it must get one through a referral process that begins at the ticket-granting service in the user account's domain and ends at the ticket-granting service in the service account's domain.

Windows Server 2003 implements the Key Distribution Center (KDC) as a domain service. It uses the domain's Active Directory as its account database and gets some information about users from the global catalog.

The KDC is located on every domain controller, as is the Active Directory directory service. Both services are started automatically by the domain controller's Local Security Authority (LSA) and run in the process space of the LSA. Neither service can be stopped. Windows Server 2003 ensures availability of these services by allowing each domain to have several domain controllers, all peers. Any domain controller can accept authentication requests and ticket-granting requests addressed to the domain's KDC.

The security principal name used by the KDC for an Active Directory domain is krbtgt, as specified by RFC 1510. An account for this security principal is created automatically when a new domain is created. The account cannot be deleted, nor can the name be changed.

A password is automatically assigned to the krbtgt account. The password for the krbtgt account is used to derive a secret key for encrypting and decrypting the TGTs that the KDC issues. Passwords for domain trusts are either automatically assigned or provided when the trust is established. The password for a domain trust is used to derive an inter-realm key for encrypting referral tickets. (Referral tickets are discussed later in this document.) Although passwords for domain trusts are changed automatically, passwords for trusts with non-Windows realms and the krbtgt accounts must be changed either manually or through a script.

All instances of the KDC within a domain use the domain account for the security principal krbtgt. A client addresses messages to a domain's KDC by including both the service's security principal name, krbtgt, and the name of the domain. Both items of information are also used in tickets to identify the issuing authority. For information about name forms and addressing conventions, see RFC 1510 in the IETF RFC Database.

**Session Key Distribution: the Session Key**

If each client were to need a unique key for every service, and if each service were to need a unique key for every client, key distribution could quickly become a tough problem to solve. Furthermore, the need to store and protect so many keys on so many computers would present an enormous security risk. Hypothetically, a network of *n* accounts would require $n(n-1)/2$ keys, where *n* is an integer greater than 1. Thus, a network of only 10 users, services, and systems would need 45 keys; a network of 100 accounts would need 4,950 keys. Every new user, service, or system would generate a new key pair for each interaction.

The name of the Kerberos protocol suggests how it solves the problem of key distribution. Kerberos (Cerberus), in Greek mythology, was the fierce, three-headed dog that guarded the gates of the Underworld. The Kerberos protocol—like Kerberos the guard—has three heads: a client, a server, and a trusted third party to mediate between the other two. The trusted intermediary in the protocol is the Key Distribution Center (KDC).

When a client wants to connect to a server, the client sends a request to the KDC, and the KDC distributes a unique, short-term session key for the two parties to use when they authenticate each other. The server's copy of the session key is encrypted in the server's long-term key. The client's copy of the session key is encrypted in the client's long-term key.

**KDC Configuration**

RFC 1510 recommends the following values for KDC configuration:

### KDC configuration

| Configuration Element | RFC 1510 Recommendation | Active Directory Domain Default Setting |
|---|---|---|
| **Maximum ticket lifetime** | One day | 600 minutes (10 hours) |
| **Maximum renewable lifetime** | One week | Seven days |
| **Empty addresses** | Only when suitable restrictions appear in authorization data | Support empty addresses |

For more information about Kerberos policy settings, see Account Policy Settings.

For more information about KDC configuration, see RFC 1510 in the IETF RFC Database.

**Pre-authentication**

By default, the KDC requires all accounts to use pre-authentication. However, pre-authentication can be disabled for individual accounts when necessary for compatibility with other implementations of the protocol.

**Active Directory as a KDC account database**

The account database that the KDC needs in order to obtain information about security principals is provided in Windows Server 2003 by the domain's Active Directory. Each principal is represented by an account object. The encryption key used in communicating with a user, computer, or service is stored as an attribute of that security principal's account object.

Only domain controllers are Active Directory servers. Because each domain controller keeps a writeable copy of the directory, you can create accounts, reset passwords, and modify group membership at any domain controller. Changes made to one replica of the directory are automatically propagated to all other replicas. Windows 2000 and Windows Server 2003 do not, however, implement the Kerberos replication protocol. Instead, the systems replicate the information store for Active Directory using a proprietary multi-master replication protocol over a secure channel between replication partners.

Physical storage of account data is managed by the Directory System Agent (DSA), a protected process integrated with the LSA on the domain controller. Clients of the directory service are never given direct access to the data store. Any client wanting

access to directory information must use one of the supported Active Directory Service Interfaces (ADSI) to connect to the DSA and then search for, read, and write directory objects and their attributes.

Requests to access an object or attribute in the directory are subject to validation by Windows 2000 or Windows Server 2003 access control mechanisms. Like file and folder objects in the NTFS file system, objects in Active Directory are protected by Access Control Lists (ACLs) that specify who can access the object and in what way. Unlike files and folders, however, Active Directory objects have an ACL for each of their attributes. Thus, attributes for sensitive account information can be protected by more restrictive permissions than those granted for other attributes of the account.

The most sensitive information about an account is, of course, its password. Although an account object's password attribute stores an encryption key derived from a password, not the password itself, this key could be just as useful to an intruder. Therefore, access to an account object's password attribute is granted only to the account holder, never to anyone else, not even administrators. Only processes with Trusted Computer Base privilege—processes running in the security context of the LSA—are allowed to read or change password information.

In order to hinder an offline attack by someone with access to a domain controller's backup tape, an account object's password attribute is further protected by a second encryption using a system key. Administrators are given the option to choose where the system key is stored and which of several algorithms is used to encrypt password attributes. You can store the system key on removable media so that it can be safeguarded separately, or store it—protected by a dispersal mechanism—on the domain controller.

**Service Principal Names**

SPNs can only be registered by a domain administrator, with one exception—a system account can register an SPN for its computer account.

In Windows 2000, SPNs were canonicalized to the SAM account name—for example, Server1, Server1$. This caused issues when clients requested tickets for a service with a non-canonical name. The system was unable to detect the existing cached service ticket and would request a new service ticket for the service. In Windows Server 2003, on the other hand, the SPN requested is used without canonicalization.

SPNs are unique identifiers for services running on servers. Every service that will use Kerberos authentication needs to have an SPN set for it so that clients can identify the service on the network. If an SPN is not set for a service, then clients will have no way of locating that service. Without properly set SPNs, Kerberos authentication is not possible.

An SPN is registered in Active Directory under a user account as an attribute called **Service-Principal-Name**. The SPN is assigned to the account under which the service the SPN identifies is running. Any service can look up the SPN for another service. When a service wants to authenticate to another service, it uses that service's SPN to differentiate it from all of the other services running on that computer.

This is why SPNs are so crucial to constrained delegation (discussed later). When you set up a computer for delegation, one step of the process is to list the services on other computers that the computer is allowed to delegate to. This list forms a type of ACL. The services running on the other computers are identified by the SPNs that are issued to those services.

Additionally, in Windows Server 2003, KDCs will not issue a service ticket for an account that does not have an SPN. If a service account were simply a user account with a human-generated password, then that account would be more vulnerable to an offline dictionary attack. For an account without an SPN, the KDC will return KDC_ERR_S_PRINCIPAL_UNKNOWN. However, the context of the error will be KRB_ERR_MUST_USE_USER2USER, which has the description of "Server principal valid for user-to-user only."

In general, SPNs should be set at the time of account creation. Setting an SPN on an account is as important—from a security standpoint—as creating that account. Special accounts that were created for services are useless until an SPN is set on those accounts for whatever service will be running under them.

The following table lists, in alphabetical order, the built-in SPNs that are recognized for computer accounts.

**Built-in SPNs Recognized for Computer Accounts**

| SPN | SPN | SPN | SPN |
|---|---|---|---|
| alerter | http | policyagent | scm |
| appmgmt | ias | protectedstorage | seclogon |
| browser | iisad | rasman | snmp |

| | | | |
|---|---|---|---|
| cifs | min | remoteaccess | spooler |
| cisvc | messenger | replicator | tapisrv |
| clipsrv | msiserver | rpc | time |
| dcom | mcsvc | rpclocator | trksvr |
| dhcp | netdde | rpcss | trkwks |
| dmserver | netddedsm | rsvp | ups |
| dns | netlogon | samss | w3svc |
| dnscache | netman | scardsvr | wins |
| eventlog | nmagent | scesrv | www |
| eventsystem | oakley | schedule | |
| fax | plugplay | | |

These SPNs are recognized for computer accounts if the computer has a host SPN. Unless they are explicitly placed on objects, a host SPN can substitute for any of the above SPNs.

**Requirements for setting an SPN**

Because multiple services can run simultaneously under the same account, setting an SPN requires four unique pieces of information. These four pieces of information uniquely identify any service running on a network and can be used to mutually authenticate to any service.

For each SPN that is set, the following information is required:

- The type of service, formally called a service class. This enables you to differentiate between multiple services running under the same account.
- The account under which the service is running.
- The computer on which the service is running, including any aliases that point to that computer.
- The port on which the service is running (optional if the default port for the service of that type is used such as port 80 for HTTP).

The syntax of an SPN itself is service/hostname:port, where:

- Service is the service class of the SPN.
- Hostname is the computer to which the SPN belongs.
- Port is the port on which the service that the SPN is registered to runs.

**KDC key version numbers**

Users can change their passwords, and therefore their keys, at any time. This poses a problem for all existing credentials that are encrypted with the older key, because the credentials would no longer be usable if the user expected to use the new key. Although this is merely inconvenient to users—who can simply get new tickets—long-running services such as batch jobs would be interrupted if there was no one available to get a new ticket with the new key for the job. To address this problem, clients keep a copy of their older key for a period of time after switching to a new password.

When parties exchange encrypted communications, they need a way to determine which keys to use to decrypt the data they have received. If there is only one key, this is easy. However, when there are many keys, some of which correspond to the same account—such as when passwords are changed—then this task becomes difficult. One way to find the right key is to try all available keys, but this wastes time and computing resources, particularly if the client has many keys to try.

To streamline this process, encrypted data includes a header that has information including a sort of serial number that is associated with the key and the encryption type used to encrypt the data. When a client receives an encrypted communication, it includes information about whose key set to use, as well as which particular key version to use to decrypt the data. This way, even if a ticket is encrypted with an older key, the recipient can still decrypt it by looking at the key version number, finding the correct key version, and decrypting the ticket. Eventually, tickets with outdated keys expire, and the system gradually shifts to using the new key in all cases, creating no problems for the user.

New to Windows Server 2003 is the read-only attribute **ms-DS-KeyVersionNumber**. When a password is changed, the key version number is incremented and the current value can be queried using **ms-DS-KeyVersionNumber**. Windows 2000 KDCs will always issue tickets with a key version number equal to 1. Windows Server 2003 KDCs only keep track of the latest key version number for a principal account because there is no reason for the KDC to use outdated keys.

Key version numbers also enable Windows Server 2003 to provide more informative errors when a message cannot be decrypted. In general cases, when information can not be decrypted, the system provides the error KRB_AP_ERR_MODIFIED, meaning that the encrypted information is not accessible, but with no further information. For example, the data could have been modified in transit, the data could have been malformed initially, or there could be no available key. Each of these possible causes requires troubleshooting at different locations and using different techniques.

On the other hand, using key version numbers can enable the system to communicate the source of the failure. For example, if the client has no key to match the key version number included in the header, the system responds with the error KRB_AP_ERR_BADKEYVER. This error message specifically informs the client that the appropriate key version is not available. The client can then resolve the failure by resetting the password, which resets the keys.

The key version number is generated each time a password is changed on long-lived keys—such as the key that results from a user password, the keys for computer accounts, or the keys for domain trusts. Key version numbers also are provided because they are required for compliance with the Kerberos RFC (1510).

Key version numbers are constructed from the update logon timestamp attribute which is updated in the SAM when a password is changed. The update logon timestamp is a 32-bit value that identifies the version of the keys generated from the password. Key version number functionality based on update logon timestamps is only available in domains that have Windows Server 2003 domain functionality.

**Kerberos Realms and Active Directory Domains**
With the release of Windows 2000, Active Directory domains became the implementation of Kerberos realms.

The RFC 1510 describes Kerberos realms and their organization as follows:

"The Kerberos protocol is designed to operate across organizational boundaries. A client in one organization can be authenticated to a server in another. Each organization wishing to run a Kerberos server establishes its own 'realm.'"

"Realms are typically organized hierarchically. Each realm shares a key with its parent and a different key with each child. If an inter-realm key is not directly shared by two realms, the hierarchical organization enables an authentication path to be easily constructed. If a hierarchical organization is not used, it might be necessary to consult some database in order to construct an authentication path between realms."

"Although realms are typically hierarchical, intermediate realms might be bypassed to achieve cross-realm authentication through alternative authentication paths (these might be established to make communication between two realms more efficient). It is important for the end-service to have information about which realms were transited when deciding how much faith to place in the authentication process. To facilitate this decision, a field in each ticket contains the names of the realms that were involved in authenticating the client."

It is clear from the RFC's discussion that the concept of Kerberos realms has similarities—such as organizational boundaries and trusts—to attributes of the Windows NT domains. Active Directory domains use inter-realm-key-based trusts and a hierarchical design. These inter-realm (also called inter-domain) keys are the basis of transitive trust in Active Directory domains.

### Note

- In literature documenting Windows operating systems, the term "domains" might be used in place of place of the term "realms." In such cases, the term "realms" will be used to denote non-Windows Kerberos realms in the environment.

In Kerberos authentication, Active Directory domains fulfill all the requirements of Kerberos realms.

**Kerberos Processes and Interactions**
This subsection will cover the following topics:

- Kerberos V5 exchange and message summary
- Windows Server 2003–based examples:
    - Local logon
    - Domain logon
    - Single domain authentication
    - Simple cross-domain authentication
    - Cross-realm authentication and shortcut trusts
    - Untrusted domain
    - Delegation
- Kerberos V5 message details:
    - Authentication service exchange
    - Ticket-granting service exchange
    - Client/server authentication exchange
    - Credentials message
- Required technologies for Active Directory domains:
    - Kerberos and IP transport: UDP/TCP
    - DNS name resolution

**Kerberos V5 Exchange and Message Summary**
The RFC standard Kerberos version 5 authentication protocol communication sequences consist of six (five required and one optional) messages. These messages compose three types of exchanges (also known as sub-protocols), which are examined more closely later in this section.

### Kerberos Exchange and Message Summary

**The Authentication Service Exchange**
**1. Kerberos authentication service request (KRB_AS_REQ)**
The client contacts the Key Distribution Center's authentication service for a short-lived ticket (a message containing the client's identity and—for Windows clients—SIDs) called a ticket-granting ticket (TGT). This happens at logon.

**2. Kerberos authentication service response (KRB_AS_REP)**

The authentication service (AS) constructs the TGT and creates a session key the client can use to encrypt communication with the ticket-granting service (TGS). The TGT has a limited lifetime. At the point that the client has received the TGT, the client has not been granted access to any resources, even to resources on the local computer.

Why use a TGT? Could the AS simply issue a ticket for the target server? Yes, but if the AS issued tickets directly, the user would have to enter a password for every new server/service connection. Issuing a TGT with a short lifespan (typically 10 hours) gives the user a valid ticket for the ticket-granting service, which in turn issues target-server tickets. The TGT's main benefit is that the user only has to enter a password once, at logon.

**The Ticket-Granting Service Exchange**
**3. Kerberos ticket-granting service request (KRB_TGS_REQ)**
The client wants access to local and network resources. To gain access, the client sends a request to the TGS for a ticket for the local computer or some network server or service. This ticket is referred to as the service ticket or session ticket. To get the ticket, the client presents the TGT, an authenticator, and the name of the target server (the Server Principal Name or SPN).

**4. Kerberos ticket-granting service response (KRB_TGS_REP)**
The TGS examines the TGT and the authenticator. If these are acceptable, the TGS creates a service ticket. The client's identity is taken from the TGT and copied to the service ticket. Then the ticket is sent to the client.

### Note

- The TGS cannot determine if the user will be able to get access to the target server. It simply returns a valid ticket. Authentication does not imply authorization.

**The Client/Server Exchange**
**5. Kerberos application server request (KRB_AP_REQ)**
After the client has the service ticket, the client sends the ticket and a new authenticator to the target server, requesting access. The server will decrypt the ticket, validate the authenticator, and for Windows services, create an access token for the user based on the SIDs in the ticket.

**6. Kerberos application server response (optional) (KRB_AP_REP)**
Optionally, the client might request that the target server verify its own identity. This is called mutual authentication. If mutual authentication is requested, the target server will take the client computer's timestamp from the authenticator, encrypt it with the session key the TGS provided for client-target server messages, and send it to the client.

**Local Logon Example**
Users can log on to computers with either a domain account or an account local to the computer. When the user logs on with an account local to the computer, the user's credentials are authenticated using the local account database. Because the local computer does not act as a KDC, and because local logon does not require network access (for example, to contact a KDC), local authentication uses NTLM to authenticate the account.

### Local Logon Sequence

1. After the Graphical Identification and Authentication (GINA) dynamic-link library has collected the user's logon information, it passes that information to the LSA for authentication.

2. The LSA simply passes the information on to the SSPI.

3. The SSPI does not determine whether the user is logging on locally or through a domain account. Because the Kerberos SSP is the default authentication provider, the authentication request is first passed to the Kerberos SSP.

4. The Kerberos SSP verifies that the logon target name is the same as the local computer name. If so, the Kerberos SSP returns an error message to the SSPI that no logon servers are available, just as if it had checked the network for a KDC and found none.

5. The SSPI now sends the request to the next security provider, NTLM. The authentication process used by the NTLM SSP is identical to versions used in Windows NT.

**Domain Logon Example**

If the user is a member of a domain, then the account database is on a domain controller. If you are logging on to one of the domain controllers for the domain you belong to, then the process it the same as for local logon as described above. If instead you are logging on to a member server or a domain controller of another domain, then Kerberos authentication will used if possible.

Users never directly access the system. The system impersonates the user and accesses resources based on the resource permissions granted to the user. This is a standard security feature of all versions of Windows NT, Windows 2000, and Windows Server 2003. The user logging on to a workstation never directly accesses even local resources. The local system impersonates the user just as a remote system would.

Because the local system relies on impersonation, the user who logs on to the domain must be authenticated as a valid local user. The only new component added to the domain logon process is Kerberos authentication prior to building an access token.

The authentication process for a domain user to access their computer is very similar to the process used to authenticate access to network resources—that is, the user must obtain a valid ticket for the local workstation.

- The Kerberos client requests and then receives a TGT from the KDC.

- The Kerberos client uses the TGT to request and then receive a service ticket for the local workstation from the KDC.

- The service ticket for a network resource would be encrypted with the system or service key depending on whether the resource is a system or service. The workstation has a system key created when the computer joined the domain. The service ticket for the workstation is encrypted with this key.

- The local LSA builds an access token from the credentials contained in the service ticket and then grants or denies the user access.

**How Logging on the Workstation Works**

Suppose the user has a network account in the domain tailspintoys.com. The user's workstation also belongs to tailspintoys.com. The user logs on to the network by pressing CTRL+ALT+DEL, which is the Secure Attention Sequence (SAS) on computers with a standard Windows configuration.

In response to the SAS, the workstation's Winlogon service switches to the logon desktop and calls the GINA DLL, a component loaded in Winlogon's process. The GINA is responsible for collecting logon data from the user, packaging it in a data structure, and sending everything to the LSA for verification. Other parties can develop replacement GINAs, but in this case Winlogon has loaded the standard component supplied with the operating system, MSGINA.DLL. Winlogon calls it, and the GINA displays the standard logon information dialog box.

The user types a user name and password. From the domains in a drop-down list, the user selects tailspintoys.com. When the user clicks OK to dismiss the dialog box, MSGINA returns the logon information to Winlogon. Winlogon sends the information to the LSA for validation by calling LsaLogonUser. This procedure is standard for any user logon regardless of the authentication method used.

At this point, the LSA begins to use the Kerberos V5 authentication protocol.

**Kerberos Keys**

A user key is derived from a password. After it receives a data structure with the user's logon data, the LSA converts the plaintext password to a cryptographic key by passing the text of the password through a cryptographic function. (All implementations of the Kerberos version 5 authentication protocol must support DES-CBC-MD5. Other algorithms are permissible.) The result of the cryptographic function is the user key.

The LSA saves the user key in the user credentials cache, where it can be retrieved when needed for TGT renewal or for NTLM authentication to servers that are not capable of Kerberos authentication.

In order to validate the user's logon information and set up the user's logon session on the computer, the LSA must obtain:

- A TGT good for admission to the ticket-granting service.
- A service ticket good for admission to the computer.

The LSA obtains these tickets by working through the Kerberos SSP, which exchanges messages directly with the KDC in tailspintoys.com. (The workstation has located a KDC through a DNS query. Every domain controller is a KDC and registers its role with DNS.)

The TGT is obtained in an authentication service (AS) exchange; the service ticket is obtained in a ticket-granting service (TGS) exchange.

**Obtaining a TGT in the authentication service exchange**

### Message 1: Authentication Service Request

The Kerberos client on the workstation sends the message KRB_AS_REQ to the KDC in tailspintoys.com.

The message includes:

- The user principal name.
- The name of the account domain.
- Pre-authentication data encrypted with the user's key derived from the user's password.

**Retrieving the user key**

The KDC gets its copy of the user key from the user's record in its account database. When it receives a request from the Kerberos client on the user's workstation, the KDC searches its database for the user, pulls up the account record, and takes the user key from a field in the record.

This process—computing one copy of the key from a password, fetching another copy of the key from a database—actually

takes place only once, when a user initially logs on to the network. Immediately after accepting the user's password and deriving the user's long-term key, the Kerberos client on the workstation requests a service ticket and TGS session key that it can use in subsequent transactions with the KDC during this logon session.

**Verifying the user's identity**

The KDC decrypts the pre-authentication data and evaluates the timestamp inside. If the timestamp passes the test, the KDC can be assured that the pre-authentication data was encrypted with the user key and thus verify that the user is genuine.

After it has verified the user's identity, the KDC creates credentials that the Kerberos client on the workstation can present to the ticket-granting service. For more information about how domain controllers create credentials in a Windows environment, see "How Access Tokens Work" in the Access Tokens Technical Reference.

### Message 2: Authentication Service Reply

The KDC replies with KRB_AS_REP containing a service ticket for itself. This special service ticket is called a ticket-granting ticket (TGT). Like an ordinary service ticket, a TGT contains a copy of the session key that the service (in this case the KDC) will use in communicating with the user. The message that returns the TGT to the user also includes a copy of the session key that the user can use in communicating with the KDC. The TGT is encrypted in the KDC's long-term key. The user's copy of the session key is encrypted in the user's long-term key.

### KRB_AS_REP Message Contents

The message includes:

- A TGS session key for the user to use with the TGS, encrypted with the user key derived from the user's password.
- A TGT for the KDC in tailspintoys.com, encrypted with the TGS key.

  The TGT includes:

  - A TGS session key for the KDC to use with the user.
  - Authorization data for the user.

  The authorization data includes:

  - The SID for the user's account.
  - SIDs for security groups which the user is a member of in the domain tailspintoys.com.

- SIDs for universal groups in the enterprise that include either the user or one of the domain groups the user is a member of.

When the client receives the KDC's reply to its initial request, the client uses its cached copy of the user key to decrypt its copy of the session key. It can then discard the user key derived from the user's password, for it is no longer needed. In all subsequent exchanges with the KDC, the client uses the TGS session key. Like any other session key, this key is temporary, valid only until the TGT expires or the user logs off. For that reason, the TGS session key is often called a logon session key.

From the client's point of view, a TGT is just another ticket. Before the client attempts to connect to any service, the client first checks the user credentials cache for a service ticket to that service. If it does not have one, it checks the cache again for a TGT. If it finds a TGT, the LSA fetches the corresponding logon session key from the cache, uses this key to prepare an authenticator, and sends both the authenticator and the TGT to the KDC, along with a request for a service ticket for the service. In other words, gaining admission to the KDC is no different from gaining admission to any other service in the domain—it requires a session key, an authenticator, and a ticket (in this case, a TGT).

From the KDC's point of view, TGTs enable the KDC to avoid the performance penalties of looking up a user's long term key every time the user requests a service. The KDC looks up the user key only once, when it grants an initial TGT. For all other exchanges with this user, the KDC can decrypt the TGT with its own long-term key, extract the logon session key, and use that to validate the user's authenticator.

**Obtaining a service ticket in the ticket-granting service exchange**

### Message 3: Ticket-Granting Service Request

The Kerberos client sends the message KRB_TGS_REQ to the KDC in tailspintoys.com.

The message includes:

- The name of the target computer.
- The name of the target computer's domain.
- The user's TGT.
- An authenticator encrypted with the session key the user shares with the KDC.

### Message 4: Ticket-Granting Service Reply

The KDC responds to the user's request to connect to a server by sending both copies of the session key to the user. The user's copy of the session key is encrypted with the key that the KDC shares with the user. The workstation's copy of the session key is embedded, along with information about the user, in a data structure called a service ticket. The entire structure is then encrypted with the key that the KDC shares with the user. The ticket—with the user's copy of the session key safely inside—becomes the workstation's responsibility to manage.

**KRB_TGS_REP Message Contents**

The KRB_TGS_REP message includes:

- A session key for the user to share with the computer encrypted with the session key the user shares with the KDC.
- The user's service ticket to the computer, encrypted with the computer's secret key.

  The service ticket includes:

  - A session key for the computer to share with the user.
  - Authorization data copied from the user's TGT.

When the Kerberos client receives the KDC's reply, it extracts the ticket and the user's copy of the session key, putting both in the user credentials cache (located in volatile memory, not on disk).

**Note**

- The KDC is simply providing a ticket-granting service. It does not keep track of its messages to make sure they reach the intended address. No harm will be done if the KDC's messages fall into the wrong hands. Only someone who knows the user's secret key can decrypt the user's copy of the session key. Only someone who knows the client's secret key can read what is inside the ticket.

**Getting the User's Credentials to Winlogon**

After credentials reach the workstation, the Windows Server 2003 access token creation process is the same as that of Windows NT versions. The LSA on the workstation receives the user's service ticket, decrypts the service ticket with the system key stored in its credentials cache, and then extracts the authorization data. The privilege attribute certificate (PAC) is taken from the service ticket and used to create the user's access token. The LSA then queries the local SAM database to discover whether the user is a member of any security groups local to the computer, and whether memberships in those groups grant the user any special rights on the local computer. It adds any SIDs returned by this query to the list taken from the ticket's authorization data. The entire list is then used to build an access token, and a handle to the access token is returned to Winlogon, along with an identifier for the user's logon session and confirmation that the logon information was valid.

Winlogon creates a window station and several desktop objects for the user, attaches the user's access token, and starts the shell process the user will use to interact with the computer. The user's access token is subsequently inherited by any application process that the user starts during the logon session.

When the user logs off, the credentials cache is flushed and all service tickets—as well as all session keys—are destroyed.

**Single Domain Authentication Example**

The process used to access resources and services on another system works basically the same as the logon example above except that the service ticket will need to be sent to the remote system. Except for the Kerberos authentication, security access checks are nearly identical with those of Windows NT 4.0 and earlier versions.

In the following example, both the user and service are in tailspintoys.com, the user has already logged on, and the user has requested and received a ticket for the workstation. The client wants to access \\server\shared folder to read a file. The process follows this sequence:

- Client and server negotiate a security package to use for authentication. They choose Kerberos.
- The client sends the service ticket (containing user credentials in the PAC) to the server.
- If the server accepts the ticket (that is, is able to decrypt the ticket with its secret key), then the server creates an access token for the user based on the PAC.
- The client redirector sends a server message block (SMB) message requesting file access.
- Server security compares file permissions with the user's credentials and grants or denies access.

## After Workstation Logon

When the user attempts to use the service on the remote server, the user has already logged on to the local workstation. Thus, the user's credentials cache will have a TGT and a session key for the domain the user's account resides in. This TGT is used to request a ticket for the service.

**Message 3: KRB_TGS_REQ**

Because the TGT will expire within a few hours, the Kerberos client must check the expiration time before requesting additional tickets. If the TGT is expired, then the Kerberos client must send a KRB_AS_REQ to get another TGT.

The Kerberos client on the user's workstation requests credentials for the service by sending the KDC a Kerberos ticket-granting service request (KRB_TGS_REQ). This message includes the user's name, an authenticator encrypted with the user's logon session key, the TGT obtained in the AS exchange from workstation logon, and the name of the service for which the user wants a ticket.

**Note**

- The KRB_TGS_REQ message will typically be sent to the same domain controller that issued the TGT. However, TGS requests can be made to any domain controller. Thus, if the original KDC becomes unavailable, the client can discover a new KDC through a DNS query and then send a KRB_TGS_REQ there.

When the KDC receives KRB_TGS_REQ, it decrypts the TGT with its own secret key, extracting the user's TGS session key (logon session key). It uses the session key to decrypt the authenticator and evaluates that. If the authenticator passes the test, the KDC extracts the user's authorization data from the TGT and creates another session key for the client to use with the service. The KDC encrypts one copy of this new session key with the user's TGS session key. It embeds another copy of the session key in a ticket, along with the user's authorization data, and encrypts the ticket with the service's key. The KDC then sends these credentials back to the client in a Kerberos ticket-granting service reply (KRB_TGS_REP).

**Message 4: KRB_TGS_REP**

When the Kerberos client receives the reply, it uses the user's TGS session key to decrypt the session key to use with the service, and stores the key in its credentials cache. Then it extracts the ticket to the service and stores that in its cache.

**Message 5: Kerberos Application Request (KRB_AP_REQ)**

The Kerberos client on the user's workstation requests service from the service by sending the service a Kerberos application request (KRB_AP_REQ).

**KRB_AP_REQ Message Contents**

This message contains:

- An application option flag indicating whether to use session key. (The setting of this flag is one of the options in configuring Kerberos applications. The user is never asked.)
- An application option flag indicating whether the client wants mutual authentication.
- The service ticket obtained in the TGS exchange.
- An authenticator encrypted with the session key for the service.

**Message 6: KRB_AP_REP (Optional)**

The service receives KRB_AP_REQ, decrypts the ticket, and extracts the user's authorization data and the session key. The service uses the session key to decrypt the user's authenticator and then evaluates the timestamp inside. If the authenticator passes the test, the service looks for a mutual authentication flag in the client's request. If the flag is set, the service uses the session key to encrypt the time from the user's authenticator and returns the result in a Kerberos application reply (KRB_AP_REP). If the flag is not set, then no response is needed.

When the client on the user's workstation receives KRB_AP_REP, it decrypts the service's authenticator with the session key it shares with the service and compares the time returned by the service with the time in the client's original authenticator. If the

times match, the client knows that the service is genuine.

**Building an access token from a Kerberos service ticket**
After credentials reach the server, the Windows Server 2003 token creation process is the same as that of earlier Windows versions. After the server authenticates the client using Kerberos authentication, the PAC is taken from the service ticket and used to create the user's access token.

**Remote resource authorization**
After the service has an access token for the user, it still needs to verify that the user is authorized to do what the user wants to do. Except for the Kerberos authentication, security access checks are nearly identical with those of Windows NT 4.0 and earlier versions:

1. The client redirector sends an SMB message requesting file access.

2. Server security compares file permissions with the user's credentials and grants or denies access.

3. If access is granted, the connection proceeds.

During the connection, the session key can be used to encrypt application data, or the client and server can share another key for this purpose.

**Simple Cross-Realm Authentication and Examples**
The functions of the KDC are divided into two distinct services: an authentication service whose job is to issue TGTs, and a ticket-granting service whose job is to issue service tickets. This division of labor enables the Kerberos protocol to operate across domain boundaries. A client can get a TGT from the authentication service of one domain and use it to get service tickets from the ticket-granting service of another domain.

**The Basic TGS Referral Process**
Clients typically need to request access to services outside of a single Kerberos realm. Whether in a pure Active Directory forest or in a mixed Kerberos environment, the referral process is the same. When a client requests a service ticket for a server in a remote Kerberos realm, the request is sent to the KDC in the client account's realm. The KDC determines that the server is in another realm, so it cannot issue a service ticket. This can only be done by a KDC in the target server's realm. So, instead of issuing the service ticket, the KDC in the client account's realm issues a TGS referral.

The TGS referral message is a normal KRB_TGS_REP message containing:

- A TGT for another trusted realm.

- Information indicating the KRB_TGS_REP is a referral to another TGS.

The client recognizes that the KRB_TGS_REP is a referral message and sends the TGT in a new KRB_TGS_REQ message to the remote realm to get the service ticket it needs.

### Cross-Realm Authentication Between Two Realms

To understand how cross-realm authentication works, first consider the simplest case: a network with only two realms, East and West. If administrators for these realms are members of the same organization, or if for some other reason they are willing to treat the other realm's users as their own, they can enable authentication across realm boundaries simply by sharing an inter-realm key. (In Active Directory domains this happens automatically when two domains establish a trust relationship.) After the inter-realm key is shared, the ticket-granting service of each realm is registered as a security principal with the other realm's KDC. As a result, the ticket-granting service in each realm can treat the ticket-granting service in the other realm as just another service, something for which properly authenticated clients can request and receive service tickets.

When a user with an account in West wants access to a server with an account in East, the process is:

1. The Kerberos client on the user's workstation sends a request for a service ticket to the ticket-granting service in the user

account's realm, West.

2. The ticket-granting service in West determines that the desired server is not a security principal in its realm, so it replies by sending the client a referral ticket—a TGT encrypted with the inter-realm key that the KDC in West shares with the KDC in East.

3. The client uses the referral ticket to prepare a second request for a service ticket, and this time sends the request to the ticket-granting service in the server account's realm, East.

4. The ticket-granting service in East uses its copy of the inter-realm key to decrypt the referral ticket. If decryption is successful, it sends the client a service ticket to the desired server in its domain.

**Three-Realm Referral Example**

The referral process is more complicated on networks with more than two realms. In theory, the KDC in each realm could establish a direct link to the KDC in every other realm on the network, in each case sharing a different inter-realm key. In practice, however, the number and complexity of these relationships could become unmanageable, especially on a large network. The Kerberos protocol solves the problem by making direct links unnecessary. A client in one realm can get a ticket to a server in another realm by traveling a referral path through one or more intermediate realms.

**Three-Realm Referral**

For example, consider a network with three realms, east.tailspintoys.com, west.tailspintoys.com, and tailspintoys.com. The KDC in east.tailspintoys.com does not share an inter-realm key with the KDC in west.tailspintoys.com, but both KDCs do share inter-realm keys with tailspintoys.com. In this case, when a user with an account in west.tailspintoys.com wants access to a server with an account in east.tailspintoys.com, the referral path begins at the KDC for the user account's realm, west.tailspintoys.com, passes through an intermediate realm, tailspintoys.com, and ends at the KDC for the server account's realm, east.tailspintoys.com. The client must send its request for a service ticket three times, to three different KDCs. The three TGS exchanges are:

1. The client requests the KDC for west.tailspintoys.com to give it a ticket to the server in east.tailspintoys.com.

   The KDC for west.tailspintoys.com replies by sending the client a referral ticket to the KDC for tailspintoys.com. This ticket is encrypted in the inter-realm key that west.tailspintoys.com shares with tailspintoys.com.

2. The client requests the KDC for tailspintoys.com to give it a ticket to the server in east.tailspintoys.com.

   The KDC for tailspintoys.com replies by sending the client a referral ticket to the KDC for east.tailspintoys.com. This ticket is encrypted in the inter-realm key that tailspintoys.com shares with east.tailspintoys.com.

3. The client requests the KDC for east.tailspintoys.com to give it a ticket to the server in east.tailspintoys.com.

   The KDC for east.tailspintoys.com can decrypt the TGT from tailspintoys.com. The TGT has the user's credentials and

verifies that they have not been tampered with because they were encrypted with a key only the two KDC have. The KDC for east.tailspintoys.com sends back a ticket for the server.

For a detailed look at the complete authentication process, see the next example, "Cross-Realm Authentication and Shortcut Trusts."

**Cross-Realm Authentication and Shortcut Trusts Example**
What happens if there are multiple trusted Kerberos realms between the client's logon realm and the target server's realm? In this case, the client receives a TGS referral for the nearest trusted realm along the shortest path to the target realm. The client must send the KRB_TGS_REQ message requesting a service ticket for the target server to each intervening realm. A KDC in each intervening realm issues another TGS referral to the client until the client has a TGT for a KDC in the target realm. The following example describes an Active Directory domain environment.

**Three Domain Cross-Realm Authentication Example**
Suppose the user logs on at a workstation in west.tailspintoys.com. The user wants to connect to a shared file on a server in east.tailspintoys.com. Two steps occur before the cross-realm authentication steps:

- The user uses Explorer to request a connection to \\server\shared folder.
- DNS resolves that the target server is located in east.tailspintoys.com.

**Cross-Realm Authentication: Three Domains**

To authenticate the user's identity to the server, the user needs a service ticket. Only the KDC in east.tailspintoys.com can issue this ticket. Although the user needs a TGT for that KDC, its initial ticket request needs to go to the local KDC for west.tailspintoys.com. The Kerberos SSP on the user's workstation must obtain a TGT for the server's domain and then use the TGT to get a ticket for the server.

This involves a referral process that proceeds as follows:

1. The user's Kerberos client sends a KRB_TGS_REQ message to a local KDC in west.tailspintoys.com, specifying server@east.tailspintoys.com as the target.

   The message includes:

   - The name of the target computer.
   - The name of the target computer's domain.
   - A TGT for admission to the KDC in west.tailspintoys.com.
   - An authenticator encrypted with the TGS session key the user shares with that KDC.

The Kerberos client compares the location with its own workstation's domain. Because they are different, the client sets a flag in the KDC Options field of the KRB_TGS_REQ message for NAME_CANONICALIZE, which indicates to the KDC that server might be in another realm.

2. The user's local KDC (for west.tailspintoys.com) receives the KRB_TGS_REQ and sends back a referral ticket for tailspintoys.com. The local KDC:

   a. Notes the flag setting.

   b. Verifies the user's TGT.

   c. Looks up the path to the server—in this case, a computer object in east.tailspintoys.com.

   d. Builds a tree of known domains until it has a structure including east.tailspintoys.com.

   e. Queries LSA for a trust list.

   f. Constructs the shortest path between its domain and east.tailspintoys.com based on the domain tree and the trust list.

   g. Constructs a new TGT for the user.

      Unless there is a direct trust between west.tailspintoys.com and east.tailspintoys.com (which there is not in this example), the TGT is issued for the next intervening domain along the shortest path to east.tailspintoys.com. In this example, the next intervening domain is tailspintoys.com.

      The TGT also has a referral flag set, so the KDC will be informed that the KRB_TGS_REQ is coming from another realm. This flag also tells the KDC to fill in the Transited Realms field.

   h. Constructs a KRB_TGS_REP message containing these four items:

   - A TGT for tailspintoys.com, encrypted with the inter-realm key shared between west.tailspintoys.com and tailspintoys.com.

   - A session key for the user to share with the KDC in tailspintoys.com, encrypted with the user's TGS session key.

   - A pre-authentication field data type of KERB-PA-SERV-REFERRAL, which tells the user's Kerberos client that the enclosed ticket is a referral TGT.

- Pre-authentication data (the realm name for the referral — in this case, tailspintoys.com).

3. The user's Kerberos client receives the KRB_TGS_REP and sends KRB_TGS_REQ to the KDC in tailspintoys.com. The Kerberos client:

   a. Notes that this is a referral and gets the referral realm (tailspintoys.com).

   b. Sends a KRB_TGS_REQ message to a KDC in tailspintoys.com with the TGT, the NAME_CANONICALIZE flag set, and a request for a service ticket to server.

   The message includes:

   - The name of the target computer.
   - The name of the target computer's domain.
   - A TGT for admission to the KDC in tailspintoys.com.
   - An authenticator encrypted with the session key the user shares with that KDC.

4. A KDC in tailspintoys.com goes through the same process as the KDC in west.tailspintoys.com, returning a TGT for east.tailspintoys.com in a TGS referral to the user.

5. The user's Kerberos client sends a KRB_TGS_REQ along with the TGT it received from the tailspintoys.com KDC to a KDC in east.tailspintoys.com.

6. The KDC in east.tailspintoys.com replies with KRB_TGS_REP.

   The message includes:

   - A session key for the user to share with the server, encrypted with the session key the user shares with the KDC in east.tailspintoys.com.
   - A service ticket for admission to the server encrypted with the server key shared with the KDC.

   The service ticket includes:

- A session key for the server to share with the user.
- Authorization data copied from the user's TGT, plus data for the local domain, east.tailspintoys.com.

The authorization data includes:

- The SID for the user's account.
- SIDs for groups in west.tailspintoys.com that include the user.
- SIDs for universal groups that include either user or one of the user's groups in west.tailspintoys.com.
- SIDs for groups in east.tailspintoys.com that include the user, one of the user's groups in west.tailspintoys.com, or one of their universal groups.

7. The user's Kerberos client sends the server a KRB_AP_REQ message.

   The message includes:

   - The user principal name.
   - A service ticket to the server.
   - An authenticator encrypted with the session key the user shares with the server.

**Note**

- If the user had asked for mutual authentication, then the server would reply with KRB_AP_REP. The reply message would include an authenticator encrypted with the session key the server shares with the user.

The same process takes place when a user logs on to a remote domain and needs a service ticket for the local workstation. The KDC in the logon domain issues a referral to the next realm between it and the workstation's realm, and so on, until the client can request a service ticket from the KDC in the workstation's realm.

**Effects of Shortcut Trusts**

You can optimize the inter-realm authentication process in your Active Directory forest by shortening the trust path with shortcut trusts. In this example, the user has an account in it.west.tailspintoys.com. The user has logged on to the domain account and has collected a TGT for the KDC in it.west.tailspintoys.com. Suppose the user needs access to a document stored in a public folder on a server in the domain it.east.tailspintoys.com.

**Forest Configuration**

Without shortcut trusts, the referral path to retrieve a service ticket would be:

1. it.west.tailspintoys.com

2. west.tailspintoys.com
3. tailspintoys.com
4. east.tailspintoys.com
5. it.east.tailspintoys.com

The following illustration shows how the referral path would change with the addition of a shortcut trust.

**Forest Configuration with Shortcut Trusts**

If Shortcut Trust 1 is created, then the referral path to retrieve a service ticket would become:

1. it.west.tailspintoys.com
2. west.tailspintoys.com
3. east.tailspintoys.com
4. it.east.tailspintoys.com

**Do shortcut trusts always affect the shortest referral path?**
If the shortest path to a realm would be to use an explicit trust that is positioned in the tree below the current domain, that path will not be used. This is because the shortest-path algorithm can only make use of explicit trusts that are at or above the current position in the tree.

If only Shortcut Trust 2 is created then the referral path to retrieve a service ticket would remain:

1. it.west.tailspintoys.com
2. west.tailspintoys.com
3. tailspintoys.com
4. east.tailspintoys.com
5. it.east.tailspintoys.com

This shortcut trust would only shorten the path from test.it.west.tailspintoys.com to east.tailspintoys.com and it.east.tailspintoys.com. But from test.it.west.tailspintoys.com and east.tailspintoys.com it would reduce the number of exchanges from five to two.

**Untrusted Domain Examples**

To use Kerberos authentication in a remote untrusted domain, the user must supply credentials as part of the connection request. Otherwise, the KRB_TGS_REQ message fails, and the system tries the next security provider, typically NTLM.

**Client Does Not Use Alternative Credentials**
Suppose user 1 is logged on to west.tailspintoys.com and wants to access a shared file on user 2's Windows Server 2003 server in sales.contoso.com, an untrusted domain.

1. User 1 opens Windows Explorer and simply tries to map a network drive to \\User2\shared folder without providing the credentials with which to connect.

2. The KRB_TGS_REQ goes to user 1's local KDC just as it would if sales.contoso.com were a trusted domain.

3. When the KDC attempts to build a domain tree and trust list, the attempt fails because there is no trust.

4. User 1 might or might not get an error message because the system automatically reverts to the next security provider. If NTLM is available, it is used. If NTLM authentication is successful, user 1 might connect, but Kerberos authentication will not have been used.

**Client Uses Alternative Credentials to Send KRB_AS_REQ Directly to Untrusted KDC**
User 1 can enter credentials. The Kerberos client responds differently when the user includes new credentials.

- A different ticket cache is created for each different set of credentials.

  **Note**

  - If user 1 connects to an untrusted resource using different credentials (for example, Administrator), a new ticket cache is created for these credentials. The tickets in this cache are not currently viewable with either Kerberos Tray or Kerberos List.

- If user 1 has used the credentials recently, a ticket cache might already exist. If so, the client checks for an existing TGT for the untrusted domain. It cannot use an existing TGT from user 1's normal ticket cache.

- The client sends a KRB_AS_REQ message to get a TGT from the KDC in the target server's realm. If the supplied credentials are correct, this request is processed normally, without the need for any TGS referrals.

**Delegation Examples**
**The Need for Delegation**
A client might need to let an application or a service connect to other servers or services on its behalf. A client might use a front-end server, for example, that then needs to authenticate with a back-end server. The front-end server needs to authenticate to the back-end server with the client's credentials, because if it authenticated under its own service account, it would have different authorization than the user.

A multi-tier client/server application presents a special situation for the Kerberos protocol. In this kind of application, a client might connect to a server that must itself connect to a second server on the back end. For this to happen, the first server must have a ticket to the second. Ideally, the ticket should limit the first server's access on the second server to whatever the client—instead of the server—is authorized to do.

The Kerberos protocol deals with this situation through a mechanism called delegation of authentication. Essentially, the client delegates authentication to a server by telling the KDC that the server is authorized to represent the client. The concept is similar to the concept of impersonation in Windows NT.

Traditionally, the Kerberos protocol enabled delegation to be accomplished using one of two mechanisms:

- **Proxy tickets.** The client can get a ticket for the back-end server and then give it to the front-end server. Tickets obtained in this way—by a client for a proxy—are called proxy tickets. The difficulty with proxy tickets is that the client must have information about the name of the back-end server.

- **Forwarded tickets.** The client can give the front-end server a TGT that the server can use to request tickets as needed. Tickets obtained in this way—with credentials forwarded by a client—are called forwarded tickets. This second method overcomes the difficulty (that the client must have information about the name of the back-end server) presented by the

first method.

Windows Server 2003 supports two new extensions for delegation:

- **Protocol transition extension.** The protocol transition extension allows a kerberized service (that is, a service designed to use Kerberos authentication features) to obtain a Kerberos service ticket on behalf of a Kerberos principal to the service itself without requiring the principal to initially authenticate to the KDC with a credential.

- **Constrained delegation extension.** The constrained delegation extension allows a kerberized service to obtain service tickets (under the delegated user's identity) to a subset of other services after it has been presented a service ticket obtained either through KRB_TGS_REQ or the protocol transition extension.

Whether the KDC will allow clients to obtain proxy tickets or forwardable TGTs is a matter for Kerberos policy.

### Note

- Technically, both proxying and forwarding are proxies, so different Kerberos documents might discuss both types as proxy. In other documents, forwarding the user's identity is also known as delegation. In many Microsoft documents, including the *Microsoft Windows 2000 Server Resource Kit Distributed Systems Guide*, both proxying and forwarding are referred to as types of delegation. The terminology is not critical, but you should be aware that terms are used differently by different organizations.

#### What Delegation Does for the Client

Delegation of authentication allows the client to send its identity in the form of a Kerberos ticket to the front-end server. The front-end server can then impersonate the client and authenticate with the back-end server as if the front-end server were the client.

Delegation is not limited to a single pair of a front-end and a back-end server. A client can delegate its identity to a service that can then authenticate with any number of back-end services. It is also possible for the client to delegate its identity to Service A, and for Service A to in turn delegate the client's identity to Service B, for Service B to delegate the client's identity to Service C, and so on.

The simpler case—in which the client delegates its identity to a front-end server so that the front-end server can authenticate in the client's security context to a back-end server—is more common.

#### Delegation of Authentication

In Windows NT, a service can impersonate clients when accessing resources on the computer where the service process is running. In Windows 2000 and Windows Server 2003, a service can use the Kerberos protocol's delegation feature to impersonate clients on other computers, as well. For delegation of authentication to work, three conditions must be met:

- The computers that host the client process, the service process, and the processes for back-end services must all be running Windows 2000, Windows XP, or Windows Server 2003 in an Active Directory domain.

- The client's account must be enabled for delegation.

- The service's account must be enabled for delegation.

#### To configure a client's account for delegation

1. Right-click the object that represents the user in Active Directory Users and Computers.

2. Click **Properties**, and then click the **Account** tab.

3. In the **Account options** list, be sure that the **Account is sensitive and cannot be delegated** option is not selected.

#### For accounts in domains that are Windows 2000 mixed, Windows 2000 native, or Windows Server 2003 interim functional level

To configure a service's account for delegation, determine whether the service runs under the host computer's Local System account or under its own domain user account.

**To configure a service's account for delegation if the service runs under the Local System account**

1. Right-click the computer object in Active Directory Users and Computers.
2. Click **Properties**.
3. Click the **General** tab.
4. Select **Trust computer for delegation**.

**To configure a service's account for delegation if the service runs under its own domain user account**

1. Right-click the user object in Active Directory Users and Computers.
2. Click **Properties**.
3. Click the **Account** tab.
4. In the **Account options** list, select **Account is trusted for delegation**.

**For accounts in domains that are Windows Server 2003 functional level**
To configure a service's account for delegation, determine whether the service runs under the host computer's Local System account or under its own domain user account.

**To configure a service's account for delegation if the service runs under the Local System account**

1. Right-click the computer object in Active Directory Users and Computers.
2. Click **Properties**.
3. Click the **Delegation** tab.

   **Note**

   - If the service's account is missing the **Delegation** tab and you have confirmed the domain is **Windows Server 2003** functional level, then the SPN for the service account has not been registered. Use Setspn to register the service account's SPN.
   - If the **Trust this user for delegation to any service (Kerberos only)** option is selected, then the account is using unconstrained delegation, which is not recommended.
   - If the **Trust this user for delegation to specified services only** option is selected, then the account is using constrained delegation.
   - If the **Use Kerberos Only** option is selected, then the account is using constrained delegation without protocol transition.
   - If the **Use any authentication protocol** option is selected, then the account is using constrained delegation with protocol transition.

**To configure a service's account for delegation if the service runs under its own domain user account**

1. Right-click the user object in Active Directory Users and Computers.
2. Click **Properties**.
3. Click the **Delegation** tab.

4. If **Do not trust this computer for delegation** is selected, select the appropriate option:

    - If the **Trust this computer for delegation to any service (Kerberos only)** option is selected, then the account is using unconstrained delegation, which is not recommended.
    - If the **Trust this computer for delegation to specified services only** option is selected, then the account is using constrained delegation.
    - If the **Use Kerberos Only** option is selected, then the account is using constrained delegation without protocol transition.
    - If the **Use any authentication protocol** option is selected, then the account is using constrained delegation with protocol transition.

**Differences Between Proxy and Forwarding**
Both proxy and forwarding are types of delegation. The credentials message (KRB_CRED) is used to deliver both proxy tickets and forwarded tickets. The KRB_CRED message is detailed later in this topic.

**Proxy is limited use.**
The client gives a front-end server a ticket and a key for a specific back-end server. The front-end server can authenticate as the client with this specific service only.

**Forwarding is general use.**
The client sends a TGT and a key for a TGS to the front-end server. The front-end server requests service tickets to wherever it needs to on the client's behalf. The service that receives the client's TGT is the client as far as the KDC is concerned.

Proxy requires that the client have information about the name of the back-end or target server or service. Rather than require that the client keep track of all possible back-end server names, most services use forwarded tickets, as described below.

When the user's identity is forwarded to another service, a special type of authentication called user-to-user authentication might be required. This special case is discussed later in this section.

**Proxy**
For a service to handle a request for a client, the service might need to complete that request in the context of the client. Proxy allows the client to send its identity in the form of a Kerberos ticket to the front-end server. The front-end server can then impersonate the client and authenticate with the back-end server as if the front-end server were the client.

**What are proxy tickets?**
Service tickets obtained by a client for a service to impersonate it are called proxy tickets. When the KDC issues a TGT to a client, it checks Kerberos policy to see if proxy tickets are allowed. If they are, the KDC sets the PROXIABLE flag in the TGT that it issues to the client.

The client obtains a proxy ticket by presenting a TGT to the ticket-granting service and asking for a ticket to the back-end server. The client's request includes a flag signaling that it wants a proxy ticket and also includes the name of the server that will represent the client. When the KDC receives the client's request, it creates a ticket for the back-end server, sets the PROXY flag in the ticket, and sends it back to the client. The client then sends the ticket to the front-end server, which uses the ticket to access the back-end server.

**Client sends a front-end service a service ticket and session key for a back-end service**
In a proxy situation, the client wants a front-end service to authenticate as the client with a specific back-end service. Delegation is limited to a specific target. For example, the client knows that it must authenticate with SQL. It also knows that SQL will need to use the client's credentials to authenticate with a specific database on another server.

To authenticate with these services, the client requests a service ticket for the database. In the request, the client specifies that this will be a proxy ticket and gives the KDC the name of the SQL server. The client sends the proxy ticket to the SQL server along with a session key for the database. The SQL server then authenticates with the database as if it were the client.

### Note

- Proxy requires that the client know the name of the back-end or target server or service. Rather than require that the client keep track of all possible back-end server names, most services use forwarded tickets, as is described in the following proxy process.

The illustrated message sequence in the following figure assumes that Client has already authenticated with Proxy. Now, Client wants Proxy to access Server on its behalf.

**Messages in the Proxy Process**

The message sequence for the proxy ticket is:

1. Client sends a request for a proxy ticket for Server to the TGS in the KDC. The request includes the client's TGT, a request for the ticket to be flagged as a proxy, and the addresses for which the ticket is valid. The addresses are those of the client computer and Proxy.

2. The TGS sends the proxy ticket and a session key for Server to Client.

3. Proxy needs the Server ticket and a valid Server session key. Client sends both of these to Proxy in a KRB_CRED (Kerberos credentials) message.

4. Proxy can now attempt to access Server as the workstation. The KRB_AP_REQ message is identical to the one the client would have sent if it were trying to access Server directly. The message contains the Server service ticket and an authenticator.

   Server decrypts the ticket with its secret key, finds the session key, and uses the session key to decrypt the authenticator. If this succeeds, Proxy is authenticated as Client.

5. If the authenticator passes the test, the service looks for a mutual authentication flag in the client's request. If the flag is set, the service uses the session key to encrypt the time from the user's authenticator and returns the result in a Kerberos application reply (KRB_AP_REP). If a mutual authentication flag is not set, no response is needed.

**Forwarding**

The difficulty with proxy tickets is that the client must have information about the name of the back-end server. This difficulty is overcome by a second method of delegation—forwarding—that enables the client to give the front-end server a TGT that it can use to request tickets as needed.

**What are forwarded tickets?**

Forwardable TGTs obtained from a client that enable the service to impersonate the client are called forwarded tickets.

If a client wants to delegate the task of obtaining tickets for back-end servers to a front-end server, it must ask the KDC for a forwardable TGT. It does this through an AS exchange, indicating to the KDC the name of the server that will act on the client's behalf. If Kerberos policy permits forwarding, the KDC creates a TGT for the front-end server to use in the client's name, sets the FORWARDABLE flag, and sends the TGT back to the client. The client then forwards the TGT to the front-end server.

When the front-end server requests a ticket to the back-end server, it presents the client's TGT to the KDC. When the KDC issues a ticket, it sees the FORWARDABLE flag in the TGT, sets the FORWARDED flag in the ticket, and returns the ticket to the front-end server.

**How the client's TGT and TGS session key are sent to front-end services**

Proxy is limited in that the client must have information about the target server's name. Forwarding relieves the client of this burden. Rather than ask the KDC for a service ticket specifically for the server, the client sends its TGT—with the FORWARDED flag set—and TGS session key to the delegate server.

When the delegate server has the client's forwarded TGT and TGS session key, it can request from the KDC directly any service tickets it needs for any additional servers or services. The client does not need to be involved. With the client's forwarded TGT, the delegate server can fully impersonate the client, and can request service tickets on the client's behalf and in the client's security context for any services.

**The Forwarded Ticket and Delegation**
In Windows 2000, Windows XP, and Windows Server 2003, Kerberos delegation allows a service running under the local system security context to take on the client's identity and authenticate as the client to another service.

A server that has a client's forwarded ticket *is* the client. Thus, the forwarded ticket enables the server to request new tickets from the TGS. Because a TGT is required to request new tickets, the forwarded ticket is the client's TGT. Then, when a client forwards its TGT to another server, the client is said to have delegated its identity.

There are two forwarding situations:

- The client delegates its identity to a service that logged on with its own credentials, has its own user account, and knows its own password.

- The client delegates its identity to a service that was started in a user context, is using that user's credentials, but did not log on and does not have information about the user's password (for example, DCOM's "activate as activator"). This situation requires a special authentication mode called user-to-user authentication, which is discussed in the next section.

### Messages in the Forwarding Process

The normal message sequence for a forwarded ticket is illustrated above.

1. The client requests a TGT with valid addresses for the client and the delegate. The TGT is requested as forwardable.

2. The KDC sends a TGT with valid addresses for the client and the delegate. The TGT is flagged as forwardable.

3. The client uses the TGT to request service ticket for the delegate server.

4. The KDC sends a service ticket for the delegate server.

5. The client uses the service ticket to connect to the delegate server and requests mutual authentication.

6. The client authenticates the delegate server.

   If the authenticator passes the test, the service looks for a mutual authentication flag in the client's request. If the flag is set, the service uses the session key to encrypt the time from the user's authenticator and returns the result in a Kerberos application reply (KRB_AP_REP). If no mutual authentication flag is set, then no response is needed.

   Up to this point, the messages are the same as a normal client-server authentication.

7. After the user is authenticated and authorized, the client sends the delegate server its TGT and a session key to be used in messages to the TGS. The KRB_CRED message is used to deliver the TGT and session key.

The delegate server now has the user's TGT and the correct session key for the user/TGS session; so Delegate can now request tickets to other resources in the user's name.

The delegate server requests and receives a service ticket for Server from the KDC. In the request, the delegate server sends the user's TGT and an authenticator encrypted with the user/TGS session key.

8. The delegate server sends the service ticket to Server. The ticket contains the user's credentials. The accompanying authenticator is encrypted with the TGS-supplied Delegate/Server session key.

   Server receives the authentication request and authenticates Delegate—that is, authenticates the user the delegate server is impersonating. Server will then build an access token based on the user's identity.

9. If the authenticator passes the test, the service looks for a mutual authentication flag in the delegate's request. If the flag is set, the service uses the session key to encrypt the time from the user's authenticator and returns the result in a Kerberos application reply (KRB_AP_REP). If no mutual authentication flag is set, then no response is needed.

**User-to-User Authentication**

The Kerberos authentication protocol supports authentication between clients, as specified in RFC 1510, when a client is running as a service that another client needs to access. In versions of Windows earlier than Windows 2000, NTLM is the only protocol that supports this type of user-to-user authentication.

It is often the case that a computer or service running in one of the new security contexts provided by Windows Server 2003 must run in a different security context to authenticate to a remote computer. For example, a local service running in the current user context would authenticate to a remote system as an Anonymous user.

User-to-user is the most complex Kerberos authentication. The following figure illustrates some typical user-to-user situations.

**Typical User-to-User Situation**

A typical situation requiring user-to-user authentication is illustrated above.

1. A user logs on and starts an application called Service A and forwards this application its identity. Service A can now access network resources on the user's behalf.

2. Then Service A, acting as the user, now starts another application called Service B. Service B shares Service A's identity of the user.

Three network entities now share the user's identity: the client, Service A, and Service B. Service B is unique, however, in that it is the only one of the three that did not have to log on.

When Service A started Service B, it did so with the user's existing identity. Service B will be associated with the user in Active Directory services, but Service B does not have information about the user's password or user key. Service B already has a copy of the user's TGT and the client/TGS session key, so it never needs to have information about the user's password.

**Why is this a problem?**
How will the user be able to authenticate with Service B? In normal authentication, the user would send Service B a ticket supplied by the TGS and an authenticator encrypted with the User/Service B session key. Service B should decrypt the ticket, get the session key, and decrypt the authenticator.

The problem is that Service B cannot decrypt the ticket because it does not have a copy of the user key. The solution to the problem is user-to-user authentication.

**The User-to-User Authentication Process**

As illustrated above, the user-to-user authentication process follows this sequence:

1. The user requests a ticket for Service B. The TGS checks with Active Directory to find the user account associated with Service B. Because Service B is impersonating, that account would be the user. Thus, the TGS checks the user object, gets the user key, and uses it to encrypt the service ticket.

2. The user sends the service ticket to Service B.

3. Even though Service B has the user's credentials, it does not have information about the user's password, cannot calculate the secret key, and thus cannot decrypt the ticket. The result is that the user cannot authenticate with Service B and so cannot use the application.

   Service B responds to the KRB_AP_REQ message with an error. With the error, Service B sends the user its TGT (which is the user's TGT in this case), along with a request for a new ticket encrypted with the session key from Service B's TGT rather than Service B's secret key.

4. The user requests a new ticket for Service B from the TGS. In the request message, the user sends its TGT, Service B's TGT in the Additional Tickets field, and the ENC-TKT-IN-SKEY flag, which is an optional request to encrypt the ticket with the additional ticket's session key.

   The TGS associates the additional ticket with Service B, because that is the target server in the ticket request. The KDC looks up Service B, finds that it is associated with the user object, gets the user key, and decrypts Service B's TGT. The TGS

gets the session key from Service B's TGT, creates a new ticket for the user to use, and encrypts it with the session key.

5. The user sends the new KRB_AP_REQ to Service B and authentication proceeds normally.

**What happens when another user tries to connect to Service B?**
The situation is not very different. Service B is using user 1's identity but does not have information about user 1's password, so it cannot decrypt a presented service ticket.

When user 2 asks the KDC for a service ticket to Service B, the KDC will send user 2 a service ticket that will be encrypted with user 1's secret key, because Service B is impersonating user 1.

When user 2 presents the ticket to Service B, Service B will respond with the same error message as when user 1 originally tried to connect. The error message will contain Service B's TGT (that is, user 1's TGT) and request a new service ticket encrypted with its session key.

Thus, it does not matter who tries to connect to Service B. The service ticket is encrypted with user 1's key regardless of the requester's identity. Because Service B never has information about user 1's password, it never has the user key and cannot decrypt the ticket.

### Note

- User-to-user tickets are not cached.

**Kerberos Protocol Transition**
Kerberos protocol transition allows a kerberized service (that is, a service designed to use Kerberos authentication features) to obtain a service ticket to itself on behalf of a Kerberos principal because no user credential is required for the transition to happen.

Kerberos protocol transition is enabled programmatically through the Win32 API LsaLogonUser(). A new logon message type (KerbS4ULogon) and a new logon information structure (KERB_S4U_LOGON) have been defined to be passed into the LsaLogonUser() call. A successful call into LsaLogonUser() will return a Windows access token. For more information about LsaLogonUser(), see "LSA Authentication" in the Microsoft Platform SDK on MSDN.

Two variants of an access token can be returned depending on whether the caller process possesses the user right, Act as part of the operating system:

- Without Act as part of the operating system, a security impersonation level of SecurityIdentification is returned.

- With Act as part of the operating system, a security impersonation level of SecurityImpersonation is returned.

An identification token allows the process to determine the identity and privileges associated with a user whereas an impersonation token also allows the process to take on the token user's identity and operate under that user's identity. With an impersonation level token, the caller process can use the service ticket obtained through protocol transition to obtain service tickets to other kerberized services if the service account has been configured correctly to use the constrained delegation extension.

The programmatic mechanism described above is the way that applications can be enabled to take advantage of protocol transition. In addition, the applications should also be configured to run as kerberized services.

**Kerberos Constrained Delegation**
In the Windows 2000 delegation model, the KDC does not limit the scope of services that a Kerberos principal's identity can be delegated to. That is, after a service account is trusted for delegation, it can request service tickets on behalf of a given user to any other service accounts. This unrestricted way of performing delegation does not provide for an application to specify a subset of service accounts that it deems trustworthy to delegate to. Thus, applications can be exposed to broader impersonation risks.

Impersonation might span across resource domains that have differing levels of security policy requirements, and some of those security policies might be weaker than the application's security requirements. From the domain administrator's point of view, it is risky to enable unconstrained Kerberos delegation in the enterprise, because there is no way to exclude untrusted servers from participating in delegation.

With constrained delegation, on the other hand, domain administrators can configure service accounts to only delegate to specific sets of service accounts. In Windows Server 2003, the **ms-DS-Allowed-To-Delegate-To** attribute is added to service

accounts to help enforce constrained delegation. The **ms-DS-Allowed-To-Delegate-To** attribute lists the service principal names (SPNs) of other service accounts that a given service account is allowed to delegate to. When a Windows Server 2003 KDC processes a service ticket request via the constrained delegation extension, it will verify that the target service account is one that is listed in the **ms-DS-Allowed-To-Delegate-To** attribute.

Thus, with the addition of the constrained delegation extension, Windows Server 2003 supports two modes of delegation:

**Unconstrained delegation**
Legacy mode of delegation is still supported only if the user has initially entered a user credential to obtain a TGT. This is not any different from the Windows 2000 implementation.

**Constrained delegation**
Can be enabled for a Kerberos principal when the principal has a TGT that is acquired through the normal process of authenticating to the KDC when:

- A user has initially entered a user credential to obtain a TGT.
- Another service account has obtained a service ticket on behalf of the principal through the protocol transition extension.

Constrained delegation is the only delegation mode supported with protocol transition and only works in the boundary of a domain.

You can configure a service account to use protocol transition in conjunction with constrained delegation by choosing **Trust this user for delegation to specified services only** and **Use any authentication protocol** on the **Delegation** tab of the account. If these options are selected for a service account, the account can use the protocol transition extension to obtain a service ticket enables it to obtain service tickets to a pre-configured subset of kerberized services. An additional requirement is that the impersonated user account must not be marked as **Account is sensitive and cannot be delegated** on the **Account** tab.

The following sections detail the contents of individual messages in each of the three Kerberos exchanges.

**Authentication Service Exchange Message Details**

### Authentication Service Exchange

**Message 1: The Authentication Service Request**
The initial message sent to the AS requesting a TGT is the KRB_AS_REQ message. This message and its corresponding response contain the most detail. Subsequent messages have less because they contain similar fields and data.

**KRB_AS_REQ message contents**
Although the same message structure is used for the initial KRB_AS_REQ message and for the KRB_TGS_REQ message (in which the client asks for a ticket for a target server), some of the fields are not be used for the KRB_AS_REQ message.

### Authentication Service Request Message Fields

| Field | Description |
|---|---|
| Protocol Version | 5 |
| Message Type | KRB_AS_REQ |

| | |
|---|---|
| **Pre-authentication Data** | The intent of these fields is to provide pre-authentication before the KDC sends the client a ticket. This is to prevent brute force or dictionary attacks on the user's password. Note that these fields are used in the KRB_TGS_REQ message for the TGT and the authenticator. |
| PAData Type | PA-AS-REQ or PA-PK-AS-REQ. |
| PAData Value | The AS_REQ includes a client timestamp encrypted with the user key. In this case, the data type will be PA-AS-REQ.<br><br>If a Smart Card is used, the user's public certificate signed with the user's private key will be placed in this field. The data type will be PA-PK-AS-REQ in this case. |
| **Request Body** | |
| KDC Options | The client can request that the TGT have certain optional features. The KDC options are detailed in the table below. |
| Client Name | Name of the requester. |
| Realm | Realm (Active Directory domain) of the requester. |
| Server Name | In the KRB_AS_REQ, this will be the KDC name. The client is specifically requesting a ticket for the TGS. |
| From | (Optional) If the ticket were postdated (not supported by Windows 2000, but is supported in Windows Server 2003), this field would specify the time from which the ticket would be valid. |
| Till | This is the requested expiration time. The KDC does not have to honor this request if the requested expiration time violates the domain's Kerberos policy. |
| Renew Time | (Optional) The requested renewal time. |
| Nonce | A random number generated by the client. The nonce can be used as the basis for sequence numbering or as an additional authenticator. The nonce supplied here will be returned in the encrypted portion of the KRB_AS_REP message. The client will compare the nonces to make sure they match. |
| Encryption Type | The desired encryption algorithm to be used. |
| Addresses | IP addresses from which ticket will be valid. |
| Encrypt Authorization Data | Not used for KRB_AS_REQ. |
| Additional Tickets | Not used for KRB_AS_REQ. |

The Encrypt Authorization Data field is not likely to be used in Microsoft implementations because the user key—or a private key if sending a certificate after logging on with a smart card—is used to encrypt a timestamp. The Additional Tickets field is only used in Kerberos authentication in some special cases, such as user-to-user authentication for distributed applications.

**KDC option flags for the KRB_AS_REQ and KRB_TGS_REQ messages**

These flags are very similar to the ticket flags discussed earlier (see the Ticket Flags table in the Kerberos Tickets topic), because you use KDC options to define the requested ticket flags. Many of these options are used in both the KRB_AS_REQ and KRB_TGS_REQ messages. Some are used only in the KRB_TGS_REQ message.

**Key Distribution Center Option Flags**

| Flag Bit | Flag Value | Flag Meaning |
|---|---|---|
| 1 | FORWARDABLE | Ticket can be forwarded. Allowed addresses are specified in the message's Addresses field. |
| 2 | FORWARDED | Ticket is a forwarded ticket. |

| | | |
|---|---|---|
| 3 | PROXIABLE | Ticket can be proxied. |
| 4 | PROXY | Ticket is a proxy ticket. |
| 5 | ALLOW POSTDATE | Ticket can be post-dated. When the service wanted the ticket to be activated, it would send a TGS request with the VALIDATE flag set (below). Not supported in Windows 2000, but supported in Windows Server 2003. |
| 6 | POST-DATED | Ticket is post-dated. Not supported in Windows 2000, but supported in Windows Server 2003. |
| 8 | RENEWABLE | Ticket can be renewed. |
| 15 | NAME_CANONICALIZE | Indicates to the KDC that the client is prepared to receive a reply with a different client or server principal name than was sent in the request. This flag is used in referrals. It also alerts the KDC that the target server might be in another realm.<br><br>The KDC option flag NAME_CANONICALIZE is important for cross-realm authentication. |
| 27 | RENEWABLE OK | This flag means that it is okay to issue a renewable ticket if a ticket with the requested expiration time cannot be provided. However, it does not mean that the ticket requested should be renewable. That flag is set by flag bit 8. |
| 28 | ENC-TKT-IN-SKEY | Encrypt ticket in session key. Normally, tickets are encrypted with the target server key. However, in user-to-user authentication, the ticket is encrypted with the session key taken from a provided TGT. This flag is used in that situation. |
| 30 | RENEW | This is not used for the KRB_AS_REQ message. If a ticket is flagged RENEWABLE and needs to be renewed, this flag would be set and the ticket needing renewal would be included with the KRB_TGS_REQ message. |
| 31 | VALIDATE | Only used with postdated tickets. Not supported in Windows 2000, but supported in Windows Server 2003. |

**Message 2: The Authentication Service Response**

The KRB_AS_REP message returns the TGT and a session key to the client.

The TGT is encrypted with the TGS's secret key, so only the TGS can decrypt it. This is important because the TGT contains the SIDs associated with the user and will be used to create the user's access token. This sensitive information needs to be protected from tampering.

The message also contains the short-lived session key that the client will use to encrypt data to the TGS or decrypt data from the TGS.

The session key is actually included in the message twice, as is true of much of the message's data. The client needs the session key, so it is included and encrypted in the user's secret key. The user will then be able to decrypt and use the session key. Another copy of the session key is included within the service ticket for the TGS (the TGT).

When the client has a valid TGT and a session key for the TGS, the client can request additional tickets for the local workstation or for network servers or services.

**KRB_AS_REP message contents**

This data structure is used for both the KRB_AS_REP message and the KRB_TGS_REP message. Thus, the field contents might change depending on the message type.

### Authentication Server Reply Message Fields

| Field | Description |
|---|---|
| Protocol Version | 5 |
| Message Type | KRB_AS_REP |

| | |
|---|---|
| Pre-authentication data | For the KRB_AS_REP message, this field will normally be empty.<br><br>One exception is if the client logged on with a smart card. In this case, because the user did not enter a name and password, the LSA does not have the user's password. So, the user's NTLM password and credentials are passed back to the LSA in this field (hashed and encrypted with the user's key). |
| Client Realm | Realm or domain of the requester. |
| Client Name | Name of the requester. |
| Ticket | The encrypted ticket is placed here. For the KRB_AS_REP message, this will be the TGT encrypted with the TGS's secret key.<br><br>Every domain controller will be a KDC and therefore will run the AS and TGS services. The client can connect to any TGS in the domain to request service tickets. Because the TGT is encrypted with the TGS's secret key, and because every TGS in the domain will need to be able to decrypt the TGT, every TGS's secret key must be identical. Thus, every domain controller will have a user account called krbtgt. This is the service account for the KDC, and its password (randomly selected and periodically changed) is used to create the TGS's secret key. |
| | The rest of the message fields are encrypted with the user's key.<br><br>The client cannot read the encrypted ticket and might need to verify the ticket information. Furthermore, the client needs to have information about start times and end times so it can determine when to request renewal or replacement tickets. Therefore, the seven fields from Authentication Time to Client Addresses are all included in the ticket and copied here into these fields. |
| Key | This is the session key the user will use to encrypt and decrypt TGS messages. |
| Last Requested | The last time a ticket was requested. This is similar to a "last logged on" time. This can be used to track how frequently a client is requesting tickets. A Kerberos policy can be set that limits how frequently ticket requests can be made. Such limits can help prevent brute force attacks. |
| Nonce | The nonce from the KRB_AS_REQ nonce field will be copied here. |
| Key Expiration | When the user's key will expire. This is used for password aging. |
| Flags | These are the flags set in the ticket, based on the flags requested in the KRB_AS_REQ message and the domain's Kerberos policy. |
| Authentication Time | The time the ticket was issued. |
| Start Time | (Optional) At what time the ticket is valid. |
| End Time | At what time the ticket expires (although it can be renewed if the ticket is renewable). |
| Renew Till | (Optional) At what time the ticket absolutely expires (cannot be renewed past this time). |
| Server Realm | Requested server's realm (domain). |
| Server Name | Requested server's name |

| | |
|---|---|
| Client Addresses | (Optional) Addresses from which the ticket will be valid. This is important in several situations. Normally, a ticket is only valid if sent from a specific address.<br><br>In Windows 2000, the KDC did not propagate the addresses to the ticket. Because of this, two new registry keys that affect Client Addresses were created for Windows Server 2003:<br><br>• **KdcUseClientAddresses**. Not created by default, this setting will configure the KDC to propagate client addresses to tickets.<br><br>• **KdcDontCheckAddresses.** Not created by default, this setting will configure the KDC to skip checking client addresses. This feature might be used in network address translation (NAT) scenarios.<br><br>If the client computer is multi-homed, the ticket needs to be valid from every IP-enabled adapter, so the addresses are added here (and in the address field in the ticket).<br><br>If a ticket is proxied or forwarded, it will be used on the client's behalf from another address (or perhaps several addresses). These addresses will also be included in this field. |

**Ticket-Granting Service Exchange Message Details**

### Ticket-Granting Service Exchange

**Message 3: The Ticket-Granting Service Request**

After the client has received a TGT, the client can begin requesting service tickets for local or network resources.

The primary contents of the KRB_TGS_REQ message are the TGT, the name of the target server for which a service ticket is requested, and the authenticator.

**KRB_TGS_REQ message contents**

As noted earlier in this section, the KRB_TGS_REQ message uses the same structure as the KRB_AS_REQ message, so many of the fields are used identically. The most important differences are the pre-authentication fields (PAData Type and PAData Value). The TGT and the authenticator are placed in the PAData Value field.

- The authenticator is encrypted with the session key.
- The TGT is encrypted with the TGS's secret key (the key based on the krbtgt user account).

The same message structure is used for the initial KRB_AS_REQ message and for the KRB_TGS_REQ message. However, some fields used in the KRB_TGS_REQ message were not used in the KRB_AS_REQ message. The following table lists and describes the fields used in the ticket-granting service request message.

### Ticket-Granting Service Request Message Fields

| Field | Description |
|---|---|
| Protocol Version | 5 |
| Message Type | KRB_TGS_REQ |

| | |
|---|---|
| **Pre-authentication Data** | The intent of these fields is to provide some authentication before the KDC sends the client a ticket. This is to prevent brute force or dictionary attacks on the user password. Note that this field is used in the KRB_TGS_REQ message for the TGT and the authenticator. |
| PAData Type | PA-TGS-REQ |
| PAData Value | TGT and authenticator. |
| **Request Body** | |
| KDC Options | The client can request that the ticket have certain optional features. The requested options take the form of a bit string. (See the Key Distribution Center Option Flags table above.) |
| Client Name | (Optional) Name of the requester. |
| Realm | Realm or domain of the requester. |
| Server Name | (Optional) Requested server name. |
| From | (Optional) If the ticket were postdated (not supported by Windows 2000, but supported in Windows Server 2003), this field would specify the time from which the ticket would be valid. |
| Till | This is the requested expiration time. The KDC does not have to honor this request, if the requested expiration time violates the domain's Kerberos policy. |
| Renew Time | (Optional) The requested renewal time. |
| Nonce | A random number generated by the client. The nonce can be used as the basis for sequence numbering or as an additional authenticator. The nonce supplied here will be returned in the encrypted portion of the KRB_TGS_REP message. The client will compare the nonces to make sure they match. |
| Encryption Type | The desired encryption algorithm to be used. |
| Addresses | (Optional) IP addresses from which ticket will be valid. |
| Encrypt Authorization Data | (Optional) In the KRB_TGS_REQ message, this will specify a key to use to encrypt any pre-authentication data. |
| Additional Tickets | (Optional) In a KRB_TGS_REQ for user-to-user authentication, a TGT will be included in this field. The TGS will use the session key from this TGT — instead of the service's secret key — to encrypt the service ticket. |

The TGS decrypts the ticket with the server key, then retrieves the session key from the ticket and uses it to decrypt the authenticator.

Only the TGT and the authenticator are encrypted in this message. A checksum is computed using the contents of fields in the request body, and that checksum is encrypted within the authenticator.

**Message 4: The Ticket-Granting Service Response**

The TGS response includes the ticket from the requested target server and a session key for the client and the target server with which to encrypt and decrypt their session messages.

The ticket is encrypted with the target server's secret key, so the client cannot decrypt and modify the ticket.

The message containing the session key for use with the target server is encrypted with the session key being used by the client and the TGS. The client can decrypt the new session key and use it to encrypt the authenticator that it will send to the target server along with the new ticket.

**KRB_TGS_REP message contents**

As noted earlier in this section, the KRB_TGS_REP and KRB_AS_REP messages are identically structured and the fields are similarly used. The major difference is that the ticket in the Ticket field is not a TGT. Instead, it is the service ticket for the target server.

### Ticket-Granting Server Reply Message Fields

| Field | Description |
|---|---|
| Protocol Version | 5 |
| Message Type | KRB_TGS_REP |
| Pre-authentication Data | In a KRB_TGS_REP message, application-specific data might be placed here. |
| Client Realm | Realm or domain of the requester. |
| Client Name | Name of the requester |
| Ticket | The encrypted ticket is placed here. For the KRB_TGS_REP message, this will be the service ticket encrypted with the target server's secret key. |
| | The message fields below are encrypted with the TGS session key. |
| Key | This is the session key the user will use with the application server. |
| Last Requested | The last time a ticket was requested. This is similar to a "last logged on" time. This can be used to track how frequently a client is requesting tickets. A Kerberos policy can be set that limits how frequently ticket requests can be made. Such limits can help prevent brute force attacks. |
| Nonce | The nonce from the KRB_TGS_REQ nonce field will be copied here. |
| Key Expiration | (Optional) When the user's key will expire. This is used for password aging. |
| Flags | These are the flags set in the ticket, based on the flags requested in the KRB_TGS_REQ message and on the domain's Kerberos policy. |
| Authentication Time | The time the ticket was issued. |
| Start Time | (Optional) At what time the ticket is valid. |
| End Time | At what time the ticket expires (although it can be renewed if the ticket is renewable). |
| Renew Till | (Optional) At what time the ticket absolutely expires (cannot be renewed past this time). |
| Server Realm | Requested server's realm (domain). |
| Server Name | Requested server's name. |
| Client Addresses | (Optional) Addresses from which the ticket will be valid. If a ticket is proxied or forwarded, it will be used on the client's behalf from another address (or perhaps several addresses). These addresses will also be included in this field. |

**Client/Server Authentication Exchange Message Details**

**Client/Server Authentication Exchange**

**Message 5: The Application Server Request**
After the client has requested and received a TGT from the AS, and has requested and received a service ticket from the TGS, the client is ready to send the ticket to the target server.

The KRB_AP_REQ message contains an authenticator encrypted with the session key that the client and target server share, the service ticket encrypted with the target server's secret key, and the optional mutual authentication request. The mutual authentication response, which takes the form of a KRB_AP_REP message, is only necessary if the client requires verification that the target server is truly the recipient of the KRB_AP_REQ and subsequent messages.

### Note

- If the target service requires user-to-user authentication, the initial service ticket will be rejected along with a copy of the target service's TGT. The client will then make a new KRB_TGS_REQ message containing the target service's TGT and requesting a new service ticket that is encrypted with the session key contained in the target service's TGT, instead of with the target service's secret key.

**KRB_AP_REQ Message Contents**
### Application Server Request Message Fields

| Field | Description |
|---|---|
| Protocol Version | 5 |
| Message Type | KRB_AP_REQ |
| **Application Options Fields** | |
| Use Session Key | During user-to-user authentication, after the client has obtained a new ticket for the target service, the client will send a new KRB_AP_REQ with this flag set. This tells the target service to use its session key to decrypt the ticket. (See the User-To-User Authentication section above.) |
| Mutual Authentication Required | If this flag is set, the target server will respond with the KRB_AP_REP message, which will authenticate the target server to the client. |
| **Other Message Fields** | |
| Ticket | The service ticket for the target server, encrypted in either the target server's secret key or in its session key, depending on whether user-to-user authentication is required. |
| Authenticator | The client's timestamp and other data, encrypted with the session key that the client and target server share. |

**Message 6: The Optional Application Server Response**
This message is optional unless mutual authentication is required. The message is used if the client needs to verify the target server's identity. This is requested in an application options field (Mutual Authentication Required) of the KRB_AP_REQ message. If this is requested, the target server will take the client computer's timestamp from the authenticator, encrypt it with the session key that the TGS provided for client/target server messages, and send it to the client.

### Note

- Most Windows services request mutual authentication.

How do the contents of the KRB_AP_REQ message prove to the client that the target server was the actual recipient of the client's authentication request? The authenticator is encrypted with the client/server session key. The session key is inside the service ticket. The service ticket is encrypted with the secret key shared by the server and the TGS. Thus, the only way the server can get access to the client's timestamp in the authenticator is to have information about the shared secret key, and the server would only have information about the secret key if it truly was the server and not an imposter.

To summarize, the steps in the mutual authentication process are:

1. The server receives the service ticket and the authenticator in KRB_AS_REQ.
2. The server uses its secret key to decrypt the ticket.
3. The server retrieves the session key from the ticket.
4. The server decrypts the authenticator with the session key.
5. The server retrieves the client's timestamp from the authenticator.
6. The server creates the mutual authentication message, includes the client's timestamp, encrypts the message with the session key, and sends KRB_AS_REP to the client.
7. The client decrypts this message with the session key, and thus the server is authenticated.

**KRB_AP_REP message contents**

The mutual authentication message is sent to authenticate the target server to the client.

The main information is simply a copy of the client's timestamp from the authenticator—that was previously included in the KRB_AP_REQ message—encrypted with the session key that the client and the target server share.

The application might require a new key for encrypting subsequent messages, replacing the session key, in which case the new key would need to be given to the server.

### Application Server Reply Message Fields

| Field | Description |
|---|---|
| Protocol Version | 5 |
| Message Type | KRB_AP_REP |
| | The following message fields are encrypted with the session key |
| Client Time | Current time on Client (from the authenticator). |
| CUSEC | Millisecond part of client time (from the authenticator). |
| Subkey | (Optional) Specifies a key to encrypt client sessions with application server. |
| Sequence Number | (Optional) Application-specific, so used if sequence number was specified in the authenticator. |

**Credentials Message Details**

### Credentials Message

The Kerberos credentials message is used to transport a user's ticket and session key securely to the service impersonating it. The ticket—because it is already encrypted—can simply be sent, but the session key will need to be encrypted.

**KRB_CRED encryption**

- The user's service ticket for Server is encrypted with Server's key (the key that Server shares with the KDC).
- The user's session key for Server is encrypted with the session key that the client and Delegate share. Server needs to use the session key, so it needs to be able to decrypt it.

**KRB_CRED message contents**

### Credentials Message Fields

| Field | Description |
|---|---|
| Protocol Version | 5 |
| Message Type | KRB_CRED |
| Ticket | The encrypted ticket is placed here. For the KRB_TGS_REP message, this will be the service ticket encrypted with the target server's secret key. |
| | The following message fields are encrypted with the session key that the client and Delegate share. |
| Key | This is the session key the client will use with the application server. |
| Principal Realm | (Optional) Name of the delegated principal's realm (domain). |
| Principal Name | (Optional) Delegated principal's name. |
| Flags | (Optional) These are the flags set in the ticket. |
| Authentication Time | (Optional) The time the ticket was issued. |
| Start Time | (Optional) At what time the ticket is valid. |
| End Time | (Optional) At what time the ticket expires (although it can be renewed if the ticket is renewable). |
| Renew Till | (Optional) At what time the ticket absolutely expires (cannot be renewed past this time). |
| Server Realm | (Optional) Requested server's realm (domain). |
| Server Name | (Optional) Requested server's name. |
| Client Addresses | (Optional) Addresses from which the ticket will be valid. If a ticket is proxied or forwarded, it will be used on the client's behalf from another address (or perhaps several addresses). These addresses will also be included in this field. |
| Nonce | The nonce from the KRB_TGS_REQ Nonce field will be copied here. |
| Timestamp | Time when KRB_CRED was generated. |
| USEC | Millisecond part of timestamp. |
| Sender Address | (Optional) Addresses, application-specific. |
| Recipient Address | (Optional) Addresses, application-specific. |

To summarize, when proxying or forwarding, the credentials message contains three necessary items to impersonate the user. When proxying, the KRB_CRD message contains the:

- Proxy service ticket.

- User's session key with target server.
- Information that a normal user would have as the result of AS exchange.

When forwarding, the KRB_CRED message contains the:

- User's forwarded TGT.
- User's TGS session key.
- Information that a normal user would have as the result of TGS exchange.

With a valid ticket, session key, and other client information, the service is ready to impersonate the client, whether proxying or forwarding.

**Kerberos and IP Transport: UDP/TCP**
According to RFC 1510, when a client contacts the KDC, it should send a User Datagram Protocol (UDP) datagram to port 88 at the KDC's IP address. The KDC should respond with a reply datagram to the sending port at the sender's IP address.

UDP is a connectionless transport protocol, making it a logical choice where an exchange of messages must precede a connection. UDP is also well suited to applications with one message and one response, such as the exchanges between clients and the KDC, so long as each message fits into a single datagram. However, UDP works best when datagrams are transmitted as single units—when each datagram fits into one frame. The capacity of a frame varies with the medium. The Maximum Transmission Unit (MTU) for an Ethernet frame is 1500 octets. Thus, if the physical network is Ethernet, it follows that Kerberos messages sent as UDP datagrams can carry up to 1500 octets of data.

On the other hand, Windows authorization data can easily total more than 1500 octets. Because Windows authorization data is needed only by computers with the Windows operating system, Windows-specific data is omitted from tickets to computers with other operating systems. Messages containing tickets to computers with other operating systems are well within the limits of UDP transport, so that is how they are transmitted. Messages containing tickets for computers running Windows are likely to exceed the limit, so those messages are transmitted using the Transmission Control Protocol (TCP), which has much greater capacity.

This physical limit constitutes two different transport possibilities when computers with the Windows operating system send Kerberos messages on an Ethernet network.

- Messages below the 1465 maximum UDP payload are sent as normal UDP datagrams without incident.
- Messages that exceed the 1465 byte limit establish a TCP connection using port 88.

**Finding the KDC: DNS Name Resolution**
RFC 1510 specifies that IP transport should be used for messages between clients and the KDC. When the Kerberos SSP on a client computer wants to send an initial authentication service (AS) request, it needs to find an IP address for the KDC in the user account's domain.

To do that, the Windows client needs the Domain Name System (DNS) name of a server where the KDC service is running. If the DNS name can be resolved to an IP address, that is where the Kerberos SSP sends its message. Otherwise, the Kerberos SSP generates an error indicating that it can find no such domain.

**Why Do Windows Systems Use DNS?**

- The client computer needs the IP address of the KDC in the user account's domain.
- Windows systems use DNS to find IP addresses.
- Every Active Directory domain controller runs the KDC service. Domain controllers are advertised in DNS service locator records (SRV RR) as defined in RFC 2052.

Therefore, all that is needed to find a domain's KDC is to locate a domain controller's IP address by querying DNS for the SRV RR for domain controllers.

**How the Kerberos SSP locates a KDC**

1. If the Netlogon service is running, the Kerberos SSP asks Netlogon for the name of a domain controller (using the DsrGetDcName internal API).

2. If the domain controller's IP address is not found in the local cache, DNS is queried. The response will contain the DNS names of one or more domain controllers, along with their IP addresses.

   Clients that do not support the SRV record type in their DNS resolver can do a standard host record (A RR) lookup on *ActiveDirectorydomainname*. The response will contain the IP addresses of all domain controllers for the domain.

3. If the computer is a domain controller, the Kerberos client assumes that the KDC is running locally. If the KDC does not start or is not running, the Kerberos SSP finds another KDC in the domain.

4. After the client locates a domain controller, the KRB_AS_REQ message is sent to the KDC service on that domain controller.

**Retrying**
The Kerberos client retries up to three times to contact a KDC. It initially waits 10 seconds for a reply, and will wait an additional 10 seconds on each retry. After a failure, the Kerberos client forces discovery of another KDC.

### Note

- In Active Directory domains, the KDC service runs on every domain controller. In addition to being KDC servers, domain controllers are also Lightweight Directory Access Protocol (LDAP) servers. Both services are registered in DNS service locator records (SRV resource records). Clients can find a domain controller by querying DNS for SRV resource records with the name _ldap._tcp.dc._msdcs.*DnsDomainName*. The KDC service can be located by querying DNS for SRV resource records with the name _kerberos._udp.*DnsDomainName*. Clients that do not support the SRV record type in their DNS resolver can query for a host record (an A resource record) with the name of the domain.

**Locating MIT Kerberos KDCs**
Computers running Windows 2000, Windows XP, and Windows Server 2003 can participate in Kerberos realms that are based on the MIT Kerberos version 5 reference implementation.

If the specified logon realm is determined to be an MIT Kerberos realm, then the Kerberos SSP retrieves the list of MIT KDCs from the registry.

The servers in the list are cycled through on each new request for a KDC without any attempt to verify if the KDC is running on the server.

Computers running Windows Server 2003 can participate in Kerberos realms that are not Active Directory domains. In this case, the KDC will not be on an Active Directory domain controller, so the DNS names for KDC servers must be stored in the client computer's registry. The Kerberos SSP looks in the registry for the DNS domain name of the user's realm, and then resolves the name to an IP address by querying a DNS server.

Windows Server 2003 includes Kerberos Setup (ksetup.exe), which you can use to configure clients to participate in Kerberos realms that are not Active Directory domains. To find more information about Kerberos Setup, see "Security Management Tools" in the Windows Support Tools section of the Tools and Settings Collection.

**Network Ports Used by the Kerberos V5 Protocol**
### Network Ports Used During Kerberos Authentication

| Service Name | UDP | TCP |
|---|---|---|
| DNS | 53 | 53 |
| Kerberos | 88 | 88 |

# Kerberos Authentication Tools and Settings

Updated: June 26, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Kerberos Authentication Tools and Settings**

### In this section

- Kerberos Protocol Tools
- Kerberos Protocol Registry Settings
- Kerberos Authentication Group Policy Settings
- Network Ports Used by the Kerberos V5 Protocol

**Kerberos Protocol Tools**

The following tools are associated with administering and troubleshooting the Kerberos version 5 authentication protocol.

**Domain.msc: Active Directory Domains and Trusts**

**Category**

Active Directory Domains and Trusts is an MMC snap-in that is installed automatically on computers running Windows Server 2003 when you install Active Directory. You can also use this tool on non-domain controllers by installing the Windows Server 2003 Administration Tools pack. You can start Active Directory Domains and Trusts in the following way: Click **Start**, then click **Programs**,then click **Administrative Tools,** and then click **Active Directory Domains and Trusts.**

**Version compatibility**

This tool is compatible with domain controllers running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition. You can also use Active Directory Domains and Trusts with the Windows Server 2003 Administration Tools pack to remotely administer Active Directory from a computer that is not a domain controller, such as a computer running Windows XP Professional. You can use this tool to target any domain controller in either Windows 2000 Server or Windows Server 2003 domains.

### Note

- When using Windows Server 2003 Active Directory administrative tools to connect to a domain controller running Windows 2000, you must first be sure that the Windows 2000–based domain controller to which you are connecting has Service Pack 3 or later installed. This is because Windows Server 2003 administrative tools sign and encrypt all Lightweight Directory Access Protocol (LDAP) traffic by default.

Active Directory Domains and Trusts provides a graphical interface in which you can view all domains in the forest. Using this tool, an administrator can manage each of the domains in the forest, trust relationships between domains, configure the functional level for each domain or forest, and configure the alternative user principal name (UPN) suffixes for a forest.

Active Directory Domains and Trusts can be used to create, view, and modify most trust-related tasks. It can be used to target all Active Directory domain controllers and can verify all Active Directory trust types. Trust verification takes place between two domains by enumerating all of the domain controllers in each domain. If you choose to have Active Directory Domains and Trusts create both sides of the trust at once, the trust password is automatically generated.

You can find more information about Active Directory Domains and Trusts on Microsoft TechNet.

**Dsa.msc: Active Directory Users and Computers**

**Category**

Active Directory Users and Computers is a Microsoft Management Console (MMC) snap-in that is automatically installed when you install Active Directory. Dsa.msc is also included with the Administration Tools Pack (Adminpak.msi).

You can access the tool from the **Start** menu: Click **Start**, click **Programs**,click **Administrative Tools,** and then click **Active Directory Users and Computers**.

**Version compatibility**

Active Directory Users and Computers runs on domain controllers that are running Windows Server 2003 or Windows 2000.

In both of these server systems, MMC provides a window in the user interface where you can add, configure, and control items. Active Directory Users and Computers is the MMC tool that you can use to administer and publish information in the directory.

The Windows Server 2003 version of Active Directory Users and Computers can target domain controllers that are running Windows Server 2003 or Windows 2000.

On administrative workstations that are running Windows XP Professional or Windows 2000, you can install the Windows Server 2003 Administration Tools Pack (Adminpak.msi) from the i386 folder on the Windows Server 2003 CD. This version of the Administration Tools Pack encrypts and signs LDAP traffic between the administrative tool clients and domain controllers.

**Note**

- You cannot run the Windows Server 2003 Administration Tools Pack (Adminpak.msi) on a computer that is running Windows XP Professional, Windows XP Home Edition, or Windows XP 64-Bit Edition Version 2003 without Windows XP Service Pack 1 (SP1).

You can use Active Directory Users and Computers to manage the following properties associated with objects. Your managing the properties will affect Kerberos V5 authentication for these objects.

**Active Directory Users and Computers Object Management**

| **Property** | **Changes That Affect Kerberos V5 Authentication** |
|---|---|
| **Computer objects** | |
| Trust computer for delegation | The service can impersonate a user to use other network services. Allows services running as local system to request services from other services. |
| **Computer objects delegation tab options** | **(This tab will only appear in domains with Windows Server 2003 Functional Level.)** |
| Do not trust this computer for delegation | |
| Trust this computer for delegation to any service (Kerberos only) | Not recommended. This enables unconstrained delegation. |
| Trust this computer for delegation to specified services only | • Use Kerberos only: Enables constrained delegation without protocol transition.<br>• Use any authentication protocol: Enables constrained delegation with protocol transition |
| **User or service objects account tab options** | |
| Account is trusted for delegation | The account is enabled for delegation. This is a security-sensitive setting. Accounts with this option enabled should be tightly controlled. This setting enables a service that runs under the account to assume a client's identity and authenticate as that user to remote servers on the network. |
| Account is sensitive and cannot be delegated | When this flag is set, the security context of the user is not delegated to a service even if the service account is set as trusted for Kerberos delegation. |
| Use DES encryption types for this account | Restrict this principal to use only Data Encryption Standard (DES) encryption types for keys. If a user account is configured to use DES encryption, a Windows 2000, Windows XP, or Windows Server 2003–based client requests a ticket-granting ticket (TGT) by using the DES-CBC-MD5 encryption type. |

| | |
|---|---|
| Do not require Kerberos pre-authentication | Overrides the default setting that the KDC requires all accounts to use pre-authentication. The default setting makes offline password-guessing attacks very difficult. You can choose to override the default setting for individual accounts when necessary for compatibility with other implementations of the protocol. |
| **User or service objects delegation tab options** | **(This tab will only appear on accounts with registered SPNs in domains with Windows Server 2003 Functional Level.)** |
| Do not trust this user for delegation | |
| Trust this user for delegation to any service (Kerberos only) | Not recommended. This enables unconstrained delegation. |
| Trust this user for delegation to specified services only | • Use Kerberos only: Enables constrained delegation without protocol transition.<br>• Use any authentication protocol: Enables constrained delegation with protocol transition. |

You can find more information about Active Directory Users and Computers on Microsoft TechNet.

**Eventvwr.msc: Event Viewer**
**Category**
Event Viewer is included in Windows Server 2003, Windows XP, and Windows 2000.

**Version compatibility**
Event Viewer is supported for Windows Server 2003, Windows XP, and Windows 2000.

The system and security logs contain Kerberos error codes and other events related to authentication.

The following table lists event IDs and information that can be associated with Kerberos authentication. An event log contains only relevant event information. For example, only failure audits have Kerberos error codes; smartcard logons have certificate information.

**Security Log Events That Might Contain Kerberos Error Codes**

| Event ID | Account Logon Event Type | Event Information Potentially Associated with Kerberos Authentication |
|---|---|---|

| | | |
|---|---|---|
| 672 | • Success audit (Windows 2000 and Windows Server 2003)<br>• Failure audit (Windows Server 2003) | Authentication Ticket Request:<br>• User Name<br>• Supplied Realm Name<br>• User ID<br>• Service Name<br>• Service ID<br>• Ticket Options<br>• Result Code: *Kerberos error code*<br>• Ticket Encryption Type<br>• Pre-Authentication Type<br>• Client Address<br>• Certificate Issuer Name<br>• Certificate Serial Number<br>• Certificate Thumbprint |
| 673 | • Success audit (Windows 2000 and Windows Server 2003)<br>• Failure audit (Windows Server 2003) | Service Ticket Request:<br>• User Name<br>• User Domain<br>• Service Name<br>• Service ID<br>• Ticket Options<br>• Ticket Encryption Type<br>• Client Address<br>• Failure Code: *Kerberos Error Code*<br>• Logon GUID<br>• Transited Services |

| | | |
|---|---|---|
| 675 | • Failure audit | Pre-authentication Failed:<br>• User Name<br>• User ID<br>• Service Name<br>• Pre-authentication Type<br>• Failure Code: *Kerberos error code*<br>• Client Address |
| 676 | • Failure audit (Obsolete in Windows Server 2003; both success and failure audits use event ID 672.) | Authentication Ticket Request Failed:<br>• User Name<br>• Supplied Realm Name<br>• Service Name<br>• Ticket Options<br>• Failure Code: *Kerberos error code*<br>• Client Address |
| 677 | • Failure audit (Obsolete in Windows Server 2003; both success and failure audits use event ID 673.) | Service Ticket Request Failed:<br>• User Name<br>• User Domain<br>• Service Name<br>• Ticket Options<br>• Failure Code: *Kerberos error code*<br>• Client Address |

**Kerberos V5 Authentication Protocol Error Messages Generated by Windows Server 2003**

| Kerberos Error Number | Kerberos Error Code | Description |
|---|---|---|
| 0x3 | KDC_ERR_BAD_PVNO | Requested protocol version number not supported. |
| 0x6 | KDC_ERR_C_PRINCIPAL_UNKNOWN | Client not found in Kerberos database. |
| 0x7 | KDC_ERR_S_PRINCIPAL_UNKNOWN | Server not found in Kerberos database. |
| 0x8 | KDC_ERR_PRINCIPAL_NOT_UNIQUE | Multiple principal entries in database. |
| 0xA | KDC_ERR_CANNOT_POSTDATE | Ticket not eligible for postdating. |

| | | |
|---|---|---|
| 0xB | KDC_ERR_NEVER_VALID | Requested start time is later than end time. |
| 0xC | KDC_ERR_POLICY | KDC policy rejects request. |
| 0xD | KDC_ERR_BADOPTION | KDC cannot accommodate requested option. |
| 0xE | KDC_ERR_ETYPE_NOSUPP | KDC has no support for encryption type. |
| 0xF | KDC_ERR_SUMTYPE_NOSUPP | KDC has no support for checksum type. |
| 0x10 | KDC_ERR_PADATA_TYPE_NOSUPP | KDC has no support for pre-authentication data type. |
| 0x12 | KDC_ERR_CLIENT_REVOKED | Client's credentials have been revoked. |
| 0x17 | KDC_ERR_KEY_EXPIRED | Password has expired - change password to reset. |
| 0x18 | KDC_ERR_PREAUTH_FAILED | Pre-authentication information was invalid. |
| 0x19 | KDC_ERR_PREAUTH_REQUIRED | Additional pre-authentication required. |
| 0x1B | KDC_ERR_MUST_USE_USER2USER | Server principal valid for user-to-user only. |
| 0x1C | KDC_ERR_PATH_NOT_ACCPETED | KDC Policy rejects transited path. |
| 0x1D | KDC_ERR_SVC_UNAVAILABLE | A service is not available. |
| 0x1F | KRB_AP_ERR_BAD_INTEGRITY | Integrity check on decrypted field failed. |
| 0x20 | KRB_AP_ERR_TKT_EXPIRED | Ticket expired. |
| 0x21 | KRB_AP_ERR_TKT_NYV | Ticket not yet valid. |
| 0x22 | KRB_AP_ERR_REPEAT | Request is a replay. |
| 0x23 | KRB_AP_ERR_NOT_US | The ticket isn't for us. |
| 0x24 | KRB_AP_ERR_BADMATCH | Ticket and authenticator do not match. |
| 0x25 | KRB_AP_ERR_SKEW | Clock skew too great. |
| 0x28 | KRB_AP_ERR_MSG_TYPE | Invalid message type. |
| 0x29 | KRB_AP_ERR_MODIFIED | Message stream modified. |
| 0x34 | KRB_ERR_RESPONSE_TOO_BIG | Response too big for UDP, retry with TCP. |
| 0x3C | KRB_ERR_GENERIC | Generic error (description in e-text). |
| 0x44 | KDC_ERR_WRONG_REALM | User-to-user TGT issued different KDC. |

To find more information about "Event Viewer", see "Event Viewer" on Microsoft TechNet.

**Kerbtray.exe: Kerberos Tray**
**Category**
Kerberos Tray is included in the Windows Server 2003 Resource Kit and the Windows 2000 Resource Kit.

**Version compatibility**
Kerberos Tray is supported for Windows Server 2003, Windows XP, and Windows 2000.

Kerberos Tray is a graphical user interface tool that displays ticket information for a computer running Microsoft's implementation of the Kerberos version 5 authentication protocol.

You can view and purge the ticket cache by using the Kerberos Tray tool icon located in the notification area of the desktop. By positioning the cursor over the icon, you can view the time left until the initial ticket-granting ticket (TGT) expires. The icon also changes in the hour before the Local Security Authority (LSA) renews the ticket.

To find more information about Kerberos Tray, see "Windows Server 2003 Resource Kit Tools Help in the Tools and Settings Collection."

**Klist.exe: Kerberos List**
**Category**
Kerberos List is included in the Windows Server 2003 Resource Kit and the Windows 2000 Resource Kit.

**Version compatibility**
Kerberos List is supported for Windows Server 2003, Windows XP, and Windows 2000.

Kerberos List is a command-line tool that is used to view and delete Kerberos tickets granted to the current logon session. To use Kerberos List to view tickets, you must run the tool on a computer that is a member of a Kerberos realm.

When Kerberos List is run from a client, it shows the:

- Ticket-granting ticket (TGT) to a Kerberos Key Distribution Center (KDC) in Windows.
- Ticket-granting ticket (TGT) to Ksserver on UNIX.

**Parameters**
Kerberos List uses the following syntax:

```
klist [tickets | tgt | purge] [-?]
```

**Tickets**
Lists the current cached tickets of services to which you have authenticated since logging on. Displays the following attributes of all cached tickets:

| Option | Description |
|---|---|
| End Time | Time at which that the ticket becomes invalid. After a ticket is past this time, it cannot be used to authenticate to a service. |
| KerbTicket Encryption Type | Encryption type used to encrypt the Kerberos ticket. |
| Renew Time | Maximum lifetime of a renewable ticket (see TicketFlags in the table below). To continue using this ticket, you must renew it before reaching the established End Time and before the expiration date established in RenewUntil. |
| Server | Server and domain for the ticket. |

**tgt**
Lists the initial Kerberos ticket-granting ticket (TGT). Displays the following attributes of the currently cached ticket:

| Option | Description |
|---|---|
| AltTargetDomainName | Name supplied to InitializeSecurityContext that generated this ticket, typically a service principal name (SPN). |
| DomainName | Domain name of the service. |
| End Time | Time when the ticket becomes invalid. When a ticket is past the end time, it cannot be used to authenticate to a service. |
| FullServiceName | Canonical name of the account principal for the service. |
| KeyExpirationTime | Expiration time from the KDC reply. |
| RenewUntil Maximum lifetime of a renewable ticket (see TicketFlags) | To continue using a ticket, you must renew it. Tickets must be renewed before the expiration time set in End Time and in RenewUntil. |

| | |
|---|---|
| ServiceName | A TGT is a ticket for the Key Distribution Center (KDC) service. The service name for a TGT is "krbtgt." |
| Start time | Time when the ticket becomes valid. |
| TargetDomainName | For a cross-realm ticket, this is the realm, rather than the issuing realm, in which the ticket is good. |
| TargetName | Service name for which the ticket was requested. This is the name of a servicePrincipalName property on an account in the directory. |
| TicketFlags | Kerberos ticket flags set on the current ticket in hexadecimal. Kerberos Tray displays these flags on the Flags tab. |
| TimeSkew | The reported time difference between the client computer and the server computer for a ticket. |

**purge**
Will list each ticket and enables you to delete specific tickets. When you choose **Yes** to a ticket, then purge tickets destroys the ticket that you have cached, so use this with caution. It might stop you from being able to authenticate to resources. If this happens, you must log off and then log on again.

**-?**
Displays command-line help.

To find more information about Kerberos List, see "Windows Server 2003 Resource Kit Tools Help" in the Tools and Settings Collection.

**Ksetup.exe: Kerberos Setup**
**Category**
Kerberos Setup is included in the Windows Server 2003 Support Tools.

**Version compatibility**
Kerberos Setup is supported for Windows Server 2003.

Kerberos Setup is a command-line tool you can use to configure Windows for Kerberos V5 interoperability. Kerberos Setup configures a client connected to a server running Windows Server 2003 to use a server running the Kerberos V5 authentication protocol. After Kerberos Setup configures the client, the client then uses a Kerberos V5 realm instead of a Windows Server 2003 domain. This provides a single sign-on to the Key Distribution Center (KDC) and a local client account connected to a computer running Windows Server 2003.

Administrators can use Kerberos Setup to:

- Set up a realm entry for a Kerberos V5 realm.
- Set up a list of KDCs for the Kerberos V5 realm for which you set up a realm entry.
- Set up a kpasswd server for the Kerberos V5 realm for which you set up a realm entry.
- Set up local account to Kerberos V5 account mappings.
- Set the computer's password in the Kerberos realm.
- Change a user's password in a Kerberos V5 realm.

To find more information about Kerberos Setup, see "Support Tools Help" in the Tools and Settings Collection.

**Ktpass.exe: Kerberos Keytab Setup**
**Category**
Kerberos Keytab Setup is included in the Windows Server 2003 Support Tools.

**Version compatibility**
Kerberos Keytab Setup is supported for Windows Server 2003.

Kerberos Keytab Setup is a command-line tool that enables an administrator to configure a non-Windows Kerberos service as a security principal in the Windows Server 2003 Active Directory. Kerberos Keytab Setup configures the server principal name for the host or service in Active Directory and generates an MIT-style Kerberos keytab file containing the shared secret key of the service. The tool enables non-Windows brand operating system services that support Kerberos authentication to use the interoperability features provided by the Kerberos KDC service that runs on Windows Server 2003.

To find more information about Kerberos Keytab Setup, see "Support Tools Help" in the Tools and Settings Collection.

**Netdom.exe: Windows Domain Manager**
**Category**
Windows Domain Manager is included in Windows Server 2003, Windows 2000, and the Windows Server 2003 Administration Tools Pack (Adminpak.msi).

**Version compatibility**
Windows Domain Manager is supported for Windows Server 2003, Windows XP, and Windows 2000.

On administrative workstations that are running Windows XP Professional, you can install the Windows Server 2003 Administration Tools Pack (Adminpak.msi) from the i386 directory on the Windows Server 2003 CD. Please see the note in the Active Directory Users and Computers subsection above regarding the Administration Tools Pack.

The Windows Server 2003 version of Windows Domain Manager can target domain controllers that are running Windows Server 2003 or Windows 2000.

This tool enables you to manage Active Directory domains and trust relationships from the command line.

Functions of Windows Domain Manager that relate to Kerberos authentication include:

- Establishing one-way or two-way trust relationships between domains, such as:
    - From an Active Directory domain to an Active Directory domain in another enterprise (also know as an uplevel external trust).
    - Between two Active Directory domains in an enterprise (a shortcut trust).
    - The Windows Server 2003 or Windows 2000 Server half of an interoperable Kerberos realm.
- Managing trust relationships between domains, including:
    - Enumerating direct and indirect trust relationships.
    - Viewing and changing some attributes on a trust — for example, transitivity to non-Windows Kerberos realms.

To find more information about Windows Domain Manager, see "Support Tools Help" in the Tools and Settings Collection.

**Netmon.exe: Network Monitor**
**Category**
A limited version of Network Monitor is included in Windows Server 2003, Windows XP, and Windows 2000. The full version of Network Monitor is included with Microsoft Systems Management Server.

**Version compatibility**
Network Monitor is supported for Windows Server 2003, Windows XP, and Windows 2000.

Network Monitor enables you to capture network traces which can be used in troubleshooting most network issues.

**Setspn.exe: Manipulate Service Principal Names for Accounts**
**Category**
Setspn is included in the Windows Server 2003 Support Tools.

**Version compatibility**
Setspn is supported for Windows Server 2003 and Windows XP Professional.

This command-line tool sets service principal names. SPNs are used to locate a target principal name for running a service. Because SPNs are security-sensitive, SPNs can only be set for user objects if you have domain administrator credentials.

It is not usually necessary to modify SPNs. They are set up by a computer when it joins a domain and when services are

installed on the computer. In some cases, however, this information can become stale. For example, if the computer name is changed, the SPNs for installed services would need to be changed to match the new computer name. Also, some services and applications might require manual modification of a service account's SPN information to correctly authenticate.

Domain administrators can use Setspn to:

- View the current SPNs.
- Reset the account's default SPNs.
- Add SPNs.
- Delete supplemental SPNs.

To find more information about Setspn, see "Support Tools Help" in the Tools and Settings Collection.

**Kerberos Protocol Registry Settings**
Registry settings in the following hives are associated with the Kerberos protocol:

- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Domains
- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\HostToRealm
- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos
- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters
- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\UserList
- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Eventlog\System
- HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, instead of editing the registry directly, use Group Policy or other Windows tools such as MMC to accomplish tasks. If you must edit the registry, use extreme caution.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Domains**
The Domains subkey stores information about non-Windows Kerberos realms.

To change the value of the entries in this subkey, use Kerberos Setup (Ksetup.exe), a tool included in Windows Server 2003 Support Tools. Do not use the registry editor.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\HostToRealm**
This subkey stores Host to Realm mapping information. The subkey does not exist in the registry by default.

**SpnMappings**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\HostToRealm

**Version**
Windows Server 2003 and Windows XP

This entry is used to create a HostToRealm mapping table.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters**
The Parameters subkey stores configuration options for the Kerberos V5 authentication protocol in Windows Server 2003.

**AllowTgtSessionKey**
**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry controls whether session keys are exported with initial or cross-realm TGTs. This entry does not exist in the registry by default. The default value is false due to security concerns.

**CacheS4UTickets**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003

This entry enables and disables Service-for-User (S4U) caching. This entry does not exist in the registry by default. The default value is true.

**ClientIpAddresses**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry controls adding IP addresses in KRB_AS_REQ, thus forcing the Caddr field to contain IP addresses in all tickets. This entry does not exist in the registry by default. The default value is false, due to potential DHCP client and network address translation (NAT) issues.

**DefaultEncryptionType**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry controls the default encryption type for PreAuth. This entry does not exist in the registry by default. The default value is KERB_ETYPE_RC4_HMAC_NT.

**FarKdcTimeout**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry controls the time-out interval, in minutes, that is used to invalidate a domain controller from a different site in the domain controller cache. This entry does not exist in the registry by default. The default value is 10 minutes.

**KdcBackoffTime**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry specifies a time value, in seconds, between successive calls to the Key Distribution Center (KDC) if the previous call failed. This entry does not exist in the registry by default. The default value is 5 seconds.

**KdcSendRetries**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry controls the number of retry attempts that a client makes in order to contact a KDC. This entry does not exist in the registry by default. The default value is 3.

**KdcWaitTime**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry specifies a time value, in seconds, that is used to time out the Winsock calls. This entry does not exist in the registry by default. The default value is 5 seconds.

**KerbDebugLevel**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry controls the verboseness level of debug log macros. This entry does not exist in the registry by default. The default value is 0, which is no logging; however, if you are using a checked build, the default value is 1, which is error logging.

### Common Debug Values

| Verboseness Level | Value |
|---|---|
| Error s | 0x00000001 |
| Warnings | 0x00000002 |
| Tracing | 0x00000004 |
| API tracing | 0x00000008 |
| Credential related tracing | 0x00000010 |
| Security Context tracing | 0x00000020 |
| Logon Session tracing | 0x00000040 |
| Logon tracing | 0x00000100 |
| KDC tracing | 0x00000200 |
| Detailed Security Context tracing | 0x00000400 |
| Time related tracing | 0x00000800 |
| User related tracing | 0x00001000 |
| Leak related tracing | 0x00002000 |
| WinSock related tracing | 0x00004000 |
| SPN cache tracing | 0x00008000 |
| S4U Errors | 0x00010000 |
| S4U tracing | 0x00020000 |
| Loopback tracing | 0x00080000 |
| Ticket renewal tracing | 0x00100000 |
| User to User tracing | 0x00200000 |
| Locks tracing | 0x01000000 |

**LogLevel**
**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

If this entry is set to anything non-zero, all Kerberos errors are logged in the system event log. This entry does not exist in the registry by default. The default value is 0.

**LogToFile**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry enables debug tracing and logging to a file. This entry does not exist in the registry by default. The default value is false.

**MaxPacketSize**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry controls the maximum size, in bytes, for using User Datagram Protocol (UDP). If the packet size is bigger than this value, TCP is used. This entry does not exist in the registry by default. The default value is 1465 bytes.

**MaxReferralCount**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry specifies the number of KDC referrals that a client pursues before the client gives up. This entry does not exist in the registry by default. The default value is 3.

**MaxTokenSize**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry specifies the maximum value, in bytes, of the Kerberos token size. Use this entry to allow query context attributes to be modified to return a value large enough for tickets containing large numbers of groups. It is recommended that this value remain less than 65,000. This entry does not exist in the registry by default. The default value is 12,000 bytes.

**NearKdcTimeout**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry specifies the time-out interval, in minutes, that is used to invalidate a domain controller in the same site in the domain controller cache. This entry does not exist in the registry by default. The default value is 30 minutes.

**RequestOptions**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003 and Windows XP

This entry indicates whether there are additional options that must be sent as KDC options in ticket-granting service (TGS) requests (KRB_TGS_REQ). This entry is meant to accommodate future modifications to the KDC options and can be any RFC 1510 value. This entry does not exist in the registry by default. The default value is 0x10000.

**RetryPDC**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003

This entry controls whether the primary domain controller (PDC) will be contacted for password-expiry errors for KRB_AS_REQ. This entry does not exist in the registry by default. The default value is false.

**S4UCacheTimeout**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003

This entry controls the lifetime, in minutes, of the S4U negative cache entries, which are used to restrict how many S4U proxy requests are made from a specific computer. This entry does not exist in the registry by default. The default value is 15 minutes.

**S4UTicketLifetime**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003

This entry controls the lifetime, in minutes, of tickets obtained by S4U proxy requests. This entry does not exist in the registry by default. The default value is 15 minutes.

**SkewTime**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003

This entry controls the maximum time difference, in minutes, that is permitted between server, client, and KDC. This entry does not exist in the registry by default. The default value is 5 minutes.

**SpnCacheTimeout**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003 and Windows XP

This entry specifies the lifetime, in minutes, of the service principal name (SPN) cache entries. This entry does not exist in the registry by default. The default value is 15 minutes.

**StartupTime**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003, Windows XP, and Windows 2000

This entry specifies the time, in seconds, that Windows waits for the KDC to start before Windows gives up. This entry does not exist in the registry by default. The default value is 120 seconds.

**TgtRenewalTime**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\Parameters

**Version**
Windows Server 2003

This entry controls the amount of time, in seconds, that a Kerberos client waits before it tries to renew a TGT before the ticket expires. Only applies to initial TGTs. This entry does not exist in the registry by default. The default value is 600 seconds.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\Kerberos\UserList**
The UserList subkey stores entries that associate a Kerberos security principal to a local Windows Server 2003 user account.

Computers that are running Windows Server 2003 can use another KDC — instead of a KDC in an Active Directory domain — to administer authentication. For ease of use, you can map a Kerberos security principal, such as the name of a principal or a realm, to a local Windows user account.

This subkey stores mappings that you enter when you use the **/MapUser** parameter with Kerberos Setup (Ksetup.exe), a tool that is included in Windows Server 2003 Support Tools. Ksetup.exe adds the entries to the registry.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Eventlog\System**
This subkey stores the event log configuration information.

**Kerberos**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Eventlog\System

**Version**
Windows Server 2003, Windows XP, and Windows 2000

The Kerberos subkey stores configuration information for Event Viewer about the log sources specified by the Kerberos protocol in the registry path. The configuration information tells Event Viewer where to find and how to display Kerberos authentication-related events. Event Viewer displays those events as part of the log specified by the system-log name in the registry path.

**Sources**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Eventlog\System

**Version**
Windows Server 2003, Windows XP, and Windows 2000

The Sources entry specifies that Kerberos writes events to this log.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc**
This subkey stores KDC configuration information.

**ExistingConnectionTimeout**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc

**Version**
Windows Server 2003 and Windows 2000

This entry controls the time-out, in seconds, for input/outputs (I/Os) on this context until the first byte of data is received. This entry does not exist in the registry by default. The default value is 60 seconds.

**KdcDebugLevel**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc

**Version**
Windows Server 2003

This entry controls the verboseness level of debug log macros. This entry does not exist in the registry by default. The default value is 0, which is no logging; however, if you are using a checked build, the default value is 1, which is error logging.

### Common Debug Values

| Verboseness Level | Value |
|---|---|
| Error s | 0x00000001 |
| Warnings | 0x00000002 |
| Tracing | 0x00000004 |
| API tracing | 0x00000008 |

| | |
|---|---|
| Credential related tracing | 0x00000010 |
| Security Context tracing | 0x00000020 |
| Logon Session tracing | 0x00000040 |
| Logon tracing | 0x00000100 |
| KDC tracing | 0x00000200 |
| Detailed Security Context tracing | 0x00000400 |
| Time related tracing | 0x00000800 |
| User related tracing | 0x00001000 |
| Leak related tracing | 0x00002000 |
| WinSock related tracing | 0x00004000 |
| SPN cache tracing | 0x00008000 |
| S4U Errors | 0x00010000 |
| S4U tracing | 0x00020000 |
| Loopback tracing | 0x00080000 |
| Ticket renewal tracing | 0x00100000 |
| User to User tracing | 0x00200000 |
| Locks tracing | 0x01000000 |
| Use Extended Errors | 0x10000000 |

**KdcDontCheckAddresses**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc

**Version**
Windows Server 2003

This entry controls whether the KDC checks if the client IP addresses match one of the IP addresses in the TGT Caddr field.

- If the entry does not exist or if DWORD = 0, client addresses are checked.
- If DWORD = 1, client addresses are not checked.

The client must send the IP address in the KRB_TGS_REQ, which is not done by default in Windows operating systems. To enable sending IP addresses as a Kerberos client, see “ClientIpAddresses” earlier in this guide. This entry does not exist in the registry by default. The default value is true due to potential DHCP and NAT issues.

**KdcExtraLogLevel**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc

**Version**
Windows Server 2003

This entry controls extra KDC logging in event logs and audits. This entry does not exist in the registry by default. The default value is 2.

### Extra KDC Log Levels

| Log Level | Value |
| --- | --- |
| Audit SPN unknown errors | 0x1 |
| Log detailed PKINIT1 errors | 0x2 |
| Log all KDC errors with KLIN information | 0x4 |

1 PKINIT is an Internet Engineering Task Force (IETF) Internet draft for "Public key Cryptography for Initial Authentication in Kerberos."

**KdcIssueForwardedTickets**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc

**Version**
Windows Server 2003

This entry controls whether the KDC issues forwarded tickets. This entry does not exist in the registry by default. The default value is true.

**KdcUseClientAddresses**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc

**Version**
Windows Server 2003

This entry controls whether the KDC accepts client IP addresses in the KRB_AS_REQ:

- If the entry does not exist or if DWORD = 0, client IP addresses are not accepted.
- If DWORD = 1, client IP addresses are accepted.

In order for the KDC to propagate the client IP addresses, the client must send them in the KRB_TGS_REQ, which does not occur by default in Windows operating systems. To enable sending IP addresses as a Kerberos client, see "ClientIpAddresses" earlier in this guide. This entry does not exist in the registry by default. The default value is false due to potential DHCP and NAT issues.

**KdcUseRequestedEtypesForTickets**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc

**Version**
Windows Server 2003

This entry controls whether the encryption type for the service ticket is:

- The first encryption type in the requested encryption types, if true.
- The strongest encryption type that the server supports, if false.

This entry does not exist in the registry by default. The default value is false.

**MaxDatagramReplySize**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Kdc

**Version**
Windows Server 2003

This entry controls the maximum size, in bytes, of a UDP packet for the KRB_TGS_REP and KRB_AS_REP, before the KDC returns a KRB_ERR_RESPONSE_TOO_BIG error, which requires the client to change to TCP. This entry does not exist in the registry by default. The default value is 1465 bytes.

**Kerberos Authentication Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with Kerberos V5 Authentication.

**Group Policy Settings Associated with Kerberos V5 Authentication**

| Group Policy Setting | Description |
|---|---|
| **User Rights Assignment:** | |
| Impersonate a client after authentication | Windows 2000 security setting that was first introduced in SP4 for Windows 2000. When you assign this user right to a user, you permit programs that run on behalf of that user to impersonate a client. This security setting helps to prevent unauthorized servers from impersonating clients that connect to it through methods such as remote procedure calls (RPC) or named pipes.<br><br>By default, members of the Administrators group and the System account are assigned this user right. The following components also are assigned this user right:<br><br>• Services that are started by the Service Control Manager<br><br>• Component Object Model (COM) servers that are started by the COM infrastructure and that are configured to run under a specific account |
| **Kerberos Policy:** | |
| Enforce user logon restrictions | Determines whether the KDC validates every request for a session ticket against the user rights policy on the target computer. When this policy is enabled, the user requesting the session ticket must have the right either to Log on locally or to Access this computer from network. Validation of each request is optional because the extra step takes time and might slow network access to services. By default, this policy is enabled. |
| Maximum lifetime for service ticket | Determines the maximum amount of time (in minutes) that a ticket granted for a service (that is, a session ticket) can be used to access the service. If the setting is zero minutes, the ticket never expires. Otherwise, the setting must be greater than ten minutes and less than the setting for Maximum lifetime for user ticket. By default, the setting is 600 minutes (10 hours). |
| Maximum lifetime for user ticket | Determines the maximum amount of time (in hours) that a user's TGT can be used. When a user's TGT expires, a new one must be requested or the existing one must be renewed. By default, the setting is ten hours. |
| Maximum lifetime for user ticket renewal | Determines the longest period of time (in days) that a TGT can be used if it is repeatedly renewed. By default, the setting is seven days. |
| Maximum tolerance for computer clock synchronization | Determines the maximum difference (in minutes) that Kerberos will tolerate between the time on a client's clock and the time on a server's clock while still considering the two clocks synchronous. By default, the setting is five minutes. |

For more information about these Group Policy settings, see "Account Policy Settings."

#### Network Ports Used by the Kerberos V5 Protocol

### Network Ports Used During Kerberos Authentication

| Service Name | UDP | TCP |
|---|---|---|
| DNS | 53 | 53 |
| Kerberos | 88 | 88 |

# TLS/SSL Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TLS/SSL Technical Reference**

How can you secure data that is being sent between applications across an untrusted network? The Transport Layer Security (TLS) protocol, Version 1, provides one answer to this common security question. TLS, along with the Secure Sockets Layer (SSL) protocol, Versions 2.0 and 3.0 authenticates and secures data transfers by using certificate-based authentication and symmetric encryption keys.

This section explains what TLS and SSL are, how TLS and SSL use the Security Support Provider Interface (SSPI) and Schannel SSP to secure the transfer of data, and which tools and settings are available for configuring TLS and SSL.

**In this section**

- What is TLS/SSL?
- How TLS/SSL Works
- TLS/SSL Tools and Settings

# What is TLS/SSL?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is TLS/SSL?**

### In this section

- Common TLS and SSL Scenarios
- Technologies Related to Schannel
- TLS and SSL Dependencies

One problem when you administer a network is securing data that is being sent between applications across an untrusted network. You can use TLS/SSL to authenticate servers and clients and then use it to encrypt messages between the authenticated parties.

The Transport Layer Security (TLS) protocol, Secure Sockets Layer (SSL) protocol, versions 2.0 and 3.0, and the Private Communications Transport (PCT) protocol are based on public key cryptography. The Security Channel (Schannel) authentication protocol suite provides these protocols. All Schannel protocols use a client/server model.

In the authentication process, a TLS/SSL client sends a message to a TLS/SSL server, and the server responds with the information that the server needs to authenticate itself. The client and server perform an additional exchange of session keys, and the authentication dialog ends. When authentication is completed, SSL-secured communication can begin between the server and the client using the symmetric encryption keys that are established during the authentication process.

For servers to authenticate to clients, TLS/SSL does not require server keys to be stored on domain controllers or in a database, such as the Microsoft Active Directory directory service. Clients confirm the validity of a server's credentials with a trusted root certification authority's (CA's) certificates, which are loaded when you install Microsoft Windows Server 2003. Therefore, unless user authentication is required by the server, users do not need to establish accounts before they create a secure connection with a server.

**History and Standards for TLS and SSL**

SSL was developed by Netscape Communications Corporation in 1994 to secure transactions over the World Wide Web. Soon after, the Internet Engineering Task Force (IETF) began work to develop a standard protocol that provided the same functionality. They used SSL 3.0 as the basis for that work, which became the TLS protocol. The implementation of the TLS protocol in Windows Server 2003 closely follows the specification defined in Request for Comments (RFC) 2246, The TLS Protocol Version 1.0. For more information about TLS, see RFC 2246 in the IETF RFC database.

TLS and SSL are most widely recognized as the protocols that provide secure HTTP (HTTPS) for Internet transactions between Web browsers and Web servers. TLS/SSL can also be used for other application level protocols, such as File Transfer Protocol (FTP), Lightweight Directory Access Protocol (LDAP), and Simple Mail Transfer Protocol (SMTP). TLS/SSL enables server authentication, client authentication, data encryption, and data integrity over networks such as the World Wide Web.

**Differences between TLS and SSL**

Although there are some slight differences between SSL 3.0 and TLS 1.0, this reference refers to the protocol as TLS/SSL.

### Note

- Although their differences are minor, TLS 1.0 and SSL 3.0 are not interchangeable. If the same protocol is not supported by both parties, the parties must negotiate a common protocol to communicate successfully.

**TLS Enhancements to SSL**

- The keyed-Hashing for Message Authentication Code (HMAC) algorithm replaces the SSL Message Authentication Code (MAC) algorithm.

  HMAC produces more secure hashes than the MAC algorithm. The HMAC produces an integrity check value as the MAC does, but with a hash function construction that makes the hash much harder to break. For more information about the HMAC, see "Hash Algorithms in The Handshake Layer in TLS/SSL Architecture" in How TLS/SSL Works.

- TLS is standardized in RFC 2246.
- Many new alert messages are added.
- In TLS, it is not always necessary to include certificates all the way back to the root CA. You can use an intermediary authority.
- TLS specifies padding block values that are used with block cipher algorithms. RC4, which is used by Microsoft, is a streaming cipher, so this modification is not relevant.
- Fortezza algorithms are not included in the TLS RFC, because they are not open for public review. (This is Internet Engineering Task Force (IETF) policy.)
- Minor differences exist in some message fields.

**Benefits of TLS/SSL**

TLS/SSL provides numerous benefits to clients and servers over other methods of authentication, including:

- Strong authentication, message privacy, and integrity
- Interoperability
- Algorithm flexibility
- Ease of deployment
- Ease of use

**Strong authentication, message privacy, and integrity**

TLS/SSL can help to secure transmitted data using encryption. TLS/SSL also authenticates servers and, optionally, authenticates clients to prove the identities of parties engaged in secure communication. It also provides data integrity through an integrity check value. In addition to protecting against data disclosure, the TLS/SSL security protocol can be used to help protect against masquerade attacks, man-in-the-middle or bucket brigade attacks, rollback attacks, and replay attacks.

**Interoperability**

TLS/SSL works with most Web browsers, including Microsoft Internet Explorer and Netscape Navigator, and on most operating systems and Web servers, including the Microsoft Windows operating system, UNIX, Novell, Apache (version 1.3 and later), Netscape Enterprise Server, and Sun Solaris. It is often integrated in news readers, LDAP servers, and a variety of other applications.

**Algorithm flexibility**

TLS/SSL provides options for the authentication mechanisms, encryption algorithms, and hashing algorithms that are used during the secure session.

### Note

- Data can be encrypted and decrypted, but you cannot reverse engineer a hash. Hashing is a one-way process. Running the process backward will not create the original data. This is why a new hash is computed and then compared to the sent hash.

**Ease of deployment**

Many applications use TLS/SSL transparently on a Windows Server 2003 operating system. You can use TLS for more secure browsing when you are using Internet Explorer and Internet Information Services (IIS) and, if the server already has a server certificate installed, you only have to select the check box.

**Ease of use**

Because you implement TLS/SSL beneath the application layer, most of its operations are completely invisible to the client. This allows the client to have little or no knowledge of the security of communications and still be protected from attackers.

**Limitations of TLS/SSL**
There are a few limitations to using TLS/SSL, including:

**Increased processor load**
This is the most significant limitation to implementing TLS/SSL. Cryptography, specifically public key operations, is CPU-intensive. As a result, performance varies when you are using SSL. Unfortunately, there is no way to know how much performance you will lose. The performance varies, depending on how often connections are established and how long they last. TLS uses the greatest resources while it is setting up connections.

**Administrative overhead**
A TLS/SSL environment is complex and requires maintenance; the system administrator must configure the system and manage certificates.

**Common TLS/SSL Scenarios**
Many people think of TLS and SSL as protocols that are used with Web browsers to browse the Internet more securely. However, they are also general purpose protocols that can be used whenever authentication and data protection are necessary. For example, you can use TLS/SSL for:

- SSL-secured transactions with an e-commerce Web site
- Authenticated client access to an SSL-secured Web site
- Remote access
- SQL access
- E-mail

This is not an exhaustive list. In fact, the ability to access these protocols through Security Service Provider Interface (SSPI) means that you can use them for just about any application. Many applications are being modified to take advantage of the features of TLS/SSL.

**SSL-secured transactions with an e-commerce Web site**
This situation is a typical use of SSL between a browser and a Web server. An example is an e-commerce shopping site where clients need to provide their credit card numbers. The protocol first confirms that the certificate of the Web site is valid, and then sends the client's credit card information as cipher text. For this type of transaction, where the server's certificate comes from a trusted source, authentication only occurs for the server. TLS/SSL must be enabled for the Web page, such as an order form, where the data transactions occur.

**Authenticated client access to an SSL-secured Web site**
Both the client and server need certificates from a mutually-trusted certification authority (CA). With Schannel, client certificates can be mapped on a one-to-one or many-to-one basis to their Windows Server 2003 user or computer accounts, and they can be managed by Active Directory Users and Computers. Users can then be authenticated to a Web site without needing to supply a password.

Many-to-one mapping has several uses. For example, if you want to give several users access to confidential material, you can create a group, map the users' certificates to the group, and give the group the necessary permissions to the material.

In one-to-one mapping, the server has a copy of the client's certificate; whenever the client logs in; the server verifies that they are identical. This one-to-one mapping is typically used for private material, such as a banking Web site where only one individual has the right to view a personal account.

**Remote access**
In this situation, telecommuting is a common use for Schannel. You can use this technology to provide authentication and data protection when users remotely log in to Windows-based systems or networks. Users can more securely access their e-mail or enterprise applications from home or while traveling, reducing the risk of exposure of the information to anyone on the Internet.

**SQL access**
With Microsoft SQL Server, you can require authentication of the client when connecting to the server running SQL Server. Either the client or server can be configured to require encryption of the data that is transferred between them. Very sensitive information, such as financial or medical databases, can be protected to prevent unauthorized access and disclosure of information about the network.

**E-mail**
When using Exchange servers, you can use Schannel to help protect data as it moves from server to server on the intranet or Internet. Full end-to-end security might require the use of Secure/Multipurpose Internet Mail Extensions (S/MIME); however, helping to protect data in a server-to-server exchange allows companies to use the Internet to securely transfer e-mail among divisions within the same company, subsidiaries, and partners. This can be done regardless of whether S/MIME is used.

**Technologies Related to Schannel**
In the Windows Server 2003 operating system, the Schannel Security Support Provider SSP authentication protocol suite contains TLS. The following diagram shows where Schannel fits among these and other technologies in Windows Server 2003. Client applications or server applications use Secur32.dll by way of SSPI calls to communicate with the Local Security Authority Subsystem (LSASS).

### Schannel Architecture

Below is a description of the components that participate in TLS/SSL.

### Security Subsystem Components used in TLS/SSL Authentication

| Component | Description |
|---|---|
| Schannel.dll | The Transport Layer Security (TLS) and Secure Sockets Layer (SSL) authentication protocol. This protocol provides authentication over an encrypted channel instead of a less-secure clear channel. |
| Lsasrv.dll | The LSA Server service, which both enforces security policies and acts as the security package manager for the LSA. |
| Netlogon.dll | TLS-relevant services that the Net Logon service performs:<br>• Net Logon passes the user's certificate information through an SSL-secured channel to the domain controller to map the user certificate to a user account. |
| Secur32.dll | The multiple authentication provider that implements SSPI. |

| | |
|---|---|
| Ntdsa.dll | The directory service module, which supports the Windows Server 2003 and Windows 2000 replication protocol and LDAP, and manages partitions of data. |

The authentication protocol suite is enabled by the Schannel .SSP, which is supported by the SSPI application programming interface (API) that provides the security services for Windows Server 2003 operating systems.

**TLS and SSL Dependencies**

TLS and SSL depend on several related technologies and resources to function properly. The following section describes these technologies and resources and summarizes how they relate to TLS/SSL authentication.

**Operating system**

TLS and SSL authentication relies on client functionality that is built into the Microsoft Windows Server 2003 operating system, the Microsoft Windows XP operating system, and the Microsoft Windows 2000 operating system. If a client or server is running an operating system that does not support TLS/SSL, it cannot use TLS/SSL authentication.

**TCP/IP network connectivity**

For TLS or SSL authentication to occur, there must be TCP/IP network connectivity between the client, and the target server. For more information about TCP/IP, see "TCP/IP Technical Reference."

**Active Directory domain**

When a server application requires client authentication, Schannel automatically attempts to map the certificate that is supplied by the client to a user account. You can authenticate users who log on with a client certificate by manually creating mappings, which relate the certificate information to a Windows user account. After you create and enable a certificate mapping, each time a client presents a client certificate; your server application automatically associates that user with the appropriate Windows user account. You must use user accounts in the Active Directory directory service if you wish to use Active Directory certificate mapping. For more information about Active Directory, see "Active Directory Collection."

**Trusted certificate authorities**

Because authentication relies on digital certificates, certification authorities (CAs) such as Verisign or Microsoft Certificate Server are an important part of TLS/SSL. A CA is a mutually-trusted third party that confirms the identity of a certificate requestor (usually a user or computer), and then issues the requestor a certificate. The certificate binds the requestor's identity to a public key. CAs also renew and revoke certificates as necessary. For example, if a client is presented with a server's certificate, the client computer might try to match the server's CA against the client's list of trusted CAs. If the issuing CA is trusted, the client will verify that the certificate is authentic and has not been tampered with. For more information about PKI Technologies, see "PKI Technologies."

# How TLS/SSL Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How TLS/SSL Works**

**In this section**

- Schannel SSP Architecture
- TLS/SSL Architecture
- TLS/SSL Processes and Interactions
- Network Ports Used by TLS/SSL
- Related Information

TLS/SSL authenticates and secures data transfers by using certificate-based authentication and symmetric encryption keys. This section discusses how the RFC-standard TLS protocol is used in the Windows Server 2003 operating system.

This section is divided into five subsections:

- **Schannel SSP Architecture** illustrates how the Microsoft Security Support Provider Interface (SSPI) in Windows Server 2003 provides a mechanism of generic routines that can access the Secure Channel (Schannel) Security Support Provider (SSP).
- **TLS/SSL Architecture** discusses the Handshake and Record Layer and related sub-protocols of TLS/SSL, as well as the Schannel session cache.
- **TLS/SSL Protocol Processes and Interactions** illustrates full handshake protocol, application data flow, resuming a secure session, and renegotiation with what is included in TLS messages. Some processes — such as certificate mapping, and how internally renegotiations are handled — are specific to Windows systems and might or might not differ in other implementations of the TLS protocol.
- **Network Ports Used by the TLS/SSL** tabulates networks ports that are used for TLS/SSL
- **Related Information** lists links of related information.

The Windows Server 2003 operating system can use three related security protocols to provide authentication and secure communications over the Internet:

- Transport Layer Security (TLS) 1.0
- Secure Sockets Layer 3.0
- Secure Sockets Layer (SSL) 2.0

All three protocols provide authentication through the use of certificates and secure communication through a variety of possible cipher suites. The generic term *cipher suite* refers to a combination of protocols such as key exchange, bulk encryption, and message integrity. Because authentication relies on digital certificates, certification authorities (CAs) like Verisign are an important part of Secure Channel (Schannel). A CA is a mutually trusted third party that confirms the identity of a certificate requestor (usually a user or computer), and then issues the requestor a certificate. The certificate binds the requestor's identity to a public key. CAs also renew and revoke certificates as necessary. For example, if a client is presented with a server's certificate, the client computer might try to match the server's CA against the client's list of trusted CAs. If the issuing CA is trusted, the client will verify that the certificate is authentic and has not been tampered with. Microsoft Internet

Explorer and Internet Information Services (IIS) make use of these protocols, and preferably TLS, for Secure Hypertext Transfer Protocol (HTTPS).

This document focuses on TLS, because TLS is replacing SSL and PCT. TLS is standardized in RFC 2246 IETF RFC database.

**Note**

- Throughout this document *TLS/SSL* refers to the common protocol features of Transport Layer Security and Secure Sockets Layer. *TLS* refers to only Transport Layer Security, and *SSL* refers to only Secure Sockets Layer.

**Schannel SSP Architecture**

The Windows Server 2003 operating system implements the TLS/SSL protocols as a Security Support Provider SSP, a dynamic-link library (DLL) called Schannel that is supplied with the operating system. Which SSP is used depends on the capabilities of the computer on the other side of the connection and the configuration of the individual application that is being used.

The Microsoft Security Support Provider Interface (SSPI) is the foundation for authentication in Windows Server 2003. That is, applications and infrastructure services that require authentication use SSPI to provide it.

The SSPI is the implementation of the Generic Security Service API (GSSAPI) in Windows Server 2003. For more information about GSSAPI, see RFC 2743 and RFC 2744 in the IETF RFC database.

The default SSPs in Windows Server 2003 — Kerberos, NTLM, Digest, Schannel, and Negotiate authentication protocols — are incorporated into the SSPI in the form of DLLs. Additional SSPs can be incorporated if they can interoperate with the SSPI.

**SSPI Architecture**

In the Windows Server 2003 operating system, SSPI provides a mechanism that carries authentication tokens over the existing communication channel between the client and server. When two parties need to be authenticated so that they can communicate more securely, the requests for authentication are routed to the SSPI, which completes the authentication process, regardless of the network protocol currently in use. The SSPI returns transparent binary large objects, and then these are passed between the applications, at which point they can be passed to the SSPI layer on that side. Thus, the SSPI enables an application to use various security models available on a computer or network without changing the interface to the security system.

The following table describes the SSP components that are plugged into the SSPI. Each of the protocols in the table is used in different ways in Windows Server 2003 to promote more secure communication in an insecure network environment.

**SSP Layer Components**

| Component | Description |
|---|---|
| Kerberos V5 authentication | An industry-standard protocol that is used with either a password or a smart card for interactive logon. It is also the preferred authentication method for services in Windows 2000 and Windows Server 2003. |
| NTLM authentication | A challenge-response protocol that is used to provide compatibility with versions of Windows earlier than Windows 2000. |
| Digest authentication | An industry standard that is used in Windows Server 2003 for Lightweight Directory Access Protocol (LDAP) and Web authentication. Digest transmits credentials across the network as a Message Digest 5 (MD5) hash or message digest. |

| | |
|---|---|
| Schannel | An SSP that implements SSL and TLS. Schannel is used for applications used in cross-organization environments, such as Web-based server authentication, in which a user attempts to access a secure Web server or corporate access using VPN. |
| Negotiate | An SSP that can be used to negotiate a specific authentication protocol. When an application calls into SSPI to log on to a network, it can specify an SSP to process the request. If the application specifies Negotiate, Negotiate analyzes the request and picks the best SSP to handle the request, based on customer-configured security policy. |

**Secure Channel SSP**

You can use the Secure Channel (Schannel) SSP for access to Web-enabled services, such as e-mail or personal information served on Web pages.

The Schannel SSP uses public key certificates to authenticate parties. It includes four authentication protocols in its suite. When authenticating parties, it will select one of the four protocols in the following order of preference:

- TLS version 1.0
- SSL version 3.0
- PCT. PCT is turned off by default in Windows Server 2003. PCT has been superseded by Secure Sockets Layer 3.0 and the TLS protocol. The Schannel SSP supports PCT 1.0 for backward compatibility only, but this protocol might not be available in future releases.
- SSL version 2.0

Schannel then selects the most preferred authentication protocol that both parties can support. For example, if a server supports all four Schannel protocols and the client supports only SSL 3.0 and PCT, Schannel uses SSL 3.0 for authentication.

**TLS/SSL Architecture**

The Schannel authentication protocol suite is based on public key cryptography. The Schannel suite includes Transport Layer Security (TLS), Secure Sockets Layer (SSL) version 3.0, SSL version 2.0, and Private Communications Transport (PCT). All Schannel protocols are based on a client/server model. An Schannel client sends a message to a server, and the server responds with the information needed to authenticate itself. The client and server perform an additional exchange of session keys, and the authentication dialogue ends. When authentication is completed, secure communication can begin between the server and the client using the secret keys established during the authentication process.

Schannel does not require server keys to be stored on domain controllers or in a database, such as Active Directory. Clients, however, must be able to confirm the validity of credentials with a trusted authority. Schannel validates the credentials with the root CA's certificates, which are loaded when you install Windows Server 2003. Therefore, users do not need to establish accounts before authenticating and creating a secure connection with a server.

The TLS/SSL security protocol is layered between the application protocol layer and the TCP/IP layer, where it can secure and send application data to the transport layer. Because it works between the application layer and the transport layer, TLS/SSL can support multiple application layer protocols.

TLS/SSL assumes that a connection-oriented transport, typically TCP, is in use. The protocol allows client/server applications to detect the following security risks:

- Message tampering
- Message interception
- Message forgery

The TLS/SSL protocol can be divided into two layers. The first layer consists of the application protocol and the three Handshake sub-protocols: the Handshake Protocol, the Change Cipher Spec Protocol, and the Alert Protocol. The second layer is the Record Protocol. The following figure illustrates the various layers and their components.

**TLS/SSL Protocol Layers**

**The Handshake Protocols**

The Handshake protocols of the TLS/SSL protocol are responsible for establishing or resuming secure sessions. The main goals of this layer are to:

- Negotiate cipher suites and compression algorithms.
- Authenticate the server to the client and, optionally, authenticate the client to the server through certificates and public or private keys.
- Exchange random numbers and a pre-master secret. Together with some further data, these values will be used to create the shared secret key that the Record Layer will use to hash and encrypt application data. The shared secret key is called the Master Secret.

The three Handshake sub-protocols are:

- **Handshake**. This sub-protocol is used to negotiate session information between the client and the server. The session information consists of a session ID, peer certificates, the cipher specification to be used, the compression algorithm to be used, and a shared secret that is used to generate keys.
- **Change Cipher Spec**. This sub-protocol changes the keying material that is used for encryption between the client and server. The keying material is raw data that is used to create keys for cryptographic use. The Change Cipher Spec sub-protocol consists of a single message to tell other party in the TLS/SSL session, who is known as the peer, that the sender wants to change to a new set of keys. The key is computed from the information that is exchanged by the Handshake sub-protocol.
- **Alert**. This sub-protocol uses messages to indicate a change in status or an error condition to the peer. There are a wide variety of alerts to notify the peer of both normal and error conditions. A full list can be found in RFC 2246, "The TLS Protocol Version 1.0." Alerts are commonly sent when the connection is closed, an invalid message is received, a message cannot be decrypted, or the user cancels the operation.

**Handshake Protocol Functions**

The Handshake protocol provides a number of very important security functions. It performs a set of exchanges that starts authentication and negotiates the encryption, hash, and compression algorithms.

**Authentication**

A certificate is a digital form of identification that is usually issued by a certification authority (CA) and contains identification information, a validity period, a public key, a serial number, and the digital signature of the issuer. For authentication purposes, the Handshake Protocol uses an X.509 certificate to provide strong evidence to a second party that helps prove the identity of the party that holds the certificate and the corresponding private key.

A CA is a mutually trusted third party that confirms the identity of a certificate requestor (usually a user or computer), and then issues the requestor a certificate. The certificate binds the requestor's identity to a public key. CAs also renew and revoke certificates as necessary. For example, if a client is presented with a server's certificate, the client computer might try to match the server's CA against the client's list of trusted CAs. If the issuing CA is trusted, the client will verify that the certificate is authentic and has not been tampered with. Finally, the client will accept the certificate as proof of identity of the server.

**Encryption**

There are two main types of encryption: *symmetrickey* (also known as *shared secret key*) and *asymmetrickey* (also known as *public key* or *public-private key*). TLS/SSL uses symmetric key for bulk encryption and public key for authentication and key exchange.

- **Symmetric Key (also known as Private Key)**. In symmetric key encryption, the same key is used to encrypt and decrypt the message. If two parties want to exchange encrypted messages securely, they must both possess a copy of the same symmetric key. Symmetric key cryptography is often used for encrypting large amounts of data because it is computationally faster than asymmetric cryptography. Typical algorithms include Data Encryption Standard (DES), Triple DES (3-DES), RC2, RC4, and Advanced Encryption Standard (AES).

- **Asymmetric Key, also known as Public Key**. Asymmetric key encryption uses a pair of keys that have been derived simultaneously through a complex mathematical process. One of the keys is made public, typically by asking a CA to publish the public key in a certificate for the certificate-holder (also called the subject). The private key is kept secret by the subject and never revealed to anyone. The keys work together, with one being used to perform the inverse operation of the other: If the public key is used to encrypt data, only the private key of the pair can decrypt it; if the private key is used to encrypt, the public key must be used to decrypt. This relationship allows a public key encryption scheme to do two important things. First, anyone can obtain the public key for a subject and use it to encrypt data that only the user with the private key can decrypt. Second, if a subject encrypts data using its private key, anyone can decrypt the data by using the corresponding public key. This is the foundation for digital signatures. The most common algorithm is Rivest, Shamir, and Adleman (RSA).

TLS/SSL uses public key encryption to authenticate the server to the client and, optionally, the client to the server. Public key cryptography is also used to establish a session key. The session key is used in symmetric algorithms to encrypt the bulk of the data with the faster, less processor-intensive symmetric key encryption.

#### Hash Algorithms

During the handshake process, the client and server agree on the hash algorithm. A hash is a one-way mapping of values to a smaller set of representative values, so that the size of the resulting hash is smaller than the original message and the hash is unique to the original data. A hash is similar to a fingerprint: a fingerprint is unique to the individual and is much smaller than the original person. Hashing is used to establish data integrity during transport. Two common hash algorithms are Message Digest 5 (MD5) and Standard Hash Algorithm 1 (SHA-1). MD5 produces a 128-bit hash value and SHA-1 produces a 160-bit value.

### Note

- Data can be encrypted and decrypted, but you cannot reverse engineer a hash. Hashing is a one-way process. Running the process backward does not recreate the original data. This is why a new hash is computed and then compared to the sent hash.

The hash algorithm includes a value that is used to check the integrity of the transmitted data. This value is established by using either a message authentication code (MAC) or a hashed message authentication code (HMAC). The MAC uses a mapping function to represent the message data as a fixed-length, preferably smaller, value and then hashes the message. The MAC ensures that the data has not been modified during transmission. The difference between a MAC and a digital signature is that a digital signature is also an authentication method. SSL uses a MAC.

The HMAC is similar to the MAC but uses a hash algorithm in combination with a shared secret key. The shared secret key is appended to the data to be hashed. This makes the hash more secure because both parties must have the same shared secret key to prove the data is authentic. TLS uses an HMAC. For more information about HMAC, see RFC 1024 in the IETF RFC Database.

#### The Change Cipher Spec Protocol

The Change Cipher Spec Protocol signals a transition of the cipher suite to be used on the connection between the client and server. This protocol is composed of a single message which is encrypted and compressed with the current cipher suite. This message consists of a single byte with the value 1. Message after this will be encrypted and compressed using the new cipher suite.

#### The Alert Protocol

The Alert Protocol includes event-driven alert messages that can be sent from either party. Following an alert message, the session is either ended or the recipient is given the choice of whether or not to end the session. The alerts are defined in the TLS specification in RFC 2246. The following table lists the possible alert messages and their descriptions. Schannel SSP will only generate these alert messages at the request of the application.

### Event-Driven Alert Messages from the Alert Sub-protocol

| Alert Message | Description |
|---|---|

| | |
|---|---|
| close_notify | Notifies the recipient that the sender will not send any more messages on this connection. |
| unexpected_message | Received an inappropriate message This alert should never be observed in communication between proper implementations. This message is always fatal. |
| bad_record_mac | Received a record with an incorrect MAC. This message is always fatal. |
| decryption_failed | Decryption of a TLSCiphertext record is decrypted in an invalid way: either it was not an even multiple of the block length or its padding values, when checked, were not correct. This message is always fatal. |
| record_overflow | Received a TLSCiphertext record which had a length more than 2^14+2048 bytes, or a record decrypted to a TLSCompressed record with more than 2^14+1024 bytes. This message is always fatal. |
| decompression_failure | Received improper input, such as data that would expand to excessive length, from the decompression function. This message is always fatal. |
| handshake_failure | Indicates that the sender was unable to negotiate an acceptable set of security parameters given the options available. This is a fatal error. |
| bad_certificate | There is a problem with the certificate, for example, a certificate is corrupt, or a certificate contains signatures that cannot be verified. |
| unsupported_certificate | Received an unsupported certificate type. |
| certificate_revoked | Received a certificate that was revoked by its signer. |
| certificate_expired | Received a certificate has expired or is not currently valid. |
| certificate_unknown | An unspecified issue took place while processing the certificate that made it unacceptable. |
| illegal_parameter | Violated security parameters, such as a field in the handshake was out of range or inconsistent with other fields. This is always fatal. |
| unknown_ca | Received a valid certificate chain or partial chain, but the certificate was not accepted because the CA certificate could not be located or could not be matched with a known, trusted CA. This message is always fatal. |
| access_denied | Received a valid certificate, but when access control was applied, the sender did not proceed with negotiation. This message is always fatal. |
| decode_error | A message could not be decoded because some field was out of the specified range or the length of the message was incorrect. This message is always fatal. |
| decrypt_error | Failed handshake cryptographic operation, including being unable to correctly verify a signature, decrypt a key exchange, or validate a finished message. |
| export_restriction | Detected a negotiation that was not in compliance with export restrictions; for example, attempting to transfer a 1024 bit ephemeral RSA key for the RSA_EXPORT handshake method. This message is always fatal. |
| protocol_version | The protocol version the client attempted to negotiate is recognized, but not supported. For example, old protocol versions might be avoided for security reasons. This message is always fatal. |
| insufficient_security | Failed negotiation specifically because the server requires ciphers more secure than those supported by the client. Returned instead of handshake_failure. This message is always fatal. |
| internal_error | An internal error unrelated to the peer or the correctness of the protocol makes it impossible to continue, such as a memory allocation failure. The error is not related to protocol. This message is always fatal. |
| user_canceled | Cancelled handshake for a reason that is unrelated to a protocol failure. If the user cancels an operation after the handshake is complete, just closing the connection by sending a close_notify is more appropriate. This alert should be followed by a close_notify. This message is generally a warning. |

| | |
|---|---|
| no_renegotiation | Sent by the client in response to a hello request or sent by the server in response to a client hello after initial handshaking. Either of these would normally lead to renegotiation; when that is not appropriate, the recipient should respond with this alert; at that point, the original requester can decide whether to proceed with the connection. One case where this would be appropriate would be where a server has spawned a process to satisfy a request; the process might receive security parameters (key length, authentication, and so on) at startup and it might be difficult to communicate changes to these parameters after that point. This message is always a warning. |

**The Record Layer**

As specified by RFC 2246, the Record Layer might have four functions:

- It fragments the data coming from the application into manageable blocks (and reassemble incoming data to pass up to the application). Schannel SSP does not support fragmentation at the Record Layer.
- It compresses the data and decompresses incoming data. Schannel SSP does not support compression at the Record Layer.
- It applies a Message Authentication Code (MAC), or hash/digest, to the data and uses the MAC to verify incoming data.
- It encrypts the hashed data and decrypts incoming data.

**Record Protocol Functions**

The Record Protocol receives and encrypts data from the application layer and delivers it to the Transport Layer. Then it takes the data, fragments it to a size appropriate to the cryptographic algorithm, optionally compresses it (or, for data received, decompresses it), applies a MAC or HMAC and then encrypts (or decrypts) the data using the information negotiated during the Handshake Protocol. HMAC is supported only by TLS.

The resulting encrypted data is then passed to the transport layer.

**Record Layer Encryption States**

The record layer changes encryption states during the session setup. That is, different encryption methods are used at different stages of the process.

- **No Encryption Used**. Prior to the negotiating a cipher suite and deciding which security methods to use, the state is Null. No message authentication or encryption is performed.
- **Public Key Encryption Used** (Uses public-private key pair). Once a cipher suite is negotiated and certificates are exchanged, The record layer hashes outgoing data with the appropriate MAC (typically both MD5 and secure hash algorithm (SHA-1), as required for RSA signing) and encrypts it with the sender's private key. Incoming data is decrypted with the sender's public key.
- **Symmetric Key Encryption Used** (Uses shared session key rather than public-private key pair). Near the end of the Handshake sequence, the handshake protocol exchanges data that allows both the client and the server to compute a Master Secret and then to derive the Client Write MAC Secret, Server Write MAC Secret, Client Write Key, and Server Write Key from it.

  When these keys are available, the client and server send a message to Change Cipher Spec. At that point, the client and server stop using the public-private key pair and start using the shared session keys derived from the Master Secret.

**TLS/SSL Processes and Interactions**

This section provides a detailed explanation of the TLS/SSL protocol, specifically the handshake protocol, its associated messages and alerts, and the record protocol.

The first three operations listed below take place using the Handshake Protocol. The parties negotiate which cipher suite they will use, authenticate, exchange keys, and exchange application data.

**Handshake and Cipher Suite Negotiation**

First, the client and server contact each other and choose a common cipher suite. The suite will include:

- A key exchange method, which determines how the shared master key will be exchanged.

- A bulk encryption method which determines how application data will be encrypted.
- A MAC, which determines how application data will be hashed and signed to prove integrity.

**Authentication**
The server always authenticates its identity to the client. However, the client might not need to authenticate with the server, depending on the application. The authentication method (primarily which digital certificate format will be used) depends on the negotiated cipher suite.

**Key Exchange**
After choosing a cipher suite, the client and server exchange a key (or the information needed to create a key) that they will use for data encryption, which again depends on the negotiated cipher suite's requirements. The key exchange operation requires the following things:

- The random values are created called the Client Random and the Server Random.
- The client generates a random Pre-Master Secret.

The client must transmit the Pre-Master Secret securely to the server.

- With RSA key exchange, the Pre-Master Secret is encrypted with the server's public key. The client gets this key from the server's certificate.
- With EDH key exchange, the pre-master secret is the result of the EDH operation. In this case the ephemeral DH key is signed by the server's private key.

Both client and server use the Pre-Master Secret to create a shared Master Secret. This is done by hashing the pre-master secret together with the ClientRandom and ServerRandom values. The Master Secret is used to create four keys that are shared by the client and server:

- **Client Write MAC Secret.** This key is added to client message hashes. The client uses the key to create the initial hash. The server uses it to authenticate client messages.
- **Server Write MAC Secret.** This key is added to server message hashes. The server uses the key to create the initial hash. The client uses it to authenticate server messages.
- **Client Write Key**. The client uses this key to encrypt messages. The server uses the key to decrypt client messages.
- **Server Write Key.** The server uses this key to encrypt messages. The client uses the key to decrypt server messages**.**

The last operation takes place at the Record Layer using the Record Protocol.

**Application Data Exchange**
The client application and the server application communicate with each other. All data is encrypted using the negotiated bulk encryption method.

**TLS/SSL Message Sequence Overview**
The process of authenticating and establishing an encrypted channel with a server using the Schannel authentication protocol involves the following steps:

### Full TLS Handshake

The Handshake protocols manage this process of exchanging key generation material, and it uses the Handshake Protocol.

Once hashing and encryption keys are ready for use, the Record Layer takes over. It uses the Record Protocol to secure application data, using the keys created in the Handshake process.

**The Full Handshake Protocol**

The handshake protocol is a series of sequenced messages that negotiate the security parameters of a data transfer session.

**Client Hello Messages**

The Client Hello is typically the first message in the TLS/SSL session setup sequence. The protocol allows the server to request a hello, but this is application-specific and not part of the normal sequence.

### Client Hello Messages

**Client Hello Message**

The client initiates a session by sending a Client Hello message to the server. The Client Hello message contains:

- **Version Number**. The version number of the highest version that the client supports. This is sent by the client to the server. Version 2 is used for SSL 2.0, version 3 for SSL 3.0, and version 3.1 for TLS. Although the IETF RFC for TLS is TLS version 1.0, the protocol uses 3.1 in the version field to indicate that it is a later version, with more functionality than SSL 3.0.

- **Client Random**. A 4-byte number that consists of the client's date and time, plus a 28-byte cryptographically-generated pseudorandom number. This is used in the calculation of the Master Secret from which the encryption keys are derived.

- **(Optional) Session Identification**. A byte string used to identify an active or resumable session state. Enables the client to resume a previous session. Resuming a previous session can be useful, because creating a new session requires processor-intensive public key operations that can be avoided by resuming an existing session with its established session keys. Previous session information, identified by the SessionID, is stored in the respective client and server session caches. This is empty if the client is not resuming a session.

- **Cipher Suite**. The list of cipher suites available on the client. An example of a cipher suite is TLS_RSA_WITH_DES_CBC_SHA, where TLS is the protocol version, RSA is the algorithm that will be used for the key exchange, DES_CBC is the encryption algorithm (using a 56-bit key in CBC mode), and SHA-1 is the hash function.

  **Note**

  - Microsoft applications typically specify RSA as the key exchange algorithm, RC4 as the encryption method, and MD5 as the Message Authentication Codes.

- **Compression Algorithm**. The client's supported compression algorithms. Compression is optional and is one of the

four operations that the Record Protocol might perform on all data after the Hello sequence is finished.

**Server Session Cache Allows Session Resume**

The Client Hello is used to either start a new session or to resume an existing session. If the Client Hello includes a Session ID, the client is attempting to resume a session.

The server maintains a session cache to allow fast resumption of recent sessions, similar to a ticket cache in Kerberos. Resuming a session does not require certificate exchanges, so it is much quicker than the normal Hello sequence.

The application determines whether client's are allowed to resume sessions and how long idle session IDs are valid.

The server uses CryptoAPI to manage both the session ID and the certificate cache.

### Note

- The Client Hello can be initiated at any time during an existing session and is not limited to just session initialization. The server application might request a new Hello periodically to request client authentication based on the resource that is requested. Either the client application or the server might request a new handshake to refresh encryption keys.

**TLS 1.0 Cipher Suites**

Schannel supports the cipher suites in the following table for TLS 1.0. In this table, the following acronyms are used:

CBC = cipher block chaining

DES = Data Encryption Standard

DHE = Ephemeral Diffie-Hellman

DSS = Digital Signature Standard

The suites are listed in order of preference.

**TLS 1.0 Cipher Suites**

| Key Exchange | Cipher | Hash |
|---|---|---|
| RSA | RC4 128 | MD5 |
| RSA | RC4 128 | SHA-1 |
| RSA | 3DES EDE CBC | SHA-1 |
| DHE DSS | 3DES EDE CBC | SHA-1 |
| RSA | DES CBC | SHA-1 |
| DHE DSS | DES CBC | SHA-1 |
| RSA Export 1024 | RC4 56 | SHA-1 |
| RSA Export 1024 | DES CBC | SHA-1 |
| DHE DSS Export 1024 | DES CBC | SHA-1 |
| RSA Export | RC4 40 | MD5 |
| RSA Export | RC2 CBC 40 | MD5 |
| RSA | None | MD5 |
| RSA | None | SHA-1 |

**SSL 3.0 Cipher Suites**

Schannel supports the cipher suites listed under TLS 1.0 Cipher Suites.

#### SSL 2.0 Cipher Suites

Schannel supports the following cipher suites for SSL 2.0. The suites are listed in order from most secure to least secure.

### SSL 2.0 Cipher Suites

| Cipher | Hash |
|---|---|
| RC4 128 | MD5 |
| DES 192 EDE3 CBC | MD5 |
| RC2 CBC 128 CBC | MD5 |
| DES 64 CBC | MD5 |
| RC4 128 Export 40 | MD5 |

#### Server Responses to Client Hello

### Server Responses to Client Hello

#### Server Hello Message

The server responds with a Server Hello message. The Server Hello message includes:

- **Version Number**. The server sends the highest version number that is supported by both sides. This is the protocol version that will be used during the connection.
- **Server Random[32]**. ServerRandom[32] is a 4-byte representation of the server's date and time plus a 28-byte, cryptographically-generated, pseudorandom number. This number, along with the Client Random, is used by both the client and the server to generate the Master Secret from which the encryption keys will be derived.
- **Session Identification** (if any). This can be one of three choices.
    - **New session ID.** The client did not indicate a session to resume, so a new ID is generated. A new session ID is also generated when the client indicates a session to resume, but the server can't or won't resume that session.
    - **Resumed Session ID**. The ID is the same as indicated in the Client Hello. The client indicated a specific session ID to resume and the server is willing to resume that session.
    - **Null**. This is a new session, but the server is not willing to resume it at a later time, so no ID is returned.
- **Cipher Suite**. The server chooses the strongest cipher that both the client and server support. If there are no cipher suites that both parties support, the session is ended with a *handshake failure* alert.
- **Compression Algorithm**. If used, specifies the compression algorithm to use.

#### Server Certificate Message

The server sends its certificate to the client. The server certificate contains the server's public key. The client uses this key to authenticate the server and to encrypt the Premaster Secret. The Server Certificate message includes:

- **The server's certificate list**. The first certificate in the list is the server's X.509v3 certificate that contains the server's public key.
- **Other validating certificates**. All other validating certificates, up to but not including the root certificate from the CA, signed by the CA.

The client also checks the name of the server in the certificate to verify that it matches the name the client used to connect. For example, if the user types http://www.contoso.com as the URL in the browser, the certificate contains a subject name of www.contoso.com or *.contoso.com. Internet Explorer warns the user if these names do not match; other client applications typically fail the connection directly.

**(Optional) Server Key Exchange Message**
The server creates and sends a temporary key to the client. This key can be used by the client to encrypt the Client Key Exchange message later in the process. The step is only required when the server's certificate does not contain a public key that is suitable for key exchange or when the cipher suite mandates the use of an ephemeral key for the key exchange operation. This message is also used when the server uses a DSS certificate. In this case, the server public key is not suitable for key exchange, and so an ephemeral DH key is created by the server and sent in the Server Key Exchange message.

In these situations, the server must create and send a temporary key that is used instead of the server's public key. The key that is created depends on the cipher suite. With export versions of RSA that do not allow a public key greater than 512 bits, the temporary shorter key is signed with the unusable public key for authenticity.

Why is this important? The client will need this key to encrypt the Premaster Secret, whichis discussed below, in the Client Key Exchange message.

### Note

- This message is not used in non-export versions of Microsoft applications, since non-export RSA certificates will always include the server's public key in its certificate.

**(Optional) Client Certificate Request Message**
The server must always present its certificates to the client, but the client is not always required to authenticate itself. Therefore, the client is not always required to send its certificates to the server. If the server does not require client authentication, then this message is not sent.

This step might be used for Web sites such as a banking Web site, where the server must confirm the identity of the client before providing sensitive information. If the application requires mutual authentication, the server sends a Client Certificate Request. The Client Certificate Request message includes:

- The type of certificate required (typically RSA or DSS)
- A list of acceptable CAs

**Server Hello Done Message**
This message indicates that the server is finished and awaiting a response from the client. This message has no content. It signals that the Server Hello sequence is finished.

**Client Responses to Server Hello**
The client receives the server's message and checks the certification hierarchy of the server's certificate.

### Client Responses to Server Hello

**Client Certificate Message (Required if Requested)**
If the server sent a Client Certificate Request, the client sends its certificate to the server for client authentication. The client's certificate contains the client's public key. The Client Certificate message includes theclient's **certificate list**. The first certificate in the list is the client's X.509v3 certificate that contains the client's public key. After that are other validating certificates, up to but not including the root certificate from the CA, signed by the CA.

#### Client Key Exchange Message

The client sends a Client Key Exchange message after computing the premaster secret using the two random values that are generated during the Client Hello message and the Server Hello message. Before it is transmitted to the server, the premaster secret is encrypted by the public key from the server's certificate. Both parties compute the master secret locally and derive the session key from it.

If the server can decrypt this data and complete the protocol, the client is assured that the server has the correct private key. This step is crucial to prove the authenticity of the server. Only the server with the private key that matches the public key in the certificate can decrypt this data and continue the protocol negotiation.

The Client Key Exchange message includes:

- **Client's protocol version**. The server will verify that it matches the original value sent in the Client Hello message. This measure guards against rollback attacks. Rollback attacks work by manipulating the message in order to cause the server and the client to use a less secure, earlier version of the protocol.

- **Pre-master secret**. This is the client-generated number (48-byte for RSA), encrypted with the server's public key, that is used with the Client Random and the Server Random to create the Master Secret.

#### Certificate Verify Message (Required if Client Certificate Is Sent)

This message is sent only if the client previously sent a Client Certificate message. The client is authenticated by using its private key to sign a hash of all the messages up to this point. The server verifies the signature with the public key of the signer, which ensures that it was signed with the client's private key. This message contains a long signature to verify the client's certificate, if one was requested and sent.

For RSA, the signature consists of:

- An MD5 hash of all previous handshake messages.

- An SHA-1 hash of all previous handshake messages.

- Both hashes, which are concatenated and encrypted with the client's private key.

For DSS, the signature consists of:

- An SHA-1 hash of all previous handshake messages.

- Encrypted with the client's private key.

#### Change Cipher Spec Message

The Change Cipher Spec message notifies the server that all future messages including the Client Finished message are encrypted using the keys and algorithms just negotiated. At this point, client and server are authenticated and the client has sent the pre-master secret. Both the client and the server have calculated the Master Secret. Up until now, however, any encryption has used the client's or server's private/public keys. The Change Cipher Spec message tells the server that the client is ready to use the Write Key for all further encryption.

### Note

- The Change Cipher Spec message is not part of the Handshake Protocol. The TLS RFC defines a separate protocol for Change Cipher Spec. This allows developers to define a specific Change Cipher Spec message.

#### Computing the Master Secret Key and Subsequent Keys

The Handshake sequence securely exchanges data that is used to create the Master Secret. This secret, however, is never used by itself in encryption; rather, several keys are derived from the Master Secret. These keys are then used for message authentication and encryption.

### Note

- The details in this section and the next (hashing in the Record Layer) provide a glimpse inside the computational "black box" and are meant to illustrate the complexity that is necessary to secure communications. The key material exchange

specifics change over time as new algorithms are developed.

**Computing the Master Secret**
The Master Secret results from the pseudorandom material that is exchanged in the Client Hello message and Server Hello message that is discussed earlier in the sections on the Client and Server Final messages. Both the server and the client create the Master Secret key. It is never exchanged.

To create the Master Secret key, the system passes the following as variables to a pseudorandom function (PRF):

- The 48-byte Pre-Master Secret.
- The literal phrase "master secret"
- The concatenation of Client Random number and Server Random number.

The result is the Master Secret.

**MAC Secret and Write Encryption Keys**
To enable message encryption and hashing, four keys need to be created on both the server and the client:

- Client Write MAC Secret
- Server Write MAC Secret
- Client Write Key
- Server Write Key

These keys are never exchanged.

To produce these keys, the Master Secret is passed to the PRF until enough output has been generated to yield a value that is divided into six parts. (The last two parts are only generated for non-export block ciphers.)

**Client Write MAC Secret**
This key is added to client message hashes. The client uses the key to create the initial hash. The server uses it to authenticate client messages.

**Server Write MAC Secret**
This key is added to server message hashes. The server uses the key to create the initial hash. The client uses it to authenticate server messages.

**Client Write Key**
The client uses this key to encrypt messages. The server uses the key to decrypt client messages.

**Server Write Key**
The server uses this key to encrypt messages. The client uses the key to decrypt server messages.

**Finished Message**
The Finished message is a hash of the entire conversation which provides further authentication of the client. This message is a complicated verification that the client who is sending the Finished message is truly the client who started the Hello conversation. It is the first message that the Record Layer encrypts and hashes with the Write Key and the Write MAC Secret.

**Construction of the message at the Handshake Protocol**
To generate the message contents, the system passes the following as variables to a pseudorandom function (PRF):

- The Master Secret.
- The literal phrase "client finished".
- The concatenation of an MD5 hash of all previous handshake messages and an SHA-1 hash of all previous handshake messages.

The Handshake protocol passes the result to the Record Layer.

**Completing the message at the Record Layer**
The Record Layer hashes the data using HMAC with the Client Write MAC Secret, which is derived from the Master Secret. Then, the Record Layer encrypts the data with the Client Write Key, which is also derived from the Master Secret.

**Server Finished Messages**
If the server has a copy of the private half of its public key pair, it can decrypt the ClientKeyExchange message and generate a matching set of encryption and MAC keys. The server responds to the client with a request to communicate with secret key cryptography, so that both parties have acknowledged that they will use the cryptography and keys that they have agreed upon.

### Server Finished Messages

**Change Cipher Spec Message**
This message notifies the client that the server will begin encrypting messages with the keys that were just negotiated. The server switches its record layer security state to symmetric encryption using the session keys.

**Finished Message**
This message is a hash of the entire exchange to this point using the session key and the MAC Secret. If the client can successfully decrypt this message and validate the contained hashes, the client is assured that the TLS/SSL handshake was successful, and the keys computed on the client machine match those computed on the server.

This message is the same as the Client Finished message with these differences:

- The literal phrase “server finished” is used instead of “client finished”.
- The hashed handshake messages include the client’s Client Finished message.
- The server uses the Server Write MAC Secret and Server Write Key for hashing and encrypting at the Record Layer.

**Application Data Flow**
So far in this process, client and server applications have been authenticated through the use of certificates and public/private keys, a Premaster Secret and other data have been exchanged to create the Master Secret, and both the server and the client have successfully proven that they have not changed identities throughout the Hello sequence. Now the applications can begin to communicate, using the established keys and parameters. The Record Layer fragments, compresses, hashes, and encrypts all further communications. When necessary, it decrypts, verifies, decompresses, and reassembles the communication

### Record Protocol

**The Record Protocol**
When the record protocol receives the data from the application layer, it might perform the following tasks:

- Fragments the data into blocks or reassembles fragmented data into its original structure. Schannel does not support fragmentation at the Record Layer.
- Numbers the sequence of data blocks in the message to protect against attacks that attempt to reorder data.
- Compresses or decompresses the data using the compression algorithm negotiated in the handshake protocol. Schannel does not support compression at the Record Layer.

- Encrypts or decrypts the data using the encryption keys and cryptographic algorithm negotiated during the handshake protocol.

- Applies an HMAC (or, for SSL 3.0, a MAC) to outgoing data. It then computes the HMAC and verifies that it is identical to the value that was transmitted in order to check data integrity when a message is received.

Once the record protocol has completed its operations on the data, it sends the data to the application for transmission. If the data is incoming, it is sent to the appropriate process for reception.

**HMAC Hashing in the Record Layer**

Fragmented, compressed application data is hashed as it passes through the Record Layer before being encrypted.

**Note**

- The details in this section provide a glimpse inside the computational "black box" and are meant to illustrate the complexity necessary to secure communications. The key material exchange specifics change over time as new algorithms are developed.

The MAC consists of two values that are hashed:

- The secret key value: Client or Server Write MAC Secret (derived from the Master Secret).

- A concatenation of:

    - The record's sequence number.

    - Packet type.

    - Protocol version.

    - Packet length.

    - The non-encrypted application data.

The result of this hashing and the original compressed data fragment are then encrypted and passed down to TCP.

When the message is decrypted at its destination, a new hash is computed, based on the compressed fragment and the MAC Secret. The new hash is compared to the hash that was sent in the message. If they match, the message's data integrity is verified.

**Note**

- Data can be encrypted and decrypted, but you cannot reverse engineer a hash. Hashing is a one-way process. Running the process backward does not recreate the original data. This is why a new hash is computed and then compared to the sent hash.

**Resuming a Secure Session**

Once a secure session has been established between a client and a server, the client can attempt to resume the session in the future, using the same keys used in the previous session. If the server is able to resume the session, then the abridged version of the Handshake Protocol below will occur. If not, then a full handshake will occur.

**Resume Session Messages**

- The client sends a Client Hello message using the Session ID of the session to be resumed.
- The server checks its session cache for a matching Session ID. If a match is found and the server is able to resume the session, it sends a Server Hello message with the Session ID.

  **Note**

  - If a session ID match is not found, the server generates a new session ID and the TLS client and server perform a full handshake.

- The server must send a Change Cipher Spec message to notify the client that the server will begin encrypting messages with a new set of encryption and MAC keys, based on the cached Master Secret and the Client Random Server Random values from the current connection. This ensures that every connection has its own set of encryption keys. The server switches its record layer security state to symmetric encryption using the session keys.
- The server sends a Server Finished message.
- The client must send a Change Cipher Spec message to notify the server that the client will start using the session keys for hashing and encrypting messages.
- The client sends a Client Finished message.
- The client and server can now resume application data exchange over the secure channel.

**Renegotiation**
**Renegotiation Methods**
Renegotiation can originate from either the client or the server with the following exceptions:

- No client-side renegotiation in Windows 2000 and Windows XP.
- No renegotiation in SSL 2.0.

**Server Renegotiation Scenarios**
The server can request renegotiation in two situations:

- After the initial handshake, the client requests an access-protected resource. The server can initiate a renegotiation to ask for client authentication. This is the case where the server sends the Hello Request. When the client receives a Hello Request, it begins a new handshake by sending a Client Hello message.
- To refresh keys. This is performed in the same way as the second case, above.

**Note**

- Schannel does not allow the client to ignore the Hello request. The client must initiate a new handshake by sending a

Client Hello message, or the server will close the connection with a fatal error.

**Typical Server Renegotiation**

**Server Initiated Renegotiation**

Server-initiated renegotiation uses the following procedure:

- The client and server successfully complete a full TLS/SSL handshake.
- The client requests for an access-protected resource.
- The server sends a Hello Request message to the client.
- The client receives the Hello Request message.

  **Note**

  - Schannel does not allow the client to ignore the Hello request, but other client's might. The client must initiate a new handshake by sending a Client Hello message or the Windows server closes the connection.

- The client sends a Client Hello message to the server to initiate a new full handshake.

**Client Renegotiation Scenarios**

The client can also initiate a renegotiation anytime by sending a Client Hello message. This is usually performed to refresh encryption keys.

**Typical Client Renegotiation**

**Client Initiated Renegotiation**

Client-initiated renegotiation uses the following procedure:

- The client and the server successfully complete a full SSL handshake.
- The client needs to refresh encryption keys. The client sends a Client Hello message to the server.
- The server receives the Client Hello message. The server has no way of knowing that this message is not application data, and so it passes the message on. It is returned as an "extra" buffer containing the unprocessed Client Hello message with a flag signaling that it is a renegotiation.

  **Note**

  - The server might not respond to the renegotiation request right away. In the most general case, the server might

have already sent some application data at the same time that the client is requesting the renegotiation, or it might decide to send some data before responding to the renegotiation request. However, the client will never send more application data after it has initiated a renegotiation.

- The server sends the Server Hello group of messages to the client.
- The client receives the Server Hello messages. The client has no way of knowing that this message is not application data, and so it passes the message on. It is returned as an "extra" buffer containing the unprocessed server hello messages with a flag signaling that it is a renegotiation
- The client sends the next set of handshake messages, which are sent to the server, and the handshake proceeds as usual.

**The Schannel Session Cache**
The first time that a client connects to a server, a full handshake is performed. Once this is complete, the Master Secret, Cipher Suite, and certificates are stored in the session cache on the respective client and server machines. TLS/SSL supports a reconnect operation that can be used to enable a client and server to resume a previously-negotiated session. This allows subsequent connections between the same client and server to use a reconnect handshake rather than a full handshake. This is desirable in many cases because the TLS/SSL reconnect requires far less CPU and network bandwidth because there is no need for a key exchange or certificate exchange. But there are cases in which reconnects can be troublesome; such as during performance testing or when the client never reconnects to the same Web server.

Schannel supports reconnects by use of the Schannel session cache because it keeps a list of previous TLS/SSL sessions that are established with the current authenticated logon data that is used by a security principal to establish its identity. The sessions are referenced by the TLS/SSL session ID. Schannel currently maintains up to ten thousand cached sessions for a maximum of ten hours.

**How Schannel Uses Certificate Mapping**
When a server application requires client authentication, Schannel automatically attempts to map the certificate that is supplied by the client to a user account. You can authenticate users who log on with a client certificate by creating mappings, which relate the certificate information to a Windows user account. After you create and enable a certificate mapping, each time a client presents a client certificate; your server application automatically associates that user with the appropriate Windows user account.

**Types of Mapping**
In most cases, a certificate is mapped to a user account in one of two ways: a single certificate is mapped to a single user account (one-to-one mapping), or multiple certificates are mapped to one user account (many-to-one mapping). By default schannel will use the following four certificate mapping methods, in order of preference.

**S4U Certificate mapping**
This is new for Windows Server 2003. Schannel uses the UPN from the client certificate and attempts an S4U logon using the Kerberos security package. The CA that issued the client certificate must have NTAuth trust. The domain of the server and the user must be running in Windows Server 2003 function level. This is the only mapping method that works even when the server is in a different forest than the client user.

**User Principal Name mapping**
Enterprise CAs place an entry, called a user principal name (UPN), in each certificate. The UPN looks very much like an e-mail name. The UPN is unique within an Active Directory forest. The UPN finds the user's account in Active Directory, and that account is logged on. UPN mappings are implicit and therefore do not require administrators to create and maintain.

Schannel uses the UPN from the client certificate, and queries Active Directory for a matching user account. The CA that issued the client certificate must have NTAuth trust.

**One-to-One Mapping also known as subject/issuer mapping**
A method that maps a single user certificate to a single Active Directory user account. Unlike UPN mapping, the administrator must explicitly map a certificate to a user's account. This certificate can come from any source, as long as the root CA for that certificate is trusted for client authentication. The client certificate can be renewed, etc without affecting this process as long as the subject and issuer name fields do not change.

For example, suppose that users obtain certificates from a CA that is approved by your company. You then take these user certificates and map them to the Active Directory user accounts. This allows users to connect to the server, using TLS from anywhere by providing their client certificate.

Schannel builds an "altSecurityId" string from the client's certificate's subject and issuer name fields, and queries Active

Directory for a user account with a matching **altSecurityId** property.

**Many-to-One Mapping**
Many-to-one mapping involves mapping many certificates to a single user account. Many-to-one mapping works the same way as one-to-one mapping, but it maps all client certificates issued by a given CA to the same user account. This certificate can come from any source, as long as the root CA for that certificate is trusted for client authentication.

Schannel builds an "altSecurityId" string from the client's certificate's issuer name field, and queries Active Directory for a user account with a matching **altSecurityId** property.

**Network Ports Used by TLS/SSL**
**Port Assignments for Common Applications over TLS/SSL**

| Service Name | TCP |
|---|---|
| smtp | 25 |
| https | 443 |
| nntps | 563 |
| ldaps | 636 |
| ftps-data | 989 |
| ftps | 990 |
| telnets | 992 |
| imaps | 993 |
| pop3s | 995 |
| ms-sql-s | 1433 |
| mfst-gc-ssl | 3269 |
| tftps | 3713 |

# TLS/SSL Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TLS/SSL Tools and Settings**

### In this section

- TLS/SSL Tools
- TLS/SSL Registry Entries
- TLS/SSL Group Policy Settings
- Network Ports Used by Schannel

**TLS/SSL Tools**

The following tools are associated with TLS/SSL.

**Dsa.msc: Active Directory Users and Computers Category**

Active Directory Users and Computers is a Microsoft Management Console (MMC) that is automatically installed when you install Active Directory. This tool also ships with the Administration Tools Pack (Adminpak.msi).

You can access the tool from the **Start** menu: To do this, click **Start**, point to **Programs**,point to **Administrative Tools,** and then click **Active Directory Users and Computers**.

**Version compatibility**

Active Directory Users and Computers runs on domain controllers that run Windows Server 2003 or Windows 2000 operating systems. You can use MMC to administer and publish information in the directory.

The Windows Server 2003 version of Active Directory Users and Computers can target domain controllers that are running Windows Server 2003 or Windows 2000 Server.

On administrative workstations that are running Windows XP Professional or Windows 2000, you can install the Windows Server 2003 Administration Tools Pack (Adminpak.msi) from the i386 folder on the Windows Server 2003 CD. This version of the Administration Tools Pack encrypts and signs Lightweight Directory Access Protocol (LDAP) traffic between the administrative tool client's and domain controllers.

### Note

- You cannot run the Windows Server 2003 Administration Tools Pack (Adminpak.msi) on a computer that is running Windows XP Professional, Windows XP Home Edition, or Windows XP 64-Bit Edition Version 2003 without Windows XP Service Pack 1 (SP1).

You can use Active Directory Users and Computers to manage the following properties that are listed in the following table, which are associated with objects in Active Directory. Any changes you make affect certificate mapping for these objects.

**Active Directory Users and Computers Object Management**

| Property | Changes That Affect Schannel |
|---|---|
| **Computer objects** | |
| Name Mapping Task | Can add, edit or remove certificates. |

| User objects | |
|---|---|
| Name Mapping Task | Can add, edit or remove certificates. |
| Published Certificates Tab | Lists the X.509 certificates published for the user account. Can view, remove, and copy to file listed certificates. Can add new certificates from the local certificate store or from a DER Encoded Binary X509 (*.cer) or PKCS #7 (*.p7b) file. |

You can find more information about Active Directory Users and Computers on the TechNet Web site.

**Eventvwr.msc: Event Viewer**
**Category**
Event Viewer is included in the Windows Server 2003, Windows XP, and Windows 2000 operating systems.

**Version compatibility**
Event Viewer is supported for the Windows Server 2003, Windows XP, and Windows 2000 operating systems.

The system log contains Secure Channel (Schannel) events that are related to authentication.

### Schannel Events

| Event ID | Severity | Description |
|---|---|---|
| 36864 | Informational | The Schannel security package has loaded successfully. |
| 36865 | Error | A fatal error occurred while opening the system *cryptographic subsystem* cryptographic module. Operations that require the SSL or TLS cryptographic protocols will not work correctly. The error code is *error code*. |
| 36866 | Error | The Schannel security package has failed to load. Operations that require the SSL or TLS cryptographic protocols will not work correctly. |
| 36867 | Informational | Creating an SSL [client\| server] credential. |
| 36868 | Informational | The SSL [client\| server] credential's private key has the following properties:<br>• CSP name<br>• CSP type<br>• Key name<br>• Key Type<br>• Key Flags<br><br>The attached data contains the certificate. |
| 36869 | Error | The SSL [client\| server] credential's certificate does not have a private key information property attached to it. This most often occurs when a certificate is backed up incorrectly and then later restored. This message can also indicate a certificate enrollment failure. |
| 36870 | Error | A fatal error occurred when attempting to access the SSL [client\| server] credential private key.<br><br>The error code returned from the cryptographic module is *error code*. |
| 36871 | Error | A fatal error occurred while creating an SSL [client\| server] credential. |

| | | |
|---|---|---|
| 36872 | Warning | No suitable default server credential exists on this system. This will prevent server applications that expect to make use of the system default credentials from accepting SSL connections. An example of such an application is the directory server. Applications that manage their own credentials, such as Microsoft Internet Information Services (IIS), are not affected by this. |
| 36873 | Error | No supported cipher suites were found when initiating an SSL connection. This indicates a configuration problem with the client application or the installed cryptographic modules. The SSL connection request has failed. |
| 36874 | Error | An SSL connection request was received from a remote client application, but none of the cipher suites supported by the client application are supported by the server. The SSL connection request has failed. |
| 36875 | Warning | The remote server has requested SSL client authentication, but no suitable client certificate could be found. An anonymous connection will be attempted. This SSL connection request might succeed or fail, depending on the server's policy settings. |
| 36876 | Error | The certificate received from the remote server has not validated correctly. The error code is *error code*. The SSL connection request has failed. The attached data contains the server certificate. |
| 36877 | Warning | The certificate received from the remote client application has not validated correctly. The error code is *error code*. The attached data contains the client certificate. |
| 36878 | Warning | The certificate received from the remote client application is not suitable for direct mapping to a client system account, possibly because the authority that issuing the certificate is not sufficiently trusted. The error code is *error code*. The attached data contains the client certificate. |
| 36879 | Warning | The certificate received from the remote client application was not successfully mapped to a client system account. The error code is *error code*. This is not necessarily a fatal error, as the server application might still find the certificate acceptable. |
| 36880 | Informational | An SSL [client\| server] handshake completed successfully. The negotiated cryptographic parameters are as follows.<br>• Protocol<br>• Cipher<br>• Cipher strength<br>• MAC<br>• Exchange<br>• Exchange strength |
| 36881 | Error | The certificate received from the remote server has expired. The SSL connection request has failed. The attached data contains the server certificate. |
| 36882 | Error | The certificate received from the remote server was issued by an untrusted certificate authority. Because of this, none of the data contained in the certificate can be validated. The SSL connection request has failed. The attached data contains the server certificate. |
| 36883 | Error | The certificate received from the remote server has been revoked. This means that the certificate authority that issued the certificate has invalidated it. The SSL connection request has failed. The attached data contains the server certificate. |
| 36884 | Error | The certificate received from the remote server does not contain the expected name. It is therefore not possible to determine whether we are connecting to the correct server. The server name we were expecting is *servername*. The SSL connection request has failed. The attached data contains the server certificate. |

| | | |
|---|---|---|
| 36885 | Warning | When asking for client authentication, this server sends a list of trusted certificate authorities to the client. The client uses this list to choose a client certificate that is trusted by the server. Currently, this server trusts so many certificate authorities that the list has grown too long. This list has thus been truncated. The administrator of this machine should review the certificate authorities trusted for client authentication and remove those that do not really need to be trusted. |

To find more information about "Event Viewer", see "Event Viewer" on TechNet.

**Netmon.exe: Network Monitor**
**Category**
A limited version of Network Monitor is included in Windows Server 2003, Windows XP, and Windows 2000 operating systems. The full version of Network Monitor is included with Microsoft Systems Management Server.

**Version compatibility**
Network Monitor is supported for Windows Server 2003, Windows XP, and Windows 2000.

Network Monitor enables you to capture network traces which can be used in troubleshooting most network issues.

**TLS/SSL Registry Entries**
The following registry subkeys and entries can help you administer and troubleshoot TLS/SSL, but they apply more to Schannel SSP than TLS/SSL. They can help you verify that the required settings are applied.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, instead of editing the registry directly, use Group Policy or other Windows tools such as MMC to accomplish tasks. If you must edit the registry, use extreme caution.

**CertificateMappingMethods**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**
Windows Server 2003

This entry does not exist in the registry by default. The default value is that all four certificate mapping methods are supported.

**Ciphers**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This subkey controls use of symmetric algorithms.

**DES 56/56**
This subkey controls use of DES 56 bit algorithm.

**NULL**
This subkey controls use of no encryption.

**RC2 128/128**
This subkey controls use of RC2 128 bit algorithm.

**RC2 40/128**
This subkey controls use of RC2 40 bit algorithm.

**RC2 56/128**
This subkey controls use of RC2 56 bit algorithm.

**RC4 128/128**
This subkey controls use of RC4 128 bit algorithm.

**RC4 40/128**
This subkey controls use of RC4 40 bit algorithm.

**RC4 56/128**
This subkey controls use of RC4 56 bit algorithm.

**Triple DES 168/168**
This subkey controls use of 3DES 168 bit algorithm.

The default for these ciphers is enabled.

To disable, create the **Enabled** entry in the appropriate subkey. (This entry does not exist in the registry by default.) After you have created the entry, change the DWORD value to 0. When you disable any algorithm, you disallow all cipher suites that use that algorithm. To re-enable the cipher, change the DWORD value to 0xffffffff.

**ClientCacheTime**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This entry controls the time to expire client side cache entries in milliseconds. A value of 0 turns off secure connection caching. This entry does not exist in the registry by default. The default values are:

### Default Client Cache Time

| Windows Version | Time |
|---|---|
| Windows NT 4.0 with Service Pack 6a | 2 minutes |
| Windows NT 4.0 with Service Pack 6a and Q265369 | 60 minutes |
| Windows 2000 | 2 minutes |
| Windows 2000 with Service Pack 2 or greater | 10 hours |
| Windows XP | 10 hours |
| Windows Server 2003 | 10 hours |

**Fipsalgorithmpolicy**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\LSA**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This entry controls FIPS compliance. The default is 0.

### FIPS Cipher Suites

| Protocol Version | Key Exchange | Cipher | Hash |
|---|---|---|---|
| SSL 3.0 | RSA | DES CBC | SHA-1 |
| SSL 3.0 | RSA | 3DES EDE CBC | SHA-1 |
| SSL 3.0 | RSA | Export 1024 DES CBC | SHA-1 |
| TLS 1.0 | RSA | DES CBC | SHA-1 |
| TLS 1.0 | RSA | 3DES EDE CBC | SHA-1 |
| TLS 1.0 | RSA | Export 1024 DES CBC | SHA-1 |

**Hashes**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This subkey controls use of hash algorithms.

**MD5**
This subkey controls use of MD5 as hashing algorithm.

**SHA**
This subkey controls use of SHA-1 as hashing algorithm.

The default for these ciphers is enabled.

To disable, create the **Enabled** entry in the appropriate subkey. (This entry does not exist in the registry by default.) After you have created the entry, change the DWORD value to 0. When you disable any algorithm, you disallow all cipher suites that use that algorithm. To re-enable the cipher, change the DWORD value to 0xffffffff.

**IssuerCacheSize**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**
Windows Server 2003

This entry controls the size of issuer cache and is used with issuer mapping. Starting with Windows Server 2003 operating systems, Schannel attempts to map all of the issuers in the client's certificate chain—not just the one that directly issues the client certificate. When the issuers do not map to an account which is the typical case, the server might attempt to map the same issuer name over and over, hundreds of times a second. To prevent this, Windows Server 2003 has a negative cache, so if an issuer name does not map to an account, then it is added to the cache and Schannel will not attempt to map the issuer name again until the cache entry expires. This registry entry specifies the cache size. This entry does not exist in the registry by default. The default value is 100.

**IssuerCacheTime**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**
Windows Server 2003

This entry controls the length of cache timeout interval in milliseconds. Starting with Windows Server 2003operating systems, Schannel attempts to map all of the issuers in the client's certificate chain—not just the one that directly issues the client certificate. In the case where the issuers do not map to an account which is the typical case, the server might attempt to map the same issuer name over and over, hundreds of times a second. To prevent this, Windows Server 2003 has a negative cache, so if an issuer name does not map to an account, then it is added to the cache and Schannel will not attempt to map the issuer name again until the cache entry expires. This cache is kept for performance reasons, so that the system does not keep trying to map the same issuers over and over. This entry does not exist in the registry by default. The default value is 10 minutes.

**KeyExchangeAlgorithm**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This subkey controls use of key exchange algorithms.

**Diffie-Hellman\Enabled**
The subkey controls use of DH for key exchange.

**PKCS**
This subkey controls use of RSA for key exchange.

The default for these ciphers is enabled.

To disable, create the **Enabled** entry in the appropriate subkey. (This entry does not exist in the registry by default.) After you have created the entry, change the DWORD value to 0. When you disable any algorithm, you disallow all cipher suites that use that algorithm. To re-enable the cipher, change the DWORD value to 0xffffffff.

**MaximumCacheSize**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**

Windows Server 2003, Windows XP, Windows 2000

This entry controls the maximum number of cache elements. Setting MaximumCacheSize to 0 disables the server-side session cache and prevents reconnects. Increasing MaximumCacheSize above the default values causes Lsass.exe to consume additional memory. Each session cache element typically requires 2-4k bytes of memory. This entry does not exist in the registry by default. The default value is 10,000 elements.

**PCT 1.0**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL\Protocols**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This subkey controls use of Private Communications Transport PCT.

**Client**
This subkey controls use of PCT on client

**Server**
This subkey controls use of PCT on server

To disable, create the **Enabled** entry in the appropriate subkey. (This entry does not exist in the registry by default.) After you have created the entry, change the DWORD value to 0. To re-enable the protocol, change the DWORD value to 0xffffffff.

**DisabledByDefault**
This entry controls disabling PCT by default. This entry does not exist in the registry by default.

**SendTrustedIssuerList**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**
Windows Server 2003

This entry controls the flag controlling sending of list of trusted issuers. In the case of servers that trust hundreds of certificate authorities for client authentication, there are too many issuers for the server to be able to send them all to the client when requesting client authentication. In this situation, this registry key can be set, and instead of sending a partial list, Schannel will not send any to the client.

Not sending a list of trusted issuers might impact what the client sends when asked for a client certificate. For example, when Internet Explorer receives a request for client authentication, it only displays the client certificates that chain up to one of the certificate authorities that is sent by the server. If the server did not send a list, then Internet Explorer displays all of the client certificates that are installed on the client machine. This behavior might be desirable, when PKI environments include cross certificates, the client and server certificates will not have the same Root CA and therefore, Internet Explorer cannot chose a certificate that chains up to on of the server's CAs. By configuring the server to not send a trusted issuer list then Internet Explorer will send all its certificates.

This entry does not exist in the registry by default. This value is true by default.

**ServerCacheTime**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This entry controls the time to expire server side cache entries in milliseconds. A value of 0 disables the server-side session cache and prevents reconnects. Increasing ServerCacheTime above the default values causes Lsass.exe to consume additional memory. Each session cache element typically requires 2-4k bytes of memory. This entry does not exist in the registry by default. The default values are:

### Default Server Cache Time

| Windows Version | Time |
|---|---|
| Windows NT 4.0 with Service Pack 6a | 2 minutes |

| | |
|---|---|
| Windows NT 4.0 with Service Pack 6a and Q265369 | 5 minutes |
| Windows 2000 | 2 minutes |
| Windows 2000 with Service Pack 2 or greater | 10 hours |
| Windows XP | 10 hours |
| Windows Server 2003 | 10 hours |

**SSL 2.0**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL\Protocols**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This subkey controls use of SSL 2.0.

**Client**
This subkey controls use of SSL 2.0 on the client.

**Server**
This subkey controls use of SSL 2.0 on the server.

To disable, create the **Enabled** entry in the appropriate subkey. (This entry does not exist in the registry by default.) After you have created the entry, change the DWORD value to 0. To re-enable the protocol, change the DWORD value to 0xffffffff.

**DisabledByDefault**
Flag to disable SSL 2.0 by default.

**SSL 3.0**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL\Protocols**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This subkey controls use of SSL 3.0.

**Client**
This subkey controls use of SSL 3.0 on client

**Server**
This subkey controls use of SSL 3.0 on server

To disable, create the **Enabled** entry in the appropriate subkey. (This entry does not exist in the registry by default.) After you have created the entry, change the DWORD value to 0. To re-enable the protocol, change the DWORD value to 0xffffffff.

**TLS 1.0**
**Registry path**
**HKLM SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL\Protocols**

**Version**
Windows Server 2003, Windows XP, Windows 2000

This subkey controls use of TLS 1.0.

**Client**
This subkey controls use of TLS 1.0 on client

**Server**
This subkey controls use of TLS 1.0 on server

To disable, create the **Enabled** entry in the appropriate subkey. (This entry does not exist in the registry by default.) After you have created the entry, change the DWORD value to 0. To re-enable the protocol, change the DWORD value to 0xffffffff.

**TLS/SSL Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with Schannel.

**Group Policy Settings Associated with Schannel**

| Group Policy Setting | Description |
|---|---|
| Security options:<br><br>System cryptography: Use FIPS compliant algorithms for encryption, hashing and signing | Changes to this setting determine whether Schannel will only support the TLS protocol as a client (and as a server, if applicable) and only use:<br><br>• Triple Data Encryption Standard (3DES) encryption algorithm for the TLS traffic encryption<br><br>• Rivest-Shamir-Adleman (RSA) public key algorithm for the TLS key exchange and authentication<br><br>• Secure Hash Algorithm version 1 (SHA-1) hashing algorithm for the TLS hashing<br><br>Both the client and the server must support these algorithms and TLS to communicate using a secure channel application. For example, if you enable this policy setting, you will also need to configure Internet Explorer to use TLS (which is Off by default) to connect using Secure Hypertext Transfer Protocol (HTTPS) to a server with this setting. |

For more information about Group Policy settings, see the "Group Policy Settings Reference for Windows Server 2003" in Tools and Settings Collection.

**Network Ports Used by Schannel**

**Port Assignments for Common Applications over TLS/SSL**

| Service Name | TCP |
|---|---|
| smtp | 25 |
| https | 443 |
| nntps | 563 |
| ldaps | 636 |
| ftps-data | 989 |
| ftps | 990 |
| telnets | 992 |
| imaps | 993 |
| pop3s | 995 |
| ms-sql-s | 1433 |
| mfst-gc-ssl | 3269 |
| tftps | 3713 |

# Authorization and Access Control Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Authorization and Access Control Technologies**
Security in the Microsoft Windows Server 2003 operating system controls the use of system and network resources through the interrelated mechanisms of authentication and authorization. After a user is authenticated, Windows Server 2003 uses the authorization and access control technologies to implement the second phase of protecting resources: determining if an authenticated user has the correct authorization to access a resource. Shared resources — resources available to users and groups other than the resource's owner — need to be protected from unauthorized use. In the Windows Server 2003 access control model, users and groups are assigned rights that inform the operating system what each user and group can and cannot do. Shared resources are assigned permissions that enable resource managers to enforce access control in two ways: by denying access to unauthorized users, and by limiting the extent of access provided to authorized users.

**Authorization and Access Control Technologies Architecture**
The authorization and access control model used in Windows Server 2003 is based on the following concepts:

**User-based authorization**
Every application that a user starts runs in that user's security context, not in the application's security context. Applications can also run in a restricted security context, with fewer privileges and more limited access than their user's security context.

**Discretionary access to securable objects**
The user who owns a securable object can control who has permission to use it and in what way. An object's owner can give permission for different kinds of access to particular users or groups of users. Owners can also allow or deny other users access to individual properties of certain types of objects, as well as to the entire object.

**Inheritance of permissions**
You can control permissions for new objects created in a container object by setting inheritable permissions on the container. The permissions that you set on a container are also inherited by existing objects in the container as well as newly created objects.

**Administrative privileges**
You can control which users or groups have the right to perform various administrative functions or to take any action that affects systemwide resources. Domain administrators can use Group Policy to manage privileges on several computers at once or even on all computers joined to a domain.

**Auditing of system events**
The auditing feature detects attempts to circumvent protections on resources and creates an audit trail of administrative actions on the system. If another administrator changes the auditing policy so that failed logon attempts are no longer audited, the log shows this event too. You can also use Group Policy to centrally control who is allowed to manage security logs on computers joined to a domain, as well as to control such configuration options as log size and retention method.

**How Access Control Works**
The access control model used by the Windows Server 2003 operating system ensures authorized use of its objects by security principals. Security principals include users and groups. Security principals perform actions on objects, which include files, folders, printers, registry keys, Active Directory directory service objects, and other types of objects.

Each object has an owner that grants permissions to security principals. During the access control check, these permissions are examined to determine which security principals can access the object and how they can access it.

Object owners generally grant permissions to security groups rather than to individual users. Users added to existing groups adopt the permissions of that group. Object owners also often define permissions for container objects, rather than individual objects, to ease access control management. If an object (such as a folder) can hold other objects (such as subfolders and files), it is called a container. In a hierarchy of objects, the relationship between a container and its content is expressed by referring to the container as the parent and to an object in the container as the child.

Although users are the ones who attempt to access a shared resource, programs actually perform the operations. More specifically, the executable program sequence within a process, called a thread, runs program instructions. A process can have several threads, all executing at the same time. In describing the access control model, the subject taking action is always a thread, never a user, program, or process.

Although only threads can act on system objects, threads do not carry their own security identifiers (SIDs). A thread assumes the rights and privileges of the security principal that initiated the process. When a user logs on, the system creates an access

token for that user. The access token contains the user's SID, the SIDs for any groups the user belongs to, and the user's privileges. This token provides the security context for whatever actions the user executes on that computer.

Threads do not access files in the same way that users do. Threads interact with objects through one of several application programming interfaces (APIs) that are provided by the operating system. For example, the thread that opens a file is probably executing code with the following instruction:

```
hfile=CreateFile(pszFile,GENERIC_WRITE,0,NULL,OPEN_EXISTING,0,NULL);
```

The second argument in the call to CreateFile() specifies a desired set of access rights, GENERIC_WRITE, which indicates to the operating system that the thread wants to open the file and modify it. Other APIs work in a similar fashion. The calling process must signal its intentions for an object by specifying a desired level of access.

Before allowing a subject to proceed with the action it intends to carry out on an object, the operating system's security subsystem performs an access check to determine whether the subject is authorized to perform the action. The access check systematically compares information in two key data structures:

- The subject's access token, which contains a SID for the user and additional SIDs for groups that the user belongs to.
- The object's security descriptor, which contains a discretionary access control list (DACL) with a list of access control entries (ACEs) that specify the access rights that are allowed or denied to particular users or groups, each of whom is identified by a SID.

The security subsystem checks the object's DACL, looking for ACEs that apply to the user and group SIDs in the subject's access token. The system examines each ACE in order until it finds one that either allows or denies access to the user or one of the user's groups, or until there are no more ACEs to check. It is possible for a DACL to have several ACEs that apply to the token's SIDs. If this occurs, the access rights granted by each ACE accumulate until the total matches or exceeds the level of access that the subject has requested. For example, if one ACE grants read access to a group and another ACE grants write access to a user who is a member of the group, the user can have both read/write access to the object. If the access check reaches the end of the DACL and the desired access is still not explicitly allowed or denied, the security subsystem denies access.

The following figure shows the authorization and access control process.

**Authorization and Access Control Process**

**Authorization and Access Control Technologies Components**

The following table provides a summary of the components that comprise the authorization and access control model.

**Components of Authorization and Access Control**

| Components | Description |
|---|---|
| Security Principal | A user, group, or computer. Security principals have accounts. Local accounts are managed by the Security Accounts Manager (SAM) on the computer. Domain accounts are managed by Active Directory. |

| | |
|---|---|
| Security Identifier (SID) | The Windows security model identifies account objects — such as users, groups, computers, and domain trusts — by SIDs. SIDs are domain-unique values, built when the user or group is created or when the computer or trust is registered with the domain. The components of a SID follow a hierarchical convention: A SID contains parts that identify the revision number, the authority — such as the domain — that issued the SID, and a variable number of sub authority or relative identifier (RID) values that uniquely identify the security principal relative to the issuing authority. |
| Access Tokens | After a user logs on and is authenticated, the system creates an access token for the user containing the SID of the user (the primary SID), and the SIDs of all the domain groups the user is a member of. The system uses this access token to determine whether to grant the user access to system resources. |
| Permissions | Authority to perform an operation or a set of operations on an object or object property. Permissions are granted or denied by an object's owner. Because access to an object is at the owner's discretion, the type of access control used in Windows Server 2003 is called discretionary access control.<br><br>Permissions are applied to any secured objects such as files, Active Directory objects, or registry objects. Permissions can be granted to any account — a user, group, or computer. You can assign permissions for objects to:<br><br>● Groups, users, and special identities in the domain.<br><br>● Groups and users in that domain and any trusted domains.<br><br>● Local groups and users on the computer where the object resides.<br><br>The permissions that can be attached to an object depend on the type of object. For example, the permissions that can be attached to a file are different from those that can be attached to a registry key. |
| User Rights | Authority to perform an operation that affects an entire computer rather than a particular object. User rights (also known as privileges) are assigned by administrators to individual users or groups as part of the security settings for the computer. Although user rights can be managed centrally through Group Policy, they are applied locally. Users can (and usually do) have different user rights on different computers. User rights grant specific privileges and logon rights to users and groups in your computing environment. |
| Security Descriptors | A data structure containing the security information associated with a securable object, such as a file or a printer. |
| Access Control Lists (ACLs) | If permissions are configured for an object, its security descriptor contains a discretionary access control list (DACL) with SIDs for the users and groups who are allowed or denied access. If auditing is configured for the object, its security descriptor also contains a system access control list (SACL) that controls how the security subsystem audits attempts to access the object. |

How authorization and access control functions also depends upon related technologies in the Windows Server 2003 security architecture. The following table provides a summary of these related technologies.

**Technologies Related to Authorization and Access Control**

| **Related Components** | **Description** |
|---|---|
| Authentication | During the authentication process, a user is identified to the local or trusted domain by presentation of credentials, usually in the form of a user name and password. Assuming these credentials are acceptable, the system creates an access token for the user. |

| | |
|---|---|
| Auditing | Establishing an audit policy allows you to track potential security problems, help to ensure user accountability, and provide evidence in the event of a security breach.<br><br>The most common types of events to be audited are:<br><br>● Access to objects, such as files and folders.<br><br>● Management of user accounts and group accounts.<br><br>● Users logging on to and logging off from the system.<br><br>You can then view these security-related events in the security log with the Event Viewer. |
| Trusts | By default, all users in a specific Microsoft Windows NT 4.0 or Active Directory domain can connect to resources contained within that domain. This means that a single domain can, by default, provide network connectivity, for users that are members of that domain, to all resources that reside within that domain. To expand resource sharing beyond the boundaries of a single domain, you will need to use trust relationships. Trust relationships provide a security channel for data to flow across domains or forests. |
| SIDHistory | In Active Directory, domain migration or restructuring across trusts is made considerably easier as a result of an attribute of Active Directory security principals called SIDHistory. SIDHistory is used to store the former SIDs of moved objects such as users and security groups. When a user is moved, the SIDHistory attribute of the user object is updated with the former SID. When the user then logs onto the system, the system retrieves the entries in the SIDHistory and adds them to the user access token. In this way SIDHistory ensures that migrated users can continue to access resources even when the resources are located in a trusting domain. |
| SID Filtering | SID filtering prevents domains from accepting SIDs with domain SIDs from outside the sender's domain. Applying SID filtering to trusts can prevent malicious users who have domain administrator level access in the trusted domain from granting, to themselves or other user accounts in their domain, elevated user rights to the trusting domain. |

**Authorization and Access Control Technologies Deployment Scenarios**
Common deployment scenarios for controlling access to resources include the User/ACL method, the Account group/ACL method, the Account group/Resource group method, and the role-based authorization method.

These methods are all based on a planning and deployment process that involves first identifying your users by workgroup, job function, or a combination of workgroup and job function. You can then identify the different types of resources that users might access, such as departmental or job-specific data. This allows you to plan for different levels of access. These access control methods rely on the following concepts:

- **Account group** An account group is a security group whose members are user or computer accounts, all of which require the same permissions for a resource

- **Resource group** A resource group is a security group that has been added to the access control list (ACL) of a resource and granted a specific set of access permissions

- **Principle of Least Access** The principle of least access states that users must have access to the software, data, and devices required to perform their daily duties, but must not have access to local or network resources that are not required for their job tasks. This minimizes potential security risks

In Windows Server 2003, there are four basic strategies for controlling access to resources:

**User/ACL Method**
Security principal accounts are added directly to the ACL for a resource. The ACL is then configured to allow the appropriate permissions for each security principal. This option is appropriate only for managing basic access to a limited number of resources for a small number of users. Otherwise, the complexity and administrator time needed to set and maintain the appropriate permissions becomes burdensome.

**Account Group/ACL Method**
Security groups, rather than individual security principal accounts, are added to the resource ACL, and the group is given a set

of access permissions. The Account group/ACL method is scalable because security groups can be nested if your domain is configured for Microsoft Windows 2000 or Windows Server 2003 native mode functional levels. If groups from multiple domains or from multiple forests require identical access permissions, they can be grouped together into one all-encompassing security group, and you can add this security group to the resource ACL. However, if different groups require different access permissions, this method requires more administrative effort from the resource owner. In this case, each group must be added to the ACL separately, and access permissions must be granted to each group.

**Account Group/Resource Group Method**

Users with similar access requirements are grouped into account groups, and the account groups are added to a resource group that is granted specific resource access permissions. The Account group/resource group method is often most appropriate for large organizations with many shared resources because it is scalable and can be maintained in all environments and at all domain functional levels. This method can be used in any environment, but it is most useful when you cannot nest groups because, for example, your domains are at Windows 2000 mixed functional levels or you need to share resources with Windows NT version 4.0 operating system domains. The Account group/resource group method is also preferable if your resources require a stable set of common permissions.

**Role-based Authorization Method**

Users with similar roles are authorized to perform predefined sets of tasks based on scripts called authorization rules. This allows you to apply fine-grained control over the mapping between access control and the structure and tasks performed in your organization. To use role-based authorization, however, programs need to be written to take advantage of this capability. Additionally, your environment must be operating at the Windows Server 2003 domain functional level.

# Security Descriptors and Access Control Lists Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security Descriptors and Access Control Lists Technical Reference**

**In this subject**

- What Are Security Descriptors and Access Control Lists?
- How Security Descriptors and Access Control Lists Work
- Security Descriptors and Access Control Lists Tools and Settings

All objects in the Active Directory directory service, and all securable objects on the network, have security descriptors to help control access to the objects. Security descriptors contain access control lists (ACLs), and they include information about who owns an object, who can access it and in what way, and what types of access are audited.

You can use this access control model to individually secure objects such as files and folders, Active Directory objects, registry keys, and printers, as well as devices, ports, services, processes, and threads. Because of this individual control, you can adjust the security of objects to meet the needs of your organization, delegate authority over objects or attributes, and create custom objects or attributes that require unique security protections to be defined.

# What Are Security Descriptors and Access Control Lists?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Technologies Related to Security Descriptors and Access Control Lists
- Related Information

All objects in Active Directory, and all securable objects on a local computer or on the network, have security descriptors to help control access to the objects. Security descriptors include information about who owns an object, who can access it and in what way, and what types of access are audited. Security descriptors, in turn, contain the access control list (ACL) of an object, which includes all of the security permissions that apply to that object. An object's security descriptor can contain two types of ACLs:

- A discretionary access control list (DACL) that identifies the users and groups who are allowed or denied access
- A system access control list (SACL) that controls how access is audited

You can use this access control model to individually secure objects such as files and folders, Active Directory objects, registry keys, and printers, as well as devices, ports, services, processes, and threads. Because of this individual control, you can adjust the security of objects to meet the needs of your organization, delegate authority over objects or attributes, and create custom objects or attributes that require unique security protections to be defined.

**Technologies Related to Security Descriptors and ACLs**
Security descriptors and ACLs are closely related to the technologies and components of the Windows Server 2003 security architecture that are described in the following sections.

**Authentication and Access Tokens**
Access tokens are created by the security system, and they contain security information about users who have logged on and been authenticated. When a user requests access to an object, the access token of the account requesting access is compared to the object's DACL.

**Permissions**
Each permission that an object's owner grants to a particular user or group is stored as an access control entry (ACE) in a DACL that is part of the object's security descriptor. In the user interface, ACEs are displayed as Permission Entries.

**Auditing**
If auditing is configured for an object, the object's security descriptor also contains a SACL that controls how the security subsystem audits attempts to access the object.

The following figure shows the relationship of security descriptors and ACLs to other key components of the authorization and access control model.

**Relationship of Security Descriptors and ACLs to Other Authorization and Access Control Components**

All objects in Active Directory, and all securable objects on a local computer or on the network, have security descriptors to help control access to the objects. Security descriptors include information about who owns an object, who can access it and in what way, and what types of access are audited. Security descriptors, in turn, contain the access control list (ACL) of an object, which includes all of the security permissions that apply to that object. An object's security descriptor can contain two types of ACLs:

- A discretionary access control list (DACL) that identifies the users and groups who are allowed or denied access
- A system access control list (SACL) that controls how access is audited

The access control model that is used by the Windows Server 2003 operating system is administered at the object level by setting different levels of access, or permissions, to objects. If permissions are configured for an object, its security descriptor contains a DACL with security identifiers (SIDs) for the users and groups that are allowed or denied access. If auditing is configured for the object, its security descriptor also contains a SACL that controls how the security subsystem audits attempts to access the object.

You can use this access control model to individually secure objects such as files and folders, Active Directory objects, registry keys, and printers, as well as devices, ports, services, processes, and threads. Because of this individual control, you can adjust the security of objects to meet the needs of your organization, delegate authority over objects or attributes, and create custom objects or attributes that require unique security protections to be defined.

The following sections define the basic elements of security descriptors and ACLs, look at where access control information comes from, discuss how access control permissions are inherited, and describe how ACLs work in an optimal environment. An optimal environment for ACLs is defined as follows:

- Security on objects is designed using the theory of least privilege. Users are assigned the least level of access that they need to perform their job functions.
- Groups, rather than individual user accounts, are used to grant or deny access to resources.
- A consistent model is used for assigning permissions.
- Permissions on Active Directory objects are not assigned to domain local groups.

**Securable Objects**

A securable object is an object that can have a security descriptor. All named Windows objects are securable. Some unnamed objects, such as process and thread objects, can also have security descriptors. Each type of securable object defines its own set of specific access rights and its own mapping of generic access rights.

The following are the common securable objects:

- Files or folders on an NTFS file system

- Active Directory objects
- Registry keys
- Network shares
- Local or remote printers
- Windows services
- Named pipes
- Anonymous pipes
- Processes
- Threads
- File-mapping objects
- Access tokens
- Window-management objects (window stations and desktops)
- Interprocess synchronization objects (events, mutexes, semaphores, and waitable timers)
- Job objects
- Distributed Component Object Model (DCOM) objects

**Security Descriptor Architecture**
Access control information that is associated with an object is contained in the object's security descriptor. When a user tries to access the object, the operating system examines the object's security descriptor to determine whether the access will be granted. Before allowing a subject to proceed with the action it intends to carry out on an object, the operating system's security subsystem performs an access check to determine whether the subject is authorized to perform the action on that object.

The information that is included in a security descriptor depends on the type of object and how it was created. In general, security descriptors can include information about the following:

- Which user owns the object
- Which users and groups are allowed or denied access
- Which users and groups' access should be audited
- How objects in a container inherit access control information from the container

**Parts of a Security Descriptor**
A security descriptor is a binary data structure of variable length. The data structure has the following parts:

**Header**
The header contains a revision number and a set of control flags that describe characteristics of the security descriptor, such as the memory layout, which elements are present, and how particular elements were added or modified.

**Owner**
The Owner field contains the SID for the object's owner. The owner of an object can modify permissions and give other users

the right to take ownership.

**Primary Group**
The Primary Group field contains the SID for the owner's primary group. This information is used only by the POSIX subsystem, and it is ignored by the rest of Windows Server 2003.

**DACL**
The DACL is a list of zero or more access control entries (ACEs). Each ACE in the list has a header that specifies whether the ACE allows or denies access, a SID that specifies a particular user or group, and an access mask that lists the operations that are allowed or denied. The content of the DACL is controlled by the object's owner. The owner can share control with other users by granting them Change Permissions (WRITE_DAC) permission. Note that it is possible for a security descriptor to have no DACL (also known as a NULL DACL); this gives unconditional access to everyone. A security descriptor with an empty DACL gives no access to anyone. For more information, see "No DACL vs. Empty DACL" later in this section.

**SACL**
The SACL is similar to the DACL except that the SACL is used to audit rather than control access to an object. When an audited action occurs, the operating system records the event in the security log. Each ACE in a SACL has a header that indicates whether auditing is triggered by success or failure or both, a SID that specifies a particular user or security group to monitor, and an access mask that lists the operations to audit. The content of the SACL is controlled by security administrators for the local system. Security administrators are users who have been assigned the Manage Auditing and Security Log (SeSecurityPrivilege) privilege. By default, this privilege is assigned to the built-in Administrators group.

**Layout in Memory**
A security descriptor's layout in memory can be either self-relative or absolute. Which of the two formats a particular security descriptor uses is indicated by a control flag in the security descriptor's header.

A self-relative security descriptor is stored in a contiguous block of memory, and the address for each part of the descriptor is expressed as an offset from the beginning of the memory block. To locate any part of the security descriptor, a process must be given only the address of the area in memory where the security descriptor begins. The process determines where the part in question begins by adding the memory offset for the part to the memory address for the security descriptor. (Hence, the name "self-relative"; the address for a part is relative to the address for the whole.)

The following figure illustrates the layout of a security descriptor in self-relative format.

**Security Descriptor in Self-Relative Format**

Self-relative layout is used for security descriptors on objects that must be stored on disk, transmitted by a communications protocol, or copied in memory.

A security descriptor in absolute format contains pointers to its information, not the information itself. This format enables each component of the security descriptor to be allocated separately and assembled on the fly. It is used for objects that do not require persistent storage, such as objects that exist only during the lifetime of a single process. The following figure illustrates the layout of a security descriptor in absolute format.

**Security Descriptor in Absolute Format**

**Security Descriptor Control Flags**
A security descriptor's header contains a set of control flags that qualify the meaning of the security descriptor or its components. In Windows 2000 and later operating systems, control flags play an important role in the automatic propagation of inheritable security information from parent (container) objects to child (contained) objects.

Security descriptor control flags are stored in a bit field, and they are turned on or off by setting individual bits. The following table lists the security descriptor control flags and their meaning.

**Security Descriptor Control Flags**

| Flag | Meaning |
| --- | --- |
| SE_DACL_AUTO_INHERITED | **Windows 2000 and later:** Inheritable ACEs in this object's DACL have been propagated to existing child objects.<br><br>This flag is not set in security descriptors for Windows NT, which does not support automatic propagation of inheritable ACEs. |
| SE_DACL_DEFAULTED | The DACL was provided by a default mechanism.<br><br>This flag can affect how the operating system treats the DACL with respect to inheritance. The operating system ignores this flag if SE_DACL_PRESENT is not set. |
| SE_DACL_PRESENT | The security descriptor has a DACL.<br><br>**Windows 2000 and later:** If this flag is not set (that is, if the security descriptor has no DACL), SE_DACL_PROTECTED must be set. Otherwise, the operating system considers the security descriptor to be invalid. |
| SE_DACL_PROTECTED | **Windows 2000 and later:** The security descriptor's DACL cannot be modified by inheritable ACEs.<br><br>If this flag is not set, the security descriptor inherits information from the security descriptor of the parent object. |
| SE_GROUP_DEFAULTED | The primary group SID was provided by a default mechanism. |
| SE_OWNER_DEFAULTED | The owner SID was provided by a default mechanism. |
| SE_SACL_AUTO_INHERITED | **Windows 2000 and later:** Inheritable ACEs in this object's SACL have been propagated to existing child objects.<br><br>This flag is not set in security descriptors for Windows NT, which does not support automatic propagation of inheritable ACEs. |
| SE_SACL_DEFAULTED | The SACL was provided by a default mechanism.<br><br>This flag can affect how the operating system treats the SACL with respect to inheritance. The operating system ignores this flag if SE_SACL_PRESENT is not set. |
| SE_SACL_PRESENT | The security descriptor has a SACL. |
| SE_SACL_PROTECTED | **Windows 2000 and later:** The security descriptor's SACL cannot be modified by inheritable ACEs. |
| SE_SELF_RELATIVE | The security descriptor is in self-relative format with all information in a contiguous block of memory. If this flag is not set, the security descriptor is in absolute format. |

**Where Access Control Information Comes From**

Access control information is first written to an object's security descriptor when the object is created. This information can later be modified. In both cases, the information that goes into a security descriptor can come from one of the following sources:

- The subject
- The Object Manager
- The parent object

When a subject creates a new object, it can assign a security descriptor to the object. If the subject does not assign a security descriptor, the operating system uses access control information inherited from the parent object to create one. If no information is available to inherit, the operating system uses default access control information provided by the object manager for the particular type of object that the subject wants to create.

After an object is created, information in its security descriptor can be changed by the object's owner or by another user who

has the owner's permission. Changes can also come from the parent object when that object's owner modifies its security descriptor. Every time the security descriptor on a container object is changed, the object manager propagates any changes that are marked as inheritable to all objects in the container.

**Subjects**
A subject is a thread executing in the security context provided by an access token. A subject's access token contains information that can be used in security descriptors for new objects that the subject creates and existing objects that the subject modifies. This information includes the following fields.

**Default Owner**
This field of an access token contains the SID that identifies the security principal that, by default, becomes the owner of objects that the subject either creates or takes ownership of. Typically, the default owner is the individual user that is represented by the access token. When the SID in the Default Owner field of the subject's access token is copied to the Owner field of an object's security descriptor, SE_OWNER_DEFAULTED is set in the security descriptor's control flags.

### Note

- When users who are members of the local Administrators group access objects on Windows Server 2003, the Default Owner field in the user's access token contains the SID for the Administrators group, not the SID for the user. A similar rule applies to users who access objects in Active Directory. If the user is a member of the Domain Admins group, the Default Owner field in the user's access token contains the SID for the Domain Admins group. In both cases, objects that the user creates or takes ownership of are owned by the group, not by the individual user.

- On Windows XP Professional, the Default Owner field always contains the user's SID. This is a change from Windows 2000 and earlier operating systems, in which the rules were the same for both Windows 2000 Server and Windows XP Professional.

**Primary Group**
This field of an access token contains the SID for the user's primary group. When the SID in the Primary Group field of the subject's access token is copied to the Primary Group field of an object's security descriptor, SE_GROUP_DEFAULTED is set in the security descriptor's control flags.

**Default DACL**
This field of an access token might contain a DACL, or it might be empty. If the subject's access token contains a DACL, it can be used as the DACL in a new object's security descriptor. If the Default DACL field is used in the security descriptor for a new object, SE_DACL_DEFAULTED is set in the security descriptor's control flags.

**Object Managers**
The object manager can provide default security information for new objects. In Windows Server 2003, the only object manager that supplies default permissions for new objects is Active Directory.

For more information, see "DACLs for Newly Created Active Directory Objects" later in this section.

**Parent Objects**
Some objects can contain other objects. For example, an NTFS folder object can contain file objects and other folder objects. A registry key object can contain subkey objects. An Active Directory organizational unit (OU) object can contain other OU objects as well as user objects, group objects, and computer objects. Terminal objects contain Window Station objects that contain Desktop objects that contain Window objects. Any object that is contained by another object is called a "child" object. A "child" object's container is its "parent" object.

Child objects can inherit access control information from their parent object. For example, suppose that the administrator for a server creates a file share with one folder, Public$. The administrator creates this folder so that users can have a place to store information that they want to share. With this purpose in mind, the administrator sets the permissions, which are implemented as ACEs, as shown in the following figure.

### Permission Entries on Public Folder (Owner: Administrators)

None of the permissions that are listed in this figure were acquired through inheritance. This is because the administrator cleared the check box for **Inherit from parent the permission entries that apply to child objects**. Clearing the check box sets the security descriptor control flag SE_DACL_PROTECTED, which protects a child object's DACL by blocking inheritance from the parent object's DACL.

Permissions that are acquired through inheritance are called "inherited" permissions. Permissions that are not inherited, but are instead defined directly on an object, are called "explicit" permissions. One way to tell an explicit permission from an inherited permission is to select an entry in the **Permission Entries** list and read the text that is displayed after the list. In this figure, the second entry is selected, and the text after the list says **This permission is defined directly on this object**. In other words, the permission is explicit, not inherited.

The text in this figure also says **This permission is inherited by child objects**. Permissions on a parent object that apply to child objects are called "inheritable" permissions. To see which of the permissions that are set on a parent object are inheritable, examine the **Apply to** column of **Permission Entries**. If **Apply to** says **This object only** (or, for folder objects, **This folder only**), the permission is not inherited by child objects. Of the four permissions that are shown in this figure, three are inheritable and one is not.

To see how inheritable permissions become inherited permissions, suppose that Alice creates a subfolder in Public$. Alice is an engineer, so she names her folder Engineering Data. Because this new object is a child of Public$, its DACL inherits permissions from the DACL on Public$. The new object's permissions are shown in the following figure.

**Permission Entries on Engineering Data Folder (Owner: Alice)**

Note that Alice has not cleared the check box for **Inherit from parent the permission entries that apply to child objects**, so inheritable permissions in the parent object's DACL are inherited by the child object's DACL. Inherited permissions are indicated in **Permission Entries** by a disabled (unavailable) symbol at the beginning of each entry. The permission is still effective; all that is disabled is the ability to modify the entry. Because inherited permissions are defined on a parent object, they can be changed only by modifying the parent object's DACL.

Even though inherited permissions cannot be changed, the owner of a child object can add explicit permissions to the object's DACL. For example, suppose Alice decides that inherited permissions that are given to Creator Owner are too restrictive because they allow only the user who creates a file to make changes to the file. She wants all members of the Engineering group to be able to edit and add information to the Engineering Data folder, so she explicitly gives this group Modify permission for all objects in the folder. Alice also feels that people in her company's marketing department will misuse information in Engineering Data, so she decides to explicitly deny the Marketing group full control of (and therefore all access to) the folder, subfolders, and files. The results of Alice's changes to the access control settings are shown in the following figure.

**Modified Permission Entries on Engineering Data Folder**

The list of permission entries in this figure now includes two explicit permissions, both with enabled symbols indicating that

the entries can be edited. Note that explicit permissions appear at the top of the list. Permissions are listed in the order in which they will be processed during an access check. Because explicit permissions are listed before inherited permissions, they are processed first. The assumption is that the owner of a child object adds explicit permissions in order to qualify inherited permissions. For example, in this figure, an inherited permission allows Everyone to read the folder, subfolders, and files. Alice has added an explicit permission that denies all access to a subset of the group Everyone — the Marketing group. The explicit deny entry is placed before any inherited entries; therefore, it is processed before any inherited entries. For more information about ACE order, see "Order of ACEs in a DACL" later in this section.

Alice applied both of her explicit permissions to **This folder, subfolders, and files** because she wants child objects in her folder to inherit the new permissions. If the Engineering Data folder were on a server running Windows NT, the new explicit permissions would affect only new objects created in her folder, because the access control model used in Windows NT supports inheritance only at the time that an object is created. To change permissions on existing objects in a Windows NT system, Alice would need to take the additional step of setting explicit permissions on each existing subfolder and file. What is new in Windows 2000 and later is inheritance after the time of creation. New or changed inheritable permissions in the DACL on a parent object are automatically propagated to existing child objects every time the DACL on the parent object changes. If Alice's folder were on a system running Windows 2000 or later, the entry denying Marketing permission to access the Engineering Data folder would be propagated to subfolders as soon as Alice clicked **Apply** in the **Advanced Security Settings** dialog box.

Automatic propagation of inheritable permissions is a powerful capability because you can use it to change permissions on an entire tree of objects by changing permissions on the top-level object in the tree. For example, suppose a member of the Administrators group realizes that information in the Public$ folder and its subfolders is proprietary, not public. In that case, it is inappropriate to allow Everyone access because that group includes the Guest account. The administrator decides that it is more prudent to allow access only to Authenticated Users, a group that includes only users whose identities can be authenticated by the server or by a trusted security authority. To tighten security on the folder, the administrator simply needs to change Everyone to Authenticated Users for two entries in the permissions list. The change is shown in the following figure.

**Modified Permission Entries on Public Folder**

When the administrator applies the changes to the access control settings on the parent object, all inheritable permissions in the parent object's DACL are propagated to DACLs on subfolders and files. The impact on the Engineering Data folder is shown in the following figure.

**Permission Entries Propagated to Engineering Data Folder**

Note that propagation of inheritable permissions from the Public$ folder to the Engineering Data folder does not change explicit permissions in the child's DACL. Only inherited permissions are replaced when inheritable permissions are propagated to existing child objects. However, if explicit permissions are also inheritable, the propagation process reapplies them as it moves down the tree. For example, both explicit permissions that Alice added to the DACL on her folder are inheritable by child objects in the folder. As the propagation process moves downward from Alice's folder, it picks up these additional inheritable permissions and applies them to the DACL of any child object that it finds.

The owner of a parent object can choose to overwrite explicit permissions that are defined on child objects. This is done by selecting the **Replace permission entries on all child objects with entries shown here that apply to child objects** check box in the **Advanced Security Settings** dialog box. When the owner of a parent object chooses this option, the propagation process removes explicit permissions from the DACLs on all child objects. It also sets the option **Inherit from parent the permission entries that apply to child objects** on all child objects, removing any protection from inheritance that might have been set by the objects' owners.

**ACL Architecture**

An ACL is an ordered list of ACEs that define the protections that apply to an object and its properties. Each ACE identifies a security principal and specifies a set of access rights that are allowed, denied, or audited for that security principal.

An object's security descriptor can contain two ACLs:

- A DACL that identifies the users and groups that are allowed or denied access
- A SACL that controls how access is audited

The following figure shows the data structure for an ACL.

**Data Structure of an ACL**

| | |
|---|---|
| ACL Size | ACL Revision |
| ACE Count | |
| ACE [1] | |
| ACE [...] | |
| ACE [*n*] | |

**Parts of an ACL**

The individual parts of an ACL are as follows.

**ACL size**

The number of bytes of memory allocated for the ACL. The size of an ACL varies with the number and size of its ACEs. The maximum size of an ACL is 64K, or approximately 1,820 ACEs, depending on the size of the ACEs. However, for performance reasons, the maximum size is not practical.

**ACL revision**

The revision number for the ACL's data structure. The structure of an ACL is the same for all revisions, but the structure of ACEs in the ACL can vary.

**ACE count**
The number of ACEs in the ACL. A value of zero means the ACL has no ACEs — it is empty; therefore, access-checking can stop. Note that an empty DACL differs from a NULL DACL. An empty DACL gives no access to anyone, but a NULL DACL gives unconditional access to everyone, and should therefore be avoided. For more information, see "No DACL vs. Empty DACL" later in this section.

**ACEs**
An ordered list containing zero or more ACEs. During an access check, ACEs are processed in the order in which they are listed.

**How the System Uses ACLs**
When a thread tries to access a securable object, the system either grants or denies access. If the object does not have a DACL, the system grants access; otherwise, the system looks for ACEs in the object's DACL that apply to the thread. Each ACE in the object's DACL specifies the access rights that are allowed or denied for a security principal or logon session.

The system compares the trustee in each ACE to the trustees that are identified in the thread's access token. An access token contains SIDs that identify the user and the group accounts to which the user belongs. A token also contains a logon SID that identifies the current logon session.

The system examines each ACE in sequence until one of the following events occurs:

- An access-denied ACE explicitly denies any of the requested access rights to one of the trustees listed in the thread's access token.
- One or more access-allowed ACEs for trustees listed in the thread's access token explicitly grant all the requested access rights.
- All ACEs have been checked and there is still at least one requested access right that has not been explicitly allowed, in which case, access is implicitly denied.

Because the system stops checking ACEs when the requested access is explicitly granted or denied, the order of ACEs in a DACL is important.

**Access Control Entries**
All ACEs include the following access control information:

- A SID that identifies a user or group
- An access mask that specifies access rights
- A set of bit flags that determine whether child objects can inherit the ACE
- A flag that indicates the type of ACE

**ACE Types**
Windows 2000 and Windows Server 2003 support six types of ACEs. Three are generic ACE types that can be present in ACLs that are attached to all securable objects. The three remaining ACE types are object specific and can occur only in ACLs for Active Directory objects. The following tables list the generic and object-specific ACE types.

**Generic ACE Types**

| Type | Description |
|---|---|
| Access-denied | Used in a DACL to deny access |
| Access-allowed | Used in a DACL to allow access |
| System-audit | Used in a SACL to log attempts to access |

**Object-Specific ACE Types**

| Type | Description |
|---|---|
| Access-denied, object-specific | Used in a DACL to deny access to a property or property set or to limit inheritance to a specified type of child object |
| Access-allowed, object-specific | Used in a DACL to allow access to a property or property set or to limit inheritance to a specified type of child object |
| System-audit, object-specific | Used in a SACL to log attempts to access a property or property set or to limit inheritance to a specified type of child object |

Generic and object-specific ACEs are fundamentally alike. What sets them apart is the degree of control they offer over inheritance and object access.

Generic ACEs offer limited control over the kinds of child objects that can inherit them. Essentially, they can distinguish only between containers and noncontainers. For example, the DACL on a Folder object in NTFS can include a generic ACE that allows a group of users to list the folder's contents. This is an operation that can be performed only on container objects; therefore, the ACE that allows the operation can be flagged as a CONTAINER_INHERIT_ACE. Only container objects in the folder (that is, only other Folder objects) inherit the ACE. Noncontainer objects (that is, File objects) do not inherit the ACE of the parent object.

Object-specific ACEs offer a greater degree of control over the types of child objects that can inherit them. For example, an OU object's ACL can have an object-specific ACE that is marked for inheritance only by User objects. Other types of objects, such as Computer objects, will not inherit the ACE. This capability is why object-specific ACEs are called object specific. Their inheritance can be limited to specific types of child objects.

There are similar differences in how the two categories of ACE types control access to objects. Generic ACEs apply to an entire object. If a generic ACE gives a particular user Read access, the user can read all the information that is associated with the object — both data and properties. This is not a serious limitation for most object types. File objects, for example, have few properties, which are all used for describing characteristics of the object rather than for storing information. Most of the information in a File object is stored as object data; therefore, there is little need for separate controls on a file's properties.

Object-specific ACEs can apply to any individual property of an object or to a set of properties. These ACE types are used only in ACLs for Active Directory objects, which, unlike other object types, store most of their information in properties. It is often desirable to place independent controls on each property of an Active Directory object, and object-specific ACEs make that possible. For example, when you define permissions for a User object, you can use one object-specific ACE to allow Principal Self (that is, the user) Write access to the Phone-Home-Primary (homePhone) property, and you can use other object-specific ACEs to deny Principal Self access to the Logon-Hours (logonHours) property and other properties that set restrictions on the user account.

**Structure of a Generic ACE**

All three generic ACE types — access denied, access allowed, and system audit — have the same data structure, which is illustrated in the following figure.

### Structure of a Generic ACE

| | |
|---|---|
| ACL Size | ACL Type |
| Inheritance and Audit Flags | |
| Access Mask | |
| SID | |

The individual parts of an ACE are as follows.

**ACE Size**

The number of bytes of memory that are allocated for the ACE.

**ACEType**

Specifies whether the ACE allows, denies, or monitors access.

**Inheritance and Audit Flags**

A set of bit flags that control inheritance and auditing. For information about inheritance flags, see "Inheritance" later in this section. The following table describes audit flags.

### Audit Flags

| Flag | Meaning |
|---|---|

| | |
|---|---|
| FAILED_ACCESS_ACE_FLAG | Meaningful only in system-audit and system-audit object ACEs. The access mask specifies operations that are logged when they fail. |
| SUCCESSFUL_ACCESS_ACE_FLAG | Meaningful only in system-audit and system-audit object ACEs. The access mask specifies operations that are logged when they succeed. |

**Access Mask**
A 32-bit value whose bits correspond to access rights for the object. Bits can be set either on or off, but the setting's meaning depends on the ACE type. For example, if the bit that corresponds to the right to read permissions is turned on, and the ACE type is Deny, the ACE denies the right to read the object's permissions. If the same bit is set on but the ACE type is Allow, the ACE grants the right to read the object's permissions.

**SID**
Identifies a user or group whose access is controlled or monitored by this ACE.

**Structure of an Object-Specific ACE**
The following figure shows the structure of an object-specific ACE.

**Structure of an Object-Specific ACE**

| | |
|---|---|
| ACE Size | ACE Type |
| Inheritance and Audit Flags | |
| Access Mask | |
| Object Type | Inherited Object Type |
| Inheritance and Audit Flags | |

The fields for ACE Size, ACEType, Inheritance and Audit Flags, Access Mask, and SID are identical to like elements in the data structure for a generic ACE. The key differences between a generic and an object-specific ACE are as described in the following sections.

**Object flags**
Object flags indicate whether Object Type or Inherited Object Type is present. The following table shows the three possible object flags.

**Object Flags**

| Flag | Meaning |
|---|---|
| 0 (no flags) | Neither Object Type nor Inherited Object Type is present. In this case, the ACE applies to the entire object. It is, in effect, a generic ACE. |
| ACE_OBJECT_TYPE_PRESENT | ACE applies to a property, property set, or extended right, or it controls the ability to create a particular type of child object. |
| ACE_INHERITED_OBJECT_TYPE_PRESENT | ACE can be inherited only by a particular type of child object. |

**Object Type**
Object Type contains a globally unique identifier (GUID) that identifies one of the following:

- schemaIDGUID. When the schema ID GUID is specified in the ACE, the ACE controls who can create a child object from the identified class schema within a container. The SID portion of the ACE identifies a user or group who can create this type of child object. The ACE's access mask contains the object-specific access right ADS_RIGHT_DS_CREATE_CHILD.

- propertyGUID. When a property GUID is specified in the ACE, the ACE controls the ability to read or write a particular property or property set. The SID portion of the ACE identifies a user or group who can read or write the property or property set. The ACE's access mask contains either ADS_RIGHT_DS_READ_PROP or ADS_RIGHT_DS_WRITE_PROP.

- rightsGUID. When an extended rights GUID is specified in the ACE, the ACE controls the right to perform the operation that is associated with the extended right. The SID portion of the ACE identifies a user or group who has the extended right. The ACE's access mask contains ADS_RIGHT_DS_CONTROL_ACCESS. For a list of Extended rights GUIDs, see the Extended Rights Reference.

**Inherited Object Type**
Inherited Object Type contains a GUID that identifies the type of child object that can inherit the ACE. Inheritance is also

controlled by the ACE's Inheritance Flags and by any protection against inheritance placed on the child object in its Security Descriptor Control Flags.

**DACLs for Newly Created Objects**
The operating system uses the following rules to set the DACL in the security descriptors for most types of new securable objects:

1. The object's DACL is the DACL from the security descriptor, which is specified by the creating process. The operating system merges any inheritable ACEs into the DACL unless SE_DACL_PROTECTED is set in the security descriptor control flags. The operating system then sets the SE_DACL_PRESENT security descriptor control flag.

2. If the creating process does not specify a security descriptor, the operating system builds the object's DACL from inheritable ACEs in the parent object's DACL. The operating system then sets the SE_DACL_PRESENT security descriptor control flag.

3. If the parent object has no inheritable ACEs, the operating system asks the object manager to provide a default DACL. The operating system then sets the SE_DACL_PRESENT and SE_DACL_DEFAULTED security descriptor control flags.

4. If the object manager does not provide a default DACL, the operating system checks the subject's access token for a default DACL. The operating system then sets the SE_DACL_PRESENT and SE_DACL_DEFAULTED security descriptor control flags.

5. If the subject's access token does not have a default DACL, the new object is assigned no DACL, which allows unconditional access by everyone. The SE_DACL_PRESENT security descriptor control flag is not set.

**DACLs for Newly Created Active Directory Objects**
The method that is used to build a DACL for a new Active Directory object is slightly different from the method that is used to build DACLs for other object types. There are two key differences:

- The rules for creating a DACL distinguish between generic inheritable ACEs and object-specific inheritable ACEs in the parent object's security descriptor. Generic inheritable ACEs can be inherited by all types of child objects. Object-specific inheritable ACEs can be inherited only by the type of child object to which they apply.

- The Active Directory schema can provide a security descriptor. Each object class that is defined in the schema has a **defaultSecurityDescriptor** attribute. If neither the creating process nor inheritance from the parent object provides a DACL for a new Active Directory object, the operating system uses the DACL in the default security descriptor that is specified by the schema.

The operating system uses the following rules to set the DACL in the security descriptor for new Active Directory objects:

1. The object's initial DACL is the DACL from the security descriptor that is specified by the creating process.

2. The operating system merges inheritable ACEs on the parent object into the new object's DACL. It then sets the SE_DACL_PRESENT security descriptor control flag.

3. If the parent object has no inheritable object-specific ACEs for the type of object being created, the operating system uses the default DACL from the Active Directory schema for that object type. It then sets the SE_DACL_PRESENT and SE_DACL_DEFAULTED security descriptor control flags.

4. If the Active Directory schema does not specify a default DACL for the object type, the operating system checks the subject's access token for a default DACL. It then sets the SE_DACL_PRESENT and SE_DACL_DEFAULTED security descriptor control flags.

5. If the subject's access token does not have a default DACL, the new object is assigned no DACL, which gives unconditional access to everyone. The SE_DACL_PRESENT security descriptor control flag is not set.

**SACLs for Newly Created Objects**
The operating system uses the following rules to set the SACL in the security descriptors for new securable objects:

1. If the creating process provides an explicit SACL, the operating system places it in the object's security descriptor. The operating system merges any inheritable ACEs into the SACL unless SE_SACL_PROTECTED is set in the security descriptor control flags. It then sets the SE_SACL_PRESENT security descriptor control flag.

2. If the creating process does not provide an explicit SACL, the operating system builds the object's SACL from inheritable ACEs in the parent object's SACL. It then sets the SE_SACL_PRESENT security descriptor control flag.

3. If the parent object has no inheritable ACEs, the operating system asks the object manager to provide a default SACL. It then sets the SE_SACL_PRESENT and SE_SACL_DEFAULTED security descriptor control flags.

4. If the object manager does not provide a default SACL, the new object is assigned no SACL.

**Inheritance**

Inheritance is the process that propagates ACEs from the ACL of a parent object to the ACL of a child object. In Windows Server 2003, inheritable ACEs can be propagated from parent to child when one of the following events takes place:

- A new child object is created.

- The DACL on the parent object is modified.

- The SACL on the parent object is modified.

In this model, any object can be the child of another object. Only container objects can be parents. The ACL for a container object can carry ACEs that are not effective on the container but are present only for the purpose of inheritance — only so that they can be passed down to subsequent levels of objects in the container hierarchy until they reach a child object that is not a container, where they become effective ACEs.

The mechanism for inheritance depends on two things: a set of inheritance flags in each ACE and a set of inheritance rules that are built into the operating system.

**Inheritance Flags**

The header for an ACE contains a set of inheritance flags that control how the ACE is inherited and how the ACE affects a child object that inherits it. The following table lists the inheritance flags.

### Inheritance Flags

| Flag | Meaning |
|---|---|
| INHERITED_ACE | **Windows 2000 and later**: The ACE was inherited from a parent object's DACL or SACL.<br><br>This flag is not set in an explicit ACE — an ACE defined directly on the object. |
| INHERIT_ONLY_ACE | Indicates that this is an inherit-only ACE. The ACE is ignored during an access check but can be propagated to child objects.<br><br>If this flag is not set, the ACE is an effective ACE — an ACE that is processed during an access check.<br><br>Both effective and inherit-only ACEs can be inherited. Whether an ACE is inherited depends on the state of the flags for OBJECT_INHERIT_ACE and CONTAINER_INHERIT_ACE. |
| CONTAINER_INHERIT_ACE | Container objects inherit this ACE as an effective ACE. When the ACE is inherited by a container object, the operating system clears the flag for INHERIT_ONLY_ACE. |
| OBJECT_INHERIT_ACE | Noncontainer objects inherit this ACE as an effective ACE. When the ACE is inherited by a noncontainer object, the operating system clears the flag for INHERIT_ONLY_ACE.<br><br>Container objects also inherit this ACE but only for the purpose of inheritance. When the ACE is inherited by a container object, the operating system sets the flag for INHERIT_ONLY_ACE. |

| | |
|---|---|
| NO_PROPAGATE_INHERIT_ACE | If a child object inherits an ACE where this flag is set, the operating system clears the flags for OBJECT_INHERIT_ACE and CONTAINER_INHERIT_ACE. This prevents the ACE from being inherited by subsequent generations of objects. |

**Rules of Inheritance**

The operating system interprets the inheritance flags and other inheritance information according to the rules of ACE inheritance that are outlined in the following table. These rules function the same way for both DACLs and SACLs. When the operating system propagates inheritable ACEs to child objects, it observes the preferred (or canonical) order. After ACEs have been propagated, the system sets the INHERITED_ACE flag in all inherited ACEs.

The following table lists the rules of inheritance from parent ACEs to child ACLs.

**Rules of Inheritance**

| Parent ACE Inheritance Flags | Effect on Child ACL |
|---|---|
| No flags | None. |
| OBJECT_INHERIT_ACE only | **Noncontainer child objects:** Inherited as an effective ACE.<br><br>**Container child objects:** Containers inherit an inherit-only ACE unless the NO_PROPAGATE_INHERIT_ACE flag is also set. |
| CONTAINER_INHERIT_ACE only | **Noncontainer child objects:** No effect on the child object.<br><br>**Container child objects:** The child object inherits an effective ACE. The inherited ACE is inheritable unless the NO_PROPAGATE_INHERIT_ACE flag is also set. |
| CONTAINER_INHERIT_ACE and OBJECT_INHERIT_ACE | **Noncontainer child objects:** Inherited as an effective ACE.<br><br>**Container child objects:** The child object inherits an effective ACE. The inherited ACE is inheritable unless the NO_PROPAGATE_INHERIT_ACE flag is also set. |

If an inherited ACE is an effective ACE for the child object, the system maps any generic rights to the specific rights for the child object. Similarly, the system maps generic SIDs, such as CREATOR_OWNER, to the appropriate SID. If an inherited ACE is an inherit-only ACE, any generic rights or generic SIDs are left unchanged so that they can be mapped appropriately when the ACE is inherited by the next generation of child objects.

When a container object inherits an ACE that is both effective on the container and inheritable by its descendants, the container might inherit two ACEs. This occurs if the inheritable ACE contains generic information. The container inherits an inherit-only ACE containing the generic information, and an effective ACE in which the generic information is mapped.

An object-specific ACE has an Inherited Object Type field that can contain a GUID to identify the type of object that can inherit the ACE. If the field does not contain a GUID, the inheritance rules are the same as for a standard ACE. If the field contains a GUID, the ACE is inheritable by objects that match the GUID if OBJECT_INHERIT_ACE is set and by containers that match the GUID if CONTAINER_INHERIT_ACE is set.

**Order of ACEs in a DACL**

The preferred order of ACEs in a DACL is called the “canonical” order. For Windows 2000 and Windows Server 2003, the canonical order is the following:

- All explicit ACEs are placed in a group before any inherited ACEs.
- Within the group of explicit ACEs, access-denied ACEs are placed before access-allowed ACEs.
- Inherited ACEs are placed in the order in which they are inherited. ACEs that are inherited from the child object’s parent come first, then ACEs inherited from the grandparent, and so on up the tree of objects.

The following figure shows the canonical order of ACEs.

**Canonical Order of ACEs**

The canonical order ensures that an explicit access-denied ACE is enforced regardless of any explicit access-allowed ACE. This means that the object's owner can define permissions that allow access to a group of users, such as Everyone, but deny access to a subset of the group, such as Marketing. If the object's ACEs are in canonical order, the ACE that denies Marketing comes before the ACE that allows Everyone. During an access check, the operating system steps through the ACEs in the order in which they appear in the object's DACL, so that the deny ACE is processed before the allow ACE. As a result, users who are members of the Marketing group are denied access. Everyone else is allowed access to the object.

The canonical order also ensures that all explicit ACEs are processed before any inherited ACE. This is consistent with the concept of discretionaryaccess control: access to a child object is at the discretion of the child's owner, not the parent's owner. The owner of a child object can define permissions directly on the child that modify the effects of inherited permissions. For example, suppose a parent object has an inheritable ACE that denies access to Marketing. And suppose the owner of a child object defines an explicit ACE that allows access to a subset of Marketing — let's say a user named Bob. If the child object's ACEs are in canonical order, the explicit ACE that allows Bob access comes before any inherited ACE, including the inherited ACE that denies access to Marketing. During an access check, the operating system reaches the ACE that allows Bob access before it gets to the ACE that denies access to Marketing. As a result, Bob is allowed access to the object even though he is a member of the Marketing group. Other members of the Marketing group are denied access.

**What Happens During an Upgrade from Windows NT 4.0**

When you upgrade a computer from Windows NT 4.0 to Windows Server 2003, the security descriptors on NTFS and registry objects must also be upgraded to reflect the new canonical order. This change does not take place during setup. Instead, the DACLs on existing objects are upgraded the first time that their security descriptors are modified after the operating system upgrade. Due to the automatic propagation of inheritable ACEs, the DACLs on all objects in the hierarchy below a modified object are also converted to the new canonical order.

The security descriptors for objects that have been converted contain the security descriptor control flags SE_DACL_AUTO_INHERITED and SE_SACL_AUTO_INHERITED.

The operating system uses the following rules for propagating inherited ACEs to child objects:

- If a child object with no DACL inherits an ACE, the result is a child object with a DACL containing only the inherited ACE.
- If a child object with an empty DACL inherits an ACE, the result is a child object with a DACL containing only the inherited ACE.
- If you remove an inheritable ACE from a parent object, automatic inheritance removes any copies of the ACE that are inherited by child objects.
- If automatic inheritance results in the removal of all ACEs from a child object's DACL, the child object has an empty DACL rather than no DACL.

**No DACL vs. Empty DACL**

A security descriptor with no DACL (also known as a NULL DACL) gives unconditional access to everyone. A security descriptor with an empty DACL gives no access to anyone.

In Windows NT, if a developer wanted to allow everyone unconditional access to an object, his code could create the object with a NULL DACL — that is, without a DACL. In Windows 2000 and later, it is still possible to create objects with a NULL DACL, but code that does this must set the SE_DACL_PROTECTED security descriptor control flag to prevent the object from acquiring a DACL through inheritance. In the worst case, forgetting to protect a NULL DACL can result in an empty DACL if the parent object has no inheritable permissions. The result would be to allow no access to anyone, exactly the opposite of what the object's creator intended.

Best practice is not to use NULL DACLs at all. If you are developing for Windows 2000 or later and want to give everyone unconditional access to an object, create a DACL with one ACE that grants Everyone full control. In Windows Server 2003, the Everyone group no longer includes Anonymous Logon; therefore you might also want to include a second ACE that grants Anonymous Logon full control.

# Security Descriptors and Access Control Lists Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Security Descriptors and Access Control Lists Tools
- Related Information

This section contains information about the tools that are associated with security descriptors and access control lists (ACLs).

**Security Descriptors and Access Control Lists Tools**
The following tools are associated with security descriptors and ACLs.

**Cacls.exe: Cacls**
**Category**
This tool ships with the Windows Server 2003.

**Version compatibility**
This tool is compatible with computers running Windows Server 2003.

Cacls is a command-line tool that displays or modifies discretionary access control lists (DACLs) on specified files.For more information about Cacls, see "Cacls" in Help and Support Center in Windows Server 2003.

**RoboCopy.exe: Robust File Copy Utility**
**Category**
This tool is included in the Windows Server 2003 Resource Kit Tools.

**Version compatibility**
This tool is compatible with computers running Windows XP Professional or Windows Server 2003 operating systems.

An administrator can use the Robust File Copy Utility (RoboCopy) to copy files with a fine level of control over which file attributes are copied. For example, you can specify whether to copy files with or without their NTFS file system ACLs, file ownership information, or file auditing information.

This command-line tool simplifies the task of maintaining an identical copy of a folder tree in multiple locations, either on the same computer or in separate network locations. RoboCopy can provide time-efficient maintenance of mirror images of large folder trees on network servers that are separated by slow or unreliable wide area network (WAN) links.By default, RoboCopy ignores source file attributes when selecting files to copy. It copies any file matching specified conditions, regardless of the attribute settings of the file.

For more information about RoboCopy, see "Robocopy.exe" in Resource Kit Tools Help in Tools and Settings Collection.

**Showacls.exe: Show ACLs**
**Category**
This tool is included in the Windows Server 2003 Resource Kit Tools.

**Version compatibility**
This tool is compatible with computers running Windows XP Professional or Windows Server 2003 operating systems.

Show ACLs (ShowACLs) is a command-line tool that enumerates access rights for files, folders, and trees. It allows masking so that you can enumerate only specific ACLs. ShowACLs works on NTFS partitions only.

You can also use ShowACLs to view permissions for a particular user. ShowACLs does this by enumerating the local and global groups to which the particular user belongs and matching the user's security identifier (SID) — and the SIDs of the groups to which the user belongs — to the SIDs in each access control entry (ACE).

For more information about Showacls, see "Showacls.exe" in Resource Kit Tools Help in Tools and Settings Collection.

**Subinacl.exe: SubInACL**
**Category**
This tool is included in the Windows Server 2003 Resource Kit Tools.

**Version compatibility**
This tool is compatible with computers running Windows XP Professional or Windows Server 2003 operating systems.

SubInACL is a command-line tool that enables administrators to obtain security information about files, registry keys, and services and transfer this information from user to user, from local or global group to group, and from domain to domain.

For example, if a user moves from one domain (DomainA) to another domain (DomainB), the administrator can replace DomainA\User with DomainB\User in the security information for the user's files. This gives the user access to the same files from the new domain.

SubInACL enables administrators to do the following:

- Display security information that is associated with files, registry keys, or services. This information includes owner, group, permission ACL, discretionary access control list (DACL), and system access control list (SACL).
- Change the owner of an object.
- Replace the security information for one identifier (account, group, well-known SID) with that of another identifier.

Migrate security information about objects. This is useful if you reorganize a network's domains and need to migrate the security information for files from one domain to another. For more information about Subinacl, see "Subinacl.exe" in Resource Kit Tools Help in Tools and Settings Collection.

# Access Tokens Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Access Tokens Technical Reference**
When a user is authenticated, the Local Security Authority (LSA) creates an access token for that user. An access token contains a security identifier (SID) for the user, all of the SIDs for the groups to which the user belongs, and the user's privileges. If you add a user to a group after the user access token has been issued, or you modify privileges assigned to the user account, the user must log off and then log on again before the access token will be updated.

This subject will explain what an access token is in the Microsoft Windows Server 2003 operating system, and how the system uses access tokens to grant access to resources.

# What Are Access Tokens?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Are Access Tokens?**

**In this section**

- Technologies Related to Access Tokens
- Related Information

An access token is a protected object that contains information about the identity and privileges associated with a user account.

When a user logs on interactively or tries to make a network connection to a computer running Windows, the logon process authenticates the user's logon credentials. If authentication is successful, the logon process returns a security identifier (SID) for the user and a list of SIDs for the user's security groups. The Local Security Authority (LSA) on the computer uses this information to create an access token — in this case, the primary access token — that includes the SIDs returned by the logon process as well as a list of privileges assigned by local security policy to the user and to the users security groups.

After LSA creates the primary access token, a copy of the access token is attached to every process and thread that executes on the user's behalf. Whenever a thread or process interacts with a securable object or tries to perform a system task that requires privileges, the operating system checks the access token associated with the thread to determine the level of authorization for the thread.

There are two kinds of access tokens, primary and impersonation. Every process has a primary token that describes the security context of the user account associated with the process. A primary access token is typically assigned to a process to represent the default security information for that process. Impersonation tokens, on the other hand, are usually used for client/server scenarios. Impersonation tokens enable a thread to execute in a security context that differs from the security context of the process that owns the thread.

**Technologies Related to Access Tokens**

Access tokens are closely related to the following technologies.

**Other authorization and access control components**

Access tokens contain account and group SIDs as well as privileges for the account. User rights and permissions to access objects such as Active Directory objects, files, and registry settings are granted to these accounts and groups:

- **Security principals.** Security principals include users or groups with either local or domain accounts, and computer accounts created when a computer running Windows NT, Windows 2000, Windows XP, or a member of the Windows Server 2003 family joins a domain. User rights and permissions to access objects such as Active Directory objects, files, and registry settings are assigned to security principals.

- **Security identifiers (SIDs).** Every account and group is automatically assigned a security identifier (SID) when the account or group is created.

- **Security descriptors and access control lists (ACLs).** A security descriptor is associated with each securable object. If permissions are configured for an object, the object's security descriptor contains a discretionary access control list (DACL), with SIDs for the user's and groups that are allowed or denied access.

- **User rights and permissions.** User rights and permissions to access objects such as Active Directory objects, files, and registry settings are assigned to security principals. When a system task that requires privileges is attempted, the operating system checks the access token associated with the thread or process to determine the level of authorization for that thread or process.

**Authentication**

A user account enables a user to log on to computers and domains with an identity that can be authenticated by the computer or domain.

**Active Directory**
Accounts and groups that are created in an Active Directory domain are stored in the Active Directory database and managed using Active Directory tools.

**Group Policy**
User rights can be assigned to Active Directory groups through Group Policy. Password and Account Lockout policy can be assigned to users through Group Policy.

The diagram below shows the relationship of access tokens to other authorization and access control components.

**Relationship of Access Tokens to Other Authorization and Access Control Components**

# How Access Tokens Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Access Tokens Work**

**In this section**

- Access Tokens Interfaces
- Access Tokens Physical Structure
- Access Tokens Processes and Interactions
- Related Information

When a user is authenticated, the Local Security Authority (LSA) creates an access token — in this case, a primary access token — for that user. An access token contains a security identifier (SID) for the user, all of the SIDs for the groups to which the user belongs, and the user's privileges. If you add a user to a group after the user's access token has been issued, or modify privileges assigned to the user account, the user must log off and then log on again before the access token will be updated.

Whenever a thread or process interacts with a securable object or tries to perform a system task that requires privileges, the operating system checks the effective access token to determine its level of authorization. If a thread is impersonating, the effective token is usually taken to be the token on the thread. If a thread interacting with the securable object is not impersonating, then the token on the process is examined for the access decision.

Thus, there are two kinds of access tokens, primary and impersonation. Every process has a primary token that describes the security context of the user account associated with the process. A primary access token is typically assigned to a process to represent the default security information for that process. Impersonation access tokens, on the other hand, are usually used for client/server scenarios. Impersonation tokens enable a thread to execute in a security context that differs from the security context of the process that owns the thread.

**Access Tokens Interfaces**

The tables below list APIs used to create, modify, or query access tokens.

**Token Creation APIs**

| API Name | Description |
|---|---|
| CreateRestrictedToken | Creates a new access token that is a restricted version of an existing access token. |
| DuplicateToken | Creates a new impersonation token that duplicates one already in existence. |
| DuplicateTokenEx | Creates a new access token that duplicates an existing token. This function can create either a primary token or an impersonation token. |
| OpenProcessToken | Opens the access token associated with a process. |
| OpenThreadToken | Opens the access token associated with a thread. Tokens with the anonymous impersonation level cannot be opened. |

**Token Modification APIs**

| API Name | Description |
|---|---|
| AdjustTokenGroups | Enables or disables groups already present in the specified access token. Access to TOKEN_ADJUST_GROUPS is required to enable or disable groups in an access token. You cannot enable a group that has the SE_GROUP_USE_FOR_DENY_ONLY attribute. |

| | |
|---|---|
| AdjustTokenPrivileges | Enables or disables existing privileges in the specified access token. Enabling or disabling privileges in an access token requires TOKEN_ADJUST_PRIVILEGES access. |
| ImpersonateAnonymousToken | Enables the specified thread to impersonate the system's anonymous logon token. To ensure that a token matches the operating system's concept of anonymous access, this function should be called before attempting network access to generate an anonymous token on the remote server. Anonymous tokens do not include the Everyone Group SID unless the system default has been overridden. |
| ImpersonateSelf | Obtains an access token that impersonates the security context of the calling process. The token is assigned to the calling thread. For this function to succeed, the DACL protecting the process token must grant the TOKEN_DUPLICATE right to itself. |
| RevertToSelf | Terminates the impersonation of a client application. |
| SetThreadToken | Assigns an impersonation token to a thread. The function can also cause a thread to stop using an impersonation token. |
| SetTokenInformation | Sets various types of information for a specified access token. The information that this function sets replaces existing information. The calling process must have appropriate access rights to set the information. Token-type information can be set only when an access token is created. |

**Token Query APIs**

| API Name | Description |
|---|---|
| CheckTokenMembership | Determines whether a specified SID is enabled in an access token. |
| GetTokenInformation | Retrieves a specified type of information about an access token. The calling process must have appropriate access rights to obtain the information. |
| IsTokenRestricted | Indicates whether a token contains a list of restricted SIDs. |
| PrivilegeCheck | Determines whether a specified set of privileges is enabled in an access token. The PrivilegeCheck function is typically called by a server application to check the privileges of a client's access token. |

For more information about token APIs, search for Authorization Structures in the Authorization reference in the Microsoft SDK documentation on MSDN.

#### Access Tokens Physical Structure

### Access Token

An access token contains a complete description of the security context for a process or thread, including the information in the following table.

**Access Token Components**

| Component | Description |
|---|---|
| User | The SID for the user's account. If the user logs on to an account on the local computer, the user's SID is taken from the account database maintained by the local Security Accounts Manager (SAM). If the user logs on to a domain account, the SID is taken from the Object-SID property of the User object in Active Directory. |
| Groups | A list of SIDs for security groups that include the user. The list also includes SIDs from the SID-History property of the User object representing the user's account in Active Directory. |
| Privileges | A list of privileges held on the local computer by the user and by the user's security groups. |
| Default Owner | The SID for the user or security group who, by default, becomes the owner of any object that the user either creates or takes ownership of. |
| Primary Group | The SID for the user's primary security group. This information is used only by the POSIX subsystem and is ignored by the rest of Windows Server 2003. |
| Default Discretionary Access Control List (DACL) | A built-in set of permissions that the operating system applies to objects created by the user if no other access control information is available. The default DACL grants Full Control to Creator Owner and System. |
| Source | The process that caused the access token to be created, such as Session Manager, LAN Manager, or Remote Procedure Call (RPC) Server. |
| Type | A value indicating whether the access token is a primary or impersonation token. |
| Impersonation Level | A value that indicates to what extent a service can adopt the security context of a client represented by this access token. |
| Statistics | Information about the access token itself. The operating system uses this information internally. |
| Restricting SIDs | An optional list of SIDs added to an access token by a process with authority to create a restricted token. Restricting SIDs can limit a thread's access to a level lower than what the user is allowed. |
| TS Session ID | A value that indicates whether the access token is associated with the Terminal Services client session. |

| | |
|---|---|
| Session Reference | Reserved for internal use. |
| SandBox Inert | Nonzero if the token includes the SANDBOX_INERT flag. |
| Audit Policy | Since Windows Server 2003, used for per user auditing. |
| Origin | Introduced with Windows Server 2003. If the token resulted from a logon using explicit credentials, then the token will contain the ID of the logon session that created it. If the token resulted from network authentication, then this value will be zero. |

**SID Attributes in an Access Token**

Each user and group SID in an access token can have one of two attributes that control how the system uses the SID in an access check. The following table lists the attributes that control access checking.

### SID Attributes

| Attribute | Description |
|---|---|
| SE_GROUP_ENABLED | A SID with this attribute is enabled for access checks. When the system performs an access check, it checks for access control entries (ACEs) that apply to the SID. |
| SE_GROUP_USE_FOR_DENY_ONLY | Since Windows 2000, a SID with this attribute is a deny-only SID. When the system performs an access check, it checks for ACEs that deny access to the SID. It ignores ACEs that allow access for the SID. |

Both attributes are mutually exclusive. If one attribute is set, the other cannot be set. If neither attribute is set, the SID is ignored. Moreover, no process is ever allowed to remove a deny-only attribute from a SID.

**SIDHistory**

SIDHistory is used to store the former SIDs of moved objects such as user's and security groups.

Prior to Windows 2000, restructuring a domain generally meant the creation of new accounts that needed to be placed in the same groups the old accounts were placed in. Since Windows 2000, domain restructuring is made considerably easier as a result of SIDHistory, which is a new attribute of Active Directory security principals.

APIs (or tools and support utilities built from these APIs) update the SIDHistory attribute of the object, representing it in Active Directory with its former SID as part of the move operation for the user or group. When the user then logs on to the system, not only the new SID, but also the old SID retrieved from the SIDHistory attribute, are added to the user's access token and used to determine the user's group memberships. The SIDs of the groups of which the user is a member through either the new SID or the old SID are then also added to the access token, together with any SIDHistory those groups might have.

Because groups can be moved, they can also have SIDHistory. The system also retrieves the SIDHistory attributes of all the groups of which the user is a member and then adds these attributes to the user's access token.

Because these SIDHistory entries in the token look to the system like normal group memberships during authorization checks, the token can grant appropriate access even on earlier versions of the system.

### Note

- The SIDHistory attribute can only be updated in native mode Windows 2000 or Windows 2003 domains, which has the effect of requiring all migration operations relying on SIDHistory to have a native mode target for restructure.

**Access Tokens Processes and Interactions**

Clients never get direct access to network resources; instead, network services build a client's access token and then impersonate the client to execute the requested operations. The Windows operating system kernel uses security identifiers in the access token to verify whether the user is authorized the desired access rights to the target object.

There are two kinds of access tokens, primary and impersonation.

**Primary Tokens**

Every process has a primary token that describes the security context of the user account associated with the process. The primary token may be assigned to a process to represent the default security information for that process.

**Creating a Primary Token**

The access token is built from the SID list acquired through authentication. Group membership can be evaluated non-transitively (as was done with Windows NT) or transitively. Since Windows 2000, chaining of groups has been possible in native domains. This allows a member of group A to be a member of group B if group A is a member of group B.

**Creating the SID List for User Account to Access System**

**Creating User SID Lists**

The following example is for a user logging onto a system. This occurs during authentication either during pass thru authentication for NTLM or when creating the ticket granting ticket and service ticket for Kerberos authentication. The user's domain controller will do two or more of the following:

1. Authenticate the user.

2. Only if the user's domain is in native mode, retrieve the user's SID history and add it to the SID list.

3. Retrieve the user's global group membership.

    a. If the user's domain is in mixed mode, retrieve global group membership of the user's SID and add these to the SID list.

    b. If the user's domain is in native mode, **transitively** retrieve the global group membership of both the user's SID and the user's SID history and add these to the SID list.

4. If the user's domain is in native mode, pass the list of SIDs to the global catalog.

    a. The global catalog will **transitively** retrieve the universal group membership for each SID in the list and add these to the SID list.

    b. Return the list back to the domain controller.

5. If the system's domain is in native mode, **transitively** retrieve the domain local group membership for each SID in the list and add these to the SID list.

6. Return the list to the system.

**Building the access token**

The system places the SIDs received from the domain controller and all the built-in groups for each SID into the access token. These built-in groups will include the following:

**Logon type**

- For specific logon types, a specific SID is added for that logon type, such as INTERACTIVE, or BATCH, for example.
- If using NTLM logon, the system adds a specific SID.

**Implicit Membership**

- In the case of the token for a "NT AUTHORITY\SYSTEM" process, the SID for "Administrators" is added to the token. Therefore SYSTEM implicitly belongs to "Administrators."
- The SID "Everyone" is added to every token, except for Anonymous tokens when the security policy option "Let Everyone permissions apply to Anonymous user's" is disabled.
- "Authenticated Users" is added to non-anonymous tokens.
- There is also a "NONE" group, which is added to local tokens on non-domain controllers; "NONE" is the SID for the primary group for local accounts.

**Summary of Conditions Required for SIDs to Be in SID List**

| **SID Type** | **User's Domain** | | **System's Domain** | |
|---|---|---|---|---|
| | **Mixed** | **Native** | **Mixed** | **Native** |
| SID History | No | Yes | No | Yes |
| Built-in | No | No | Yes, system's built-in | Yes, system's built-in |
| Domain Local | No | No | Yes, if system is DC in User's domain | Yes, transitive |
| Global | Yes, not transitive | Yes, transitive | | |
| Universal | No | Yes, transitive | No | No |

**Impersonation Tokens**

Impersonation tokens are access tokens that have been created to capture the security information of a client process, thus enabling a server to impersonate the client process in security operations.

Impersonation is the ability of a thread to execute in a security context that is different from the context of the process that owns the thread. Impersonation is designed to meet the security requirements of client/server applications. When running in a client's security context, a service "is" the client, to some degree. One of the service's threads uses an access token representing the client's credentials to obtain access to the objects to which the client has access.

The primary reason for impersonation is to cause access checks to be performed against the client's identity. Using the client's identity for access checks can cause access to be either restricted or expanded, depending on what the client has permission to do. For example, suppose a file server has files containing confidential information, and each of these files is protected by a DACL. To prevent a client from obtaining unauthorized access to information in these files, the service can impersonate the client before accessing the files.

Every process has a primary token that describes the security context of the user account associated with the process. In an ordinary application process, the user associated with the process is the human user who started the application. In a service process, however, services run under their own accounts and have identities in their own right.

System services installed with the operating system run under the Local System, local service, or Network Service account. Other services can be configured to run three different account types: Local System account, service accounts on the local system, or service accounts in Active Directory.

The primary token for a service is associated with the control thread in the service process and with all other threads acting on behalf of the service. It identifies the service's account, group memberships, and privileges. The service uses this information during access checks when the service requests access to objects needed for its own housekeeping.

Then, when a service accepts a client, it creates a thread to do the work and associates the client's access token with the worker

thread. Once associated in this way, the client's access token is an impersonation token that identifies the client, the client's groups, and the client's privileges. The impersonation token's information is used during access checks when the thread requests access to resources on the client's behalf. When impersonation is over, the thread reverts to using the primary token and returns to operating in the service's security context instead of the client's.

**The Mechanism for Impersonation**

**Impersonation Levels**

A client process can control to what extent a service is able to act as the client by selecting an impersonation level when it connects to the service. By choosing an impersonation level, the client tells the service to what extent it can impersonate the client. In other words, the impersonation levels described in the table below define to what extent the client agrees to let the service "be" the client.

Users cannot select an impersonation level. One is specified as Security Quality of Service (SQoS) information in the code for client/server applications. There are four impersonation levels: anonymous, identify, impersonate, and delegate. The anonymous level has never been supported. Prior to Windows 2000, only the identify and impersonate levels were supported. Windows 2000 added support for the delegate level.

**Impersonation Levels**

| Impersonation Level | Description |
|---|---|
| Anonymous | The client is anonymous to the service. The service can impersonate the client but the impersonation token does not contain any information about the client. |
| Identify | The service can get the identity of the client and can use this information in its own security mechanism, but it cannot impersonate the client. |
| Impersonate | The service can impersonate the client. If the service is on the same computer as the client process, it can access network resources as the client. If the service is on a remote computer, it can impersonate the client only when accessing resources on the service's computer. |
| Delegate | The service can impersonate the client not only when it accesses resources on the service's computer but also when it accesses resources on other computers. This level is supported only in Windows 2000 and later versions of the Windows operating system. |

**Configuring Clients and Services for Delegation**

Impersonation works at the delegate level only under the following conditions:

- The computers hosting the client process, the service process, and processes for any backend services must all be running Windows 2000 or later in a Windows 2000 or later domain. This is because delegation requires the Kerberos authentication protocol.

- The client's user account must be enabled for delegation.

- The service's account must be enabled for delegation.

The way you configure the service account depends on whether the service runs under the Local System account on a computer or under its own domain user account.

- If the service is configured to run under the Local System account, the computer where the service runs must be trusted for delegation. (Note that when you trust a computer for delegation, you enable delegation for all services that run under the Local System account on the computer. If an unwary administrator installs an untrusted service on the computer and configures it to run as Local System, it too can access network resources while impersonating other user's. A better practice is to configure services that use delegation to run under their own domain user accounts managed by domain administrators.)

- If the service is configured to run under its own domain user account, the service's user account must be enabled to act as a delegate.

**Restricted Tokens**
A restricted token is a primary or impersonation access token that has been modified by the CreateRestrictedToken function. A process or impersonating thread running in the security context of a restricted token is restricted in its ability to access securable objects or perform privileged operations. In Windows 2000 and later, an application can start a child process in a restricted security context so that code executing in the child process has more limited access to resources than the application's user has. For example, when you use Internet-browsing software to display a Web page in an untrusted security zone, code associated with the Web page can execute with fewer privileges on your computer than you have. (This feature is not used by Microsoft Internet Explorer version 5.0 and earlier.)

Applications can create restricted security contexts for child processes and impersonation threads by creating a restricted token and assigning it to the child process or the impersonating thread. Restricted tokens are created by removing privileges, by applying the deny-only attribute to SIDs, or by adding a list of restricting SIDs to the original access token.

When a restricted process or thread tries to access a securable object, the system performs two access checks by:

- Reading the token's enabled and deny-only SIDs.

- Reading the list of restricting SIDs.

Access is granted only if both access checks allow the requested access rights.

For more information about restricted tokens, see Access Control in the Microsoft Platform SDK on MSDN.

# Access Tokens Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Access Tokens Tools and Settings**

**In this section**

- Access Tokens Tools
- Access Tokens Registry Entries
- Access Tokens Group Policy Settings
- Access Tokens WMI Classes

**Access Tokens Tools**

The following tools are associated with access tokens.

**Dsa.msc: Active Directory Users and Computers**

**Category**

Active Directory Users and Computers is a Microsoft Management Console (MMC) snap-in that is installed automatically when you install Active Directory. This tool also ships with the Administration Tools Pack (Adminpak.msi).

You can access the tool from the **Start** menu: Click **Start**, then click **Programs**,then click **Administrative Tools**,and then click **Active Directory Users and Computers**.

**Version Compatibility**

Active Directory Users and Computers runs on domain controllers that are running Windows Server 2003 and Windows 2000. In both of these server systems, MMC provides a window in the user interface where you can add, configure, and control items. Active Directory Users and Computers is the MMC snap-in that you can use to administer and publish information in the directory.

The Windows Server 2003 version of Active Directory Users and Computers can target domain controllers that are running Windows Server 2003 or Windows 2000.

On administrative workstations that are running Windows XP Professional or Windows 2000, you can install the Windows Server 2003 Administration Tools Pack (Adminpak.msi) from the i386 directory on the Windows Server 2003 CD. This version of the Administration Tools Pack encrypts and signs LDAP traffic between the administrative tool clients and domain controllers.

**Note**

- You cannot run the Microsoft Windows Server 2003 Administration Tools Pack (Adminpak.msi) on a computer that is running Windows XP Professional, Windows XP Home Edition, or Windows XP 64-Bit Edition Version 2003 without Windows XP Service Pack 1 (SP1).

You can manage the following objects and their associated properties with this tool, which in turn will affect access tokens created for these objects.

**Active Directory Users and Computers Object Management**

| Object Type | Changes That Affect Access Tokens |
|---|---|
| User objects | Configure user or service account for delegation. |
| Computer objects | Configure computer account for delegation. This will affect services running under the local System account. |

To find more information about Active Directory Users and Computers, see Windows Server 2003 Tools Help in the Tools and Settings Collection.

**Ntrights.exe: Ntrights**
**Category**
Ntrights is included in the Windows Server 2003 Resource Kit and the Windows 2000 Resource Kit.

**Version compatibility**
Ntrights is supported for Windows Server 2003, Windows XP Professional, and Windows 2000.

Ntrights is a command-line tool that enables you to assign or revoke a right for a user or group of users on a local or remote computer. You can also place an entry that notes the change in the event log of the computer.

Ntrights is useful in unattended or automated installations during which you might want to change the default rights. You can also use the tool in situations where you need to change a right in an existing installation, but you cannot access and log on to all computers.

To find more information about Ntrights, see Windows Server 2003 Resource Kit Tools Help in the Tools and Settings Collection.

**Services.msc: Services**
**Category**
Services is a Microsoft Management Console (MMC) snap-in that is automatically installed when you install Windows Server 2003. There are two ways to access the tool:

- Click **Start**, then click **Programs**,then click **Administrative Tools**,and then click **Services**.

Or,

- Right-click **My Computer**, and then click **Manage**.

**Version compatibility**
Services runs on systems that are running Windows Server 2003, Windows XP, and Windows 2000.

Services can configure the security context of services that impact access tokens. Services affects access tokens when you use it to:

- Manage the services on your computer.
- Set up recovery actions to take place if a service fails.
- Create custom names and descriptions for services so you can easily identify them.

To find more information about Services, see Windows Server 2003 Tools Help in the Tools and Settings Collection.

**Showpriv.exe: Show Privilege**
**Category**
Show Privilege is included in the Windows Server 2003 Resource Kit and the Windows 2000 Resource Kit.

**Version Compatibility**
Show Privilege is supported for Windows Server 2003, Windows XP Professional, and Windows 2000.

Show Privilege is a command-line tool that displays the rights assigned to users and groups. The tool must be run locally on the target computer. To display users and groups that have domain privileges, Show Privilege must be run on a domain controller. The following table shows the privileges specific to access tokens.

### Access Token Privileges

| Privilege Name | Equivalent Security Policy User Right Setting | Description |
|---|---|---|
| SeCreateTokenPrivilege | Create a token object | Allows a process to create an access token. |
| SeAssignPrimaryTokenPrivilege | Replace a process-level token | Allows a process that has this privilege to replace the access token associated with a process. |

| | | |
|---|---|---|
| SeImpersonatePrivilege | Impersonate a client after authentication | Allows a process to impersonate. |

To find more information about Show Privilege, see Windows Server 2003 Resource Kit Tools Help in the Tools and Settings Collection.

**Whoami.exe: Whoami**
**Category**
Whoami is a command-line tool included in the Windows Server 2003 family. The tool is also included in the Windows 2000 Resource Kit.

**Version Compatibility**
Whoami is supported for Windows Server 2003 and Windows 2000.

You can use this command-line tool to display the complete contents of the access token in the command window. For the current user's security context, Whoami can display, for example:

- User name and security identifier (SID)
- Groups and their SIDs
- Privileges and their status (for example, enabled or disabled)
- Logon ID

To find more information about Services, see Windows Server 2003 Tools Help in the Tools and Settings Collection.

**Access Tokens Registry Entries**
The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, instead of editing the registry directly, use Group Policy or other Windows tools such as MMC to accomplish tasks. If you must edit the registry, use extreme caution.

The following registry settings that affect access tokens cannot be modified by using Group Policy or other Windows tools.

**EveryoneIncludesAnonymous**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

**Version compatibility**
**EveryoneIncludesAnonymous** is supported for Windows Server?2003 and Windows XP.

This registry setting controls whether the Everyone SID is included in the access token generated for an anonymous user.

### EveryoneIncludesAnonymous Settings

| Setting | Effect |
|---|---|
| 0 | (default) Do not include the Everyone SID in the access token generated for an anonymous user. |
| 1 | Include the Everyone SID in the access token generated for an anonymous user. |

**RestrictAnonymous**
**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\

**Version compatibility**
**RestrictAnonymous** is supported for Windows Server 2003, Windows XP, and Windows 2000.

This registry setting restricts anonymous users from displaying lists of users, and from viewing security permissions.

### RestrictAnonymous Settings

| Setting | Effect |
|---|---|

| | |
|---|---|
| 0 | (default) Anonymous users are not restricted. Rely on default permissions. |
| 1 | Do not allow enumeration of Security Accounts Manager (SAM) accounts and shares. |
| 2 | In Windows 2000, do not include the Everyone SID in the access token generated for an Anonymous user.<br><br>Not supported in Windows Server 2003. |

**Results of Anonymous User Settings**

**Anonymous User: Windows 2000**

| Restrict Anonymous Setting | Can Enumerate Local SAM Accounts and Shares? | Can Access Other Securable Objects If: |
|---|---|---|
| 0 | Yes | Anonymous or Everyone is granted access by the object's access control list (ACL). |
| 1 | No | Anonymous or Everyone is granted access by the object's ACL. |
| 2 | No | Anonymous is explicitly granted access by the object's ACL. |

**Anonymous User: Windows Server 2003 and Windows XP**

| Restrict Anonymous Setting | EeveryoneIncludesAnonymous Setting | Can Enumerate Local SAM Accounts and Shares? | Can Access Other Securable Objects If: |
|---|---|---|---|
| 0 | 0 | Yes | Anonymous is explicitly granted access by the object's ACL. |
| 0 | 1 | Yes | Anonymous or Everyone is granted access by the object's ACL. |
| 1 | 0 | No | Anonymous is explicitly granted access by the object's ACL. |
| 1 | 1 | No | Anonymous or Everyone is granted access by the object's ACL. |

**Effects of Anonymous User Settings Entered in a Domain Controller's Registry**

**Ability of anonymous users to enumerate account information**

There is no local SAM on a domain controller. Thus, **RestrictAnonymous** does not control the ability of anonymous users to enumerate account information. Instead, access to account information is controlled by ACLs on account objects in Active Directory.

**Ability of anonymous users to enumerate shared resources**

Anonymous users will not be able to enumerate shared resources or pipes if **RestrictAnonymous** is set to equal 1.

**Ability of Anonymous Users to Access Active Directory Data on Windows 2000 Domain Controllers**

| Restrict Anonymous Setting | Pre-Windows 2000 Compatible Access Security Group Membership | Access to Any Active Directory Data |
|---|---|---|
| 0 or 1 | No | No |
| 0 or 1 | Yes | Yes, if Everyone is a member of this group. |
| 2 | No | No |
| 2 | Yes | No |
| 2 | Yes, Anonymous must be explicitly a member. | Yes |

**Ability of Anonymous Users to Access Active Directory Data on Windows Server 2003 Domain Controllers**

| EeveryoneIncludesAnonymous Setting | Pre-Windows 2000 Compatible Access Security Group Membership | Access to Any Active Directory Data |
|---|---|---|
| 0 | No | No |
| 0 | Yes | Yes, if Anonymous is also a member of this group. |
| 1 | Yes | Yes, even if Anonymous is not a member of this group as long as Everyone is a member of this group. |

**Note**

- Both Everyone and Anonymous are members of Pre-Windows 2000 Compatible Access group by default in Windows Server 2003.

#### Access Tokens Group Policy Settings

The following table lists and describes the Group Policy settings that are associated with access tokens.

**Group Policy Settings Associated with Access Tokens**

| Group Policy Setting | Description |
|---|---|
| User Rights Assignment:<br>• Create a token object<br>• Replace a process level token | Changes to these settings control:<br>• Calling APIs to create tokens.<br>• Whether a process can replace a token. |
| Audit Policy:<br>• Audit policy change<br>• Audit privilege use<br>• Audit process tracking | Changes to this setting will:<br>• Generate audits when rights are assigned with one of the tools discussed earlier.<br>• Enable audit privilege use. Will log when SeAssignPrimaryTokenPrivilege was used.<br>• Create an audit for assigning a primary token that contains the two processes involved and the identity of the token assigned. |
| Security Options:<br>• Network access: Let Everyone permissions apply to anonymous users | Changes to this setting will affect whether Everyone is in the token for anonymous users. |

For more information about these Group Policy settings, see Account Policy Settings.

#### Access Tokens WMI Classes

The following table lists and describes the Windows Management Information (WMI) classes that are associated with access tokens. These WMI classes are shipped with Windows Server 2003.

**WMI Classes Associated with Access Tokens**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Win32_TokenGroups | \root\cimv2 | Windows Server 2003<br>Windows XP |

| | | |
|---|---|---|
| Win32_TokenPrivileges | \root\cimv2 | Windows Server 2003<br><br>Windows XP |

For more information about these WMI classes, see the WMI reference in the SDK documentation on MSDN.

# Permissions Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Permissions Technical Reference**

**In this subject**

- What Are Permissions?
- How Permissions Work
- Permissions Tools and Settings

Permissions are a key component of the Microsoft Windows Server 2003 security architecture that you can use to manage the process of authorizing users, groups, and computers to access objects on a network.

Permissions enable the owner of each securable object, such as a file, Active Directory directory service object, or registry key, to control who can perform an operation or a set of operations on the object or object property. Because access to an object is at the discretion of the object's owner, the type of access control that is used in Windows Server 2003 is called discretionary access control.

# What Are Permissions?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Are Permissions?**

**In this section**

- Technologies Related to Permissions
- Related Information

Permissions are a key component of the Windows Server 2003 security architecture that you can use to manage the process of authorizing users, groups, and computers to access objects on a network.

Permissions enable the owner of each securable object, such as a file, Active Directory object, or registry key, to control who can perform an operation or a set of operations on the object or object property. Because access to an object is at the discretion of the object's owner, the type of access control that is used in Windows Server 2003 is called discretionary access control.

Permissions are different from user rights in that permissions are attached to objects and user rights apply to user accounts. Administrators use user rights (also known as privileges) to assign specific privileges and logon rights to groups or users. These rights authorize users to perform specific actions, such as logging on to a system interactively or backing up files and directories.

On computers, user rights enable administrators to control who has the authority to perform operations that affect an entire computer, rather than a particular object. Administrators assign user rights to individual users or groups as part of the security settings for the computer. Although user rights can be managed centrally through Group Policy, they are applied locally. Users can (and usually do) have different user rights on different computers.

Permissions are expressed in the security architecture as access control entries (ACEs). The following figure shows the relationship of permissions to other key components of the authorization and access control model.

**The Role of Permissions (as ACEs) in the Authorization and Access Control Model**

**Technologies Related to Permissions**

Permissions are closely related to the following technologies and security components.

**File systems (FAT and NTFS)**

The file system determines how files on a volume are named, stored, and organized. A file system manages files and folders and the information that is needed by local and remote users to locate and access these items.

**Security principals**

A security principal can be a user or computer account or a group of these accounts — that is, any entity that the security system recognizes. User accounts can be used by human users as well as by autonomous processes. Permissions to access

objects such as Active Directory objects, files, and registry settings are granted to security principals.

**Access tokens**
After a user logs on and is authenticated, the system creates an access token for the user that contains the security identifier (SID) of the user and the SIDs of all the domain groups that the user is a member of. Every process that the user creates contains the user's access token, which is then used to determine whether to grant that user access to a system resource in a given logon session.

**Security descriptors and access control lists**
If permissions are configured for an object, the object's security descriptor contains a discretionary access control list (DACL) with SIDs for the users and groups who are allowed or denied access.

# How Permissions Work

Updated: June 21, 2013

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

**How Permissions Work**

**In this section**

- Permissions
- Conflicts Between User Rights and Permissions
- Related Information

Permissions are a key component of the Windows Server 2003 security architecture that you can use to manage the process of authorizing users, groups, and computers to access objects on a network.

Permissions enable the owner of each secured object, such as a file, Active Directory object, or registry key, to control who can perform an operation or a set of operations on the object or object property. Because access to an object is at the owner's discretion, the type of access control that is used in Windows Server 2003 is called discretionary access control. An owner of an object always has the ability to read and change permissions on the object.

Permissions are applied to secured objects, such as files and folders, Active Directory objects, services, or registry objects. Permissions can be granted to a user, group, or computer. You can assign permissions on objects to the following:

- Groups, users, and special identities in the domain
- Groups and users in the domain and any trusted domains
- Local groups and users on the computer where the object resides

The permissions that are attached to an object depend on the type of object. For example, the permissions that can be attached to a file are different from the permissions that can be attached to a registry key.

**Optimal Environment**

The following sections provide general guidelines for how permissions should be applied to files and folders and Active Directory objects in an optimal environment.

**Permissions on Files and Folders**

- Shared folders are stored on NTFS file system volumes. You can set permissions at the file level only if the files are stored on an NTFS volume. On a FAT or FAT32 volume, you can set permissions for shared folders but not for files and folders within a shared folder. Moreover, share permissions on a FAT or FAT32 volume restrict network access only, not access by users working directly on the computer.
- Security templates are used wherever possible, rather than individual permissions.
- Default permission entries are used on file system objects, particularly on system folders and root folders. Changing default permissions can cause unexpected access problems or reduce security.

**Permissions on Active Directory Objects**

- The same set of permissions is assigned to multiple objects wherever possible. Access control lists (ACLs) in Windows Server 2003 feature single instancing: If multiple objects have identical ACLs, Active Directory stores only one instance of the ACL.
- Default permissions on Active Directory objects are left unchanged. Changing default permissions can cause unexpected

access problems or reduce security.

- The number of access control entries (ACEs) that apply to child objects is kept to a minimum. When you use the **Apply Onto** option to control inheritance, be aware that not only will the specified objects inherit that ACE, but all child objects will also receive a copy of that ACE. If there are enough objects that will get copies of this ACE, the increased amount of data can cause performance problems on your network.

**Permissions**

A permission is authorization to perform an operation on a specific object, such as a file. Permissions can be granted by owners and by anyone with the permission to grant permissions, which normally includes administrators on the system.

If you own an object, you can grant any user or security group any permission on that object, including the permission to take ownership.

When permission to perform an operation is not explicitly granted, it is implicitly denied. For example, if Alice allows the Marketing group, and only the Marketing group, permission to read her file, users who are not members of the Marketing group are implicitly denied access.

Permissions can also be explicitly denied. For example, Alice might not want Bob to be able to read her file, even though he is a member of the Marketing group. She can exclude Bob by explicitly denying him permission to read the file. This is normally how explicit denies are used — to exclude a subset (such as Bob) from a larger group (such as Marketing) that has been given permission to perform an operation. Note that use of explicit denials, while possible, increase the complexity of the authorization policy and can create unexpected errors. For example, you might want to allow domain administrators to perform an action but deny domain users. If you attempt to implement this by explicitly denying domain users, you also deny any domain administrators who are also domain users. Though it is sometimes necessary, you can and should avoid the use of explicit denies in most cases.

Each permission that an object's owner grants to a particular user or group is stored as an ACE in a discretionary access control list (DACL) that is part of the object's security descriptor.

**Permissions and Security Descriptors**

Every container and object on the network has a set of access control information attached to it that is called a security descriptor. This information controls the type of access that is allowed to users and groups. The security descriptor is automatically created along with the container or object that is created. For example, each file has a security descriptor.

An object's security descriptor contains its permissions. Permissions are associated with, or assigned to, specific users and groups. For example, for a file Temp.dat, the Administrator group might be assigned Read, Write, and Delete permissions, while the Operator group might be assigned Read and Write permissions only.

Each assignment of permissions to a user or group is called a permission entry, which is a type of ACE. The entire set of permission entries in a security descriptor is known as a permission set or ACL. Therefore, for the file named Temp.dat, the permission set includes two permission entries, one for the Administrator group and one for the Operator group.

**Ownership**

Every object has an owner, whether in an NTFS volume or in Active Directory. The owner controls how permissions are set on the object and to whom permissions are granted.

By default, in Windows Server 2003, the owner is the creator of the object. If the creator of an object is a member of the Administrators group, the Administrators group is the owner. The owner can always change permissions on an object, even when denied all access to the object.

Ownership can be taken by the following:

- Any user with the **Take ownership of files or other objects** user right, which can be granted to any user. By default, the Administrators group is given the **Take ownership of files or other objects** user right.

  An administrator who wants to repair or change permissions on a file must begin by taking ownership of the file.

- Anyone or any group who has the **Take ownership** permission on the object in question

- A user who has the **Restore files and directories** user right

Ownership can be transferred in the following ways:

- The current owner can grant the **Take ownership** permission to another user, allowing that user to take ownership at any time. The user must actually take ownership to complete the transfer.
- An administrator can take ownership.
- A user who has the **Restore files and directories** user right can assign ownership to any user or group.

#### Explicit vs. Inherited Permissions

There are two types of permissions, explicit permissions and inherited permissions:

- Explicit permissions are those that are set by default when the object is created or by user action.
- Inherited permissions are those that are propagated to a child object from a parent object. Inherited permissions ease the task of managing permissions and ensure consistency of permissions among all objects in a given container.

By default, objects that are created in a container inherit the permissions from that container when the objects are created. For example, when you create a folder called MyFolder, all subfolders and files that are created in MyFolder automatically inherit the permissions from MyFolder. Therefore, MyFolder has explicit permissions, while all subfolders and files in it have inherited permissions.

### Notes

- Inherited Deny permissions do not prevent access to an object if the object has an explicit Allow permission entry.
- Explicit permissions take precedence over inherited permissions, even inherited Deny permissions.

#### Access Masks

In an ACE, permissions are represented by one or more bits in a 32-bit value called an access mask. When a thread requests access to an object, it specifies the type of access that it desires by using an access mask as well. During an access check, the operating system compares the desired access mask that is supplied by the thread with the access mask in each ACE of the object's DACL, looking for bits that match. The following figure illustrates the layout of an access mask.

### Layout of an Access Mask

| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| GR | GW | GE | GA | Reserved | | | | AS | Standard Access Rights | | | | | | | Object-Specific Access Rights | | | | | | | | | | | | | | | |

Key
GR Generic Read
GW Generic Write
GE Generic Execute
GA Generic All
AS Right to access SACL

Each bit corresponds to an access right — a particular operation or set of operations that can be performed on the object. Turning a bit on in a desired access mask signals that the thread requests the right to perform the corresponding operation. Turning a bit on in the access mask for an ACE signals that the corresponding operation is either allowed or denied, depending on the type of ACE.

Although many of the access rights in an access mask correspond to permissions that can be set through the user interface, not all of them do. Some can be set only by a process, such as the process that creates an object, and they cannot be manipulated through the user interface. Windows Server 2003 uses an access mask format that includes the following types of access rights.

#### Generic access rights

These rights apply to all objects, but they mean different things for different object types. Each object type maps each generic access right to a different set of standard and object-specific access rights. The following table lists generic access rights.

### Generic Access Rights

| Constant in Win32 API | Meaning |
|---|---|

| | |
|---|---|
| GENERIC_ALL | Read, write, and execute access |
| GENERIC_EXECUTE | Execute access |
| GENERIC_READ | Read access |
| GENERIC_WRITE | Write access |

**Standard access rights**
These rights are more specific than generic access rights, but they still apply to operations that are available for most object types. The following table lists standard access rights.

**Standard Access Rights**

| Constant in Win32 API | Meaning |
|---|---|
| DELETE | The right to delete the object |
| READ_CONTROL | The right to read the information in the object's security descriptor, not including the information in the system access control list (SACL) |
| SYNCHRONIZE | The right to use the object for synchronization. Some object types do not support this access right. |
| WRITE_DAC | The right to modify the DACL in the object's security descriptor |
| WRITE_OWNER | The right to change the owner in the object's security descriptor |

**SACL access right**
This right controls the ability to read or change an object's SACL, which controls auditing for the object. The operating system allows access to the SACL only if the subject's access token includes the **Manage auditing and security log** (SeSecurityPrivilege) user right.

**Object-specific access rights**
Each type of securable object defines its own set of access rights. For a list of the specific access rights that apply to each type of object, see the Microsoft Platform SDK link on MSDN.

**Permissions for Files and Folders**
Folder permissions include Full Control, Modify, Read & Execute, List Folder Contents, Read, and Write. Each of these permissions consists of a logical group of special permissions that are listed and defined in the following table.

**Permissions for Files and Folders**

| Permission | Description |
|---|---|
| Traverse Folder/ Execute File | For folders: Traverse Folder allows or denies moving through folders to reach other files or folders, even if the user has no permissions on the traversed folders. (Applies to folders only.) Traverse folder takes effect only when the group or user is not granted the **Bypass traverse checking** user right in the Group Policy snap-in. (By default, the Everyone group is given the **Bypass traverse checking** user right.)<br><br>For files: Execute File allows or denies running program files. (Applies to files only.)<br><br>Setting the Traverse Folder permission on a folder does not automatically set the Execute File permission on all files in that folder. |
| List Folder/ Read Data | List Folder allows or denies viewing file names and subfolder names in the folder. List Folder only affects the contents of that folder; it does not affect whether the folder you are setting the permission on will be listed. (Applies to folders only.)<br><br>Read Data allows or denies viewing data in files. (Applies to files only.) |
| Read Attributes | Allows or denies viewing the attributes of a file or folder, such as read-only and hidden. Attributes are defined by NTFS. |

| | |
|---|---|
| Read Extended Attributes | Allows or denies viewing the extended attributes of a file or folder. Extended attributes are defined by programs and may vary by program. |
| Create Files/ Write Data | Create Files allows or denies creating files in the folder. (Applies to folders only.)<br><br>Write Data allows or denies making changes to the file and overwriting existing content. (Applies to files only.) |
| Create Folders/ Append Data | Create Folders allows or denies creating folders in the folder. (Applies to folders only.)<br><br>Append Data allows or denies making changes to the end of the file but not changing, deleting, or overwriting existing data. (Applies to files only.) |
| Write Attributes | Allows or denies changing the attributes of a file or folder, such as read-only or hidden. Attributes are defined by NTFS.<br><br>The Write Attributes permission does not imply creating or deleting files or folders, it only includes the permission to make changes to the attributes of a file or folder. To allow (or deny) create or delete operations, see Create Files/Write Data, Create Folders/Append Data, Delete Subfolders and Files, and Delete. |
| Write Extended Attributes | Allows or denies changing the extended attributes of a file or folder. Extended attributes are defined by programs and may vary by program.<br><br>The Write Extended Attributes permission does not imply creating or deleting files or folders, it only includes the permission to make changes to the attributes of a file or folder. To allow (or deny) create or delete operations, see Create Files/Write Data, Create Folders/Append Data, Delete Subfolders and Files, and Delete. |
| Delete Subfolders and Files | Allows or denies deleting subfolders and files, even if the Delete permission has not been granted on the subfolder or file. (Applies to folders.) |
| Delete | Allows or denies deleting the file or folder. If you do not have Delete permission on a file or folder, you can still delete it if you have been granted Delete Subfolders and Files on the parent folder. |
| Read Permissions | Allows or denies reading permissions of the file or folder, such as Full Control, Read, and Write. |
| Change Permissions | Allows or denies changing permissions of the file or folder, such as Full Control, Read, and Write. |
| Take Ownership | Allows or denies taking ownership of the file or folder. The owner of a file or folder can always change permissions on it, regardless of any existing permissions that protect the file or folder. |
| Synchronize | Allows or denies different threads to wait on the handle for the file or folder and synchronize with another thread that may signal it. This permission applies only to multithreaded, multiprocess programs. |

You cannot access an encrypted file without the Encrypting File System (EFS) key, even if you have the necessary permissions.

The following table lists the special permissions and their corresponding file and folder permissions.

**Special Permissions**

| Special Permissions | Full Control | Modify | Read & Execute | List Folder Contents (folders only) | Read | Write |
|---|---|---|---|---|---|---|
| Traverse Folder/Execute File | ● | ● | ● | ● | | |
| List Folder/Read Data | ● | ● | ● | ● | ● | |
| Read Attributes | ● | ● | ● | ● | ● | |
| Read Extended Attributes | ● | ● | ● | ● | ● | |
| Create Files/Write Data | ● | ● | | | | ● |

| | | | | | | |
|---|---|---|---|---|---|---|
| Create Folders/Append Data | ● | ● | | | | ● |
| Write Attributes | ● | ● | | | | ● |
| Write Extended Attributes | ● | ● | | | | ● |
| Delete Subfolders and Files | ● | | | | | |
| Delete | ● | ● | | | | |
| Read Permissions | ● | ● | ● | ● | ● | ● |
| Change Permissions | ● | | | | | |
| Take Ownership | ● | | | | | |
| Synchronize | ● | ● | ● | ● | ● | ● |

You should also be aware of the following:

- Groups or users that are granted Full Control on a folder can delete any files in that folder, regardless of the permissions protecting the file.

- Although List Folder Contents and Read & Execute appear to have the same special permissions, these permissions are inherited differently. List Folder Contents is inherited by folders but not files, and it should only appear when you view folder permissions. Read & Execute is inherited by both files and folders, and it is always present when you view file or folder permissions.

- In Windows Server 2003, by default, Everyone does not include Anonymous Users; therefore, permissions that are applied to Everyone do not affect Anonymous Users.

**Permissions on a Shared Folder**

Access on a shared folder is determined through two sets of permission entries; the permissions that are set on the share (called share permissions) and the permissions that are set on the folder (called NTFS file and folder permissions). Share permissions are often used for managing computers with FAT32 file systems or for managing other computers that do not use the NTFS file system.

Share permissions and NTFS permissions are independent in the sense that neither changes the other. The final access permissions on a shared folder are determined by taking into consideration both the share permission and the NTFS permission entries. The more restrictive permissions are then applied.

The following table suggests permissions that a security-conscious administrator can grant to the Users group for certain shared folder types. The recommended permissions have been tested and they work correctly, but there are alternative approaches. For example, some experienced administrators prefer to always set share permissions to Full Control for Everyone and to rely entirely on NTFS permissions to restrict access.

**Permissions for File Servers**

| **Folder Type** | **Share Permissions** | **NTFS Permissions** |
|---|---|---|
| Public folder. A folder that can be accessed by everyone. | Grant Change permission to the Users group. | Grant Modify permission to the Users group. |

| | | |
|---|---|---|
| Drop folder. A folder where users can drop confidential reports or homework assignments that only the group manager or instructor can read. | Grant Change permission to the Users group.<br><br>Grant the Full Control permission to the group manager. | Grant the Write permission for the users' group that is applied to This Folder only. (This option is available on the Advanced page.)<br><br>If each user needs to have certain permissions to the files that he or she dropped, you can create a permission entry for the Creator Owner well-known security identifier (SID) and apply it to Subfolder and files only. For example, you can grant the Read and Write permission to the Creator Owner SID on the drop folder and apply it to all subfolders and files. This grants the user who dropped or created the file (the Creator Owner) the ability to read and write to the file. The Creator Owner can then access the file through the Run command using \\ServerName\DropFolder\FileName.<br><br>Note that as creator of the file, the user has the ability to Read and Change the permission on the file independent of any permissions that are granted explicitly.<br><br>Grant the Full Control permission for the group manager. |
| Application folder. A folder containing applications that can be run over the network. | Grant Read permission to the Users group. | Grant Read, Read & Execute, and List Folder Content permissions to the Users group. |
| Home folders. Individual folders for each user. Only the user has access to the folder. | Grant the Full Control permission to each user for their respective folders. | Grant the Full Control permission to each user for their respective folders. |

In addition, you should know the following information:

- NTFS permissions affect access both locally and remotely. NTFS permissions apply regardless of protocol. Share permissions, by contrast, apply only to network shares. Share permissions do not restrict access to any local user, or to any terminal server user, of the computer on which you have set share permissions. Therefore, share permissions do not provide privacy between users on a computer that is used by several users, nor on a terminal server that is accessed by several users.

- By default, Everyone does not include Anonymous Users; therefore, permissions that are applied to Everyone do not affect Anonymous Users. This default behavior is new for Windows Server 2003.

- A user who places a file on a share is the creator of that copy of the file and therefore has the ability to read and change the permissions on the file independent of the permissions that are inherited.

- When possible, you should attempt to grant permissions to groups instead of to specific user accounts.

**Permissions on Active Directory Objects**

You can manage permissions on objects in Active Directory at two levels:

- **At the object level**. Permissions that are allowed or denied at the object level apply to the entire object. For example, you can set an object-level permission on an organizational unit (OU) object that allows a particular group, such as Account Operators, to create child objects in the OU.

- **At the property level**. Permissions that are allowed or denied at the property level apply only to specific properties. For example, you can set a property-level permission on a User object that allows a particular user, such as Principal Self (that is, the user that is represented by the object), to change the **Home Address** property of the User object.

There is an important difference between how permissions are propagated from container objects in NTFS and how they are propagated from container objects in Active Directory. If you own a folder object in an NTFS volume, you can control who has access to the folder and all that it contains by setting a permission on the folder that applies not only to the folder but to all

objects in the folder. For example, you can add a permission to a Folder object that allows the Marketing group read access. If you apply the permission to **This folder, subfolders and files**, it is propagated to all objects that are contained in the folder. The Marketing group then has read access to the folder and to all its subfolders and files.

Propagation of permissions works differently for Active Directory objects. If you own a container object in Active Directory, you can allow access to certain types of objects in the container without allowing access to other types of objects in the container. For example, if you own an OU object, you can add a permission that allows the Marketing group read access and then apply the permission to a particular type of child object that is contained by the OU. If you apply it to Contact objects, for example, the permission is propagated only to Contact objects but not to User objects or to any other type of child object. In other words, permissions that are propagated from container objects in Active Directory can be object specific, whereas permissions that are propagated from container objects in an NTFS volume cannot be object specific.

**Permissions on Registry Keys**

Registry permissions are set on container objects only, and the individual keys inherit their permissions from the container. A registry key has two basic permissions: Full Control and Read. The Read permission includes the special permissions Read Control, Query Value, Notify, and Enumerate Subkeys. The Full Control permission includes all the special registry permissions, as shown in the following table. You can use Regedit.exe or the Subinacl.exe command-line tool to modify registry permissions.

**Special Registry Permissions**

| Permission | Description |
|---|---|
| Query Value | Allow the registry key value to be read. |
| Set Value | Allow the value of an existing key to be written. |
| Create Subkey | Allow the creation of subkeys. |
| Enumerate Subkeys | Allow the enumeration of subkeys. |
| Notify | Notify permission is required to request change notifications for registry keys or subkeys. |
| Create Link | Reserved by the operating system. |
| Delete | Allow the key to be deleted. |
| Write DACL | Allow modification of the container's DACL. |
| Write Owner | Allow modification of the container's owner. |
| Read Control | Allow the SACL to be read. |

**Permissions on Services**

Each service has a DACL containing the permissions on the service. You can view or modify the DACL by using Subinacl.exe. You can also export the security configuration of a computer into a security template and view the DACL by using the Security Templates Microsoft Management Console (MMC) snap-in. The following table shows the permissions for services.

**Permissions on Services**

| Permission | Description |
|---|---|
| Full Control | Grant full control of the service. |
| Query Template | Allow the service configuration to be viewed. |
| Change Template | Allow the service configuration to be modified. |
| Query Status | Allow the Service Control Manager (SCM) to be queried for the service status. |
| Enumerate Dependents | Allow the dependent services to be displayed. |
| Start | Allow the service to be started. |
| Stop | Allow the service to be stopped. |

| | |
|---|---|
| Pause and Continue | Allow the service to be paused and resumed. |
| Interrogate | Allow the service to respond to status queries. |
| User Defined Control | Allow special instructions to be given to the service. |
| Delete | Allow the service to be deleted. |
| Read Permissions | Allow the DACL of the service to be viewed. |
| Change Permissions | Allow the DACL of the service to be changed. |
| Take Ownership | Allow the owner of the service to be changed. |

**Conflicts Between User Rights and Permissions**

User rights enable administrators to assign specific privileges and logon rights to groups or users. These rights authorize users to perform specific actions, such as logging on to a system interactively or backing up files and directories. User rights are different from permissions because user rights apply to user accounts and permissions are attached to objects.

Administrators can use user rights to manage who has the authority to perform operations that span an entire computer, rather than a particular object. Administrators assign user rights (also known as privileges) to individual users or groups as part of the security settings for the computer. Although user rights can be managed centrally through Group Policy, they are applied locally. Users can (and usually do) have different user rights on different computers.

Unlike permissions, which are granted by an object's owner, user rights are assigned as part of the local security policy for the computer.

There are two types of user rights: privileges, such as the right to back up files and directories, and logon rights, such as the right to log on to a system locally. For more information about user rights and their descriptions and default settings, see "Security Policy Settings."

Conflicts between privileges and permissions normally occur only in situations where the rights that are required to administer a system overlap the rights of resource ownership. When rights conflict, a privilege overrides a permission.

For example, to create a backup of files and folders, backup software must be able to traverse all folders in an NTFS volume, list the contents of each folder, read the attributes of every file, and read data in any file that has its archive attribute set. It is impractical to arrange this access by coordinating with the owner of every file and folder; therefore, the required rights are included in the **Back up files and directories** (SeBackupPrivilege) privilege, which is assigned by default to two built-in groups: Administrators and Backup Operators. Any user who has this privilege can access all files and folders on the computer for the purpose of backing up the system. The same default permissions granted to Backup Operators that allow them to back up and restore files also make it possible for Backup Operators to use the group's permissions for other purposes, such as reading another user's files or installing Trojan horse programs. Therefore, the backup operators group should be limited to only highly trusted user accounts that require the ability to back up and restore computers.

The ability to take ownership of files and other objects is another case where an administrator's need to maintain the system takes priority over an owner's right to control access. Normally, you can take ownership of an object only if its current owner gives you permission to do so. Owners of NTFS objects can allow another user to take ownership by granting the other user Take Ownership permission; owners of Active Directory objects can grant another user Modify Owner permission. A user who has this privilege can take ownership of an object without the current owner's permission. By default, the privilege is assigned only to the built-in Administrators group. It is normally used by administrators to take and reassign ownership of resources when their current owner is no longer available.

# Permissions Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Permissions Tools and Settings**

**In this section**

- Permissions Tools

This section contains information about the tools that are associated with permissions.

**Permissions Tools**

The following tools are associated with permissions.

**Permcopy.exe: Share Permissions Copy**

**Category**

This tool is included in Windows Server 2003 Resource Kit Tools.

**Version compatibility**

This tool is compatible with computers running Windows XP Professional or Windows Server 2003.

Share Permissions Copy is a command-line tool that copies share-level permissions (Full Control, Read, and Change) from one share to another.

To find more information about Share Permissions Copy, see "Permcopy.exe" in "Resource Kit Tools" in the Tools and Settings Collection.

**Perms.exe: User File Permissions Tool**

**Category**

This tool is included in Windows Server 2003 Resource Kit Tools.

**Version compatibility**

This tool is compatible with computers running Windows Server 2003.

The User File Permissions Tool is a command-line tool that displays user access permissions for a file or directory on an NTFS file system volume. It queries the permissions that are associated with a specific access control entry (ACE), displaying only the permissions that are granted by that particular ACE.

To find more information about the User File Permissions Tool, see "Perms.exe" in "Resource Kit Tools" in the Tools and Settings Collection.

**Takeown.exe: Take Ownership**

**Category**

This tool ships with Windows Server 2003.

**Version compatibility**

This tool is compatible with computers running Windows Server 2003.

Take Ownership is a command-line tool that displays or modifies discretionary access control lists (DACLs) on specified files.

To find more information about "Take Ownership," see "Takeown" in "Command-line reference A-Z" in Help and Support Center in Windows Server 2003.

# Security Principals Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security Principals Technical Reference**

**In this subject**

- What Are Security Principals?
- How Security Principals Work
- Security Principals Tools and Settings

Security principals include the following:

- Any entity that can be authenticated by the system, such as a user account, a computer account, or a thread or process that runs in the security context of a user or computer account.
- Security groups of these accounts.

Every security principal is automatically assigned a security identifier (SID) when it is created.

Accounts and security groups that are created in an Active Directory directory service domain are directory objects, and they can be used to manage access to domain resources.

Local user accounts and security groups are created on a local computer, and they can be used to manage access to resources on that computer. Local user accounts and security groups are stored in and managed by the Security Accounts Manager (SAM) on the local computer.

In Microsoft Windows Server 2003, security principals are a foundation for controlling access to securable resources.

# What Are Security Principals?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Are Security Principals?**

**In this section**

- Accounts and Security Groups
- Technologies Related to Security Principals
- Related Information

Security principals include the following:

- Any entity that can be authenticated by the system, such as a user account, a computer account, or a thread or process that runs in the security context of a user or computer account.
- Security groups of these accounts.

Every security principal is automatically assigned a security identifier (SID) when it is created.

In Windows Server 2003, security principals are a foundation for controlling access to securable resources.

**Accounts and Security Groups**

Accounts and security groups that are created in an Active Directory domain are directory objects, and they can be used to manage access to domain resources.

Local user accounts and security groups are created on a local computer, and they can be used to manage access to resources on that computer. Local user accounts and security groups are stored in and managed by the Security Accounts Manager (SAM) on the local computer.

**User Accounts**

A user account uniquely identifies a person using a computer system, thereby allowing the system to enforce the appropriate authorization to allow or deny access to resources. User accounts can be created in Active Directory and also on local computers. User accounts are used to:

- Represent, identify, and authenticate the identity of a user. A user account enables a user to log on to computers and domains with a unique identity that can be authenticated by the computer or domain.
- Authorize (grant or deny) access to resources. After a user has been authenticated, the user is authorized (granted or denied) access to resources based on the permissions that are assigned to that user on the resource.

In addition, the actions that are carried out by a user account can be audited.

**Security Groups**

A security group is a collection of user accounts, computer accounts, and other groups that can be managed as a single unit from a security perspective. Groups can be either Active Directory based or local to a particular computer. In Windows Server 2003, there are several built-in security groups that are preconfigured with the appropriate rights and permissions to perform specific tasks. Additionally, you can (and, typically, will) also create a security group for each unique combination of security requirements that applies to multiple users in your organization.

You use groups in Active Directory to manage rights and permissions to domain resources.

Local groups exist in the SAM database on local computers (on all Windows-based computers) except domain controllers. You use local groups to manage rights and permissions only to resources on the local computer.

Using security groups to manage access control solves the following problems. Using security groups:

- Simplifies administration. You can assign a common set of rights, a common set of permissions, or both to many accounts at one time, rather than assigning them to each account individually. Also, when users transfer jobs or leave the organization, permissions are not tied to their user accounts, making permission reassignment or removal easier.

- Allows you to implement a role-based access-control model for granting permissions by using groups with different scopes (local, global, domain local, and universal) for the appropriate purposes.

- Minimizes the size of access control lists (ACLs) and speeds security checking. A security group has its own SID; therefore, the group SID can be used to specify permissions for a resource. In an environment with more than a few thousand users, if the SIDs of individual user accounts are used to specify access to a resource, the ACL of that resource can become unmanageably large, and the time needed for the system to check permissions to the resource can become unacceptable.

**Technologies Related to Security Principals**

Security principals are closely related to the following components and technologies in Windows Server 2003.

**Authorization and Access Control Components**

- **SIDs**. Each security principal is automatically assigned a SID when it is created.

- **Access Tokens**. After a user logs on and is authenticated, the system creates an access token for the user that contains the SID of the user, the SIDs of all the domain and local security groups that the user is a member of, and some well-known SIDs. Every process the user creates inherits the user's access token, which is then used to determine whether to grant that user access to a system resource in a given logon session.

- **Security Descriptors and ACLs**. A security descriptor is a data structure that is associated with each securable object. The security descriptor contains a discretionary access control list (DACL), with SIDs for the user's and groups that are allowed or denied access to that object.

- **Permissions**. Permissions to access securable objects such as Active Directory objects, files, and registry settings are granted to security principals.

**Authentication**

A user account enables a user to log on to computers and domains with an identity that can be authenticated by the computer or domain.

**Active Directory**

Accounts and security groups that are created in an Active Directory domain are stored in the Active Directory database and managed using Active Directory tools.

The following diagram shows the Windows Server 2003 authorization and access control process. In this diagram, the subject (a thread in a process that is initiated by a user) attempts to access an object, such as a shared folder. The information in the user's access token is compared to the access control entries (ACEs) in the object's security descriptor, and the access decision is made. The SIDs of security principals are used in the users access token and in the ACEs in the object's security descriptor.

### Authorization and Access Control Process

# How Security Principals Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Security Principals Work**

**In this section**

- Active Directory Accounts and Security Groups
- Local Accounts and Security Groups
- Related Information

Security principals include the following:

- Any entity that can be authenticated by the system, such as a user account, a computer account, or a thread or process that runs in the security context of a user or computer account.
- Security groups of these accounts.

Every security principal is automatically assigned a security identifier (SID) when it is created.

Security principals that are created in an Active Directory domain are Active Directory objects, which can be used to manage access to domain resources. Local users and security groups are created on a local computer and can be used to manage access to resources on that computer. Local user accounts and groups are managed by the Security Accounts Manager (SAM) on the local computer.

**Active Directory Accounts and Security Groups**

Active Directory user accounts and computer accounts can represent a physical entity, such as a computer or person. User accounts can also be used as dedicated service accounts for some applications. Groups are used to collect user accounts, computer accounts, and other groups into manageable units.

In Windows Server 2003 there are several built-in accounts and security groups that are preconfigured with the appropriate rights and permissions to perform specific tasks. For Active Directory, there are two types of administrative responsibility. Service administrators are responsible for maintaining and delivering the directory service, including domain controller management and directory service configuration. Data administrators are responsible for maintaining the data that is stored in the directory service and on domain member servers and workstations.

It is important to understand which default accounts and groups are service administrators. Service administration accounts and groups have the most widespread power in the network environment and require the most protection.

**User Accounts**

User accounts can be created, disabled, reset, and deleted by using the Active Directory Users and Computers snap-in in Microsoft Management Console (MMC) and by using command-line tools. In addition, built-in accounts are created when you create the Active Directory domain.

**Built-in User Accounts**

The Users container in Active Directory Users and Computers displays the built-in user accounts: Administrator, Guest, KRBTGT, and Support_388945a0. These built-in user accounts are created automatically when you create the domain. The HelpAssistant account is installed when a Remote Assistance session is established.

Each built-in account has a different combination of rights and permissions. The Administrator account has the most extensive rights and permissions over the domain, while the Guest account has limited rights and permissions.

Some of the administrative accounts that are listed in these tables are protected by a background process that periodically checks and applies a specific security descriptor, which is a data structure that contains security information that is associated with a protected object. This process ensures that any successful unauthorized attempt to modify the security descriptor on one of the administrative accounts or groups will be overwritten with the protected settings.

This security descriptor is present on the AdminSDHolder object. This means that if you want to modify the permissions on one

of the service administrator groups or on any of its member accounts, you must modify the security descriptor on the AdminSDHolder object so that it will be applied consistently. Be careful when making these modifications, because you are also changing the default settings that will be applied to all of your protected administrative accounts.

The following table describes each default user account on domain controllers running Windows Server 2003.

**Built-in User Accounts on Domain Controllers Running Windows Server 2003**

**Administrator**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-500 |
| **Type** | User |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | N/A |
| **Default member of** | Administrators, Domain Admins, Enterprise Administrators, Domain Users<br><br>(Membership in Domain Users is due to the fact that the Primary Group ID of all user accounts is Domain Users.) |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Yes |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Notes** | This account is the first account created during installation of the operating system. The account cannot be deleted or locked out, but it can be renamed or disabled. It is a member of the Administrators group and cannot be removed from that group.<br><br>The Administrator account is a default member of the Administrators, Domain Admins, Enterprise Admins, Group Policy Creator Owners, and Schema Admins groups in Active Directory. The Administrator account is known to exist on many versions of Windows; therefore, renaming or disabling this account makes it more difficult for malicious users to try and gain access to it.<br><br>When the Administrator account is disabled, it can still be used to gain access to a domain controller using Safe Mode. |

**Guest**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-501 |
| **Type** | User |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | Domain Guests, Guests |

| | |
|---|---|
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Can be moved out, but it is not recommended. |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Notes** | A user account for people who do not have individual accounts. This user account does not require a password. By default, the Guest account is disabled, and it is recommended that it stay disabled.<br><br>You can set rights and permissions for the Guest account just like any user account. By default, the Guest account is a member of the built-in Guests group and the Domain Guests global group, which allows a user to log on to a domain. |

**HelpAssistant**

| Attribute | Value |
|---|---|
| **Type** | User |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Notes** | The primary account that is used to establish a Remote Assistance session. This account has limited access to the computer. The HelpAssistant account is managed by the Remote Desktop Help Session Manager service and is automatically deleted if no Remote Assistance requests are pending. |

**KRBTGT**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-502 |
| **Type** | User |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | Domain Users (This membership is due to the fact that the Primary Group ID of all user accounts is Domain Users.) |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Can be moved out, but it is not recommended. |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Notes** | A service account that is used by the Key Distribution Center (KDC) service. |

**Support_388945a0**

| Attribute | Value |
|---|---|
| **Type** | User |
| **Default container** | CN=Users, DC=<domain>, DC= |

| | |
|---|---|
| **Notes** | The Support_388945a0 account enables Help and Support Service interoperability with signed scripts. This account is primarily used to control access to signed scripts that are accessible from within Help and Support Services. Administrators can use this account to delegate the ability for an ordinary user, who does not have administrative access over a computer, to run signed scripts from links embedded within Help and Support Services. These scripts can be programmed to use the Support_388945a0 account credentials instead of the user's credentials to perform specific administrative operations on the local computer that otherwise would not be supported by the ordinary user's account. When the delegated user clicks on a link in Help and Support Services, the script executes under the security context of the Support_388945a0 account. This account has limited access to the computer and is disabled by default. |

**Account Options**

Each Active Directory user account has a number of account options. The following table describes options that you can use to configure password settings and security-specific information for user accounts.

**Account Options for User Accounts**

| Account Option | Description |
|---|---|
| User must change password at next logon | Forces user to change their password the next time that the user logs on to the network. Use this option when you want to ensure that the user will be the only person to know their password. |
| User cannot change password | Prevents users from changing their password. Use this option when you want to maintain control over a user account, such as for a guest or temporary account. |
| Password never expires | Prevents a user password from expiring. It is recommended that service accounts have this option enabled and use strong passwords. |
| Store passwords using reversible encryption | Provides support for applications that use protocols that require knowledge of the plaintext form of the user's password for authentication purposes.<br><br>This option is required when using Challenge-Handshake Authentication Protocol (CHAP) in Internet Authentication Services (IAS), and when using Digest Authentication in Internet Information Services (IIS). |
| Account is disabled | Prevents user from logging on with the selected account. Many administrators use disabled accounts as templates for common user accounts. |
| Smart card is required for interactive logon | Requires that a user possess a smart card to log on to the network interactively. The user must also have a smart card reader attached to their computer and a valid personal identification number (PIN) for the smart card. |
| Account is trusted for delegation | Allows a service running under this account to perform operations on behalf of other user accounts on the network. A service running under a user account (otherwise known as a service account) that is trusted for delegation can impersonate a client to gain access to resources, either on the computer where the service is running or on other computers. In a forest that is set to the Windows Server 2003 functional level, this setting is found on the Delegation tab, and it is available only for accounts that have been assigned service principal names (SPNs), as set using the **setspn** command from Windows Support Tools. This is a security-sensitive capability, and it should be assigned cautiously.<br><br>This option is available only on domain controllers running Windows Server 2003 where the domain functionality is set to Windows 2000 mixed or Windows 2000 native. On domain controllers running Windows Server 2003 where the domain functional level is set to Windows Server 2003, the **Delegation** tab is used to configure delegation settings. The **Delegation** tab appears only for accounts that have an assigned SPN. |
| Account is sensitive and cannot be delegated | Allows control over a user account, such as for a guest or temporary account. This option can be used if this account cannot be assigned for delegation by another account. |
| Use DES encryption types for this account | Provides support for the Data Encryption Standard (DES). DES supports multiple levels of encryption, including Microsoft Point-to-Point Encryption (MPPE) Standard (40-bit and 56-bit), MPPE Strong (128-bit), Internet Protocol security (IPSec) DES (40-bit), IPSec 56-bit DES, and IPSec Triple DES (3DES). |

| | |
|---|---|
| Do not require Kerberos preauthentication | Provides support for alternate implementations of the Kerberos protocol. Domain controllers running Windows 2000 or Windows Server 2003 can use other mechanisms to synchronize time. Because preauthentication provides additional security, use caution when enabling this option. |

**Active Directory Groups**

Groups are used to collect user accounts, computer accounts, and other groups into manageable units. Working with groups instead of with individual users helps simplify network maintenance and administration.

There are two types of groups in Active Directory: distribution groups and security groups. You can use distribution groups to create e-mail distribution lists and security groups to assign permissions to shared resources.

**Distribution Groups**

Distribution groups can be used only with e-mail applications (such as Exchange) to send e-mail to collections of users. Distribution groups are not security enabled, which means that they cannot be listed in discretionary access control lists (DACLs). Distribution groups are not covered in this Technical Reference subject.

**Security Groups**

When they are used with care, security groups provide an efficient way to assign access to resources on your network. Using security groups, you can:

- Assign user rights to security groups in Active Directory.

  User rights are assigned to a security group to determine what members of that group can do within the scope of a domain (or forest). User rights are automatically assigned to some security groups when Active Directory is installed to help administrators define a person's administrative role in the domain. For example, a user who is added to the Backup Operators group in Active Directory has the ability to back up and restore files and directories that are located on each domain controller in the domain.

  This is possible because, by default, the user rights **Backup files and directories** and **Restore files and directories** are automatically assigned to the Backup Operators group. Therefore, members of this group inherit the user rights that are assigned to that group.

  You can assign user rights to security groups, by using Group Policy, to help delegate specific tasks. You should always use discretion when assigning delegated tasks because an untrained user who is assigned too many rights can potentially cause significant harm to your network.

- Assign permissions to security groups on resources.

  Permissions should not be confused with user rights. Permissions are assigned to the security group on the shared resource. Permissions determine who can access the resource and the level of access, such as Full Control. Some permissions that are set on domain objects are automatically assigned to allow various levels of access to default security groups such as the Account Operators group or the Domain Admins group.

  Security groups are listed in DACLs that define permissions on resources and objects. When assigning permissions for resources (file shares, printers, and so on), administrators should assign those permissions to a security group rather than to individual users. The permissions are assigned once to the group, instead of several times to each individual user. Each account that is added to a group receives the rights that are assigned to that group in Active Directory and receives the permissions that are defined for that group at the resource.

Like distribution groups, security groups can also be used as an e-mail entity. Sending an e-mail message to the group sends the message to all the members of the group.

**Converting Between Security and Distribution Groups**

A group can be converted from a security group to a distribution group, and vice versa, at any time, but only if the domain functional level is set to Windows 2000 native or higher. No groups can be converted while the domain functional level is set to Windows 2000 mixed.

### Note

- Although a contact can be added to a security group as well as to a distribution group, contacts cannot be assigned rights and permissions. Contacts in a group can be sent e-mail.

**Group Scope**

Groups are characterized by a scope that identifies the extent to which the group is applied in the domain tree or forest. There are three group scopes that are defined by Active Directory: Universal, Global, and Domain Local.

### Note

- In addition to these three scopes, the default groups in the Builtin container have a Group Scope of Builtin Local. Their Group Scope and Group Type cannot be changed.

The scope of the group defines where the group can be granted permissions. Universal groups are only available when the domain functional level is set to Windows 2000 native or Windows Server 2003.

The following table lists the three group scopes and more information about each scope for a security group.

**Group Scopes**

| Scope | Possible Members | Scope Conversion | Can Grant Permissions | Possible Member of |
|---|---|---|---|---|
| Universal | Accounts from any domain in the same forest<br><br>Global groups from any domain in the same forest<br><br>Other universal groups from any domain in the same forest | Can be converted to domain local scope<br><br>Can be converted to global scope as long as the group does not contain any other universal groups | On any domain in the same forest or trusting forests | Other universal groups in the same forest<br><br>Domain local groups in the same forest or trusting forests<br><br>Local groups on computers in the same forest or trusting forests |
| Global | Accounts from the same domain<br><br>Other global groups from the same domain | Can be converted to universal scope as long as the group is not a member of any other global group | On any domain in the same forest or trusting domains or forests | Universal groups from any domain in the same forest<br><br>Other global groups from the same domain<br><br>Domain local groups from any domain in the same forest or from any trusting domain |
| Domain Local | Accounts from any domain or any trusted domain<br><br>Global groups from any domain or any trusted domain<br><br>Universal groups from any domain in the same forest<br><br>Other domain local groups from the same domain<br><br>Accounts, global groups, and universal groups from other forests and from external and Windows NT 4.0 domains | Can be converted to universal scope as long as the group does not contain any other domain local groups | Within the same domain | Other domain local groups from the same domain<br><br>Local groups on computers in the same domain, excluding built-in groups that have well-known SIDs |

**Default Groups**

Default groups, such as the Domain Admins group, are security groups that are created automatically when you create an Active Directory domain. You can use these predefined groups to help control access to shared resources and to delegate specific domain-wide administrative roles.

Many default groups are automatically assigned a set of user rights that authorize members of the group to perform specific actions in a domain, such as logging on to a local system or backing up files and folders. For example, a member of the Backup Operators group has the right to perform backup operations for all domain controllers in the domain.

When you add a user to a group, the user receives all the user rights that are assigned to the group and all the permissions that are assigned to the group on any shared resources.

Default groups are located in the Builtin container and the Users container in Active Directory Users and Computers. The Builtin container contains groups that are defined with domain local scope. The Users container contains groups that are defined with global scope and groups that are defined with domain local scope. You can move groups that are located in these containers to other groups or organizational units (OU) within the domain, but you cannot move them to other domains.

Some of the administrative groups that are listed in these tables and all members of these groups are protected by a background process that periodically checks and applies a specific security descriptor, which is a data structure that contains security information that is associated with a protected object. This process ensures that any successful unauthorized attempt to modify the security descriptor on one of the administrative accounts or groups will be overwritten with the protected settings.

This security descriptor is present on the AdminSDHolder object. This means that if you want to modify the permissions on one of the service administrator groups or on any of its member accounts, you must modify the security descriptor on the AdminSDHolder object so that it will be applied consistently. Be careful when making these modifications because you are also changing the default settings that will be applied to all of your protected administrative accounts.

The following tables provide descriptions of the default groups that are located in the Builtin and Users containers.

**Account Operators**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-548 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | Allow log on locally<br><br>Shut down the system |
| **Notes** | By default, this built-in group has no members, and it can create and manage users and groups in the domain, including its own membership and that of the Server Operators. This group is a service administrator because it can modify Server Operators, which in turn can modify domain controller settings. As a best practice, leave the membership of this group empty and do not use it at all for any delegated administration. This group cannot be renamed, deleted, or moved. |

**Administrators**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-544 |

| | |
|---|---|
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | Administrator, Domain Admins, Enterprise Admins |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | Access this computer from the network<br>Adjust memory quotas for a process<br>Back up files and directories<br>Bypass traverse checking<br>Change the system time<br>Create a pagefile<br>Debug programs<br>Enable computer and user accounts to be trusted for delegation<br>Force a shutdown from a remote system<br>Increase scheduling priority<br>Load and unload device drivers<br>Allow log on locally<br>Manage auditing and security log<br>Modify firmware environment values<br>Profile single process<br>Profile system performance<br>Remove computer from docking station<br>Restore files and directories<br>Shut down the system<br>Take ownership of files or other objects |

| | |
|---|---|
| **Notes** | The Administrators group has built-in capabilities that give its members full control over the system. This group cannot be renamed, deleted, or moved. This built-in group controls access to all the domain controllers in its domain, and it can change the membership of all administrative groups. Its own membership can be modified by the default service administrator groups Administrators and Domain Admins in the domain, as well as by the Enterprise Admins group. This group has the special privilege to take ownership of any object in the directory or any resource on a domain controller. This account is considered a service administrator because its members have full access to the domain controllers in the domain. |

**Backup Operators**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-551 |
| **Type** | Builtin Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | Back up files and directories<br><br>Allow log on locally<br><br>Restore files and directories<br><br>Shut down the system |
| **Notes** | Backup Operators can back up and restore all files on a computer, regardless of the permissions that protect those files. Backup Operators also can log on to the computer and shut it down. This group cannot be renamed, deleted, or moved. By default, this built-in group has no members, and it can perform backup and restore operations on domain controllers. Its membership can be modified by the default service administrator groups Administrators and Domain Admins in the domain, as well as by the Enterprise Admins group. It cannot modify the membership of any administrative groups. While members of this group cannot change server settings or modify the configuration of the directory, they do have the permissions needed to replace files (including operating system files) on domain controllers. Because of this, members of this group are considered service administrators. |

**Cert Publishers**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-517 |
| **Type** | Domain Local |
| **Default container** | CN=Users, DC=<domain>, DC= |

| | |
|---|---|
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | No |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | No default user rights |
| **Notes** | A group that includes all computers that are running an enterprise certification authority. Cert Publishers are authorized to publish certificates for User objects in Active Directory. |

**Domain Admins**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-512 |
| **Type** | Domain Global |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | Administrator |
| **Default member of** | Administrators |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Yes |
| **Safe to delegate management of this group to non-Service admins?** | No |

| | |
|---|---|
| **Default User Rights** | Access this computer from the network<br>Adjust memory quotas for a process<br>Back up files and directories<br>Bypass traverse checking<br>Change the system time<br>Create a pagefile<br>Debug programs<br>Enable computer and user accounts to be trusted for delegation<br>Force a shutdown from a remote system<br>Increase scheduling priority<br>Load and unload device drivers<br>Allow log on locally<br>Manage auditing and security log<br>Modify firmware environment values<br>Profile single process<br>Profile system performance<br>Remove computer from docking station<br>Restore files and directories<br>Shut down the system<br>Take ownership of files or other objects |
| **Notes** | A group whose members are authorized to administer the domain. By default, the Domain Admins group is a member of the Administrators group on all computers that have joined a domain, including the domain controllers. Domain Admins is the default owner of any object that is created in Active Directory for the domain by any member of the group. If members of the group create other objects, such as files, the default owner is the Administrators group. This group controls access to all domain controllers in a domain, and it can modify the membership of all administrative accounts in the domain. Its own membership can be modified by the service administrator groups Administrators and Domain Admins in its domain, as well as the Enterprise Admins group. This is a service administrator account because its members have full access to a domain's domain controllers. |

**Domain Computers**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-515 |
| **Type** | Domain Global |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | All computers joined to the domain, excluding domain controllers |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Yes (but not required) |

| | |
|---|---|
| **Safe to delegate management of this group to non-Service admins?** | Yes |
| **Default User Rights** | No default user rights |
| **Notes** | The group includes all computers that have joined the domain, excluding domain controllers. |

**Domain Controllers**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-516 |
| **Type** | Domain Global |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | Computer accounts for all Domain Controllers of the domain |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | No |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | No default user rights |
| **Notes** | The group includes all domain controllers in the domain. New domain controllers are added to this group automatically. |

**Domain Guests**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-514 |
| **Type** | Domain Global |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | Guest |
| **Default member of** | Guests |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Can be moved out but it is not recommended |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | No default user rights |
| **Notes** | This group includes the domain's built-in Guest account. |

**Domain Users**

| Attribute | Value |
|---|---|

| | |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-513 |
| **Type** | Domain Global |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | All user accounts in the domain |
| **Default member of** | Users |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Yes |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | No default user rights |
| **Notes** | This group includes all user accounts in a domain. When you create a user account in a domain, it is added to this group automatically. |

**Enterprise Admins**

| **Attribute** | **Value** |
|---|---|
| **Well-Known SID/RID** | S-1-5-<root domain>-519 |
| **Type** | Universal (if Domain is in Native-Mode) else Domain Global |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | Administrator |
| **Default member of** | Administrators |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Yes |
| **Safe to delegate management of this group to non-Service admins?** | No |

| | |
|---|---|
| **Default User Rights** | Access this computer from the network<br>Adjust memory quotas for a process<br>Back up files and directories<br>Bypass traverse checking<br>Change the system time<br>Create a pagefile<br>Debug programs<br>Enable computer and user accounts to be trusted for delegation<br>Force shutdown from a remote system<br>Increase scheduling priority<br>Load and unload device drivers<br>Allow log on locally<br>Manage auditing and security log<br>Modify firmware environment values<br>Profile single process<br>Profile system performance<br>Remove computer from docking station<br>Restore files and directories<br>Shut down the system<br>Take ownership of files or other objects |
| **Notes** | This group exists only in the root domain of an Active Directory forest of domains. It is a universal group if the domain is in native mode; it is a global group if the domain is in mixed mode. The group is authorized to make forest-wide changes in Active Directory, such as adding child domains. By default, the only member of the group is the Administrator account for the forest root domain. This group is automatically added to the Administrators group in every domain in the forest, providing complete access to the configuration of all domain controllers. This group can modify the membership of all administrative groups. Its own membership can be modified only by the default service administrator groups in the root domain. This account is considered a service administrator. |

**Group Policy Creators Owners**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-520 |
| **Type** | Domain Global |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | Administrator |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | No |

| | |
|---|---|
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | No default user rights |
| **Notes** | This group that is authorized to create new Group Policy objects in Active Directory. By default, the only member of the group is Administrator. |

**Guests**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-546 |
| **Type** | Builtin Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | Guest |
| **Default member of** | Guest, Domain Guests |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | No default user rights |
| **Notes** | A built-in group. By default, the only member is the Guest account. The Guests group allows occasional or one-time users to log on with limited privileges to a computer's built-in Guest account. |

**Incoming Forest Trust Builders**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-557 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | No default user rights |
| **Notes** | This group cannot be renamed, deleted, or moved. |

**Network Configuration Operators**

| Attribute | Value |
| --- | --- |
| **Well-Known SID/RID** | S-1-5-32-556 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | Yes |
| **Default User Rights** | No default user rights |
| **Notes** | This group cannot be renamed, deleted, or moved. |

**Performance Log Users**

| Attribute | Value |
| --- | --- |
| **Well-Known SID/RID** | S-1-5-32-559 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | Yes |
| **Default User Rights** | No default user rights |
| **Notes** | This account cannot be renamed, deleted, or moved. |

**Performance Monitor Users**

| Attribute | Value |
| --- | --- |
| **Well-Known SID/RID** | S-1-5-32-558 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |

| | |
|---|---|
| **Safe to delegate management of this group to non-Service admins?** | Yes |
| **Default User Rights** | No default user rights |
| **Notes** | This group cannot be renamed, deleted, or moved. |

**Pre–Windows 2000 Compatible Access**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-554 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | Refer to the Notes column |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | Access this computer from the network<br><br>Bypass traverse checking |
| **Notes** | In Windows 2000, if you choose the Pre–Windows 2000 Compatible Permissions mode, Everyone (including Anonymous) is a member, and if you choose the Windows 2000–only permissions mode, the membership is empty. In Windows Server 2003, if you choose the Pre–Windows 2000 Compatible Permissions mode, Everyone and Anonymous are members, and if you choose the Windows 2000-only permissions mode, Authenticated Users are members. |

**Print Operators**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-550 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Cannot be moved |

| | |
|---|---|
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | Allow log on locally<br><br>Shut down the system |
| **Notes** | A built-in group that exists only on domain controllers. By default, the only member is the Domain Users group. Print Operators can manage printers and document queues. This group cannot be renamed, deleted, or moved. |

**RAS and IAS Servers**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<domain>-553 |
| **Type** | Domain Local |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Yes |
| **Safe to delegate management of this group to non-Service admins?** | Yes |
| **Default User Rights** | No default user rights |
| **Notes** | By default, this group has no members. Computers that are running the Routing and Remote Access service are added to the group automatically. Members of this group have access to certain properties of User objects, such as Read Account Restrictions, Read Logon Information, and Read Remote Access Information. |

**Remote Desktop Users**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-555 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | Yes |

| | |
|---|---|
| **Default User Rights** | No default user rights |
| **Notes** | This group cannot be renamed, deleted or moved. |

**Schema Admins**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-<root domain>-518 |
| **Type** | Universal (if Domain is in Native-Mode) else Domain Global |
| **Default container** | CN=Users, DC=<domain>, DC= |
| **Default members** | Administrator |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Yes |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | No default user rights |
| **Notes** | This group exists only in the root domain of an Active Directory forest of domains. It is a universal group if the domain is in native mode; it is a global group if the domain is in mixed mode. The group is authorized to make schema changes in Active Directory. By default, the only member of the group is the Administrator account for the forest root domain. This group has full administrative access to the schema. The membership of this group can be modified by any of the service administrator groups in the root domain. This account is considered a service administrator because its members can modify the schema, which governs the structure and content of the entire directory. |

**Server Operators**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-549 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | Yes |
| **Safe to move out of default container?** | Cannot be moved |

| | |
|---|---|
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | Back up files and directories<br><br>Change the system time<br><br>Force shutdown from a remote system<br><br>Allow log on locally<br><br>Restore files and directories<br><br>Shut down the system |
| **Notes** | This group exists only on domain controllers. By default, the group has no members. Server Operators can log on to a server interactively, create and delete network shares, start and stop services, back up and restore files, format the hard disk of the computer, and shut down the computer. This group cannot be renamed, deleted, or moved. By default, this built-in group has no members, and it has access to server configuration options on domain controllers. Its membership is controlled by the service administrator groups Administrators and Domain Admins in the domain, as well as the Enterprise Admins group. It cannot change any administrative group memberships. This is a service administrator account because its members have physical access to domain controllers and they can perform maintenance tasks (such as backup and restore), and they have the ability to change binaries that are installed on the domain controllers. |

**Terminal Server License Servers**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-561 |
| **Type** | BuiltIn Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | None |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | Yes |
| **Notes** | This group cannot be renamed, deleted, or moved. |

**Users**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-545 |
| **Type** | Builtin Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | Authenticated Users, Domain Users |
| **Default member of** | Domain Users (This membership is due to the fact that the Primary Group ID of all user accounts is Domain Users.) |

| | |
|---|---|
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | No |
| **Default User Rights** | No default user rights |
| **Notes** | After the initial installation of the operating system, the only member is the Authenticated Users group. When a computer joins a domain, the Domain Users group is added to the Users group on the computer. Users can perform tasks such as running applications, using local and network printers, shutting down the computer, and locking the computer. Users can install applications that only they are allowed to use if the installation program of the application supports per-user installation. This group cannot be renamed, deleted, or moved. |

**Windows Authorization Access Group**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-32-560 |
| **Type** | Builtin Local |
| **Default container** | CN=BuiltIn, DC=<domain>, DC= |
| **Default members** | Enterprise Domain Controllers |
| **Default member of** | None |
| **Protected by ADMINSDHOLDER?** | No |
| **Safe to move out of default container?** | Cannot be moved |
| **Safe to delegate management of this group to non-Service admins?** | Yes |
| **Notes** | This group cannot be renamed, deleted, or moved. |

**Special Identities**

In addition to the groups in the Users and Builtin containers, servers running Windows Server 2003 include several special identities. For convenience, these identities are generally referred to as groups. These special groups do not have specific memberships that can be modified, but they can represent different users at different times, depending on the circumstances.

Although the special identities can be assigned rights and permissions to resources, the memberships cannot be modified or viewed. Group scopes do not apply to special identities. Users are automatically assigned to these special identities whenever they log on or access a particular resource.

The special groups are described in the following tables.

**Anonymous Logon**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-7 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A user who has logged on anonymously. |

**Authenticated User**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-11 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A group that includes all users whose identities were authenticated when they logged on. Membership is controlled by the operating system. |

**Batch**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-3 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A group that implicitly includes all users who have logged on through a batch queue facility such as task scheduler jobs. Membership is controlled by the operating system. |

**Creator Group**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-3-1 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A placeholder in an inheritable access control entry (ACE). When the ACE is inherited, the system replaces this SID with the SID for the primary group of the object's current owner. The primary group is used only by the Portable Operating System Interface for UNIX (POSIX subsystem. |

**Creator Owner**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-3-0 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A placeholder in an inheritable ACE. When the ACE is inherited, the system replaces this SID with the SID for the object's current owner. |

**Dialup**

| Attribute | Value |
|---|---|

| | |
|---|---|
| **Well-Known SID/RID** | S-1-5-1 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | Used for accounts that are connected to the computer over a dial-up connection. |

**Digest Authentication**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-64-21 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |

**Enterprise Domain Controllers**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-9 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A group that includes all domain controllers in an Active Directory forest of domains. Membership is controlled by the operating system. |

**Everyone**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-1-0 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A group that includes Authenticated Users and Guest. Whenever a user logs on to the network, the user is automatically added to the Everyone group. On computers running Windows 2000 and earlier, the Everyone group included the Anonymous Logon group as a default member, but in Windows Server 2003, the Everyone group contains only Authenticated Users and Guest; it no longer includes Anonymous Logon by default (although this can be changed).<br><br>Membership is controlled by the operating system. |

**Interactive**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-4 |
| **Object Class** | Foreign Security Principal |

| | |
|---|---|
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A group that includes all users who have logged on interactively. Membership is controlled by the operating system. |

**Local Service**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-19 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | The Local Service account is similar to an authenticated user account. The Local Service account has the same level of access to resources and objects as members of the Users group. This limited access helps safeguard your system if individual services or processes are compromised. Services that run as the Local Service account access network resources as a null session with anonymous credentials. The name of the account is NT AUTHORITY\LocalService. This account does not have a password. |

**LocalSystem**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-18 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A service account that is used by the operating system. The Local System account is a powerful account that has full access to the system and acts as the computer on the network. If a service logs on to the Local System account on a domain controller, that service has access to the entire domain. Some services are configured by default to log on to the Local System account. Do not change the default service setting. The name of the account is LocalSystem. This account does not have a password. |

**Network**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-2 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A group that implicitly includes all users who are logged on through a network connection. Membership is controlled by the operating system. |

**Network Service**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-20 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | The Network Service account is similar to an authenticated user account. The Network Service account has the same level of access to resources and objects as members of the Users group. This limited access helps safeguard your system if individual services or processes are compromised. Services that run as the Network Service account access network resources using the credentials of the computer account. The name of the account is NT AUTHORITY\NetworkService. This account does not have a password. |

**NTLM Authentication**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-64-10 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |

**Other Organization**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-1000 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A group that implicitly includes all users who are logged on to the system through a dial-up connection. Membership is controlled by the operating system. |

**Principal Self**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-10 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |

| | |
|---|---|
| **Description** | A placeholder in an ACE on a user, group, or computer object in Active Directory. When you grant permissions to Principal Self, you grant them to the security principal that is represented by the object. During an access check, the operating system replaces the SID for Principal Self with the SID for the security principal that is represented by the object. |

**Proxy**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-8 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | Does not currently apply: this SID is not used in Windows 2000 Server or Windows Server 2003. |

**Remote Interactive Logon**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-14 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | Represents all users who are currently logged on to the computer using a Remote Desktop connection. This group is a subset of the Interactive group. Access tokens that contain the Remote Interactive Logon SID also contain the Interactive SID. |

**Restricted Code**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-12 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | Used by a process that is executing in a restricted security context, such as running an application with the RunAs service. When code executes at the restricted security level, the Restricted SID is added to the user's access token. |

**SChannel Authentication**

| Attribute | Value |
|---|---|
| **Well-Known SID/RID** | S-1-5-64-14 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |

**Service**

| Attribute | Value |
| --- | --- |
| **Well-Known SID/RID** | S-1-5-6 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A group that includes all security principals that have logged on as a service. Membership is controlled by the operating system. |

**Terminal Server User**

| Attribute | Value |
| --- | --- |
| **Well-Known SID/RID** | S-1-5-13 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |
| **Description** | A group that includes all users who have logged on to a Terminal Services server. Membership is controlled by the operating system. |

**This Organization**

| Attribute | Value |
| --- | --- |
| **Well-Known SID/RID** | S-1-5-15 |
| **Object Class** | Foreign Security Principal |
| **Default Location in Active Directory** | cn=WellKnown Security Principals, cn=Configuration, dc=<forestRootDomain> |

**Local Accounts and Security Groups**

You manage local user accounts and security groups by using Local Users and Groups, which is located in Computer Management, a collection of administrative tools that you can use to manage a single local or remote computer. You can use Local Users and Groups to secure and manage user accounts and groups that are stored locally on your computer. A local user or group can be assigned permissions and rights on a particular computer and that computer only. Local Users and Groups is available on the following client and server operating systems:

- Client computers running Windows 2000 Professional or Windows XP Professional.
- Member servers running Windows 2000 Server or Windows Server 2003.
- Stand-alone servers running Windows 2000 Server or Windows Server 2003.

You can use Local Users and Groups to limit the ability of users and groups to perform certain actions by assigning them rights and permissions. A right authorizes a user to perform certain actions on a computer, such as backing up files and folders or shutting down a computer. A permission is a rule that is associated with an object (usually a file, folder, or printer), and it regulates which users can have access to the object and in what manner.

You cannot use Local Users and Groups to view local users and groups after a member server has been promoted to a domain controller. However, you can use Local Users and Groups on a domain controller to target remote computers (that are not domain controllers) on the network.

Use Active Directory Users and Computers to manage users and groups in Active Directory.

**Local User Accounts**

The Users folder that is located in the Local Users and Groups snap-in in MMC displays the default user accounts as well as the user accounts that you create. The default user accounts are created automatically when you install a stand-alone server or

member server running Windows Server 2003. The following table describes the default user accounts on servers running Windows Server 2003.

**Default Local User Accounts on Servers Running Windows Server 2003**

| Default User Account | Description |
|---|---|
| Administrator account | The Administrator account has full control of the server and can assign user rights and access control permissions to users as necessary. This account must be used only for tasks that require administrative credentials. It is highly recommended that you set up this account to use a strong password.<br><br>The Administrator account is a member of the Administrators group on the server. The Administrator account can never be deleted or removed from the Administrators group, but it can be renamed or disabled. Because the Administrator account is known to exist on many versions of Windows, renaming or disabling this account will make it more difficult for malicious users to try and gain access to it.<br><br>The Administrator account is the account you use when you first set up the server. You use this account before you create an account for yourself.<br><br>Even when the Administrator account has been disabled, it can still be used to gain access to a computer by using Safe Mode. |
| Guest account | The Guest account is used by people who do not have an actual account on the computer. A user whose account is disabled, but not deleted, can also use the Guest account. The Guest account does not require a password. The Guest account is disabled by default, but you can enable it.<br><br>You can set rights and permissions for the Guest account just like any user account. By default, the Guest account is a member of the default Guests group, which allows a user to log on to a server. Additional rights, as well as any permissions, must be granted to the Guests group by a member of the Administrators group. The Guest account is disabled by default, and it is recommended that it stay disabled. |
| Support_388945a0 account | The Support_388945a0 account enables Help and Support Service interoperability with signed scripts. This account is primarily used to control access to signed scripts that are accessible from within Help and Support Services. Administrators can use this account to delegate the ability for an ordinary user, who does not have administrative access over a computer, to run signed scripts from links that are embedded in Help and Support Services. These scripts can be programmed to use the Support_388945a0 account credentials instead of the user's credentials to perform specific administrative operations on the local computer that otherwise would not be supported by the ordinary user's account. When the delegated user clicks on a link in Help and Support Services, the script will execute under the security context of the Support_388945a0 account. This account has limited access to the computer and is disabled by default. |
| HelpAssistant account (installed with a Remote Assistance session) | The primary account that is used to establish a Remote Assistance session. This account is created automatically when you request a Remote Assistance session, and it has limited access to the computer. The HelpAssistant account is managed by the Remote Desktop Help Session Manager service, and it will be automatically deleted if no Remote Assistance requests are pending. |

**Local Groups**

The Groups folder that is located in Local Users and Groups displays the default local groups as well as the local groups that you create. The default local groups are automatically created when you install a stand-alone server or a member server running Windows Server 2003. Belonging to a local group gives a user the rights and abilities to perform various tasks on the local computer.

You can add local user accounts, domain user accounts, computer accounts, and security groups to local groups. However, you cannot add local user accounts and local groups to domain group accounts.

The following table provides descriptions of the default groups that are located in the Groups folder, and it lists the assigned user rights for each group. These rights are assigned within the local security policy.

**Default Local Groups on Servers Running Windows Server 2003**

| Group | Description | Default User Rights |
|---|---|---|

| | | |
|---|---|---|
| Administrators | Members of this group have full control of the server and can assign user rights and access control permissions to users as necessary. The Administrator account is also a default member. When this server is joined to a domain, the Domain Admins group is automatically added to this group. Because this group has full control of the server, add users with caution. | Access this computer from the network<br><br>Adjust memory quotas for a process<br><br>Allow log on locally<br><br>Allow log on through Terminal Services<br><br>Back up files and directories<br><br>Bypass traverse checking<br><br>Change the system time<br><br>Create a pagefile; Debug programs<br><br>Force shutdown from a remote system<br><br>Increase scheduling priority<br><br>Load and unload device drivers<br><br>Manage auditing and security log<br><br>Modify firmware environment variables<br><br>Perform volume maintenance tasks<br><br>Profile single process |

| | | |
|---|---|---|
| | | Profile system performance<br><br>Remove computer from docking station<br><br>Restore files and directories<br><br>Shut down the system<br><br>Take ownership of files or other objects |
| Backup Operators | Members of this group can back up and restore files on the server, regardless of any permissions that protect these files. This is because the right to perform a backup takes precedence over all file permissions. File permissions cannot change security settings. | Access this computer from the network<br><br>Allow log on locally<br><br>Back up files and directories<br><br>Bypass traverse checking<br><br>Restore files and directories<br><br>Shut down the system |
| DHCP Administrators (installed with the DHCP Server service) | Members of this group have administrative access to the Dynamic Host Configuration Protocol (DHCP) Server service. This group provides a way to assign limited administrative access to the DHCP server only, while not providing full access to the server. Members of this group can administer DHCP on a server using the DHCP console or the Netsh command, but they are not able to perform other administrative actions on the server. | No default user rights |
| DHCP Users (installed with the DHCP Server service) | Members of this group have read-only access to the DHCP Server service. This allows members to view information and properties that are stored at a specified DHCP server. This information is useful to support staff when they need to obtain DHCP status reports. | No default user rights |
| Guests | Members of this group have a temporary profile created at log on, and when the member logs off, the profile is deleted. The Guest account (which is disabled by default) is also a default member of this group. | No default user rights |
| HelpServicesGroup | This group allows administrators to set rights that are common to all support applications. By default, the only group member is the account that is associated with Microsoft support applications, such as Remote Assistance. Do not add users to this group. | No default user rights |

| | | |
|---|---|---|
| Network Configuration Operators | Members of this group can make changes to TCP/IP settings and renew and release TCP/IP addresses. This group has no default members. | No default user rights |
| Performance Monitor Users | Members of this group can monitor performance counters on the server locally and from remote clients without being a member of the Administrators or Performance Log Users groups. | No default user rights |
| Performance Log Users | Members of this group can manage performance counters, logs, and alerts on the server locally and from remote clients without being a member of the Administrators group. | No default user rights |
| Power Users | Members of this group can create user accounts and then modify and delete the accounts that they have created. They can create local groups and then add or remove users from the local groups that they have created. They can also add or remove users from the Power Users, Users, and Guests groups. Members can create shared resources and administer the shared resources that they have created. They cannot take ownership of files, back up or restore directories, load or unload device drivers, or manage security and auditing logs. | Access this computer from the network<br><br>Allow log on locally<br><br>Bypass traverse checking<br><br>Change the system time<br><br>Profile single process<br><br>Remove computer from docking station<br><br>Shut down the system |
| Print Operators | Members of this group can manage printers and print queues. | No default user rights |
| Remote Desktop Users | Members of this group can remotely log on to a server. | Allow log on through Terminal Services |
| Replicator | The Replicator group supports replication functions. The only member of the Replicator group should be a domain user account that is used to log on the Replicator services of a domain controller. Do not add user accounts of actual users to this group. | No default user rights |
| Users | Members of this group can perform common tasks, such as running applications, using local and network printers, and locking the server. Users cannot share directories or create local printers. By default, the Domain Users, Authenticated Users, and Interactive groups are members of this group. Therefore, any user account that is created in the domain becomes a member of this group. | Access this computer from the network<br><br>Allow log on locally<br><br>Bypass traverse checking |

| | | |
|---|---|---|
| WINS Users (installed with WINS service) | Members of this group are permitted read-only access to Windows Internet Name Service (WINS). This allows members to view information and properties that are stored at a specified WINS server. # Security Principals Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security Principals Tools and Settings**

**In this section**

- Security Principals Tools
- Related Information

This section contains information about the tools that are associated with security principals.

**Security Principals Tools**

The following tools are associated with security principals.

**Dsa.msc: Active Directory Users and Computers**

**Category**

Active Directory Users and Computers is an Active Directory Administrative Tools Microsoft Management Console (MMC) snap-in. This tool is installed automatically when you install Active Directory, and it is available on the **Start** menu under **Programs** and then **Administrative Tools**. This tool also ships with the Windows Server 2003 Administration Tools Pack (Adminpak.msi).

**Version compatibility**

Active Directory Users and Computers runs on domain controllers that are running Windows Server 2003 and Windows 2000 Server.

The Windows Server 2003 version of Active Directory Users and Computers (which you can install on a domain controller or on an administrative workstation by using the Administration Tools Pack) can target domain controllers that are running Windows Server 2003 and Windows 2000 Server.

You can manage the following objects and their properties with this tool:

- User objects
- Group objects
- Computer objects

**Dsadd.exe: Dsadd**

**Category**

This tool ships with Windows Server 2003.

**Version compatibility**

This tool is compatible with domain controllers running Windows Server 2003.

You can use this tool to add specific types of objects to the directory.

For more information about Dsadd, see “Dsadd” in “Command-line reference A-Z” in Help and Support Center in Windows Server 2003.

**Dsget.exe: Dsget**

**Category**

This tool ships with Windows Server 2003.

**Version compatibility**

This tool is compatible with domain controllers running Windows Server 2003.

You can use this tool to display the selected properties of a specific object in the directory.

For more information about Dsget, see “Dsget” in “Command-line reference A-Z” in Help and Support Center in

Windows Server 2003.

**Dsmod.exe: Dsmod**
**Category**
This tool ships with Windows Server 2003.

**Version compatibility**
This tool is compatible with domain controllers running Windows Server 2003.

You can use this tool to modify an existing object of a specific type in the directory.

For more information about Dsmod, see “Dsmod” in “Command-line reference A-Z” in Help and Support Center in Windows Server 2003.

**Dsmove.exe: Dsmove**
**Category**
This tool ships with Windows Server 2003.

**Version compatibility**
This tool is compatible with domain controllers running Windows Server 2003.

You can use this tool to move a single object, within a domain, from its current location in the directory to a new location or to rename a single object without moving it in the directory tree.

For more information about Dsmove, see “Dsmove” in “Command-line reference A-Z” in Help and Support Center in Windows Server 2003.

**Dsquery.exe: Dsquery**
**Category**
This tool ships with Windows Server 2003.

**Version compatibility**
This tool is compatible with domain controllers running Windows Server 2003.

You can use this tool to query Active Directory according to specified criteria.

For more information about Dsquery, see “Dsquery” in “Command-line reference A-Z” in Help and Support Center in Windows Server 2003.

**Dsrm.exe: Dsrm**
**Category**
This tool ships with Windows Server 2003.

**Version compatibility**
This tool is compatible with domain controllers running Windows Server 2003.

You can use this tool to delete an object of a specific type or any general object from the directory.

For more information about Dsrm, see “Dsrm” in “Command-line reference A-Z” in Help and Support Center in Windows Server 2003.

**Ldifde.exe: Ldifde**
**Category**
This tool ships with Windows Server 2003.

**Version compatibility**
This tool is compatible with domain controllers running Windows Server 2003.

You can use Ldifde to create, modify, and delete directory objects on domain controllers running Windows Server 2003. You can also use Ldifde to extend the schema, export Active Directory user and group information to other applications or services, and populate Active Directory with data from other directory services.

For more information about Ldifde, see “Ldifde” in “Command-line reference A-Z” in Help and Support Center in Windows Server 2003.

**Ldp.exe: Active Directory Administration Tool**
**Category**
This tool ships with the Windows Server 2003 Support Tools.

**Version compatibility**

This tool is compatible with domain controllers running Windows Server 2003.

Ldp.exe is a Lightweight Directory Access Protocol (LDAP) graphical user interface (GUI) tool that you can use to perform operations, such as connect, bind, search, modify, add, and delete, against any LDAP-compatible directory, such as Active Directory. You can also use Ldp.exe to view objects that are stored in Active Directory, along with their metadata, such as security descriptors and replication metadata.

To find more information about Ldp.exe, see "Support Tools Help" in Tools and Settings Collection.

**Lusrmgr.msc: Local Users and Groups**
**Category**
Local Users and Groups is an MMC snap-in. This tool is included as part of the Windows Server 2003, Windows XP Professional, and Windows 2000 operating systems, and it is available in the Administration Tools Pack (Adminpak.msi).

**Version compatibility**
Local Users and Groups is supported for administering local groups on Windows Server 2003, Windows XP Professional, and Windows 2000.

Local Users and Groups manages users and groups of users for your computer. You can create new users and groups, add users to groups, remove users from groups, disable user and group accounts, and reset passwords.

You might need to be logged on as an administrator or a member of the Administrators group to perform some tasks.

For more information about Local Users and Groups, search for "Local users and groups overview" in Help and Support Center in Windows Server 2003.

**Net localgroup**
**Category**
This tool ships with Windows Server 2003.

**Version compatibility**
This tool is compatible with computers running Windows Server 2003.

You can use this tool to add, display, or modify local groups. When it is used without parameters, Net localgroup displays the name of the server and the names of local groups on the computer.

For more information about Net localgroup, search for "Net localgroup" in Help and Support Center in Windows Server 2003.

**Whoami**
**Category**
Whoami is a command-line tool in Windows Server 2003. This tool is also included in the Windows 2000 Resource Kit.

**Version compatibility**
Whoami is supported for Windows Server 2003 and Windows 2000.

You can use Whoami to display the complete contents of a user's access token in the command window.

Whoami displays the following:

- User name and security identifier (SID)
- Groups and their SIDs
- Privileges and their status (for example, enabled or disabled)
- Logon ID

To find more information about Whoami, see "Command-line reference A-Z" in Help and Support Center in Windows Server 2003.

# Security Identifiers Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security Identifiers Technical Reference**
A security identifier (SID) is a unique name (alphanumeric value) that identifies an object — such as a user, group, or computer account — on a network. Each account or group is issued a unique SID when it is first created.

During the authentication process, a user is identified to the local or trusted domain by presentation of credentials, usually in the form of a user name and password. Assuming these credentials are acceptable, the system creates an access token for the user that contains the SID of the user (the primary SID) and the SIDs of all the domain groups of which the user is a member. The system uses this access token to determine whether to grant the user access to system resources.

SIDs are a fundamental building block of the Microsoft Windows Server 2003 security model, which controls the use of network resources through the interrelated mechanisms of authentication and authorization. The authorization and access control technologies in Windows Server 2003 use SIDS, along with other security features and components (such as access tokens, security descriptors, and access control lists), to help determine if an authenticated user has the correct authorization to access a resource.

# What Are Security Identifiers?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Are Security Identifiers?**

**In this section**

- Security Identifiers Dependencies and Interactions
- Related Information

A security identifier (SID) is a value of variable length that is used to uniquely identify a security principal or security group.

Each account or group has a unique SID that is issued by an authority, such as a Windows domain controller, and stored in a security database. The system generates the SID that identifies a particular account or group at the time the account or group is created. When a SID has been used as the unique identifier for a user or group, it can never be used again to identify another user or group.

Each time a user logs on, the system creates an access token for that user. The access token contains the user's SID, the SIDs for any groups the user belongs to, and the user's privileges. This token provides the security context for whatever actions the user executes on that computer.

In addition to the uniquely created, domain-specific SIDs that are assigned to specific users and groups, there are well-known SIDs that identify generic groups and generic users. For example, the Everyone and World SIDs identify a group that includes all users. Well-known SIDs have values that remain constant across all operating systems.

SIDs are a fundamental building block of the Windows security model. They work together with specific components of the authorization and access control technologies in the Windows Server 2003 security infrastructure to help protect access to network resources and provide a more secure computing environment.

**Security Identifiers Dependencies and Interactions**

The Windows Server 2003 operating system uses SIDs in the following authorization and access control components:

**Security principals**

A security principal can be a user or computer account, or a group of these accounts — any entity that the security system recognizes. User accounts can be used by human users as well as autonomous processes. A security principal is automatically assigned a security identifier when it is created.

Although all security principals incorporate a unique SID, it is important to note that SIDs are generated and stored differently depending on the type of account they are associated with:

- The SID for a local account or group is generated by the Local Security Authority (LSA) on the computer and stored with other account information in a secure area of the registry.
- The SID for a domain account or group is generated by the domain security authority and stored as an attribute of the User or Group object in Active Directory directory service.

**Access tokens**

One SID in an access token identifies the user. Other SIDs identify the security groups to which the user belongs.

**Security descriptors and ACLs**

One SID in an object's security descriptor identifies the object's owner. Another SID identifies the owner's primary group. Within the security descriptor are access control lists (ACLs) that contain access control entries (ACEs). Each ACE contains a SID that identifies the user or group for which access is allowed, denied, or audited.

These related security components are discussed in depth in separate sections of the Microsoft Windows Server 2003 Technical Reference.

The following diagram shows the relationship of SIDs to other key components of the authorization and access control model.

**Security Identifiers in the Authorization and Access Control Process**

# How Security Identifiers Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Security Identifiers Work**

**In This Section**

- Security Identifier Architecture
- Relative Identifier Allocation
- Security Identifiers and Globally Unique Identifiers
- Well-Known SIDs

Users refer to accounts by using the account name, but the operating system internally refers to accounts by their security identifiers (SIDs). For domain accounts, the SID of a security principal is created by concatenating the SID of the domain with a relative identifier (RID) for the account. SIDs are unique within their scope (domain or local) and are never reused.

The system generates the SID that identifies a particular account or group at the time the account or group is created. The SID for a local account or group is generated by the Local Security Authority (LSA) on the computer and it is stored with other account information in a secure area of the registry. The SID for a domain account or group is generated by the domain security authority and stored as an attribute of the User or Group object in Active Directory directory service.

For every local account and group, the SID is unique for the computer where it was created; no two accounts or groups on the computer ever share the same SID. Likewise, for every domain account and group, the SID is unique within an enterprise. This means that the SID for an account or group created in one domain will never match the SID for an account or group created in any domain in the enterprise.

SIDs always remain unique. Security authorities never issue the same SID twice, and they never reuse SIDs for deleted accounts. For example, if a user with a user account in a Windows Server 2003 domain leaves her job, an administrator deletes her account, including the SID that identifies the account. If she later returns to a different job at the same company, an administrator creates a new account, and the Windows Server 2003 operating system generates a new SID. The new SID does not match the old one; so none of the users access from her old account is transferred to the new account. Her two accounts represent two completely different security principals.

**Security Identifier Architecture**

A security identifier is a data structure in binary format that contains a variable number of values. The first values in the structure contain information about the SID structure. The remaining values are arranged in a hierarchy, like a telephone number, and identify the SID-issuing authority (for example, the Windows Server 2003 operating system), the SID-issuing domain, and a particular security principal or group. The following figure illustrates the structure of a SID.

**SID Structure**

The individual values of a SID are described in the table below.

**SID Components**

| Component | Description |
|---|---|
| Revision | Indicates the version of the SID structure that is used in a particular SID. The structure used in all SIDs that are created by a Windows Server 2003 operating system and earlier versions is revision level 1. |

| | |
|---|---|
| Identifier Authority | Identifies the highest level of authority that can issue SIDs for a particular type of security principal. For example, the identifier authority value in the SID for the Everyone group is 1 (World Authority). The identifier authority value in the SID for a specific Windows NT, Windows 2000, or Windows Server 2003 account or group is 5 (NT Authority). |
| Subauthorities | Holds the most important information in a SID. Contained in a series of one or more subauthority values. All values up to, but not including, the last value in the series collectively identify a domain in an enterprise. This part of the series is called the domain identifier. The last value in the series, which is called the relative identifier (RID), identifies a particular account or group relative to a domain. |

The components of a SID are easier to visualize when SIDs are converted from binary to string format by using standard notation:

```
S-R-X-Y1-Y2-Yn-1-Yn
```

In this notation, the components of a SID are as follows:

**SID Components in String Format**

| Component | Definition |
|---|---|
| S | Indicates that the string is a SID |
| R | Revision level |
| X | Identifier authority value |
| Y | A series of subauthority values, where *n* is the number of values |

The SID's most important information is contained in the series of subauthority values. The first part of the series (-Y1-Y2-Y*n*-1) is the domain identifier. This element of the SID becomes significant in an enterprise with several domains, because the domain identifier differentiates SIDs that are issued by one domain from SIDs that are issued by all other domains in the enterprise. No two domains in an enterprise share the same domain identifier.

The last item in the series of subauthority values (-Y*n*) is the relative identifier. It distinguishes one account or group from all other accounts and groups in the domain. No two accounts or groups in any domain share the same relative identifier.

For example, the SID for the built-in Administrators group is represented in standardized SID notation as the following string:

```
S-1-5-32-544
```

This SID has four components:

- A revision level (1)
- An identifier authority value (5, NT Authority)
- A domain identifier (32, Builtin)
- A relative identifier (544, Administrators)

SIDs for built-in accounts and groups always have the same domain identifier value: 32. This value identifies the domain Builtin, which exists on every computer that is running a version of the Windows NT, Windows 2000, or Windows Server 2003 operating systems. It is never necessary to distinguish one computer's built-in accounts and groups from another computer's built-in accounts and groups because they are local in scope: local either to a single computer; or in the case of domain controllers for a network domain, local to several computers that are acting as one. However, built-in accounts and groups do need to be distinguished from one another within the scope of the Builtin domain; therefore, the SID for each account and group has a unique relative identifier. A relative identifier value of 544 is unique to the built-in Administrators group. No other account or group in the Builtin domain has a SID with a final value of 544.

In another example, consider the SID for the global group Domain Admins. Every domain in an enterprise has a Domain Admins group, and the SID for each group is different. The following is the SID for the Domain Admins group in the Contoso domain (Contoso\Domain Admins):

```
S-1-5-21-1004336348-1177238915-682003330-512
```

The SID for Contoso\Domain Admins has:

- A revision level (1)
- An identifier authority (5, NT Authority)
- A domain identifier (21-1004336348-1177238915-682003330, Contoso)
- A relative identifier (512, Domain Admins)

The SID for Contoso\Domain Admins is distinguished from the SIDs for other Domain Admins groups in the same enterprise by its domain identifier: 21-1004336348-1177238915-682003330. No other domain in the enterprise uses this value as its domain identifier. The SID for Contoso\Domain Admins is distinguished from the SIDs for other accounts and groups created in the Contoso domain by its relative identifier, 512. No other account or group in the domain has a SID with a final value of 512.

**Relative Identifier Allocation**

Where accounts and groups are stored in an account database that is managed by a local Security Accounts Manager (SAM), it is fairly easy for the system to generate a unique relative identifier for each account and group that it creates on a stand-alone computer. The SAM on a stand-alone computer can simply keep track of the relative identifier values that it has used before and make sure that it never uses them again.

In a network domain, however, generating unique relative identifiers is a more complex process. Windows Server 2003 network domains can have several domain controllers. Each domain controller stores Active Directory account information. This means that, in a network domain, there are as many copies of the account database as there are domain controllers. In addition to this, every copy of the account database is a master copy. New accounts and groups can be created on any domain controller. Changes that are made to Active Directory on one domain controller are replicated to all other domain controllers in the domain. The process of replicating changes in one master copy of the account database to all other master copies is called a multimaster operation.

The process of generating unique relative identifiers is a single-master operation. One domain controller is assigned the role of relative identifier (RID) master, and it allocates a sequence of relative identifiers to each domain controller in the domain. When a new domain account or group is created in one domain controller's replica of Active Directory, it is assigned a SID. The relative identifier for the new SID is taken from the domain controller's allocation of relative identifiers. When its supply of relative identifiers begins to run low, the domain controller requests another block from the RID master.

Each domain controller uses each value in a block of relative identifiers only once. The RID master allocates each block of relative identifier values only once. This process assures that every account and group created in the domain has a unique relative identifier.

**Security Identifiers and Globally Unique Identifiers**

When a new domain user or group account is created, Active Directory stores the account's SID in the Object-SID (objectSID) property of a User or Group object. It also assigns the new object a globally unique identifier (GUID), which is a 128-bit value that is unique not only in the enterprise, but also across the world. GUIDs are assigned to every object that is created by Active Directory, not just User and Group objects. Each object's GUID is stored in its Object-GUID (objectGUID) property.

Active Directory uses GUIDs internally to identify objects. For example, the GUID is one of an object's properties that is published in the global catalog. Searching the global catalog for a User object's GUID produces results if the user has an account somewhere in the enterprise. In fact, searching for any object by Object-GUID might be the most reliable way of finding the object you want to locate. The values of other object properties can change, but the Object-GUID never changes. When an object is assigned a GUID, it keeps that value for life.

If a user moves from one domain to another, the user gets a new SID. The SID for a group object does not change because groups stay in the domain where they were created. However, if people move, their accounts can move with them. If an employee moves from North America to Europe, but stays in the same company, an administrator for the enterprise can move the employee’s User object from, for example, Contoso\Noam to Contoso\Europe. If the administrator does this, the User object for the account needs a new SID. The domain identifier portion of a SID that is issued in Noam is unique to Noam; so the SID for the user’s account in Europe has a different domain identifier. The relative identifier portion of a SID is unique relative to the domain; so if the domain changes, the relative identifier also changes.

When a User object moves from one domain to another, a new SID must be generated for the user account and stored in the

Object-SID property. Before the new value is written to the property, the previous value is copied to another property of a User object, SID-History (sIDHistory). This property can hold multiple values. Each time a User object moves to another domain, a new SID is generated and stored in the Object-SID property and another value is added to the list of old SIDs in SID-History. When a user logs on and is successfully authenticated, the domain authentication service queries Active Directory for all the SIDs that are associated with the user — the user's current SID, the user's old SIDs, and the SIDs for the user's groups. All these SIDs are returned to the authentication client and are included in the user's access token. When the user tries to gain access to a resource, any one of the SIDs in the access token, including one of the SIDs in SID-History, can allow or deny the user access.

If you allow or deny user's access to a resource based on their jobs, you should allow or deny access to a group, not an individual. That way, when users change jobs or move to other departments, you can easily adjust their access by removing them from certain groups and adding them to others. However, if you allow or deny an individual user access to resources, you probably want that user's access to remain the same no matter how many times the user's account domain changes. The SID-History property makes this possible. When a user changes domains, there is no need to change the access control list (ACL) on any resource. If an ACL has the user's old SID but not the new one, the old SID is still in the user's access token, listed among the SIDs for the user's groups, and the user is granted or denied access based on the old SID.

The reason for using SIDs, and not GUIDs, is for backward compatibility. Windows NT uses SIDs to identify users and groups in ACLs on resources; so you do not have to change ACLs on your resources when you upgrade. In Windows 2000 and Windows Server 2003, ACLs continue to identify users and groups by SID, not GUID — even ACLs on resources in Active Directory. For example, a user gains access to a Group Policy object based on one of the user's SIDs, not on the GUID for the User object.

**Well-Known SIDs**
The values of certain SIDs are constant across all systems. They are created during installation of the operating system or domain and are called well-known SIDs because they identify generic users or generic groups. For example, well-known SIDs identify the following users and groups:

**Everyone (S-1-1-0)**
The generic group Everyone automatically includes everyone who uses the computer, even anonymous guests. The identifier authority value for this SID is 1 (World Authority). It has only one subauthority value, 0 (Null RID).

**Creator Owner (S-1-3-0)**
The generic user Creator Owner is a placeholder in an inheritable access control entry (ACE). When the ACE is inherited, the system replaces the SID for Creator Owner with the SID for the object's current owner. The identifier authority value for this SID is 3 (Creator Authority). It has only one subauthority value, 0 (Null RID).

**Principal Self (S-1-5-10)**
The generic user Principal Self is a placeholder in an ACE on a User, Group, or Computer object in Active Directory. When you grant permission to Principal Self, you grant it to the security principal represented by the object. During an access check, the operating system replaces the SID for Principal Self with the SID for the security principal represented by the object. The identifier authority for this SID is 5 (NT Authority). It has only one subauthority value, 10 (Self RID).

There are universal well-known SIDs that are meaningful on all secure systems that use this security model, including operating systems other than Windows. In addition, there are well-known SIDs that are meaningful only on Windows operating systems.

The following table lists the universal well-known SIDs.

### Universal Well-known SIDs

| Universal Well-Known SID | Value | Identifies |
|---|---|---|
| Null SID | (S-1–0–0) | A group with no members. This is often used when a SID value is not known. |
| World | (S-1–1–0) | A group that includes all users. |
| Local | (S-1–2–0) | Users who log on to terminals that are locally (physically) connected to the system. |
| Creator Owner ID | (S-1–3–0) | A security identifier to be replaced by the security identifier of the user who created a new object. This SID is used in inheritable ACEs. |

| | | |
|---|---|---|
| Creator Group ID | (S-1–3–1) | A security identifier to be replaced by the primary-group SID of the user who created a new object. Use this SID in inheritable ACEs. |

The following table lists the predefined identifier authority constants. The first four values are used with universal well-known SIDs; the last value is used with well-known SIDs in Windows XP, Windows NT, Windows 2000, and Windows Server 2003 operating systems.

**Predefined Identifier Authority Constants**

| Identifier Authority | Value | SID String Prefix |
|---|---|---|
| SECURITY_NULL_SID_AUTHORITY | 0 | S-1–0 |
| SECURITY_WORLD_SID_AUTHORITY | 1 | S-1–1 |
| SECURITY_LOCAL_SID_AUTHORITY | 2 | S-1–2 |
| SECURITY_CREATOR_SID_AUTHORITY | 3 | S-1–3 |

The following RID values are used with universal well-known SIDs. The Identifier authority column shows the prefix of the identifier authority with which you can combine the RID to create a universal well-known SID.

**RID Values Used with Universal Well-known SIDs**

| Relative Identifier Authority | Value | Identifier Authority |
|---|---|---|
| SECURITY_NULL_RID | 0 | S-1–0 |
| SECURITY_WORLD_RID | 0 | S-1–1 |
| SECURITY_LOCAL_RID | 0 | S-1–2 |
| SECURITY_CREATOR_OWNER_RID | 0 | S-1–3 |
| SECURITY_CREATOR_GROUP_RID | 1 | S-1–3 |

The SECURITY_NT_AUTHORITY (S-1–5) predefined identifier authority produces SIDs that are not universal and are meaningful only in Windows XP, Windows NT, Windows 2000, and Windows Server 2003 installations. The following table lists the well-known SIDs.

**Well-Known Security Identifiers**

| SID | Display Name | Description |
|---|---|---|
| S-1-5-1 | Dialup | A group that includes all users who are logged on to the system by means of a dial-up connection. |
| S-1-5-2 | Network | A group that includes all users who are logged on by means of a network connection. Access tokens for interactive users do not contain the Network SID. |
| S-1-5-3 | Batch | A group that includes all users who have logged on by means of a batch queue facility, such as task scheduler jobs. |
| S-1-5-4 | Interactive | A group that includes all users who log on interactively. A user can start an interactive logon session by logging on directly at the keyboard, by opening a Remote Desktop connection from a remote computer, or by using a remote shell such as telnet. In each case, the user's access token contains the Interactive SID. If the user logs on using a Remote Desktop connection, the user's access token also contains the Remote Interactive Logon SID. |
| S-1-5-5-*X*-*Y* | Logon Session | A logon session. The *X* and *Y* values for these SIDs uniquely identify a particular logon session. |
| S-1-5-6 | Service | A group that includes all security principals that have logged on as a service. |

| | | |
|---|---|---|
| S-1-5-7 | Anonymous Logon | A user who has connected to the computer without supplying a user name and password.<br><br>The Anonymous Logon identity is different from the identity used by Internet Information Services (IIS) for anonymous Web access. IIS uses an actual account—by default, IUSR_*ComputerName*—for anonymous access to resources on a Web site. Strictly speaking, such access is not anonymous; the security principal is known even though unidentified people are using the account. IUSR_*ComputerName* (or whatever you name the account) has a password, and IIS logs the account on when the service starts. As a result, the IIS "anonymous" user is a member of Authenticated Users while Anonymous Logon is not. |
| S-1-5-8 | Proxy | Does not currently apply: this SID is not used in the Windows 2000 Server or Windows Server 2003 operating systems. |
| S-1-5-9 | Enterprise Domain Controllers | A group that includes all domain controllers in a forest of domains. |
| S-1-5-10 | Self | A placeholder in an ACE on a user, group, or computer object in Active Directory. When you grant permissions to Self, you grant them to the security principal represented by the object. During an access check, the operating system replaces the SID for Self with the SID for the security principal represented by the object. |
| S-1-5-11 | Authenticated Users | A group that includes all users and computers whose identities have been authenticated. Authenticated Users does not include Guest even if the Guest account has a password.<br><br>**Note:** This group includes authenticated security principals from any trusted domain, not just the current domain. |
| S-1-5-12 | Restricted | An identity used by a process that is executing in a restricted security context. In Windows XP and Windows Server 2003 operating systems, a software restriction policy can assign one of three security levels to executable code: unrestricted, restricted, or disallowed. When code executes at the restricted security level, the Restricted SID is added to the user's access token. |
| S-1-5-13 | Terminal Server User | A group that includes all users who log on to a server with Terminal Services enabled: specifically, a server that is in Terminal Services version 4.0 application compatibility mode. |
| S-1-5-14 | Remote Interactive Logon | A group that includes all users who log on to the computer by using a Remote Desktop Connection. This group is a subset of the Interactive group. Access tokens that contain the Remote Interactive Logon SID also contain the Interactive SID. |
| S-1-5-18 | System (or LocalSystem) | An identity that is used locally by the operating system and by services configured to log on as LocalSystem.<br><br>System is a hidden member of Administrators. That is, any process running as System has the SID for the built-in Administrators group in its access token.<br><br>When a process that is running locally as System accesses network resources, it does so by using the computer's domain identity. Its access token on the remote computer includes the SID for the local computer's domain account plus SIDs for security groups that the computer is a member of, such as Domain Computers and Authenticated Users. |
| S-1-5-19 | LocalService | An identity used by services that are local to the computer, have no need for extensive local access and do not need authenticated network access. Services that run as LocalService access local resources as ordinary users, and access network resources as anonymous users. As a result, a service that runs as LocalService has significantly less authority than a service that runs as LocalSystem — both locally and on the network. |
| S-1-5-20 | NetworkService | An identity used by services that have no need for extensive local access but do need authenticated network access. Services running as NetworkService access local resources as ordinary users and access network resources using the computer's identity. As a result, a service that runs as NetworkService has the same network access as a service that runs as LocalSystem but has significantly reduced local access. |

| | | |
|---|---|---|
| S-1-5-*domain*-500 | Administrator | A user account for the system administrator. Every computer has a local Administrator account and every domain has a domain Administrator account.<br><br>The Administrator account is the first account created during operating system installation. The account cannot be deleted, disabled, or locked out, but it can be renamed.<br><br>By default, the Administrator account is a member of the Administrators group and cannot be removed from that group. |
| S-1-5-*domain*-501 | Guest | A user account for people who do not have individual accounts. Every computer has a local Guest account and every domain has a domain Guest account.<br><br>By default, Guest is a member of Everyone and Guests. The domain Guest account is also a member of the Domain Guests and Domain Users groups.<br><br>Unlike Anonymous Logon, Guest is a real account and can be used to log on interactively. By default, the account is enabled on Windows XP and disabled on all editions of the Windows Server 2003 operating system. The Guest account does not require a password, but can have one. |
| S-1-5-*domain*-502 | krbtgt | A user account that is used by the Key Distribution Center (KDC) service. The account exists only on domain controllers. |
| S-1-5-*domain*-512 | Domain Admins | A global group whose members are authorized to administer the domain. By default, the Domain Admins group is a member of the Administrators group on all computers that have joined the domain, including domain controllers.<br><br>Domain Admins is the default owner of any object that is created in the domain's Active Directory by any member of the group. If members of the group create other objects, such as files, the default owner is the Administrators group. |
| S-1-5-*domain*-513 | Domain Users | A global group that includes all users in a domain. When you create a new User object in Active Directory, the user is automatically added to this group. |
| S-1-5-*domain*-514 | Domain Guests | A global group that, by default, has only one member, the domain's built-in Guest account. |
| S-1-5-*domain*-515 | Domain Computers | A global group that includes all computers that have joined the domain, excluding domain controllers. |
| S-1-5-*domain*-516 | Domain Controllers | A global group that includes all domain controllers in the domain. New domain controllers are added to this group automatically. |
| S-1-5-*domain*-517 | Cert Publishers | A global group that includes all computers that host an enterprise certification authority.<br><br>Cert Publishers are authorized to publish certificates for User objects in Active Directory. |
| S-1-5-*root domain*-518 | Schema Admins | A group that exists only in the forest root domain. It is a universal group if the domain is in native mode and a global group if the domain is in mixed mode. The Schema Admins group is authorized to make schema changes in Active Directory. By default, the only member of the group is the Administrator account for the forest root domain. |

| | | |
|---|---|---|
| S-1-5-*root domain*-519 | Enterprise Admins | A group that exists only in the forest root domain. It is a universal group if the domain is in native mode, a global group if the domain is in mixed mode.<br><br>The Enterprise Admins group is authorized to make changes to the forest infrastructure, such as adding child domains, configuring sites, authorizing DHCP servers, and installing enterprise Certificate Authorities.<br><br>By default, the only member of Enterprise Admins is the Administrator account for the forest root domain. The group is a default member of every Domain Admins group in the forest. |
| S-1-5-*domain*-520 | Group Policy Creator Owners | A global group that is authorized to create new Group Policy objects in Active Directory. By default, the only member of the group is Administrator.<br><br>Objects that are created by members of Group Policy Creator Owners are owned by the individual user who creates them. In this way, the Group Policy Creator Owners group is unlike other administrative groups, such as Administrators and Domain Admins. Objects that are created by members of these groups are owned by the group rather than by the individual. |
| S-1-5-*domain*-553 | RAS and IAS Servers | A domain local group. By default, this group has no members. Computers that are running the Routing and Remote Access service are added to the group automatically.<br><br>Members of this group have access to certain properties of User objects, such as Read Account Restrictions, Read Logon Information, and Read Remote Access Information. |

The following RIDs are relative to each domain.

**RIDs Relative to Each Domain**

| RID | Identifies |
|---|---|
| DOMAIN_USER_RID_ADMIN | The administrative user account in a domain. |
| DOMAIN_USER_RID_GUEST | The guest-user account in a domain. Users who do not have an account can automatically log on to this account. |
| DOMAIN_GROUP_RID_ADMINS | The domain administrators' group. This account exists only on systems running Windows 2000 Server or Windows NT Server. |
| DOMAIN_GROUP_RID_USERS | A group containing all user accounts in a domain. All users are automatically added to this group. |
| DOMAIN_GROUP_RID_GUESTS | The guest-group account in a domain. |
| DOMAIN_GROUP_RID_COMPUTERS | The domain computers' group. All computers in the domain are members of this group. |
| DOMAIN_GROUP_RID_CONTROLLERS | The domain controllers' group. All Domain controllers in the domain are members of this group. |
| DOMAIN_GROUP_RID_CERT_ADMINS | The certificate publishers' group. Computers running Certificate Services are members of this group. |
| DOMAIN_GROUP_RID_SCHEMA_ADMINS | The schema administrators' group. Members of this group can modify the Active Directory schema. |
| DOMAIN_GROUP_RID_ENTERPRISE_ADMINS | The enterprise administrators' group. Members of this group have full access to all domains in the Active Directory forest. Enterprise administrators are responsible for forest-level operations such as adding or removing new domains. |
| DOMAIN_GROUP_RID_POLICY_ADMINS | The policy administrators' group. |

The following table provides examples of domain-relative RIDs that are used to form well-known SIDs for local groups.

**Examples of RIDs for Local Groups**

| RID | Identifies |
| --- | --- |
| DOMAIN_ALIAS_RID_ADMINS | A local group that is used for administration of the domain. |
| DOMAIN_ALIAS_RID_USERS | A local group that represents all users in the domain. |
| DOMAIN_ALIAS_RID_GUESTS | A local group that represents guests of the domain. |
| DOMAIN_ALIAS_RID_POWER_USERS | A local group that is used to represent a user or set of users who expect to treat a system as if it were their personal computer rather than as a workstation for multiple users. |
| DOMAIN_ALIAS_RID_ACCOUNT_OPS | A local group that exists only on systems running Windows 2000 Server or Windows NT Server. This local group permits control over non-administrator accounts. |
| DOMAIN_ALIAS_RID_SYSTEM_OPS | A local group that exists only on systems running Windows 2000 Server or Windows NT Server. This local group performs system administrative functions, not including security functions. It establishes network shares, controls printers, unlocks workstations, and performs other operations. |
| DOMAIN_ALIAS_RID_PRINT_OPS | A local group that exists only on systems running Windows 2000 Server or Windows NT Server. This local group controls printers and print queues. |
| DOMAIN_ALIAS_RID_BACKUP_OPS | A local group that is used for controlling assignment of file backup-and-restoring user rights. |
| DOMAIN_ALIAS_RID_REPLICATOR | A local group responsible for copying security databases from the primary domain controller to the backup domain controllers. These accounts are used only by the system. |
| DOMAIN_ALIAS_RID_RAS_SERVERS | A local group that represents remote access and servers running Internet Authentication Service (IAS). This group permits access to various attributes of user objects. |
| DOMAIN_ALIAS_RID_PREW2KCOMPACCESS | A local group that exists only on systems running Windows 2000 Server and Windows Server 2003. This group provides access rights equal to anonymous access under Windows NT, which is Everyone access. |

# Security Identifiers Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security Identifiers Tools**
The following tools are associated with security identifiers (SIDs).

**Getsid.exe: Get Security ID**
**Category**
Included with Windows Server 2003 Support Tools.

**Version compatibility**
This tool is compatible with domain controllers running Windows Server 2003.

Use this command-line tool to compare the user SIDs of two accounts. For example, you can use Getsid.exe to compare account SIDs between domain controllers when you suspect user database corruption.

For more information about Getsid.exe, see "Support Tools Help" in the Tools and Settings Collection.

**Sidwalk.exe, Sidwalk.msc, and Showaccs.exe: SIDWalker Security Administration tools**
**Category**
Included with Windows Server 2003 Support Tools.

**Version compatibility**
These tools are compatible with domain controllers running Windows Server 2003.

Use these tools to help you migrate or merge computers from a Windows NT 4.0 resource domain to a Windows Server 2003 domain. You can also use these tools to help manage server resources that you move between domains. The SIDWalker toolset allows you to change the access control lists (ACLs) on objects that were previously owned by accounts that have been moved or deleted. You can use these tools to either delete or replace every occurrence of an old security identifier (SID) with the corresponding new SID.

For more information about the SIDWalker Security Administration tools, see "Support Tools Help" in the Tools and Settings Collection.

**Netdom.exe: Windows Domain Manager**
**Category**
A command-line tool that is included in Windows Server 2003 Support Tools.

**Version compatibility**
This tool is compatible with Windows Server 2003.

You can use Netdom.exe to apply or remove SID filtering. SID filtering is set on outgoing external or forest trusts to prevent malicious users who have domain-level or enterprise-level administrator access in a trusted forest from granting (to themselves or to other user accounts in their forest) elevated user rights to a trusting forest. SID filtering does this by preventing misuse of the SID-History attribute on security principals in the trusted forest.

For more information about SID filtering, see "Security Considerations for Trusts."

For more information about Netdom.exe, see "Support Tools Help" in the Tools and Settings Collection.

**Ntdsutil.exe: Ntdsutil**
**Category**
A command-line tool that is included in Windows Server 2003.

**Version compatibility**
This tool is compatible with Windows Server 2003.

You can use Ntdsutil with the **security account management** command to check for and resolve duplicate SIDs in Active Directory — in the unlikely situation that duplicates are issued. Only experienced administrators should use this tool.

For more information about Ndtsutl, see "Command-Line References" in the Tools and Settings Collection.

# Data Security Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Data Security Technologies**
In a distributed computing environment, data exists in many locations. In some situations, data is stored on a centralized server. Other situations may call for a decentralized data storage scenario, where each user maintains his own data on his own computer. The most common scenario is a hybrid of these two, where some data is stored on a centralized server and retrieved by client computers, while other data is stored only on local computers and never shared.

All of these scenarios present some security issues to consider. In most environments, at the very least some of this data must be kept secure. To help provide data security in a variety of scenarios, there are several security technologies that can help protect sensitive data during storage and network transmission.

**Data Security Architecture**
There is no single data security component that protects all data against all forms of attack. There are, however, several technologies that can act in concert to provide a comprehensive security infrastructure that protects against many types of attacks. This type of attack defense is known as "defense in depth" and is the most appropriate method to ensure that sensitive data is not compromised. The data security components that provide the various data safeguards are described later in this overview.

**Data Security Components**
There are three main data security components in the Microsoft Windows operating system: Internet Protocol security (IPSec), Encrypting File System (EFS), and Syskey.

**Internet Protocol Security**
Internet Protocol security (IPSec) is a framework of open standards for ensuring private, secure communications over Internet Protocol (IP) networks, through the use of cryptographic security services. The implementation of IPSec in the Microsoft Windows Server 2003 operating system is based on standards developed by the Internet Engineering Task Force (IETF) IPSec working group.

IPSec provides aggressive protection against private network and Internet attacks through end-to-end security. The only computers that must know about IPSec protection are the sender and receiver in the communication. In Windows Server 2003, IPSec provides the ability to protect communication between workgroups, local area network computers, domain clients and servers, branch offices (which might be physically remote), extranets, and roving clients.

Although IPSec provides strong data security when data is transmitted on an IP network, it does not protect the data when it is stored by a computer on a disk drive. To help protect stored data, EFS must be used.

**Encrypting File System**
With Encrypting File System (EFS), you can store data securely. EFS does this by encrypting data in selected NTFS file system files and folders.

Because EFS is integrated with the file system, it is easy to manage, difficult to attack, and transparent to the user. This is particularly useful for securing data on computers that may be vulnerable to theft, such as mobile computers. However, EFS is useful in helping to protect sensitive data stored on any computer.

EFS is designed to store data securely on local computers. As such, it does not support the secure transmission of files over a network. Other technologies, such as Internet Protocol security (IPSec), can be used in conjunction with EFS to provide a larger solution.

**Syskey**
Syskey is used to manage a computer's startup key, which protects all of a system's master keys. Users have their own master key, which is a cryptographic key that is used to protect other keys used by applications and services. At system startup, a startup key is used to decrypt the user's master key, which is then used to encrypt all of the private keys on the computer, including private keys that are used for EFS. Startup keys are automatically generated and used for computers in a domain, but must be manually configured on stand-alone computers. Startup key security can be increased by storing the key on removable media or by requiring a system startup password. You can make those changes with Syskey.

Syskey is useful in protecting EFS keys that are stored on the local hard drive. Although it does not protect the EFS data itself, it protects the keys that can be used to access that data. By using Syskey in combination with EFS, you employ more than one layer of security between an attacker and your encrypted data.

**Data Security Deployment Scenarios**
There are several scenarios where data security technologies will help provide important safeguards for data. The following are two of the most common.

**Portable laptops during travel**
Laptops are, by their very nature, designed to be taken on trips. Modern laptops often contain large hard drives and powerful processors, enabling owners to work while they travel. These laptops can store any information the owner wants, including sensitive information such as trade secrets, undisclosed financial reports, personnel data, and so forth.

Unfortunately, laptops get stolen frequently. Without physical control of the computer, the user has no way to protect the data it contains. An attacker has numerous ways to extract the data from the laptop. If the data is unprotected, it's a very simple matter.

To protect against these types of attacks, you should use both EFS and Syskey. EFS encrypts sensitive files so that they are cryptographically protected. This provides very strong protection, but the EFS key that is used for decryption must also be protected. Syskey is used to provide that strong protection of the EFS private keys. In combination, these two technologies make it computationally infeasible for an attacker to decrypt your data.

**Insecure network infrastructure**
Most modern building tenants share hollow walls with their neighbors. This is often a security concern because network wiring frequently runs through these common walls. An attacker can easily connect their own computer to a network without being detected by simply making a hole on the other side of the wall and splicing into the network wiring.

The insecure network infrastructure may not always be a building's hollow walls. For example, remote users might use virtual private networks (VPNs) to communicate with the office. This VPN communication frequently uses the Internet to relay the data. Because the Internet is an insecure network itself, the data could easily be compromised during transmission.

This type of threat can be easily mitigated by using IPSec. You should use IPSec in this scenario to encrypt all network traffic that might contain sensitive data, such as file transfers and database interaction. Less sensitive network transmissions, such as identification broadcasts and Web surfing, might not require IPSec protection. IPSec can be configured to include or exclude any desired data to provide the appropriate amount of security.

# Encrypting File System Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Encrypting File System (EFS) is a Microsoft technology that makes it possible for users to encrypt files on their computers and control who can decrypt or recover these files. When data is encrypted, it cannot be read or modified by intruders, even if they gain physical access to the hard disk on a computer.

**In this subject**

- What is Encrypting File System?
- How Encrypting File System Works
- Encrypting File System Tools and Settings

# What is Encrypting File System?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is Encrypting File System?**

**In this section**

- Problems Solved by EFS
- EFS Scenarios
- EFS Interactions and Dependencies

Encrypting File System (EFS) provides the core file encryption technology for storing files on NTFS file system volumes. Security features such as logon authentication and file permissions protect network resources from unauthorized access. However, anyone with physical access to a computer such as a stolen laptop can bypass security in the operating system by installing a new operating system on that computer. In this way, sensitive data can be exposed. Encrypting sensitive files by means of EFS adds another layer of security. When files are encrypted, data in them is protected even if an attacker has full access to the data storage system on the computer.

**Problems Solved by EFS**

EFS addresses security concerns raised by tools available on other operating systems that allow users to access files stored on an NTFS volume without an access check. With EFS, data in NTFS files is encrypted on disk. The encryption technology used is public key–based and runs as an integrated system service, making it easy to manage, difficult to attack, and transparent to the user. If a user attempting to access an encrypted NTFS file has the private key associated with that file, the user is able to open the fileandwork with it transparently as a normal document. A user without the private key to the file is denied access.

Because EFS is tightly integrated with NTFS, file encryption and decryption are transparent. When users open a file, it is decrypted by EFS as data is read from disk. When users save the file, EFS encrypts the data as it is written to disk. Authorized users might not even realize that the files are encrypted because they can work with the files as they normally do.

**EFS Scenarios**

EFS allows users to store confidential information on a computer when people who have physical access to a computer might otherwise compromise that information, intentionally or unintentionally. EFS is especially useful for securing sensitive data on portable computers, such as those commonly used by consultants or sales people who frequently conduct business away from the offices of an organization. It can also be useful on computers shared by several users, such as in banks or medical facilities. Both kinds of systems are susceptible to attack by techniques that circumvent the restrictions of access control lists (ACLs). In a shared system, an attacker can gain access by starting a different operating system. An attacker can also steal a computer, remove a hard disk, place the hard disk in another system, and gain access to the files stored on the disk. Files encrypted by EFS, however, appear as unintelligible characters when the attacker does not have the decryption key.

In its default configuration, EFS enables users to start encrypting files with no administrative effort. From the point of view of the user, encrypting a file is simply a matter of setting a file attribute. The encryption attribute can also be set for a file folder. This means that any file created in or added to the folder is automatically encrypted.

Only authorized users and designated data recovery agents (DRAs) can decrypt encrypted files. Other system accounts that have permissions for a file — even the Take Ownership permission — cannot open the file without authorization. Even the local administrator account cannot open the file if that account is not designated as a DRA. If an unauthorized user tries to open an encrypted file, access is denied.

**What Can Be Encrypted**

Individual files and file folders (or sub-folders) on NTFS volumes can be encrypted. Although it is common to refer to file folders as having the encryption attribute set as "encrypted," the folder itself is not encrypted. When encryption is set for a folder, EFS automatically encrypts all new files created in the folder. All files copied or moved into the folder Offline Files can also be encrypted.

**Note**

- When offline files are encrypted, the entire offline files database is encrypted rather than individual files. Individual files do not display the encryption attribute. The database is encrypted using the startup key for the system.

System files and any files in the *systemroot* folder or its subfolders cannot be encrypted. No files or directories in a roaming user profile can be encrypted. A file cannot be both compressed and encrypted. Being compressed does not prevent encryption, but when the file is encrypted, it is uncompressed.

**Note**

- Encrypting the temp directory can cause some applications to not function properly, and therefore is not recommended.

**Recovering Data Protected with EFS**

EFS supports data recovery in the sense that it makes it possible for designated data recovery agents (DRAs) to decrypt files that user has encrypted. A DRA is established by default on Windows 2000 systems. The DRA is optional on Windows XP Professional and Windows Server 2003 in order to provide organizations with greater flexibility in implementing data recovery strategies. With Windows XP Professional and Windows Server 2003, one or more DRAs can be established for individual computers, for a domain, or for a combination of individual computers and the domain. However, in no case is the private key of any user revealed to a recovery agent.

**EFS Interactions and Dependencies**

EFS is available only on computers running Windows Server 2003, Windows XP Professional, Windows 2000 Server, and Windows 2000 Professional, and using the NTFS file system.

However, there are differences between how EFS is implemented on Windows Server 2003 and Windows XP Professional compared to Windows 2000. In particular, systems running Windows Server 2003 and Windows XP Professional do not require the existence of a DRA, whereas EFS is disabled on systems running Windows 2000 unless there is a DRA.

On computers running Windows 2000, an EDRP is automatically configured on stand-alone computers when the local administrator initially logs on. This policy makes the local Administrator account the DRA for the computer. Recovery keys and a self-signed file recovery certificate are automatically generated. The local Administrator can change the default EDRP if needed.

In Windows 2000 Active Directory environments, a default recovery policy is configured for a domain when the first domain controller is set up. The default recovery policy uses a self-signed certificate to make the domain administrator account the DRA. The domain Administrator can change the default EDRP if needed.

The following interactions and dependencies also affect how EFS can be used:

- You can use EFS to encrypt or decrypt data on a remote computer, but you cannot use it to encrypt data sent over the network unless Web Distributed Authoring and Versioning (WebDAV) encryption is configured. Otherwise, IPSec should be used to protect data across the network.

- You cannot encrypt system files or folders.

- You cannot encrypt compressed files and folders until you decompress them.

- If you encrypt an entire folder, temporary copies of encrypted files that it contains are also encrypted.

- If you copy a file into an encrypted folder encrypts the file, but if you move it into the folder the file remains encrypted or unencrypted, just as it was before you copied the file.

- If you move or copy EFS files to another file system, encryption is removed, but if you back them up, the encryption is preserved.

- When you encrypt a file, other file permissions are unaffected. An administrator, for instance, can still delete your EFS file even though the administrator cannot open it.

- You must have EFS certificates available to use EFS. If you do not currently have a public key infrastructure (PKI), you can use self-signed certificates. If you have a PKI, you can configure them to provide EFS certificates.

EFS in Windows Server 2003 and Windows XP Professional includes the following features that are not available on systems running Windows 2000:

- Additional users can be authorized to access encrypted files.
- Certificates can be checked for revocation status when encrypted files are shared. (revocation is checked only when a user is added to an encrypted file)
- Offline files can be encrypted.
- The Advanced Encryption Standard (AES) and DES (3DES) encryption algorithms are supported.
- Encrypted files can be stored in Web folders using WebDav.
- EFS can be used with Windows Server 2003 clusters.
- File recovery policy can be configured with greater flexibility.

# How Encrypting File System Works

Updated: November 11, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Encrypting File System Works**

**In this section**

- Encrypting File System Architecture
- Physical Structure of an Encrypted File
- Encrypting File System Processes and Interactions
- Related Information

Encrypting File System (EFS) provides file encryption for NTFS files stored on disk. EFS supplements other security features such as logon authentication or file permissions that protect network resources from unauthorized access. Encrypting sensitive files by using EFS adds a layer of security that protects data even if an attacker gains full access to the computer where the data is stored.

EFS functions equally well on standalone systems running Windows XP Professional and Windows Server 2003, and in Active Directory domain environments. On standalone systems, EFS is automatically enabled but can be disabled by editing local security policy. In Active Directory environments, EFS can be managed using the domain security policy.

In a domain controller, a default recovery policy is automatically put in place when the administrator logs on to the computer for the first time, making the enterprise administrator the data recovery agent for computers that are members of the domain. For standalone computers, a default data recovery agent is not created. As a security best practice, if you decide to use the default data recovery agent, you should export the private key and save it separately and then remove the private key from the domain controller. However, it is strongly recommended that you create at least one data recovery agent in case the original account or credentials used to encrypt data with EFS become unavailable. For example, you can create a key pair on a smart card, and then set that certificate as the data recovery agent instead of the default data recovery agent. This enables you to recover data by using the smart card without exposing the private key to other software.

This section is divided into three subsections:

- **Encrypting File System Architecture** describes and illustrates the relationships between the operating system components that make up EFS in both user mode and kernel mode.
- **Physical Structure of an Encrypted File** describes the fields that are added to a data file when it is encrypted and the role of each field.
- **Encrypting File System Processes and Interactions** describes the processes used by EFS to encrypt, decrypt, recover and share data.

**Encrypting File System Architecture**

In order to provide transparent encryption, EFS relies on several components that operate at the user mode and kernel mode levels of the operating system:

**EFS Components**

| User Mode Components | Kernel Mode Components |
|---|---|

| | |
|---|---|
| • Efsadu .dll<br>• Feclient.dll<br>• Local Security Authority (LSA)<br>• CryptoAPI<br>• Cryptographic service providers (CSPs) | • NTFS<br>• Ksecdd<br>• FIPS.sys |

The following diagram illustrates the relationships among these components.

**Relationship of EFS Components**

One additional kernel mode component, the WebDAV Redirector, is required to manage encrypted files on Web Distributed Authoring and Versioning (WebDAV) file shares.

For more information about the encryption and decryption processes, see "Encrypting File System Processes and Interactions." The following sections describe the components of EFS in detail.

**Efsadu**

The Efsadu dynamic link library (DLL) provides the EFS user interface. Efsadu is called when a user access the Advanced Properties page for a file or folder to modify file or folder encryption options. The options processed through Efsadu include whether to apply the encryption to file or folder only, or to a folder and all subfolders and files that it contains. EFSadu also contains the user interface for adding users to an encrypted file.

**Feclient**

When a user modifies EFS options for a file or folder, or when an application attempts to access an encrypted file on an NTFS volume, the Win32 application programming interface (API) passes the resulting EFS-related calls to the Feclient DLL. Feclient then calls the EFS remote procedure call (RPC) interfaces in the LSA.

This two-stage process for calling the EFS routines in LSA is required because EFS supports remote storage of encrypted files on servers running Windows Server 2003 or servers running Windows 2000. The role of Feclient is to determine which client computer or server has the requested file and to then contact the LSA on that computer or server.

**Note**

- Users can also modify EFS options from the command line by using Cipher.exe. For more information about Cipher.exe, see "Encrypting File System Tools and Settings."

**Local Security Authority**

The Local Security Authority (LSA) performs the majority of user mode EFS operations. The LSA responds to requests from the kernel to create a file encryption key (FEK) and encapsulate it with the proper user and recovery agent public keys. The FEK is returned to the kernel and used to encrypt a file. The LSA also performs the reverse operation of unwrapping a FEK and returning it to the kernel to decrypt a file.

During the encapsulation process, the recovery policy for the local computer is checked to determine whether the FEK should also be encapsulated by one or more recovery agent public keys. During decryption, the recovery policy is checked again to see if additional or new recovery certificates have been added; if so, the LSA reencapsulates the FEK using the new recovery agent public keys. The LSA also checks to determine whether the EFS certificate belonging to the current user has changed, which would also require the FEK to be reencapsulated.

To improve performance, the LSA maintains a cache of handles (or pointers) to private keys used for encapsulating and extracting FEKs. These handles point to private keys that remain in the cryptographic service provider (CSP) and are, therefore, protected from unauthorized access.

**CryptoAPI**
CryptoAPI consists of a set of functions that allow applications to encrypt or digitally sign data while providing protection for private key data. Applications can use the functions in CryptoAPI independently of the underlying implementation.

EFS uses CryptoAPI for user mode cryptographic operations; CryptoAPI also provides underlying security services for secure channels and code signing. CryptoAPI supports public key and symmetric-key operations such as key generation, key management and secure storage, key exchange, encryption, decryption, hashing, digital signatures, and verification of signatures. In addition, application developers can use CryptoAPIservices to add cryptography to their 32-bit Windows applications.

**Cryptographic Service Providers**
The public-private key pairs for EFS users and recovery agent accounts are obtained from the Microsoft Base cryptographic service provider (CSP), also called the RSA base provider, or the Microsoft Enhanced CSP. These CSPs are included with Windows Server 2003 and Windows XP Professional.

### Note

- Only Microsoft CSPs for RSA are supported for EFS. EFS does not support the Microsoft smart card CSP.

Depending on the CSP you select, you can select one of three encryption algorithms to encrypt and decrypt the contents of files:

- **Advanced Encryption Standard (AES) algorithm.** This is the default encryption standard for Windows Server 2003 and Windows XP Professional with Service Pack 1 installed. AES uses a 256-bit key for encryption and decryption.

- **DESX.** An enhanced variant of the Data Encryption Standard (DES).

- **Triple-DES (3DES).** 3DES, which is compliant with Federal Information Processing Standards (FIPS 140-1 Level 1), offers significantly stronger encryption using a 128-bit or 168-bit key. 3DES is enabled through a Group Policy setting. All EFS FIPS mode encryption processes are completed using 3DES.

The encryption algorithms available to EFS depend on which version of Windows is running on the computer:

- Windows XP with SP1 or later can encrypt or decrypt files using DESX, 3DES, or AES.

- Versions of Windows XP Professional earlier than SP1 can use the DESX or the Triple-DES (3DES) algorithm for EFS encryption and decryption.

- Windows 2000 Professional and Windows 2000 Server use the DESX algorithm for EFS encryption and decryption.

### Note

- When 3DES is enabled in FIPS mode, it is used as the encryption algorithm for IP Security as well as for EFS. When 3DES is enabled, all new encryption processes are completed by using 3DES, but DESX and 3DES are always available for decryption, regardless of the encryption policy.

If a user attempts to view files that have been encrypted using an encryption algorithm not supported by the operating system, the file appears to be corrupted or filled with random characters.

**NTFS**
The NTFS driver contains the majority of the EFS code in the kernel. This driver responds to file system controls (FSCTLs) from the LSA to encrypt or decrypt a file. When a file is opened, the driver passes the wrapped FEK to Ksecdd to be unwrapped by the LSA. The driver then decrypts the data when it is read from the file and encrypts the data when it is written to the file.

The EFS API in the NTFS driver also provides a set of functions for reading and writing encrypted files in raw mode. Raw mode allows direct reading and writing of the ciphertext (text that has been encrypted using an encryption key). This allows the Windows backup utilities to read and write the encrypted data for backup purposes, while preserving the confidentiality of the data.

To improve performance for files opened multiple times in quick succession, the NTFS driver maintains a cache of unwrapped FEKs that it receives from the LSA. By default, FEKs are cached for five seconds; the cache time is configurable from two to thirty seconds.

**Ksecdd**
Ksecdd is a very thin component that NTFS calls to communicate with the LSA. Ksecdd is used to set up local procedure call (LPC) communications to the LSA.

**FIPS.sys**
Microsoft Kernel Mode Cryptographic Module (FIPS.sys) is a FIPS 140-1 Level 1 compliant, general-purpose, software-based cryptographic module located at the kernel mode level of the Windows operating system. It runs as a kernel mode export driver (kernel-mode DLL) and includes several different cryptographic algorithms in an easy-to-use cryptographic module accessible by other kernel mode drivers. It can be linked into other kernel mode services to permit the use of FIPS 140-1 Level 1 compliant cryptography.

### Note

- Federal Information Processing Standard (FIPS) 140-1 is a security implementation designed for certifying cryptographic software. FIPS 140-1–validated software is required by the U.S. Government and requested by other prominent organizations.

In Windows 2000, Windows XP Professional, and Windows Server 2003, both IPSEC and EFS use FIPS.sys to encrypt traffic packet data and file contents, respectively, provided that you use FIPS-compliant algorithms.

**WebDAV Redirector**
The Web Distributed Authoring and Versioning (WebDAV) client redirector is responsible for managing encrypted files on WebDAV file shares. The redirector works by retrieving the file from the server and then caching it locally while edits are performed. When the file is closed, the redirector stores the file on the server. While the file is cached locally, the redirector calls the NTFS driver to read and write the file.

When the file is stored on the server, the client redirector performs a backup read on the locally cached file and takes the data and stores it on the server. When a file is retrieved from the server, the redirector performs a backup write to the cached file which takes the encrypted data and restores it to a normal, but encrypted, NTFS file.

**Physical Structure of an Encrypted File**
EFS uses a combination of public key and symmetric key encryption to ensure that files are protected from all but the most computationally infeasible methods of attack.

EFS follows the standard cryptographic procedure of key encipherment. Data is encrypted using a symmetric file encryption key (FEK) for speed; the FEK is then secured asymmetrically for maximum security. When a user requests that a file be encrypted, EFS uses a uniquely generated FEK to encrypt a file and then encrypts the FEK itself by using the public key from the public key certificate belonging to the user. The encrypted FEK is stored in a file header called EFS metadata. When a user requests decryption, EFS decrypts the FEK using the user's private key, and then uses the FEK to decrypt the file.

An encrypted file contains encrypted data and a header with fields to store copies of the encrypted FEK for authorized users and designated data recovery agents. The structure of an encrypted file is shown in the following figure.

### Encrypted File Structure

**Data Decryption Field**

An encrypted file contains a minimum of one stored FEK, the FEK encrypted by using the public key belonging to the initial encryptor. The storage field for this encrypted FEK is called the data decryption field(DDF). Additionally, if an EFS-encrypted file is shared, a copy of the FEK is encrypted by using the public key belonging to the newly authorized user, and the encrypted FEK is stored in another DDF. In this way, there is a separate data decryption file for every user of an encrypted file.

**Data Recovery Field**

If the effective security policy for a computer designates one or more data recovery agents, copies of the FEK are encrypted for each data recovery agent by using the public key of each data recovery agent, and the copies are stored in another file header field called the data recovery field (DRF).

**Key Storage**

When an encrypted file is saved, Windows XP Professional and Windows Server 2003 automatically provide four levels of encryption to protect the encryption keys that protect the file, and a fifth level, the startup key, can be configured. These levels operate as follows:

- **Level One:** EFS generates a unique FEK for every file that is encrypted.
- **Level Two:** EFS uses the public key in the EFS certificate of the user to encrypt the FEK. The certificate containing the public key is stored by default in the certificate store of the computer. The corresponding private key, used to decrypt the FEK, is stored in an encrypted form in the profile of the corresponding user or data recovery agent account in the RSA folder.
- **Level Three:** The Data Protection API generates the master key for the user that is used to encrypt the private keys belonging to the user.
- **Level Four:** The Data Protection API generates a symmetric password encryption key, derived from the credentials of the user, which encrypts the master key belonging to the user.
- **Level Five:** A startup key (also called the syskey) can be used to protect all master keys as well as a variety of other secrets that are stored on computers. At system startup, the startup key is used to encrypt all of the private keys on the computer, including private keys that are used for EFS. Startup keys are automatically generated and used for computers in a domain, but must be manually configured on stand-alone computers. Startup key security can be increased by storing the key on removable media or by requiring a system startup password.

Windows XP Professional and Windows Server 2003 provide several additional configuration options that increase security. To prevent loss of access to your master keys on stand-alone computers, you can create a password reset disk (PRD). You can also implement options to prevent your computer from entering hibernation mode and to delete paging files at system shutdown so that data is not needlessly exposed.

**Certificate and Public Key Storage**

Windows Server 2003 and Windows XP Professional store public key certificates for a user in the personal certificate store of that user. Certificates can be stored in plaintext because they are public information, and they are digitally signed by

certification authorities to protect against tampering.

User certificates are located in the Documents and Settings*username*\Application Data\Microsoft\SystemCertificates\My\Certificates folder for each user profile. These certificates are written to the personal store of the user in the system registry each time the user logs on to the computer. For roaming profiles, the certificates of users are located in a shared folder on a server configured by the domain administrator and follow users when they log on to different computers in the domain.

**Encrypting File System Processes and Interactions**
The following processes are associated with EFS:

- Encryption
- Decryption
- File recovery
- Multi-user sharing

**Encrypting a File with EFS**
When a user encrypts an existing file, the following process occurs:

1. EFS opens the file for exclusive access.
2. EFS creates a temporary file in the current directory and carries out the following series of operations:
    a. Each data stream in the source file is copied to the temporary file for backup purposes.
    b. Each data stream in the original file is next truncated to a length of zero, and its length is then set back to its original size. This essentially deletes all the data in the stream.
    c. EFS writes the encryption metadata to the original file. At this point EFS has the plaintext data in a temporary file and an empty source file that is marked encrypted (because of the presence of the EFS metadata).
3. A file encryption key (FEK) is randomly generated and used to encrypt the file with the AES, 3DES, or DESX algorithms, depending on the version of the operating system and the effective security policy.
4. A data decryption field (DDF) is created to contain the FEK encrypted by using the user's public key. In addition:
    - If a data recovery agent has been designated through Group Policy, a data recovery field (DRF) is created to contain the FEK encrypted by using RSA and the public key of the data recovery agent.
    - If there are multiple data recovery agents, a copy of the FEK is encrypted by using the public key of each data recovery agent, and a DRF is created to store each encrypted FEK.

    **Note**

    - The file recovery property in the certificate is an example of an enhanced key usage (EKU) field. An EKU extension and extended property specify and limit the valid uses of a certificate. File Recovery is one of the EKU fields defined by Microsoft as part of the Microsoft public key infrastructure (PKI).
5. EFS writes the encrypted data, along with the DDF and any DRFs, back to the file. Because symmetric encryption does not add data to a file, file sizes change very little after encryption. The encryption metadata, consisting primarily of encrypted FEKs, is quite small (depending on how many users are added to the file).

    **Note**

- The size of EFS metadata is limited to 256 KB.

6. The plaintext temporary file is deleted.

**Note**

- Data from deleted files might not be erased when the file is deleted. The **cipher /w** command can be used to remove data from available unused disk space on the entire volume.

When a user saves a file to a folder that has been configured for encryption, the encryption process is similar, except that no temporary file is created.

The following figure shows the EFS encryption process when a data recovery agent is being used.

**EFS Encryption with a Data Recovery Agent**

**Decrypting a File with EFS**

Conversion to plaintext follows a similar process as for encryption, in that a temporary file is created and the source file is written to it. The source file is then truncated and the data is read from the temporary file and written back to the source file in the clear. When an application accesses an encrypted file, decryption proceeds as follows:

1. NTFS recognizes that the file is encrypted, retrieves the DDF, and passes it to EFS.

2. EFS retrieves the private key belonging to the user from the profile of the user and uses it to decrypt the DDF and obtain the FEK.

3. EFS then uses the FEK to decrypt sections of the file as needed by the application.

**Note**

- Because EFS uses cipher block chaining, when an application opens a file, only those sections of the file that the application is using are decrypted. The behavior is different if the user removes the encryption attribute from the file. In this case, the entire file is decrypted and rewritten as plaintext.

4. EFS returns the decrypted data to NTFS, which then sends the data to the requesting application.

The following figure illustrates the decryption process:

**EFS Decryption**

**Recovering a File**

Data recovery is similar to the decryption process except:

- The DRF is used instead of the DDF.
- EFS decrypts the DRF with the private key of a data recovery agent to recover the FEK.

The recovery process is as follows:

1. NTFS recognizes the file as encrypted and sends a request to EFS.
2. EFS retrieves the DRF (instead of the DDF) and decrypts the DRF (instead of the DDF) with the private key of the data recovery agent (instead of the private key of the user) to obtain the FEK.
3. EFS uses the FEK to decrypt the file
4. NTFS then completes the file request and sends the data to the requesting application.

The following figure illustrates the file recovery process.

**EFS File Recovery**

**Authorizing Users to Access Encrypted Files**

Users can share encrypted files with other local, domain, and trusted domain users. Authorizing user access to encrypted files is a separate process from sharing files for network access by using share-level security and access control lists (ACLs).

Therefore, sharing access to encrypted files involves the configuration of both file system ACL permissions, and EFS permissions.

Because there is no method for issuing a certificate and assigning a key pair for a group, groups cannot be authorized for access: Only individual user accounts can be authorized for access to an encrypted file.

After a file has been encrypted, additional users can be authorized to access encrypted files by opening the Advanced Attributes dialog box from the Properties dialog box for the file.

EFS certificates can also be imported to the profile of a user. If the EFS certificate is self-signed, it is added to the Trusted People container. If the EFS certificate was issued by a certification authority CA, it is added to the Other People container. Certificates added to either container appear in the Select User dialog box.

**Note**

- If you import a certificate belonging to a user, you have the option to manually select its location. If you import a self-signed certificate, be sure to add it to Trusted People. Certificates in Trusted People are the only certificates that are not chain validated, because these certificates are already trusted. Self-signed certificates always fail chain validation because no CA was involved in certifying them, so placing them anywhere other than in Trusted People makes them unusable.

Before a user can be authorized to access an encrypted file and be added to the file, EFS needs to determine whether the certificate can be trusted. When a certificate for a user is selected, EFS attempts to validate the certificate chain. If the chain validation fails, CryptoAPI also checks to see if the certificate is in Trusted People store. If not, the certificate cannot be used.

Sharing an encrypted file can be illustrated with a simple example. Assume that Alice already has access to the encrypted file. She is either the original encryptor, or she has been authorized for access. Alice wants to authorize Bob to access the file. To accomplish this, EFS performs the following steps:

1. EFS obtains the private key belonging to Alice from her user profile to decrypt the FEK contained in the data decryption field of the file.

2. EFS obtains the public key belonging to Bob from his certificate and uses it to encrypt the FEK.

3. The encrypted FEK belonging to Bob is stored in a new data decryption field with the file.

**Note**

- At no time in this process is the file itself decrypted, so it is not directly at risk. However, the FEK is briefly decrypted. But because EFS performs this operation in nonpaged memory, the decrypted FEK is never paged and so is never exposed.

The following Figure shows what happens when Alice shares an encrypted file with Bob.

**EFS Access Authorization**

Users electing to share encrypted files should remember the following:

- Shared EFS files are not file shares. If authorized users need to access shared EFS files over the network, a file share or a Web folder is required. Alternatively, users can establish remote sessions with computers that store encrypted files by using Terminal Services.

- Any user who is authorized to decrypt a file can authorize other users to access the file. Granting access is not limited to the file owner. Caution users to share files only with trusted accounts, because those accounts can authorize other accounts. Removing the Write permission from a user or group of users can prevent this problem, but it also prevents the user or group from modifying the file.

- EFS sharing requires that the users who will be authorized to access the encrypted file have EFS certificates. These certificates can be located in roaming profiles or in the user profiles on the computer on which the file to be shared is stored , or they can be stored in and retrieved from Active Directory.

- EFS sharing of an encrypted file often means that the file will be accessed across the network. To enhance the security of file data, it is best if Web folders are used for encrypted file storage whenever possible.

- If a user chooses to remotely access an encrypted file stored on a file share and to authorize other users to access the file, the authorization process and requirements are the same as on the local computer. Additionally, EFS must impersonate the user in order to perform this operation, and all of the requirements for remote EFS operations on files stored on file shares apply.

- If a user chooses to remotely access an encrypted file stored on a Web folder and to authorize other users to access the file, the file is automatically transmitted to the local computer in ciphertext. The authorization process takes place on the local computer with the same requirements as for encrypted files stored locally.

**Validating Certificate Chains**

Imported self-signed certificates for EFS are automatically placed in Trusted People, and there is no certificate chain to validate, so the user can be added to the encrypted file.

**Note**

- Certificates are not verified for valid chains or revocation status during encryption or decryption.

However, if the certificate was signed by a CA, EFS attempts to build a certification chain and validate the certificate only when

adding a user to the file. If the chain ends with an untrusted root CA, EFS will not use the certificate, and the user is not added to the file.

For more information about how chain validation works, see the "Certificate Services Technical Reference."

# Encrypting File System Tools and Settings

Updated: September 10, 2008

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Encrypting File System Tools and Settings**

**In this section**

- Encrypting File System Tools
- Encrypting File System Registry Entries
- Encrypting File System Group Policy Settings
- Related Information

**Encrypting File System Tools**

The following tools are associated with Encrypting File System.

**Cipher.exe: Cipher**

**Category**

Cipher is an operating system command-line tool.

**Version compatibility**

This tool is compatible with Windows 2000, Windows XP, Windows Server 2003.

Allows a user or administrator to display or alter the encryption of files. In addition to encrypting or decrypting a file or folder, Cipher can be used to update the file encryption keys or the keys of the data recovery agent (DRA) should there be a change in the data recovery policy.

When used with the **/w** switch, Cipher can also remove data from portions of the volume it can access that have not been allocated to files or directories. Cipher does not lock the drive, so other programs can obtain space on the drive which cipher cannot erase. Because the /w option writes to a large portion of the volume, it might take a long time to complete and should only be used when necessary.

For more information about Cipher, see “Command-Line References” in the Tools and Settings Collection.

**Efsinfo.exe: Encrypting File System Information**

**Category**

Encrypting File System Information is a Windows Server 2003 command-line tool.

**Version compatibility**

This tool is compatible with Windows 2000, Windows XP, Windows Server 2003.

Encrypting File System Information displays information about files and folders encrypted with Encrypting File System (EFS) on partitions that use the NTFS file system. Options include displaying encryption information about the files and folders in the current folder, recovery agent information, and certificate thumbnail information.

For more information about EFSinfo, see “Command-Line References” in the Tools and Settings Collection.

**Xcopy.exe: Xcopy**

**Category**

Xcopy is a command line tool that ships with Windows Server 2003 and Windows XP Professional.

**Version compatibility**

This tool is compatible with Windows 2000, Windows XP Professional, Windows Server 2003.

Encrypted files are copied from Web folders in the same way that plaintext files are copied from file shares. The Xcopy command does not require any special parameters. The file is transmitted in ciphertext and remains encrypted on the local computer if possible. The encryption status for files copied from Web folders is the same as for files copied locally.

Encrypted files are copied from Web folders in the same way that plaintext files are copied from file shares. The Copy and Xcopy commands do not require any special parameters. The file is transmitted in ciphertext and remains encrypted on the

local computer if possible. The encryption status for files copied from Web folders is the same as that for files copied locally.

For more information about Xcopy, see "Command-Line References" in the Tools and Settings Collection.

**SecPol.msc: Local Security Settings Snap-in**
**Category**
Local Security Settings is a Microsoft Management Console (MMC) snap-in that ships with Windows Server 2003, Windows 2000 Server, and Windows XP Professional.

**Version compatibility**
This tool is compatible with Windows 2000, Windows XP Professional, Windows Server 2003.

Local Security Settings is compatible with Windows Server 2003 and Windows 2000 Server, and can be used to EFS data recovery agents on computers running Windows Server 2003, Windows XP Professional, and Windows 2000.

To find more information about the Local Security Settings snap-in, see "Security Policy Settings."

**Encrypting File System Registry Entries**
The following registry entries are associated with Encrypting File System.

- HKEY_CURRENT_USER\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys
- HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys
- HKEY_CURRENT_USER\Software\Microsoft\Cryptography\CertificateTemplateCache
- HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Explorer

The following information is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_CURRENT_USER\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys**
The following registry entries are created only when EFS is used for the first time.

**CertificateHash**
**Registry path**
HKEY_CURRENT_USER\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys\CertificateHash

**Version**
Windows Server 2003, Windows 2000, and Windows XP.

This registry entry contains the certificate hash used by the current user to encrypt and decrypt data.

**Flag**
**Registry path**
HKEY_CURRENT_USER\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys\Flag

**Version**
Windows Server 2003, Windows 2000, and Windows XP.

This registry entry identifies the encryption algorithm used to encrypt and decrypt new EFS files.

| **Note** |
| --- |
| For more information about the encryption algorithms that can be used with EFS, see "How Encrypting File System Works" in the Technical Reference. |

**KeyCacheValidationPeriod**
**Registry path**
HKEY_CURRENT_USER\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys\KeyCacheValidationPeriod

**Version**

Windows Server 2003, Windows 2000, and Windows XP.

This registry entry identifies the length of time in seconds a cached EFS certificate is assumed to be valid before revalidation is required.

**HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys**
The following registry entries control how EFS is used on the local machine.

**UserCacheSize**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys\UserCacheSize

**Version**
Windows Server 2003, Windows 2000, and Windows XP.

This registry entry identifies the number of user EFS certificates to cache.

**EFSDomainGPOCreated**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys\EFSDomainGPOCreated

**Version**
Windows Server 2003, Windows 2000, and Windows XP.

This registry entry records whether domain-based EFS Group Policy settings are in effect.

**EFSBlob**
**Registry path**
HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\EFS\CurrentKeys\EFSBlob

**Version**
Windows Server 2003, Windows 2000, and Windows XP.

This registry entry contains data about the file recovery certificates that have been registered for the system.

**HKEY_CURRENT_USER\Software\Microsoft\Cryptography\CertificateTemplateCache**
The template cache is used to cache copies of the domain's certificate templates which are distributed by Active Directory Domain Services. When your domain administrator configures certificate templates for your organization this registry key will contain sub-keys for each template in the domain.

**HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\EFS**
The following registry entries are added when domain Group Policy is used to enable or disable EFS.

**EFSConfiguration**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\EFS\EFSConfiguration

**Version**
Windows Server 2003, Windows 2000, and Windows XP

This registry setting makes it possible to disable and re-enable EFS on a local computer using Group Policy.

**LastGoodEFSConfiguration**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\EFS\LastGoodEFSConfiguration

**Version**
Windows Server 2003, Windows 2000, and Windows XP

This registry setting is added when EFS is disabled through domain Group Policy. This registry setting is deleted if EFS is re-enabled using domain Group Policy.

**HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Explorer**
**Registry path**
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Explorer

**Version**
Windows Server 2003, Windows 2000, and Windows XP

This registry setting can be used to display **Encrypt** and **Decrypt** options on the Windows Explorer shortcut menu when a user

right-clicks a file or folder.

**Encrypting File System Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with Encrypting File System.

**Group Policy Settings Associated with Encrypting File System**

| Group Policy Setting | Description |
|---|---|
| Computer Configuration\Windows Settings\Security Settings\Public Key Policies\Autoenrollment | Can be used to enroll certificates automatically, renew expired certificates, update pending certificates, and remove certificates that have been revoked. In addition, this setting can be used to block certificate auto-enrollment. |
| Computer Configuration\Windows Settings\Security Settings\Public Key Policies\Encrypting File System | Can be used to disable or enable encryption of files using EFS. The default setting is enabled. In addition, this setting can be used to register one or more data recovery agents for use with EFS or to remove data recovery agents if they are no longer desired. |
| Computer Configuration\Windows Settings\Security Settings\Public Key Policies\Automatic Certificate Request Settings | Can be used to configure automatic certificate request settings for a specific certificate template for a domain by using the Automatic Certificate Request Setup Wizard. The request will be processed automatically at the first occurrence of any of the following: a user logs on, Group Policy is refreshed, or a computer joins the domain and is subject to a Group Policy setting. |

To find more information about these Group Policy settings, see "Group Policy Settings Reference" in the Tools and Settings Collection.

# IPSec Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Internet Protocol security (IPSec) in the Microsoft Windows Server 2003 operating system helps protect networks from active and passive attacks by securing IP packets through the use of packet filtering, cryptographic security services, and the enforcement of trusted communications. IPSec is integrated within the security framework of Windows Server 2003, which allows you to use Active Directory domains to provide identity and manage trust relationships between users and computers in different departments within an organization.

This subject provides a high-level description of IPSec that includes the scenarios for which it is intended and not intended.

**In This Subject**

# What Is IPSec?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Is IPSec?**

**In This Subject**

- IPSec Scenarios
- IPSec Dependencies
- IPSec and ICF
- Related Information

Internet Protocol security (IPSec) is a framework of open standards for helping to ensure private, secure communications over Internet Protocol (IP) networks through the use of cryptographic security services. IPSec supports network-level data integrity, data confidentiality, data origin authentication, and replay protection. Because IPSec is integrated at the Internet layer (layer 3), it provides security for almost all protocols in the TCP/IP suite, and because IPSec is applied transparently to applications, there is no need to configure separate security for each application that uses TCP/IP.

IPSec helps provide defense-in-depth against:

- Network-based attacks from untrusted computers, attacks that can result in the denial-of-service of applications, services, or the network
- Data corruption
- Data theft
- User-credential theft
- Administrative control of servers, other computers, and the network.

You can use IPSec to defend against network-based attacks through a combination of host-based IPSec packet filtering and the enforcement of trusted communications.

IPSec is integrated with the Windows Server 2003 operating system and it can use the Active Directory directory service as a trust model. You can use Group Policy to configure Active Directory domains, sites, and organizational units (OUs), and then assign IPSec policies as required to Group Policy objects (GPOs). In this way, IPSec policies can be implemented to meet the security requirements of many different types of organizations.

This section describes the solution that IPSec is intended to provide by providing information about core IPSec scenarios, IPSec dependencies, and related technologies.

The following figure shows an Active Directory-based IPSec policy being distributed to two IPSec peers and IPSec-protected communications being established between those two peers.

**Two IPSec Peers Using Active Directory-based IPSec Policy**

The MicrosoftWindows implementation of IPSec is based on standards developed by the Internet Engineering Task Force (IETF) IPSec working group. For a list of relevant IPSec RFCs, see the "Related Information" section later in this subject.

**IPSec Scenarios**

IPSec is a general-purpose security technology that can be used to help secure network traffic in many scenarios. However, you must balance the need for security with the complexity of configuring IPSec policies. Additionally, due to a lack of suitable standards, IPSec is not appropriate for some types of connectivity. This section describes IPSec scenarios that are recommended, IPSec scenarios that are not recommended, and IPSec scenarios that require special consideration.

**Recommended Scenarios for IPSec**

IPSec is recommended for the following scenarios:

- Packet filtering
- End-to-end security between specific hosts
- End-to-end traffic through a Microsoft Internet Security and Acceleration (ISA) Server-secured network address translator
- Secure server
- Layer Two Tunneling Protocol (L2TP) over IPSec (L2TP/IPSec) for remote access and site-to-site virtual private network (VPN) connections
- Site-to-site IPSec tunneling with non-Microsoft IPSec gateways

**Packet Filtering**

IPSec can perform host-based packet filtering to provide limited firewall capabilities for end systems. You can configure IPSec to permit or block specific types of unicast IP traffic based on source and destination address combinations and specific protocols and specific ports. For example, nearly all the systems illustrated in the following figure can benefit from packet filtering to restrict communication to only specific addresses and ports. You can strengthen security by using IPSec packet filtering to control exactly the type of communication that is allowed between systems.

**Filtering Packets by Using IPSec**

As illustrated in this figure:

- The internal network domain administrator can assign an Active Directory-based IPSec policy (a collection of security settings that determines IPSec behavior) to block all traffic from the perimeter network (also known as a demilitarized zone [DMZ], demilitarized zone, or screened subnet).
- The perimeter network domain administrator can assign an Active Directory-based IPSec policy to block all traffic to the

internal network.

- The administrator of the computer running Microsoft SQL Server on the internal network can create an exception in the Active Directory-based IPSec policy to permit structured query language (SQL) protocol traffic to the Web application server on the perimeter network.

- The administrator of the Web application server on the perimeter network can create an exception in the Active Directory-based policy to permit SQL traffic to the computer running SQL Server on the internal network.

- The administrator of the Web application server on the perimeter network can also block all traffic from the Internet, except requests to TCP port 80 for the HyperText Transfer Protocol (HTTP) and TCP port 443 for HTTPS (HTTP over Secure Sockets Layer/Transport Layer Protocol [SSL/TLS]), which are used by Web services. This provides additional security for traffic allowed from the Internet in case the firewall was misconfigured or compromised by an attacker.

- The domain administrator can block all traffic to the management computer, but allow traffic to the perimeter network.

You can also use IPSec with the IP packet-filtering capability or NAT/Basic Firewall component of the Routing and Remote Access service to permit or block inbound or outbound traffic, or you can use IPSec with the Internet Connection Firewall (ICF) component of Network Connections, which provides stateful packet filtering. However, to ensure proper Internet Key Exchange (IKE) management of IPSec security associations (SAs), you must configure ICF to permit UDP port 500 and port 4500 traffic needed for IKE messages.

**End-to-End Security Between Specific Hosts**

IPSec establishes trust and security from a unicast source IP address to a unicast destination IP address (end-to-end). For example, IPSec can help secure traffic between Web servers and database servers or domain controllers in different sites. As shown in the following figure, only the sending and receiving computers need to be aware of IPSec. Each computer handles security at its respective end and assumes that the medium over which the communication takes place is not secure. The two computers can be located near each other, as on a single network segment, or across the Internet. Computers or network elements that route data from source to destination are not required to support IPSec.

**Securing Communications Between a Client and a Server by Using IPSec**

The following figure shows domain controllers in two forests that are deployed on opposite sides of a firewall. In addition to using IPSec to help secure all traffic between domain controllers in separate forests, as shown in the figure, you can use IPSec to help secure all traffic between two domain controllers in the same domain and between domain controllers in parent and child domains.

**Securing Communications Between Two Domain Controllers in Different Forests by Using IPSec**

**End-to-End Traffic Through an ISA-Secured Network Address Translator**

Windows Server 2003 supports IPSec NAT Traversal (NAT-T). IPSec NAT-T allows traffic to be secured by IPSec and also to be translated by a network address translator. For example, you can use IPSec transport mode to help secure host-to-host traffic through a computer that is running ISA Server and that is functioning as a network address translator if ISA (or any other NAT device) does not need to inspect the traffic between the two hosts. IPSec transport mode is used to protect traffic between hosts and it can provide security between computers that are on the same local area network (LAN) or connected by private wide area network (WAN) links. In the following figure, a computer running Windows Server 2003 and Microsoft Internet Security and Acceleration (ISA) Server is functioning as a network address translator. The IPSec policy on Server A is configured to secure traffic to the IP address of Server B, while the IPSec policy on Server B is configured to secure traffic to the external IP address of the computer running ISA Server.

**Securing Communications Through an ISA-Secured NAT by Using IPSec NAT-T**

**Secure Server**

You can require IPSec protection for all client computers that access a server. In addition, you can set restrictions on which computers are allowed to connect to a server running Windows Server 2003. The following figure shows IPSec in transport mode securing a line of business (LOB) application server.

**Securing an Application Server by Using IPSec**

In this scenario, an application server in an internal corporate network must communicate with clients running Windows 2000 or Windows XP Professional; a Windows Internet Name Service (WINS) server, Domain Name System (DNS) server, and Dynamic Host Configuration Protocol (DHCP) server; Active Directory domain controllers; and a non-Microsoft data backup

server. The users on the client computers are company employees who access the application server to view their personal payroll information and performance review scores. Because the traffic between the clients and the application server involves highly sensitive data, and because the server should only communicate with other domain members, the network administrator uses an IPSec policy that requires ESP encryption and communication only with trusted computers in the Active Directory domain.

Other traffic is permitted as follows:

- Traffic between the WINS server, DNS server, DHCP server, and the application server is permitted because WINS servers, DNS servers, and DHCP servers must typically communicate with computers that run on a wide range of operating systems, some of which might not support IPSec.

- Traffic between Active Directory domain controllers and the application server is permitted, because using IPSec to secure communication between domain members and their domain controllers is not a recommended usage.

- Traffic between the non-Microsoft data backup server and the application server is permitted because the non-Microsoft backup server does not support IPSec.

**L2TP/IPSec for Remote Access and Site-to-Site VPN Connections**

You can use L2TP/IPSec for all VPN scenarios. This does not require the configuration and deployment of IPSec policies. Two common scenarios for L2TP/IPSec are securing communications between remote access clients and the corporate network across the Internet and securing communications between branch offices.

### Note

- Windows IPSec supports both IPSec transport mode and tunnel mode. Although VPN connections are commonly referred to as "tunnels," IPSec transport mode is used for L2TP/IPSec VPN connections. IPSec tunnel mode is most commonly used to help protect site-to-site traffic between networks, such as site-to-site networking through the Internet.

**L2TP/IPSec for remote access connections**

A common requirement for organizations is to secure communications between remote access clients and the corporate network across the Internet. Such a client might be a sales consultant who spends most of the time traveling, or an employee working from a home office. In the following figure, the remote gateway is a server that provides edge security for the corporate intranet. The remote client represents a roaming user who requires regular access to network resources and information. An ISP is used as an example to demonstrate the path of communication when the client uses an ISP to access the Internet. L2TP/IPSec provides a simple, efficient way to build a VPN tunnel and help protect the data across the Internet.

**Securing Remote Access Clients by Using L2TP/IPSec**

**L2TP/IPSec for site-to-site VPN connections**

A large corporation often has multiple sites that require communication — for example, a corporate office in New York and a sales office in Washington. In this case, L2TP/IPSec provides the VPN connection and helps protect the data between the sites. In the following figure, the router running Windows Server 2003 provides edge security. The routers might have a leased line, dial-up, or other type of Internet connection. The L2TP/IPSec VPN tunnel runs between the routers only and provides protected communication across the Internet.

**Establishing an L2TP/IPSec VPN Tunnel Between Sites**

**Site-to-Site IPSec Tunneling with Non-Microsoft Gateways**

For interoperability with gateways or end systems that do not support L2TP/IPSec or Point-to-Point Tunneling Protocol (PPTP) VPN site-to-site connections, you can use IPSec in tunnel mode. When IPSec tunnel mode is used, the sending gateway encapsulates the entire IP datagram by creating a new IP packet that is then protected by one of the IPSec protocols. The following figure illustrates site-to-site IPSec tunneling.

**Establishing an IPSec Gateway-to-Gateway Tunnel Between Sites**

In this figure, traffic is being sent between a client computer in a vendor site (Site A) and a File Transfer Protocol (FTP) server at the corporate headquarters site (Site B). Although an FTP server is used for this scenario, the traffic can be any unicast IP traffic. The vendor uses a non-Microsoft IPSec-enabled gateway, while corporate headquarters uses a gateway running Windows Server 2003. An IPSec tunnel is used to secure traffic between the non-Microsoft gateway and the gateway running Windows Server 2003.

**Scenarios for Which IPSec Is Not Recommended**

IPSec policies can be quite complex to configure and manage. Additionally, IPSec can incur performance overhead to establish and maintain secure connections, and it can incur network latency. In some deployment scenarios, the lack of standard methods for user authentication and address assignment make IPSec an unsuitable choice. Because IPSec depends on IP addresses for establishing secure connections, you cannot specify dynamic IP addresses. It is often necessary for a server to have a static IP address in IPSec policy filters. In large network deployments and in some mobile user cases, using dynamic IP addresses at both ends of the connection can increase the complexity of IPSec policy design. For these reasons, IPSec is not recommended for the following scenarios:

- Securing communication between domain members and their domain controllers
- Securing all traffic in a network
- Securing traffic for remote access VPN connections using IPSec tunnel mode

**Securing Communication Between Domain Members and their Domain Controllers**

Using IPSec to help secure traffic between domain members (either clients or servers) and their domain controllers is not recommended because:

- If domain members were to use IPSec-secured communication with domain controllers, increased latency might occur, causing authentication and the process of locating a domain controller to fail.
- Complex IPSec policy configuration and management is required.
- Increased load is placed on the domain controller CPU to maintain SAs with all domain members. Depending on the number of domain members in the domain controller's domain, such a load might overburden the domain controller.

**Securing All Traffic in a Network**

In addition to reduced network performance, using IPSec to help secure all traffic in a network is not recommended because:

- IPSec cannot secure multicast and broadcast traffic.
- Traffic from real-time communications, applications that require Internet Control Message Protocol (ICMP), and peer-to-peer applications might be incompatible with IPSec.
- Network management functions that must inspect the TCP, UDP, and other protocol headers are less effective, or cannot function at all, due to IPSec encapsulation or encryption of IP payloads.

**Securing Traffic for Remote Access VPN Connections by Using IPSec Tunnel Mode**

IPSec tunnel mode is not a recommended technology for remote access VPN connections, because there are no standard methods for user authentication, IP address assignment, and name server address assignment. Using IPSec tunnel mode for gateway-to-gateway VPN connections is possible using computers running Windows Server 2003. But because the IPSec tunnel is not represented as a logical interface over which packets can be forwarded and received, routes cannot be assigned to use the IPSec tunnel and routing protocols do not operate over IPSec tunnels. Therefore, the use of IPSec tunnel mode is only recommended as a VPN solution for site-to-site VPN connections in which one end of the tunnel is a non-Microsoft VPN server or security gateway that does not support L2TP/IPSec. Instead, use L2TP/IPSec or PPTP for remote access VPN connections.

**IPSec Uses That Require Special Considerations**
The following scenarios merit special consideration, because they introduce an additional level of complexity for IPSec policy configuration and management:

- Securing traffic over IEEE 802.11wireless networks
- Securing traffic in home networking scenarios
- Securing traffic in environments that use dynamic IP addresses

**Securing Traffic Sent over 802.11 Networks**
You can use IPSec transport mode to protect traffic sent over 802.11 wireless networks. However, IPSec is not the recommended solution for providing security for corporate 802.11 wireless LAN networks. Instead, it is recommended that you use either 802.11 Wired Equivalent Privacy (WEP) encryption or Wi-Fi Protected Access (WPA) and IEEE 802.1X authentication.

To use IPSec to help secure traffic sent over 802.11 networks, you must ensure that client computers and servers support IPSec. Configuration management and trust are also required on client computers and servers when IPSec is used. Because many computers on a network do not support IPSec or are not managed, it is not appropriate to use IPSec alone to protect all 802.11 corporate wireless LAN traffic.

**Securing Traffic in Home Networking Scenarios**
Although IPSec is not optimized for use in general home networking scenarios, when network security administrators deploy IPSec with appropriate scripts and support tools, it can be used effectively on home computers for specific scenarios.

IPSec can be used to connect home computers to a corporate intranet for remote access. Network security administrators can use scripts and support tools to deploy IPSec on the home computers of employees who require secure connectivity to the corporate network. For example, an administrator can use a Connection Manager profile to deploy an L2TP/IPSec-based VPN connection on home computers. Employees can then establish IPSec-secured connections across the Internet to the corporate network by using the VPN client built-in to Network Connections.

### Note

- In some cases, non-Microsoft VPN or firewall clients might disable the IPSec service, which is required for IPSec to function. If you encounter this problem, it is recommended that you contact the VPN or firewall vendor.

IPSec is not recommended for end users in general home networking scenarios for the following reasons:

- The IPSec policy configuration user interface (IP Security Policy Management) is intended for professional network security administrators, rather than for end users. Improper policy configuration can result in blocked communications, and if problems occur, built-in support tools are not yet available to aid end users in troubleshooting.
- Some home networking applications use broadcast and multicast traffic, for which IPSec cannot negotiate security.
- Many home networking scenarios use a wide range of dynamic IP addresses.
- Many home networking scenarios involve the use of a network address translator. To use IPSec across a NAT, both IPSec peers must support IPSec NAT-T.

**Securing Traffic in Environments That Use Dynamic IP Addresses**
IPSec depends on IP addresses for establishing secure connections, and it is often necessary for a server to have a static IP address in IPSec policy filters. In large network deployments and in some mobile user cases, using dynamic IP addresses at

both ends of the connection can increase the complexity of IPSec policy design.

**IPSec Dependencies**
There is no single optimal environment for IPSec. However, there are dependencies that are critical to the successful deployment of IPSec. This section describes how the following two IPSec dependencies affect the deployment of IPSec:

- Active Directory (if your deployment requires the use of Active Directory-based IPSec policies, rather than local IPSec policies)
- Successful mutual authentication

**Active Directory**
For organizations with large numbers of computers that must be managed in a consistent way, it is best to distribute IPSec policies by using Group Policy to configure Active Directory domains, sites, and organizational units (OUs), and then assigning IPSec policies as required to Group Policy objects (GPOs). Although you can assign local IPSec policies to computers that are not members of a trusted domain, distributing IPSec policies and managing IPSec policy configuration and trust relationships is much more time-consuming for computers that are not members of a trusted domain.

If you do use Active Directory-based IPSec policies, IPSec policy design and management must take into account the delays that result from the replication of Group Policy data from domain controllers to domain members. Often, the first step in troubleshooting a problem with IPSec connectivity is to determine whether the computer in question has the most current Group Policy assignment. To do this, you must be a member of the local Administrators group on the computer for which troubleshooting is being performed.

**Successful Mutual Authentication**
For IPSec-secured communications to be established, there must be successful mutual authentication between IPSec peers. IPSec requires the use of one of the following authentication methods: Kerberos version 5, an X.509 version 3 computer certificate issued by a public key infrastructure (PKI), or a preshared key. The two IPSec peers must use at least one common authentication method or communication will fail. Make sure that you choose an authentication method that is appropriate for your environment.

When you deploy IPSec to negotiate security for upper-layer protocols such as TCP connections, failures to communicate are often caused by the failure of IPSec to mutually authenticate the two communication endpoints. Authentication might succeed for some computers and fail for others due to issues within the authentication system itself (typically, Kerberos or public key certificates, rather than preshared keys, because preshared keys are not recommended). For these reasons, it is important to evaluate how the dependency of IPSec connectivity on authentication affects your environment and support practices. Additional training is recommended so that administrators can quickly determine whether a connectivity problem is caused by an IPSec authentication failure and understand how to investigate the authentication system.

**IPSec and ICF**
IPSec is similar to the ICF feature of Network Connections. However, there are important differences between these two technologies as well. It is important to understand the similarities and differences, so that you can deploy IPSec where it is truly needed and obtain the maximum benefits from the security that IPSec provides. This section describes similarities and differences between IPSec and ICF.

Microsoft ICF is a locally managed, stateful host firewall that, by default, discards all incoming packets except those sent in response to packets sent by the host. One primary difference between IPSec and ICF is that IPSec provides complex static filtering based on IP addresses, while ICF provides stateful filtering for all addresses on a network interface. For example, when you use IPSec, you can configure a filter to block all inbound traffic that is sent to a specific IP address over a specific protocol and port (for example, "Block all inbound traffic from the Internet to TCP port 135"). You can also configure exemptions to permit specific types of traffic from specific source IP addresses. When you use ICF, you can configure exemptions to permit traffic based solely on the port, regardless of the source IP address.

It is recommended that you use ICF when you want a firewall for a network interface that can be accessed through the Internet. It is recommended that you use IPSec when you want to secure traffic over upper-layer protocols or when you need to allow access only to a group of trusted computers. Note that it is easier to configure ICF to permit traffic over a certain port than it is to configure an IPSec policy.

IPSec is not a full-featured host firewall. However, it does provide the ability to centrally manage policies that can permit, block, or secure unicast IP traffic based on specific addresses, protocols, and ports. Some of the functions found in standard firewalls that IPSec does not provide include stateful inspection, application protocol awareness, intrusion detection, and packet logging. Although IPSec lacks some features of firewalls, the packet blocking and filtering it provides can be effective in helping to limit the spread of viruses and thwart specific attacks known to use specific ports. You can also use IPSec to prevent specific

applications and services from being used on the network.

# How IPSec Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How IPSec Works**

**In this section**

- IPSec Architecture
- IPSec Protocols
- IPSec Processes and Interactions
- Network Ports and Protocols Used by IPSec
- Related Information

In the Microsoft Windows Server 2003 operating system, Internet Protocol security (IPSec) helps provide defense-in-depth against network-based attacks from untrusted computers. IPSec provides protection from attack in host-to-host, virtual private network (VPN), site-to-site (also known as gateway-to-gateway or router-to-router), and secure server environments. You can configure IPSec policies to meet the security requirements of a computer, an organizational unit, a domain, a site, or a global organization.

IPSec uses packet filtering and cryptography. Cryptography provides user authentication, ensures data confidentiality and integrity, and enforces trusted communication. The strong cryptographic-based authentication and encryption support that IPSec provides is especially effective for securing traffic that must traverse untrusted network paths, such as those on a large corporate intranet or the Internet. IPSec also is especially effective for securing traffic that uses protocols and applications that do not provide sufficient security for communications.

To successfully deploy IPSec for Windows Server 2003, you must ensure the following:

- If your scenario requires Active Directory-based IPSec policy (a collection of IPSec rules that determine IPSec behavior), the Active Directory directory service and Group Policy must be configured correctly on the corporate network, appropriate trusts must be defined, and appropriate permissions must be applied. Although Group Policy applies to both users and computers, IPSec policy is a computer configuration Group Policy setting that applies only to computers.
- Each computer that will establish IPSec-secured communications must have an IPSec policy assigned. This policy must be compatible with the IPSec policy that is assigned to other computers with which that computer must communicate.
- Authentication must be configured correctly and an appropriate authentication method must be specified in the IPSec policy so that mutual authentication can occur between IPSec peers.
- Routers, firewalls, or other filtering devices must be configured correctly to permit IPSec protocol traffic on all parts of the corporate network, if IPSec negotiation messages and IPSec-secured traffic must pass through these devices.
- Computers must run operating systems that automatically support IPSec or must have appropriate client software installed.
- If computers are running different versions of the Microsoft Windows operating system (for example, Windows Server 2003, the Microsoft Windows XP operating system, and the Microsoft Windows 2000 operating system), you must address the compatibility of the IPSec policies.
- If clients must establish IPSec-secured connections with servers, those servers must be adequately sized to support those connections. If necessary, you can use IPSec hardware offload network adapters.
- The number of IPSec policies are kept to a minimum, and the IPSec policies are made as simple as possible.

- Systems administrators who will configure and support IPSec must be properly trained and must be members of the appropriate administrative groups.

**IPSec Architecture**
Several Requests for Comments (RFCs) define the architecture and components of IPSec. These components and their interrelationship comprise the logical architecture of IPSec. This section briefly describes the fundamental components of the IPSec logical architecture and then explains how these components are implemented in Windows Server 2003.

For comprehensive descriptions of IPSec architecture and components, see the RFCs that are listed in "Related Information" later in this section.

**Logical Architecture**
The IPSec architecture can be categorized into four main areas:

- Security Associations
- SA and key management support
- IPSec protocols
- Algorithms and methods

**Security Associations**
Security Associations (SAs) are a combination of a mutually agreeable policy and keys that defines the security services, mechanisms, and keys used to protect communications between IPSec peers. Each SA is a one-way or simplex connection that provides security services to the traffic that it carries.

Because SAs are defined only for one-way communication, each IPSec session requires two SAs. For example, if both IPSec protocols, Authentication Header (AH) and Encapsulating (ESP), are used for an IPSec session between two peers, then four SAs would be required.

SAs for IPSec-secured communications require two databases: a security policy database (SPD) and security association database (SAD). The SPD stores the security requirements or policy requisites for an SA to be established. It is used during both inbound and outbound packet processing. IPSec checks inbound packets to ensure that they have been secured according to policy. Outbound packets are secured according to policy.

The SAD contains the parameters of each active SA. The Internet Key Exchange (IKE) protocol automatically populates the SAD. After an SA is established, the information for each SA is stored in the SAD. The following figure shows the relationship between SAs, the SPD, and the SAD.

**SA, SPD, and SAD Architecture**

**SA and Key Management**
IPSec requires SA and key management support. The Internet Security Association and Key Management Protocol (ISAKMP) defines the framework for authentication and key exchange by providing procedures for negotiating, establishing, changing, and deleting SAs. It does not define the actual key exchange: it merely provides the framework.

IPSec requires support for both manual and automatic management of SAs and keys. IKE is the default automated key management protocol for IPSec. IKE is a hybrid protocol that incorporates parts of the Oakley key exchange protocol and the SKEME keying techniques protocol. The following figure shows the relationship between the ISAKMP, IKE, Oakley, and SKEME protocols.

**ISAKMP, IKE, Oakley, and SKEME Protocol Architecture**

The Oakley protocol uses the Diffie-Hellman key exchange or key agreement algorithm to create a unique, shared, secret key, which is then used to generate keying material for authentication or encryption. For example, such a shared secret key could be used by the DES encryption algorithm for the required keying material. A Diffie-Hellman exchange can use one of a number of groups that define the length of the base prime numbers (key size) which are created for use during the key exchange process. The longer the number, the greater the key strength. Well-known groups include Groups 1, 2, and 14.

The following figure shows the relationship between the Oakley protocol, the Diffie-Hellman algorithm, and well-known Diffie-Hellman key exchange groups.

**Oakley Protocol, Diffie-Hellman Key Exchange Algorithm, and Well-Known Diffie-Hellman Groups Architecture**

The Oakley protocol defines several modes for the key exchange process. These modes correspond to the two negotiation phases defined in the ISAKMP protocol. For phase 1, the Oakley protocol defines two principle modes: main and aggressive. IPSec for Windows does not implement aggressive mode. For phase 2, the Oakley protocol defines a single mode, quick mode.

**IPSec Protocols**

To provide security for the IP layer, IPSec defines two protocols: Authentication Header (AH) and Encapsulating Security Payload (ESP). These protocols provide security services for the SA. Each SA is identified by the Security Parameters Index (SPI), IP destination address, and security protocol (AH or ESP) identifier.

The SPI is a unique, identifying value in an SA that is used to distinguish among multiple SAs on the receiving computer. For example, IPSec communication between two computers requires two SAs on each computer. One SA services inbound traffic and the other services outbound traffic. Because the addresses of the IPSec peers for the two SAs are the same, the SPI is used to distinguish between the inbound and outbound SA. Because the encryption keys differ for each SA, each SA must be uniquely identified.

The following figure shows the relationship between the SA, SPI, IP destination address, and security protocol.

**IPSec Protocols and SA Architecture**

**Algorithms and Methods**

The IPSec protocols use authentication, encryption, and key exchange algorithms. Two authentication or keyed hash algorithms, HMAC-MD5 (Hash Message Authentication Code - MD5) and HMAC-SHA-1, are used with both the AH and ESP protocols, The DES and 3DES encryption algorithms are used with ESP. The following figure shows the relationship between the authentication and encryption algorithms and the AH and ESP protocols.

**IPSec Protocols and Algorithms for Authentication and Encryption**

The authentication methods for IPSec, as defined by the IKE protocol, are grouped into three categories: digital signature, public-key, and pre-shared key. The following figure shows the relationship between the IKE protocol and the authentication methods.

**IKE Protocol and Authentication Methods Architecture**

**Windows Server 2003 IPSec Architecture and Components**

The components and architecture of Windows Server 2003 IPSec are based on the IPSec RFCs. The basic IPSec architecture for Windows Server 2003 has the following components: Active Directory, a Policy Agent, the IKE protocol, an IPSec driver, and a TCP/IP driver.

The following figure illustrates how these components interact.

**Windows Server 2003 IPSec Architecture**

The following table describes each of these components.

**IPSec Components**

| Component | Description |
|---|---|
| Active Directory | Windows Server 2003 Active Directory stores domain-wide IPSec policies for computers that are members of the domain. Active Directory-based IPSec policies are polled and retrieved by the Policy Agent. |
| Policy Agent | The Policy Agent retrieves IPSec policy from an Active Directory domain, a configured set of local policies, or a local cache. The Policy Agent then distributes authentication and security settings to the IKE component and the IP filters to the IPSec driver. |
| IKE | IKE receives authentication and security settings from the Policy Agent and waits for requests to negotiate IPSec SAs. When requested by the IPSec driver, IKE negotiates both kinds of SAs (main mode and quick mode) with the appropriate endpoint requested by the IPSec driver based on the policy settings obtained from the Policy Agent. After negotiating an IPSec SA, IKE sends the SA settings to the IPSec driver. |

| | |
|---|---|
| IPSec driver | The IPSec driver monitors and secures outbound unicast IP traffic and monitors, decrypts, and validates inbound unicast IP traffic. After the IPSec driver receives the filters from the Policy Agent, it determines which packets are permitted, which are blocked, or which are secured. For secure traffic, the IPSec driver either uses active SA settings to secure the traffic or requests that new SAs be created. The IPSec driver is bound to the TCP/IP driver to provide IPSec processing for IP packets that pass through the TCP/IP driver. |
| TCP/IP driver | The TCP/IP driver is the Windows Server 2003 implementation of the TCP/IP protocol. It is a kernel-mode component that is loaded from the tcpip.sys file during startup. |

The architecture of the Policy Agent, IKE protocol, and IPSec driver are described in more detail in the following sections.

**Policy Agent Architecture**

The Policy Agent retrieves IPSec policy information, handles the internal interpretation and processing of the policy, and sends it to the other IPSec components that require the information to perform security services. The Policy Agent has the following components: policy store, Policy Agent service, local registry, local cache, and Interface Manager.

The following figure shows the architecture of the Policy Agent.

**Policy Agent Architecture**

The following table briefly describes the Policy Agent components.

**Policy Agent Components**

| Component | Description |
|---|---|
| Policy store | The IPSec policy store maintains both IPSec policy descriptions and interfaces to applications and other tools that provide policy data management. The policy store accesses IPSec policy data that is stored in either the local registry or in Active Directory. |
| Policy Agent | The IPSec Policy Agent controls the retrieval and distribution of IPSec policy and maintains the data about the configured policy for the IPSec driver and IKE. |
| Local registry | The local registry stores the locally configured IPSec policies, the local cache, and other IPSec settings. |
| Local cache | The local cache stores IPSec policies after they are downloaded from an Active Directory domain controller by the Policy Agent. |
| Interface Manager | Interface Manager manages a list that contains items that correspond to each physical and logical network adapter on the system. |

The following sections provide additional detail about each of these components.

**Policy store**

The policy store organizes IPSec policy data and stores it in a format that the Policy Agent can use. In Windows Server 2003, policy data can be stored in the following:

- Active Directory

- Local and remote registry
- A file (for exporting and importing only)

In addition to providing an interface that UI services can use to store policy in each of these media, the policy store does the following:

- Provides policy data for default IPSec policies
- Checks policy information for consistency
- Retrieves policy version information

The policy store reads and writes policy information both to and from persistent storage and is aware of shared policy-setting dependencies. This ensures that all policies using shared settings are marked as changed when they are modified and that Windows Server 2003 IPSec components download the modified policies.

**Policy Agent**

The Policy Agent retrieves IPSec policy information and delivers it to other IPSec components that require this information to perform security services, as shown in the following illustration.

**Policy Agent Service Retrieving and Delivering IPSec Policy Information**

The Policy Agent performs the following tasks:

- Retrieves the appropriate IPSec policy (if one has been assigned) from Active Directory if the computer is a domain member or from the local registry if the computer is not a member of a domain
- Determines filter list order
- Delivers the assigned IPSec policy information (IP filters) to the IPSec driver
- Delivers both main mode and quick mode settings to IKE
- Polls for changes in policy configuration. If the computer is a member of a domain, policy retrieval occurs when the computer starts, at the interval specified in the IPSec policy, and at the default Winlogon polling interval. You can also manually poll Active Directory for policy by using the **gpupdate /target:computer** command.

If there are no IPSec policies in Active Directory or the registry, or if the IPSec Policy Agent cannot connect to Active Directory, the IPSec Policy Agent waits for policy to be assigned or activated.

The Policy Agent appears in the list of computer services in the Services snap-in under the name IPSEC Services and starts automatically as part of the initialization of the Local Security Authority (LSA) service.

**Local registry**

Each computer running Windows XP or a Windows Server 2003 has only one local Group Policy object, often called the local computer policy. Using this local Group Policy object allows Group Policy settings to be stored on individual computers regardless of whether they are members of an Active Directory domain.

The local registry maintains the IPSec policy configuration in the following registry key and its subkeys: **HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows\IPSec**.

If you assign local IPSec policies and you do not assign Active Directory-based IPSec policies, the local policies are stored in the following registry key: **HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows\IPSec\Policy\Local**.

If you assign Active Directory-based IPSec policies, the policies are read from Active Directory and stored in the local cache.

**Local cache**
The local cache is part of the registry. If you assign an IPSec policy in Active Directory, the policy is stored in and read from Active Directory. A copy of the current policy in Active Directory is maintained in a cache in the local registry at: **HKEY_LOCAL_MACHINE\Software\Policies \Microsoft\Windows\IPSec\Policy\Cache**.

If a computer to which an IPSec policy in Active Directory is assigned cannot connect to the domain, the cached copy of the policy in Active Directory is applied. When the computer reconnects to the domain, new policy information for that computer replaces old, cached information. You cannot configure or manage the cached copy of an IPSec policy in Active Directory.

**Interface Manager**
Interface Manager maintains a list of physical and logical network adapters on the computer and notifies the Policy Agent when interface and address changes occur. Interface Manager also maintains a complete list of generic filters. Generic filters are filters that are configured to use My IP Address either as a source address or as a destination address. Generic filters are saved in the appropriate IPSec policy storage location with either a source address or a destination address of 0.0.0.0 and a corresponding subnet mask of 255.255.255.255.

**IKE Module Architecture**
The IKE module receives authentication and security settings from the Policy Agent and waits for requests to negotiate SAs. When the IKE module receives a request to negotiate an SA from the IPSec driver, the IKE module negotiates both kinds of SAs (the main mode SA and the quick mode SA) with the appropriate endpoint based on the request of the IPSec driver that the policy settings obtained from the Policy Agent. After it has negotiated an SA, the IKE module sends the SA settings to the IPSec driver.

The IKE module has the following components:

- CryptoAPI
- Diffie-Hellman Cryptographic Service Provider (CSP)
- RSA CSP
- Certificate store
- Security Support Provider Interface (SSPI)
- Kerberos Security Support Provider (SSP)

The following figure shows the architecture of the IKE module.

**IKE Module Architecture**

- A cryptographic service provider (CSP) is an independent software module that provides implementations of cryptographic standards and algorithms. The CSP carries out the cryptographic functions of CrytoAPI, creating keys, destroying them, and using them to perform a variety of cryptographic operations.

- The following table briefly describes the IKE module components.

**IKE Module Components**

| Component | Description |
|---|---|
| CryptoAPI | CryptoAPI provides a set of functions that allows applications based on Windows to encrypt or digitally sign data in a flexible manner while providing protection for the user's sensitive private key data. Actual cryptographic operations are performed by independent modules known as CSPs.<br><br>The IKE negotiation must be encrypted. This encryption is limited by what can be configured in IPSec policy. The standard CryptoAPI functions for keyed hashing (using HMAC-MD5 and HMAC-SHA1) and data encryption (using DES and 3DES) are used |
| Diffie-Hellman CSP | The Diffie-Hellman CSP contains the implementation of the Diffie-Hellman key exchange and determination algorithm. IKE uses only the Microsoft Base or Enhanced CSP for Diffie-Hellman. However, the Diffie-Hellman calculation can be accelerated using the CryptoAPI exponentiation offload interface (OffloadModExpo), as documented in the CryptoAPI SDK. |
| RSA CSP | The RSA CSP contains the implementation of the Rivest-Shamir-Adleman (RSA) cryptographic algorithms. When certificate authentication is selected, IKE checks the CryptoAPI default provider to see if it is capable of performing RSA 512-bit digital signatures. If so, then IKE uses this default CSP. If not, IKE enumerates the RSA providers, selects hardware-based providers first and ensures that they can provide 512-bit signatures. IKE performs these actions to open the certificate store.<br><br>The CSP that is used for signature operations during IKE negotiation is specified by the certificate selected during the IKE negotiation; the certificate's associated CSP for the private key signature is used. As long as the RSA CSP supports the NOHASHID flag for the **CryptSignHash( )** API call, IKE can use that CSP for private key signing of IKE payloads. Because the enumeration process does not permit IKE to know if the CSP supports the NOHASHID option, it is possible to choose a certificate that appears valid, but whose CSP does not allow IKE to construct the proper signature. |
| Certificate store | The certificate store is a permanent storage location where certificates, certificate revocation lists, and certificate trust lists are stored. The certificate store is a physical store on the Windows Server 2003 computer, but it is viewed logically as belonging to the user account of the currently logged-on user, a service account, or the computer account. IKE can use only the computer account, usually referred to as the computer store. You can view the computer store by using the Certificates snap-in. |
| SSPI | The SSPI enables network applications to access one of several security providers to establish authenticated connections and exchange data securely over those connections. |
| Kerberos SSP | The Kerberos SSP contains an implementation of the Kerberos security protocol. The Kerberos SSP is an SSPI provider |

**IPSec Driver Architecture**

The IPSec driver is a kernel-mode component that monitors and secures IP packets. In addition to the Policy Agent and IKE, the IPSec driver uses the following components: the Security Association Database (SAD), the Security Policy Database (SPD), the

TCP/IP driver, TCP/IP applications, and the network interface.

The IPSec driver matches IP packet information with the IP filters that are configured in the active SPD. If traffic must be secured, the IPSec driver either uses the appropriate SA to determine how to provide packet security or requests that the IKE module negotiate SAs to be used to provide packet security. After the IPSec driver determines which SA to use, it creates and validates encrypting, decrypting, and hashing to create or interpret the AH and ESP headers on an IPSec-protected packet.

The following figure shows the IPSec driver architecture and how the driver interacts with other components in Windows Server 2003.

**IPSec Driver Architecture**

The following table briefly describes the IPSec driver components.

**IPSec Driver Components**

| Component | Description |
|---|---|
| SAD | The SAD is a database in the IPSec driver that contains the parameters associated with each active SA. This database is populated automatically from the IKE module. |
| SPD | The SPD is a database in the IPSec driver that specifies the filter lists and associated settings that determine the status of all inbound or outbound IP traffic. Inbound packets are checked to ensure that they have been secured according to policy. Outbound packets are permitted, blocked, or secured, according to policy. For secured traffic, the security policy that is used is the negotiated SA, which is stored in the SAD. |
| TCP/IP driver | The TCP/IP driver is the Windows Server 2003 implementation of the TCP/IP protocol. It is a kernel-mode component that is loaded from the Tcpip.sys file during startup. |
| TCP/IP applications | TCP/IP applications use TCP/IP and access TCP/IP network services through an appropriate network API, such as Windows Sockets, NetBIOS, or Remote Procedure Call (RPC). |
| Network interface | The network interface is the logical or physical interface over which IP packets are sent and received. The details of the Network Driver Interface Specification (NDIS) interface, the network adapter driver, and the physical media over which the IP packets are sent and received are beyond the scope of this subject. |

**Policy Data Structure**

The data in a policy indicates the desired protection for the traffic between computers on a network. The data is made up of various computer-related attributes (for example, IP address and port number), the communication methods allowed (for example, algorithms and key lengths), and the IKE key negotiation and management. The policy store updates and stores the policy data. The Policy Agent retrieves the stored policy data and makes it available to all IPSec components.

As shown in the following figure, an IPSec policy contains several subsets of information.

**IPSec Policy Structure**

The following table describes the components of an IPSec policy.

**IPSec Policy Components**

| Component | Description |
|---|---|
| Policy-wide parameters | Policy-wide parameters specify the polling interval used to detect changes in policy.<br><br>The policy-wide parameters are configured on the **General** tab in the properties of an IPSec policy. |
| ISAKMP policy | The ISAKMP policy contains IKE parameters, such as encryption key lifetimes, and other settings. The ISAKMP policy settings are configured in the **Key Exchange Settings** dialog box, which is available from the **Advanced** button on the **General** tab in the properties of an IPSec policy.<br><br>The ISAKMP policy also contains a list of security methods for protecting the identity of IPSec peers during authentication. These methods are, listed in order of preference, and are configured in the **Key Exchange Security Methods** dialog box, which is available from the **Methods** button on the **Key Exchange Settings** dialog box. |
| IPSec rules | IPSec rules contain a statement that associates a filter list with a filter action, an authentication method, an IPSec mode, and other settings. Typically, an IPSec rule is configured for a specific purpose (for example, "Block all inbound traffic from the Internet to TCP port 135"). You can define many IPSec rules in a single IPSec policy.<br><br>IPSec rules are configured on the **Rules** tab in the properties of an IPSec policy. |

IPSec rules associate IKE negotiation parameters with one or more IP filters. The following table describes the components of an IPSec rule.

**IPSec Rule Components**

| Component | Description |
|---|---|
| Filter list | The filter list contains one or more predefined filters that describe the types of traffic to which an action (permit, block, or secure) is applied.<br><br>The filter list is configured on the **IP Filter List** tab in the properties of an IPSec rule within an IPSec policy. |

| | |
|---|---|
| Filter action | The filter action defines the security requirements for the data transmission. A filter action can be configured to permit traffic, block traffic, or negotiate secure communications with IPSec for packets matching the filter list. If security negotiation is selected, you must also configure security methods and their order: whether initial incoming unsecured traffic should be accepted, whether unsecured communication with computers that do not support IPSec should be allowed, and whether to use perfect forward secrecy (PFS). PFS is a mechanism that determines whether the existing keying material for a master key can be used to derive a new session key. Session key PFS performs a new Diffie-Hellman key exchange to generate new master key keying material instead of using master key keying material to derive more than one session key.<br><br>The negotiation settings are configured on the **Filter Action** tab in the properties of an IPSec rule within an IPSec policy. |
| Authentication method(s) | An IPSec rule contains one or more authentication methods, listed in order of preference, that are used for protection during IKE negotiations. The available authentication methods are the Kerberos v5 protocol, the use of a certificate issued from a specified certification authority (CA), or a preshared key.<br><br>The negotiation data is configured on the **Authentication Methods** tab in the properties of an IPSec rule within an IPSec policy. |
| Tunnel endpoint | A setting that specifies whether traffic is tunneled and, if it is, specifies the tunnel endpoint, which is the tunneling computer that is closest to the IP traffic destination, as specified by the associated IP filter list. Two rules are required to describe an IPSec tunnel. For the outbound traffic rule, the tunnel endpoint is the IP address or subnet of the IPSec peer on the other end of the tunnel. For the inbound traffic rule, the tunnel endpoint is an IP address or subnet configured on the local computer.<br><br>The tunnel endpoint is configured on the **Tunnel Setting** tab in the properties of an IPSec rule within an IPSec policy. |
| Connection type | The connection type setting specifies whether the rule applies to only local area network (LAN) connections, to only dial-up connections, or to both types of connections.<br><br>The interface applicability is configured on the **Connection Type** tab in the properties of an IPSec rule within an IPSec policy. |

**Note**

- The Kerberos v5 authentication method is not supported on computers running the Microsoft Windows XP Home Edition operating system.

**Default response rule**

Each policy has a default response rule. The default response rule has the IP filter list of **<Dynamic>** and the filter action of **Default Response** when the list of rules is viewed with the IP Security Policies snap-in. The default response rule cannot be deleted, but it can be deactivated. It is activated for all of the default policies and in the IP Security Policy wizard.

IPSec uses the default response rule to ensure that the computer responds to requests for secure communication. If an active policy does not include a rule for a computer requesting secure communication, IPSec applies the default response rule and negotiates security. For example, if Host A intends to communicate securely with Host B, but Host B does not have an inbound filter defined for Host A, then IPSec uses the default response.

For the defense response rule, you can configure only the security methods for secure traffic and the authentication methods. The following table lists the default security methods for the default response rule.

**Default Security Methods for the Default Response Rule**

| Type | AH Integrity | ESP Confidentiality | ESP Integrity |
|---|---|---|---|
| Encryption and Integrity | <None> | 3DES | SHA1 |
| Custom | <None> | 3DES | MD5 |
| Custom | <None> | DES | SHA1 |
| Custom | <None> | DES | MD5 |

| | | | |
|---|---|---|---|
| Custom | SHA1 | <None> | <None> |
| Custom | MD5 | <None> | <None> |

You can configure the security methods and their preference order on the **Security Methods** tab in the properties of the default response rule in the IP Security Policies snap-in.

The default response rule works in the following way:

1. If the IKE module receives a request to negotiate security, it queries the Policy Agent for a matching filter for traffic to and from the source and destination address of the ISAKMP message. If a matching filter is explicitly configured, the IKE negotiation is based on the settings of the associated rule.

2. If no matching filter is found and the default response rule is not activated, IKE negotiation fails.

3. If no matching filter is found and the default response rule is activated, then IKE dynamically creates an IP filter within the Policy Agent that corresponds to the traffic specification of the incoming ISAKMP message. IKE authenticates and negotiates security based on the settings on the **Authentication Methods** and **Security Methods** tabs for the default response rule.

You configure the default authentication method for the default response rule by using the IP Security Policy wizard.

**Example: Default response rule**
Typically, the default response rule is used when a group of servers are configured with policy to secure communications between themselves and any IP address and to accept unsecured communication, but respond using secured communications. The client computers are configured with the default response rule. When the clients communicate with each other, the traffic is not secured. When the clients communicate with the server, the traffic is secured (with the exception of the initial packet sent by the client to the server).

For example, a client computer can reliably exchange data with a server by using Transmission Control Protocol (TCP). A TCP connection is established through the exchange of three TCP segments: SYN (synchronize), SYN-ACK (synchronize-acknowledgement), and ACK (acknowledgement).

Because the client computer does not have an explicit rule to secure traffic to the server, the client computer sends an unsecured SYN segment to the server. The server receives the SYN segment and checks its filters. It finds the filter that requires secure traffic to and from any IP address. However, the filter action settings also allow the server to accept unsecured communication, responding with secured communication. Consequently, the SYN segment sent by the client and received by the server is sent to the TCP/IP protocol on the server.

The TCP/IP protocol on the server responds by sending a SYN-ACK segment back to the client. This IP packet is sent to the IPSec driver on the server. Checking the filter settings to require secured communications, the IPSec driver notes that there are no active SAs between itself and the client. The IPSec driver requests that the IKE module negotiate SAs for secure communication.

The IKE module on the server sends an ISAKMP message to the client to begin the process of negotiating SAs for secure communications. When the ISAKMP message is received on the client computer, the IKE module on the client computer queries the filter lists in the Policy Agent. Because it finds no explicit filter match and the default response rule is activated, the IKE module creates a dynamic filter for traffic to and from the client and server computer.

IKE negotiation continues based on the policy settings of the server and the client. After IKE negotiation is finished, the server sends the secured TCP SYN-ACK segment to the client. The client responds with a secured TCP ACK segment and secured TCP data can be exchanged between the client and the server.

**IPSec Protocols**
IPSec is integrated at the IP layer (layer 3) of the TCP/IP stack, so it provides security for almost all protocols in the TCP/IP suite. Because IPSec is applied to all applications, you do not need to configure separate security for each application that uses TCP/IP.

### IPSec Protocol Architecture

**IPSec AH and ESP Protocols**

The IPSec protocols — Authentication Header (AH) and Encapsulating Security Payload (ESP) — provide data and identity protection for each IP packet. The AH protocol is an IPSec protocol that provides data origin authentication, data integrity, and anti-replay protection for the entire packet (the IP header and the data payload carried in the packet, except fields in the IP header that are allowed to change in transit). AH can be used alone, in combination with the ESP protocol, or in IPSec tunnel mode. IPSec tunnel mode is used to protect site-to-site (gateway-to-gateway) traffic between networks, such as site-to-site networking through the Internet. The sending gateway encapsulates the entire IP datagram by adding a new IP header and then protects the new packet using one of the IPSec protocols. Windows Server 2003 supports IPSec tunnel mode for configurations where Layer Two Tunneling Protocol (L2TP) cannot be used.

The ESP protocol is an IPSec protocol that provides data confidentiality, data origin authentication, data integrity, and anti-replay protection for the ESP payload. The ESP protocol can be used alone, in combination with the AH protocol, or in IPSec tunnel mode.

**IPSec AH and ESP Protocols in IPSec Transport Mode**

IPSec protocols provide data and identity protection for each IP packet by adding their own security protocol header to each packet. This section describes how AH and ESP protect IP packets when IPSec is used in transport mode.

You use IPSec in transport mode to protect traffic in end-to-end communications scenarios (for example, for communications between a client and a server). You can also use IPSec in transport mode for basic packet filtering (that is, to statically permit or block traffic based on source and destination address combinations and on the IP protocol and TCP and UDP ports).

IPSec transport mode encapsulates the original IP payload with an IPSec header (AH or ESP).

**AH transport mode**

The AH protocol provides data origin authentication, data integrity, and anti-replay protection *for the entire packet* (both the IP header and the data payload carried in the packet), except for the fields in the IP header that are allowed to change in transit. AH does not provide data confidentiality, which means that it does not encrypt the data. The data is readable, but protected from modification and spoofing.

### AH Transport Mode Packet Structure

As shown in the figure, data integrity and authentication are provided by the placement of the AH header between the IP header and the IP packet payload. The AH protocol uses keyed hash algorithms to sign the packet for integrity. The AH protocol is identified in the IP header with an IP protocol ID of 51. This protocol can be used alone or with the ESP protocol.

The following table describes the AH header fields.

### AH Header Fields

| AH Header Field | Function |
|---|---|
| Next header | Identifies the IP payload by using the IP protocol ID. For example, a value of 6 represents TCP. |
| Length | Indicates the length of the AH header. |
| SPI | Used in combination with the destination address and the security protocol (AH or ESP) to identify the correct SA for the communication. The receiver uses this value to determine with which SA the packet is identified. |

| | |
|---|---|
| Sequence number | Provides anti-replay protection for the packet. The sequence number is a 32-bit, incrementally increasing number (starting from 1) that indicates the packet number sent over the SA for the communication. The sequence number cannot repeat for the life of the quick mode security association. The receiver checks this field to verify that a packet for a security association with this number has not already been received. If one has been received, the packet is rejected. |
| Authentication data | Contains the integrity check value (ICV), also known as the message authentication code, which is used to verify both data origin authentication and data integrity. The receiver calculates the ICV value and checks it against this value (which is calculated by the sender) to verify integrity. The ICV is calculated over the IP header, the AH header, and the IP payload. |

**ESP transport mode**

The ESP protocol provides data origin authentication, data integrity, anti-replay protection, and the option of confidentiality *for the IP payload only*. ESP in transport mode does not protect the entire packet with a cryptographic checksum nor does it protect the IP header.

**ESP Transport Mode Packet Structure**

As shown in the figure, the ESP header is placed before the IP payload and an ESP trailer and ESP trailer and authentication data field are placed after the IP payload. The ESP protocol is identified in the IP header with the IP protocol ID of 50.

The following table describes the ESP header fields.

**ESP Header Fields**

| ESP Header Field | Function |
|---|---|
| SPI | When used in combination with the destination address and the security protocol (AH or ESP), the SPI identifies the SA for the communication. The receiver uses this value to determine the SA with which this packet should be identified. |
| Sequence number | Provides anti-replay protection for the packet. The sequence number is a 32-bit, incrementally increasing number (starting from 1) that indicates the packet number sent over the quick mode SA for the communication. The sequence number cannot repeat for the life of the quick mode SA. The receiver checks this field to verify that a packet for an SA with this number has not already been received. If one has been received, the packet is rejected. |

The following table describes the ESP trailer fields.

**ESP Trailer Fields**

| ESP Trailer Field | Function |
|---|---|
| Padding | Padding of 0 to 255 bytes is used to ensure that the encrypted payload is on byte boundaries required by encryption algorithms. |
| Padding length | Indicates the length of the Padding field in bytes. The receiver uses this field to remove padding bytes after the encrypted payload with the padding bytes has been decrypted. |
| Next header | Identifies the type of data in the payload, such as TCP or UDP. |

The following table describes the ESP authentication trailer field.

**ESP Authentication Trailer Field**

| ESP Authentication Trailer Field | Function |
|---|---|
| Authentication data | Contains the ICV, also known as the message authentication code, which is used to verify both message authentication and integrity. The receiver calculates the ICV value and checks it against this value (which is calculated by the sender) to verify integrity. The ICV is calculated over the ESP header, the payload data, and the ESP trailer. |

**IPSec AH and ESP Protocols in IPSec Tunnel Mode**

You use IPSec tunnel mode primarily to protect traffic between sites that must traverse an untrusted path. For example, you can use tunnel mode to do the following:

- Establish gateway-to-gateway tunnels between sites, when the gateways or end systems do not support L2TP/IPSec Virtual Private Network (VPN) connections.
- Protect traffic end-to-end when one endpoint of the communication does not support IPSec. You can send protected traffic to a computer that supports tunnel mode and that is placed immediately in front of the computer that does not support IPSec.

With tunnel mode, an entire IP packet is encapsulated with an AH or ESP header and an additional IP header. The IP addresses of the outer IP header are the tunnel endpoints, and the IP addresses of the encapsulated IP header are the ultimate source and destination addresses.

You can use both the ESP and AH protocols in combination when tunneling to provide both confidentiality for the tunneled IP packet and integrity and authentication for the entire packet.

**AH tunnel mode**

AH tunnel mode encapsulates an IP packet with an AH and IP header and signs the entire packet for integrity and authentication.

### AH Tunnel Mode Packet Structure

**ESP tunnel mode**

ESP tunnel mode encapsulates an IP packet with both an ESP and IP header and an ESP authentication trailer.

### ESP Tunnel Mode Packet Structure

The signed portion of the packet indicates where the packet has been signed for integrity and authentication. The encrypted portion of the packet indicates what information is protected with confidentiality.

Because a new header for tunneling is added to the packet, everything that comes after the ESP header is signed (except for the ESP authentication trailer) because it is now encapsulated in the tunneled packet. The original header is placed after the ESP header. The entire packet is appended with an ESP trailer before encryption occurs. All data that follows the ESP header, except for the ESP authentication trailer, is encrypted. This includes the original header, which is now considered to be part of the data portion of the packet.

The entire ESP payload is then encapsulated within the new tunnel header. The tunnel header is not encrypted because it is used only to route the packet from origin to tunnel endpoint.

If the packet is being sent across a public network, it is routed to the IP address of the gateway for the receiving intranet. The gateway decrypts the packet, discards the ESP header, and uses the original IP header to route the packet to the intranet computer.

**IPSec Processes and Interactions**

This section describes the following IPSec processes and interactions:

- Policy Agent initialization
- Policy data retrieval and distribution
- IKE main mode and quick mode negotiation
- Key protection
- IPSec Driver Processes

**Policy Agent Initialization**
When the Policy Agent is started by the Local Security Authority (LSA) service, it performs a number of initialization steps and then begins a cycle during which it waits for a number of events to be signaled.

At startup, the Policy Agent checks the registry for the value that indicates the location of the computer's IPSec policy in Active Directory. To find the value, it checks the following registry key **HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\Windows\IPSec\GPTIPSECPolicy\DSIPSECPolicyPath**.

If the computer is a member of a domain and an IPSec policy has been configured in Active Directory, this value was set during computer initialization. If the computer is not a member of a domain or there is no IPSec policy in Active Directory, the Policy Agent finds no value.

After initializing interval values for event processing, the Policy Agent starts the Interface Manager (IM). The IM establishes the event processing that needs to be signaled whenever a network interface configuration or status changes. The Policy Agent then starts the IPSec driver.

Next, IKE starts. At this point, additional initialization occurs. This includes determining through the IPSec driver whether strong cryptography is available.

In preparation for loading the IPSec policy from either Active Directory or the local registry, the Policy Agent initializes the policy state and polling interval. It then loads the IPSec policy from the appropriate store, as described in the following section. After the policy is loaded, the Policy Agent begins a service loop.

If, during the service wait cycle, the Policy Agent encounters either an unexpected event or the Policy Agent service stop event, the Policy Agent shuts down IKE, stops the IPSec driver, cleans up local data, and then stops itself.

**Policy Data Retrieval and Distribution**
The Policy Agent loads the static IPSec policy from one of the stores if one of the following situations occurs:

- The Policy Agent has initialized and started IKE and the IPSec driver.
- An event has signaled the Policy Agent to reload the policy.
- A polling interval timeout occurs when the Policy Agent unsuccessfully accesses the current policy location to check for updates.

The Policy Agent first attempts to retrieve the policy from Active Directory. If it successfully does so, the Policy Agent supplies the retrieved policy data to IKE and the IPSec driver. The Policy Agent then copies the IPSec policy to the registry cache.

If the Policy Agent fails to retrieve the policy from Active Directory, it checks the local cache for the IPSec policy data. If the local cache contains policy data, the Policy Agent supplies the data to IKE and the IPSec driver.

If the Policy Agent fails to retrieve policy from Active Directory and the local cache, it checks the registry for local policy data. If the policy is successfully retrieved and the data is successfully provided to IKE and the IPSec driver, the Policy Agent is placed in the Local Downloaded policy state.

If the Policy Agent successfully loads a policy, the polling interval for policy checks is set from the value in the policy data. If the Policy Agent fails to load a policy, it goes into the Initial policy state and sets the polling interval to the default value.

While loading the static IPSec policy, the Policy Agent notes the state of the static policy data. If a service loop timeout occurs, the Policy Agent uses the state information to determine activity.

**IKE Main Mode and Quick Mode Negotiation**
The IKE component is a Policy Agent service. IKE is started by the Policy Agent, restarted by the Policy Agent as needed, and shut down when the Policy Agent shuts down. All policy data that IKE requires for operation is provided by the Policy Agent.

IKE establishes a combination of mutually agreeable policy and keys that defines the SA; the security services, protection mechanisms, and cryptographic keys between communicating peers.

To ensure successful and secure communication, IKE performs a two-phase negotiation operation. Phase 1 negotiation is known as main mode negotiation and Phase 2 is known as quick mode negotiation. The IKE main mode SA (also known as the ISAKMP SA) protects the IKE negotiation itself. The SAs created during the second IKE negotiation phase are known as the quick mode SAs (also known as IPSec SAs). The quick mode SAs protect application traffic. Two quick mode SAs are negotiated, one for inbound and one for outbound traffic.

**Main Mode Negotiation**
IKE performs main mode negotiation with an IPSec peer to establish protection mechanisms and keys for subsequent use in protecting quick mode IKE communications. IKE main mode negotiation occurs in three parts:

- Part one: Negotiation of protection mechanisms
- Part two: Diffie-Hellman exchange
- Part three: Authentication

Main mode negotiation consists of the exchange of a series of six ISAKMP messages. An ISAKMP message is the payload of a (User Datagram Protocol) UDP message with the source and destination UDP ports set to 500 (or 4500). An ISAKMP message has an ISAKMP header and one or more ISAKMP payloads as defined in RFC 2408.

Both the initiator and the responder in the exchange send three messages. The initiator is the IPSec peer that initiates secure communications by sending the first message. The responder, which sends the second message, is the IPSec peer with which the initiator is requesting secure communications.

The following table shows the first four main mode messages, which are not encrypted.

**Main Mode Messages 1 Through 4**

| Main Mode Message | Sender | Payload |
|---|---|---|
| 1 | Initiator | ISAKMP header, Security Association (contains proposals) |
| 2 | Responder | ISAKMP header, Security Association (contains a selected proposal) |
| 3 | Initiator | ISAKMP header, Key Exchange (contains Diffie-Hellman key), Nonce, additional payloads (depending on authentication method) |
| 4 | Responder | ISAKMP header, Key Exchange (contains Diffie-Hellman key), Nonce, additional payloads (depending on authentication method) |

The first four main mode messages contain the following ISAKMP payloads:

- **Security Association**. The Security Association payload sent in message 1 is a list of proposed protection mechanism for the main mode SA. The Security Association payload sent in message 2 is a specific protection suite for the main mode SA that is common to both IPSec peers. It is selected by the responder.
- **Key Exchange**. The Key Exchange payload is sent in message 3 by the initiator and in message 4 by the responder and contains Diffie-Hellman key determination information for the Diffie-Hellman key exchange process.
- **Nonce**. The Nonce payload is sent in messages 3 and 4 and contains a nonce, which is a pseudorandom number that is used only once. The initiator and responder each send their own unique nonces. Nonces are used to provide replay protection.

Depending on the authentication method that is selected in the IPSec policy, messages 3 and 4 might contain additional

payloads. The payloads of all messages beyond the first four messages are encrypted and vary based on the authentication method selected.

**Note**

- It is important to understand the differences in negotiation behavior between initiating an IKE main mode negotiation and quick mode negotiation and responding to one, and rekeying an existing one. The IKE RFC 2409 requires that rekeys can be performed by either peer (in either direction) at any time, regardless of the security association lifetimes negotiated. Therefore, the computer that initiates a negotiation might become the responder and these roles might alternate many times. Some of these differences are due to behavior required for interoperability and some are caused by enforcement of policy settings.

**Part One: Negotiation of protection mechanisms**

When initiating an IKE exchange, IKE proposes protection mechanisms based on the applied security policy. Each proposed protection mechanism includes attributes for encryption algorithms, hash algorithms, authentication methods, and Diffie-Hellman groups. The first part of the main mode is contained in main mode messages 1 and 2.

The following table lists the protection mechanism attribute values that are supported by Windows Server 2003 IKE. These values are described in more detail in later sections.

**Main Mode Attribute Values Supported by IKE**

| Main Mode Attribute | Value |
|---|---|
| Encryption algorithm | DES, 3DES |
| Integrity algorithm | HMAC-MD5, HMAC-SHA1 |
| Authentication method | Kerberos v5, public key certificate, preshared key |
| Diffie-Hellman group | Group 1, Group 2, Group 14 (2048) |

The encryption algorithm, integrity algorithm, and Diffie-Hellman group are configured as one of multiple key exchange security methods.

The initiating IKE peer proposes one or more protection suites in the same order as they appear in the applied security policy. If one of the protection suites is acceptable to the responding IKE peer, the responder selects it for use and responds to the initiator with its choice. Because the responding IKE peer might not be running Windows Server 2003 or Windows 2000 and is selecting the first proposed protection suite that is acceptable, the protection suites in the applied security policy should be configured in the order of most secure to least secure.

**Part Two: Diffie-Hellman exchange**

After a protection suite is negotiated, IKE queries a Diffie-Hellman CSP through CryptoAPI to generate a Diffie-Hellman public and private key pair based on the negotiated Diffie-Hellman group. The Diffie-Hellman public key is sent to the IKE peer in an ISAKMP Key Exchange payload. Main mode negotiation part 2 is contained in main mode messages 3 and 4.

The cryptographic strength of a Diffie-Hellman key pair is related to its prime number length (key size). Windows Server 2003 IKE supports the following Diffie-Hellman groups:

- Group 1 (768 bits)
- Group 2 (1024 bits)
- Group 14 (2048 bits)

  **Note**

  - For enhanced security, Windows Server 2003 IPSec includes Diffie-Hellman Group 14, which provides 2048 bits of keying strength. However, Diffie-Hellman Group 14 is not currently supported in Windows 2000 or Windows XP for general IPSec policy use. For updated information about the availability of Diffie-Hellman Group 14 for L2TP/IPSec connections for Windows XP and Windows 2000, search for article 818043, L2TP/IPSec NAT-T Update for Windows XP and Windows 2000, in the Microsoft Knowledge Base.

After the Diffie-Hellman public keys are exchanged, IKE accesses CryptoAPI to compute the shared key based on the mutually agreeable authentication method.

The following figure shows the Diffie-Hellman exchange between the IPSec peers and the relationship between IKE, CryptoAPI, and the Diffie-Hellman CSP.

**IKE Diffie-Hellman Key Exchange**

The Diffie-Hellman exchange occurs in the following steps:

1. On each IPSec peer, IKE requests that the first Diffie-Hellman CSP generate a Diffie-Hellman public and private key pair based on the Diffie-Hellman group selected during main mode messages 1 and 2.

2. The public portion of the Diffie-Hellman public and private key pair is returned to IKE.

3. The initiator sends the Diffie-Hellman public key to the responder in a Key Exchange payload (main mode message 3).

4. The responder sends its Diffie-Hellman public key to the initiator in a Key Exchange payload (main mode message 4).

5. On each IPSec peer, the IKE component sends the other IPSec peer's Diffie-Hellman public key to the Diffie-Hellman CSP.

6. The Diffie-Hellman CSP computes the shared secret and returns the value to the IKE component.

**Part Three: Authentication**

IKE supports three methods of authentication:

- Kerberos v5

- Public key certificate

- Preshared key

The authentication that occurs is a computer-based authentication, also known as machine-based authentication. The authentication process verifies only the identity of the computers, not the individual using the computer when the authentication process occurs.

**Kerberos v5 authentication**

Kerberos v5 authentication is the default authentication standard in Windows Server 2003 and Windows 2000 domains. Any computer in the domain or a trusted domain can use this method of authentication.

**Note**

- In Windows Server 2003, the Kerberos protocol is no longer a default exemption. Therefore, if you want to enable Kerberos authentication, you must create filters in the IPSec policy that explicitly allow such traffic. For more information, see article 810207, "IPSec Default Exemptions Are Removed in Windows Server 2003" in the Microsoft Knowledge Base.

Windows IKE Kerberos authentication is based on the Generic Security Service (GSS) API IKE authentication method, which is described in the Internet draft entitled "A GSS-API Authentication Method for IKE."

The following table lists the ISAKMP messages exchanged during a Kerberos authentication main mode negotiation.

**Kerberos Authentication Method Main Mode Messages**

| Main Mode Message | Sender | Payload |
|---|---|---|
| 1 | Initiator | ISAKMP header, Security Association (contains proposals) |
| 2 | Responder | ISAKMP header, Security Association (contains a selected proposal) |
| 3 | Initiator | ISAKMP header, Key Exchange (contains Diffie-Hellman key), Nonce, Initiator Kerberos Token |
| 4 | Responder | ISAKMP header, Key Exchange, Nonce, Responder Kerberos Token |
| 5* | Initiator | ISAKMP header, Identification, Initiator Hash |
| 6* | Responder | ISAKMP header, Identification, Responder Hash |

* ISAKMP payloads of message are encrypted.

Authentication occurs when:

- Each peer authenticates the other peer's Kerberos token: The responder verifies the initiator's Kerberos token and the initiator verifies the responder's Kerberos token.
- Each peer's hash is calculated and verified: The responder verifies the initiator's hash and the initiator verifies the responder's hash.

The hash calculation is performed over the following:

- The Diffie-Hellman public values of the initiator and responder
- The initiator and responder cookies
- The ISAKMP payloads of message 2
- The identity name string for the IPSec peer
- The IPSec peer's Kerberos token

To perform Kerberos authentication, Windows Server 2003 uses a Kerberos SSP that is accessible through the SSPI. The following figure shows the exchange of Kerberos tokens between the IKE peers and the relationship between the IKE, SSPI, and the Kerberos SSP.

**IKE Authentication with Kerberos**

Kerberos authentication is performed in the following steps:

1. IKE on the initiator accesses the SSPI to initialize a security context.
2. The initiator's Kerberos SSP creates a Kerberos token and returns it to the IKE component.

3. The initiator sends the initiator's Kerberos token and computer identity to the responder in main mode message 3.

4. The responder IKE component accesses the SSPI to acquire a security context.

5. The responder's Kerberos SSP creates a Kerberos token and returns it to IKE.

6. The responder sends the responder Kerberos token and computer identity to the sender in main mode message 4.

7. On each IPSec peer, IKE creates the hash for the next main mode message to be sent and then requests that SSPI sign the hash with the Kerberos session key.

8. The Kerberos SSP returns the signature to the IKE component.

9. The initiator sends the signed initiator hash to the responder in main mode message 5.

10. The responder sends the signed responder hash to the initiator in main mode message 6.

11. On each IPSec peer, IKE accesses the SSPI to compute the hash for the other peer. The initiator accesses the SSPI to compute the responder hash. The responder accesses the SSPI to compute the initiator hash.

12. The Kerberos SSP returns the computed hash to the IKE component where the hash value is verified to complete IKE authentication. The initiator compares its calculated responder hash with the responder hash received in main mode message 6. The responder compares its calculated initiator hash with the initiator hash received in main mode message 5.

The following sections describe the IKE certificate selection and acceptance process. If you decide to use certificates for IKE authentication, understanding this process and its requirements is integral to ensuring proper deployment.

**Public key certificate authentication**

Windows IKE performs public key certificate authentication during main mode in compliance with RFC 2409. IKE uses CryptoAPI to retrieve the computer certificate, verify peer certificates and certificate chains, check certificate revocation, and create and verify digital signatures. All certificate, certificate chain, and signature information is exchanged in main mode messages, as shown in the following table.

**Certificate-based IKE Authentication Main Mode Messages**

| Main Mode Message | Sender | Payload |
|---|---|---|
| 1 | Initiator | ISAKMP header, Security Association (contains proposals) |
| 2 | Responder | ISAKMP header, Security Association (contains a selected proposal) |
| 3 | Initiator | ISAKMP header, Key Exchange (contains Diffie-Hellman key), Nonce |
| 4 | Responder | ISAKMP header, Key Exchange (contains Diffie-Hellman key), Nonce, Certificate Request |
| 5* | Initiator | ISAKMP header, Identification, Certificate, Certificate Request, Signature |
| 6* | Responder | ISAKMP header, Identification, Certificate, Signature |

* ISAKMP payloads of message are encrypted.

**IKE certificate selection process**

When IKE negotiates to use certificates for authentication, the following process is used to select a computer certificate:

1. The list of trusted roots is prepared. This is the list of the CA root names provided by the peer in the Certificate Request Payloads (CRPs), and it matches the CA root names configured in the list of trusted roots in the appropriate authentication method of the IPSec policy. If there are no matching CA root names, all trusted CA root names from the appropriate authentication method are used.

2. IKE searches the computer store for an IPSec certificate that chains to any of the trusted CA roots identified in step 1. An IPSec certificate contains an Enhanced Key Usage (EKU) attribute with a value equal to the IP security IKE intermediate object identifier (OID) 1.3.6.1.5.5.8.2.2.

3. For each certificate chain found, checks are performed to verify the following:

   - The certificate chain does not have any trust errors.
   - The certificate chain is not a root-only chain.
   - The computer certificate has a private key.
   - The computer certificate has an RSA type public/private key pair.
   - The computer certificate has a public key length that is greater than 512 bits.
   - The computer certificate has a Digital Signature key usage.
   - The computer certificate is not a CA signing certificate that is used to issue certificates.
   - The certificate chain passes certificate revocation list (CRL) checking, which is performed by default or if the value of the **StrongCRLCheck** registry subkey is set to **1** or **2**. For more information about CRL checking, see "IPSec CRL checking" later in this section.

   If all of these checks succeed, IKE selects the certificate chain to be sent to the IPSec peer. If any of these checks fails, IKE continues to search for another IPSec type certificate, using the same list of root CA names.

4. If a valid computer certificate chain is not located, IKE retries the process, from step 2. Although it uses the same list of root CA names, IKE does not search for an IPSec type certificate.

5. If a valid computer certificate chain is still not found and if the list of root CA names in step 1 is a subset of the names allowed by the local IPSec policy, IKE retries, from step 2. This time, IKE uses the entire list of root CA names allowed by the local authentication method.

   This step is required for successful authentication when cross-certificates are used to establish trust relationships.

6. After IKE selects a computer certificate, it includes all intermediate certificates in the chain up to the root, except for the root CA certificate. A certificate chain in PKCS#7 format is then sent to the IPSec peer. If there are no intermediate CAs, only the computer certificate is sent.

   If a computer certificate cannot be selected, the authentication fails.

   **Note**

   - If IKE negotiates with another computer running Windows Server 2003, or with other Microsoft IKE implementations that use IPSec NAT-T (such as Microsoft L2TP/IPSec VPN Client), a special method to avoid fragmentation of ISAKMP UDP packets might be implemented. Otherwise, the ISAKMP message that contains the certificate chain will likely be fragmented as the packet is transmitted.

**IKE certificate acceptance process**

1. IKE receives the peer's certificates or certificate chains and verifies that the peer's certificates chain up to any of the root CAs in the appropriate authentication method of the local IPSec policy.

2. For each peer certificate chain, checks are performed to verify that:

- The computer certificate Subject Name or Subject AltName is consistent with the peer's ID field passed in the IKE negotiation.
- The computer certificate chain does not have any trust errors. If there is a trust error, the peer authentication fails.

3. If the two checks in step 2 succeed, checks are performed for the peer certificate chain to verify that:

   - The certificate chain passes CRL checking, which is performed by default or if the value of the **StrongCRLCheck** registry subkey is set to **1** or **2**.
   - The computer certificate has an RSA type public/private key pair.
   - The computer certificate has a public key length that is greater than 512 bits.
   - The computer certificate has a Digital Signature key usage.

   If any of these checks fails, the peer authentication fails.

4. If certificate-to-account mapping is enabled in the IPSec policy for the certificate root CA of the peer, IKE calls the Windows secure channel (Schannel) APIs to perform the mapping. Schannel completes the mapping and builds an access token for the computer account. This access token is automatically evaluated against the **Access this computer from the network** or the **Deny this computer access from the network** logon right defined in Group Policy Security settings.

   If the logon right evaluation fails, the peer authentication fails.

### IPSec CRL checking

If you use certificate-based authentication, you can also enable IPSec certificate revocation list (CRL) checking. By default, in Windows XP and Windows Server 2003, IPSec CRLs are automatically checked during IKE certificate authentication, but a fully successful CRL check is not required for the certificate to be accepted. However, if enhanced security is required, a fully successful CRL check is also required. CRL checking can cause delays in authentication or unnecessary failures, and some non-Microsoft PKI systems might not support it. You can disable IPSec CRL checking or specify a stronger level of IPSec CRL checking by using the Netsh IPSec context or by modifying the registry.

To disable IPSec CRL checking or specify a different level of IPSec CRL checking, use the following command:

```
netsh ipsec dynamic set config strongcrlcheck value={0 | 1 | 2}
```

#### To enable IPSec CRL checking through the registry

**Note**

- Incorrectly editing the registry might severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

1. Under the **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\PolicyAgent**\ key, add a new Oakley subkey, with a DWORD entry named **StrongCRLCheck**.

2. Assign this entry any value from 0 through 2, where:

   - A value of **0** disables CRL checking (this is the default for Windows 2000).
   - A value of **1** causes CRL checking to be attempted and certificate validation to fail only if the certificate is revoked

(this is the default for Windows XP and Windows Server 2003). Other failures that are encountered during CRL checking (such as the revocation URL not being reachable) do not cause certificate validation to fail.

- A value of **2** enables strong CRL checking, which means that CRL checking is required and that certificate validation fails if any error is encountered during CRL processing. Set this registry value for enhanced security.

3. Do one of the following:

   - Restart the computer.
   - Stop and then restart the IPSec service by running the **net stop policyagent** and **net start policyagent** commands at the command prompt.

Note that IPSec CRL checking does not guarantee that certificate validation fails immediately when a certificate is revoked. There is a delay between the time that the revoked certificate is placed on an updated and published CRL and the time when the computer that performs the IPSec CRL checking retrieves this CRL. The computer does not retrieve a new CRL until the current CRL has expired or until the next time the CRL is published. By default, IKE requests that CryptoAPI wait 15 seconds to complete the CRL retrieval. If the CRL cannot be retrieved at that time, IKE either ignores the error (if the value of the **StrongCRLCheck** registry subkey is set to **1**, or it causes authentication to fail (if the value of **StrongCRLCheck** is set to **2**). CRLs are cached in memory and in **\Documents and Settings*UserName*\Local Settings\Temporary Internet Files** by CryptoAPI. Because CRLs persist across computer restarts, if a CRL cache problem occurs, restarting the computer does not resolve the problem.

**Excluding the CA name from certificate requests**

If you use certificate authentication to establish trust between IPSec peers, you can also use Windows Server 2003 to exclude CA names from certificate requests. Excluding the CA name prevents a malicious user from learning sensitive information about the trust relationships of a computer, such as the name of the company that owns the computer and the domain membership of the computer (if an internal PKI is being used). Although excluding the CA name from certificate requests enhances security, computers with multiple certificates from different roots might require the CA root names to select the correct certificate. Also, some non-Microsoft IKE implementations might not respond to a certificate request that does not include a CA name. For these reasons, excluding the CA name from certificate requests might cause IKE certificate authentication to fail in certain cases.

**Certificate-to-account mapping**

In Windows Server 2003, a specific group of computers can be authorized to use IPSec when either Kerberos v5 or certificates are used for IKE authentication. This capability enables much stronger peer authentication and allows IPSec to be used to restrict network access to a server. When you enable IPSec certificate-to-account mapping, the IKE protocol associates (that is, maps) a computer certificate to a computer account in an Active Directory domain or forest, and then retrieves an access token, which includes the list of computer security groups. This process ensures that the certificate offered by the IPSec peer corresponds to an active computer account in the domain, and that the certificate is one that should be used by that computer.

Certificate-to-account mapping can be used only for computer accounts that are in the same forest as the computer performing the mapping. This provides much stronger authentication than simply accepting any valid certificate chain. For example, you can use this capability to restrict access to computers that are within the same forest. Certificate-to-account mapping, however, does not ensure that a specific trusted computer is allowed IPSec access.

If the certificate-to-account mapping process is not completed properly, authentication will fail and IPSec-protected connections will be blocked.

**Preshared key authentication**

Preshared key authentication requires that each IKE peer use a predefined and shared key to authenticate the IKE exchange.

The following table describes the main mode messages for preshared key authentication.

**Preshared Key Authentication Main Mode Messages**

| Main Mode Message | Sender | Payload |
|---|---|---|
| 1 | Initiator | ISAKMP header, Security Association (contains proposals) |

| | | |
|---|---|---|
| 2 | Responder | ISAKMP header, Security Association (contains a selected proposal) |
| 3 | Initiator | ISAKMP header, Key Exchange (contains Diffie-Hellman key), Nonce |
| 4 | Responder | ISAKMP header, Key Exchange (contains Diffie-Hellman key), Nonce |
| 5* | Initiator | ISAKMP header, Identification, Initiator Hash |
| 6* | Responder | ISAKMP header, Identification, Responder Hash |

* ISAKMP payloads of message are encrypted.

Messages 5 and 6 contain an initiator and responder hash calculated with the preshared key. Each IPSec peer authenticates the other peer's packet by decrypting and verifying the hash inside the packet (the hash inside the packet is a hash of the preshared key).

**Note**

- Preshared keys are easily implemented but can be compromised if they are not used correctly. Microsoft does not recommend the use of preshared key authentication because the key value is not securely stored, and it is, therefore, difficult to keep secret. Preshared key authentication is provided for interoperability purposes and compliance with RFC standards.

#### Quick Mode Negotiation

When main mode negotiation completes or an existing quick mode SA expires, IKE begins quick mode negotiation. During quick mode negotiation, IKE queries the Policy Agent for information required to perform the appropriate filter actions, including whether the IPSec mode is tunnel or transport, whether the protocol is ESP or AH or both, and which encryption and hashing algorithms are proposed or accepted.

#### Quick Mode SA negotiation

The quick mode negotiation process is implemented as defined in RFC 2409. All quick mode negotiation messages are protected with the main mode SA that was established during the main mode negotiation. Each successful quick mode negotiation establishes two quick mode SAs. One SA is inbound and the other SA is outbound.

The following table lists the quick mode messages exchanged by two IPSec peers running Windows IPSec.

**Quick Mode Messages**

| Quick Mode Message | Sender | Payload |
|---|---|---|
| 1* | Initiator | ISAKMP header, Security Association (contains proposals and secure traffic description) |
| 2* | Responder | ISAKMP header, Security Association (contains a selected proposal) |
| 3* | Initiator | ISAKMP header, Hash |
| 4* | Responder | ISAKMP header, Notification |

* ISAKMP payloads of message are encrypted.

The four quick mode messages contain the following payloads:

- **Security Association.** This payload contains a list of proposals and encryption and hashing algorithms (AH or ESP, DES or 3DES, and HMAC-MD5 or HMAC-SHA1) for securing the traffic and a description of the traffic that is protected. This description might include IP addresses, IP protocols, TCP ports, or UDP ports, and is based on the matching filter of the initiator. The Security Association in the second quick-mode message includes a Security Association payload that contains the chosen method of securing the traffic.

- **Hash.** This payload provides verification and replay protection.

- **Notification.** This payload has a connected notify message. This message is requested and sent between two IPSec peers running Windows Server 2003. Quick mode message 4 with the Notification payload is not required by the IKE standard and is used to prevent the initiator from sending IPSec-protected packets to the responder before the responder is ready to receive them.

- For more information about the contents of ISAKMP payloads for quick mode exchanges, see RFC 2407 and RFC 2408 in the IETF RFC Database.

Windows Server 2003 IPSec supports the filter action choices listed in the following table.

**Filter Action Choices**

| Filter Action Choices | ESP Encryption/Integrity Algorithm | AH |
|---|---|---|
| Encryption and integrity | 3DES/HMAC-SHA1 | None |
| Integrity only | None/HAMC-SHA1 | None |
| Custom | DES, 3DES, or none/HMAC-MD5, HMAC-SHA1, or none | HMAC-MD5 or HMAC-SHA1 |

**Note**

- Computers running Windows Server 2003 and Windows XP support the 3DES and DES algorithms and do not require installation of additional components. However, computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use 3DES. If a computer running Windows 2000 is assigned a policy that uses 3DES encryption, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the security method defaults to the weaker DES algorithm.

**Generating and regenerating session key material**

IKE generates session keys for both the inbound and outbound quick mode SAs based on the main mode shared master key and nonce material exchanged during the quick mode negotiation. Additionally, Diffie-Hellman key exchange material can also be exchanged and used to enhance the cryptographic strength of the IPSec session key.

**Key Protection**

The following features enhance the base prime numbers (keying material) and the strength of the keys for master and session keys.

**Key Lifetimes**

Key lifetimes control when a new key is generated. A key lifetime allows you to force automatic key regeneration after a specific interval of either kilobytes (KB) or seconds, whichever occurs first. This ensures that even if an attacker is able to decipher part of a communication protected by one key, new keys protect the remainder of the communication. Whenever a key lifetime is reached, the SA is also renegotiated and the key is refreshed or regenerated. For this reason, key lifetimes are also referred to as SA lifetimes. You can specify key lifetimes for the master key and for session keys.

The master key lifetime corresponds to the main mode SA lifetime created by the IKE main mode negotiation. It is configured in terms of time and number of quick mode negotiations and it applies to all security rules in the IPSec policy. The main mode SA and master key typically have a long lifetime (the default value is eight hours). Master keys are much more resource-intensive to generate than session keys because they require reauthentication and additional Diffie-Hellman exchanges.

The session keys correspond to the quick mode SAs that are used to protect program traffic. The session keys and quick mode SAs are quickly derived from the master key by IKE quick mode negotiation. Session keys are used to protect data and they have lifetimes based on the amount of data sent and the amount of time elapsed since the key started being used. Typically, session keys have shorter lifetimes than master keys. The default values are 100,000 KB (approximately 100 megabytes) or one hour.

When session keys are refreshed, new quick mode SAs replace the old ones. Quick mode SA session keys must be refreshed before either the data or time lifetime expires; otherwise, traffic is discarded. A session key will be deleted if the quick mode SAs become idle (by default, SAs become idle after five minutes). Because the master key lives longer than the session key, it allows new quick mode SAs and session keys to be established quickly. To prevent data loss, the quick mode SA session key is generated shortly before the main mode SA expires. The main mode SA and corresponding master key are not deleted when session keys and quick mode SAs are deleted, unless the specified number of quick mode SA negotiations has elapsed.

For example, if a communication takes one hour (3,600 seconds) and if you specify the minimum session key lifetime of five minutes (300 seconds), more than 12 keys are generated to complete the communication. If a 100 MB file is transferred over a fast corporate LAN using an IPSec security association with a 100 MB and one hour lifetime, at least one, if not two, session rekeys occur.

**Session Key Refresh Limit**
Repeated rekeying from a session key can compromise the Diffie-Hellman shared secret. Consequently, you might want to limit the number of quick mode session keys that can be derived from a main mode negotiation.

If you have enabled master key PFS, the session key limit is disregarded. Setting a session key limit to 1 is identical to enabling master key PFS. If both a master key lifetime and a session limit are specified, whichever limit is reached first causes a new main mode negotiation. By default, IPSec policy does not specify a session limit.

**Diffie-Hellman Groups**
Diffie-Hellman groups are used to determine the length of the base prime numbers (key material) for the Diffie-Hellman exchange. The cryptographic strength of any key derived from a Diffie-Hellman exchange depends, in part, on the strength of the Diffie-Hellman group on which the prime numbers are based. When a stronger group is used, the key that is derived from a Diffie-Hellman exchange is stronger and more difficult for an attacker to break.

IKE negotiates which group to use, ensuring that there are not any negotiation failures that result from a mismatched Diffie-Hellman group between the two peers.

If session key PFS is enabled, a new Diffie-Hellman key is negotiated during the first quick mode SA negotiation. This new key removes the dependency of the session key on the Diffie-Hellman exchange that is performed for the master key.

Both the initiator and responder must have session key PFS enabled, or negotiation fails.

The Diffie-Hellman group is the same for both the main mode and quick mode SA negotiations. When session key PFS is enabled, even though the Diffie-Hellman group is set as part of the main mode SA negotiation, it affects any rekeys during session key establishment.

**Perfect Forward Secrecy**
Unlike key lifetimes, PFS determines how a new key is generated, rather than when it is generated. Specifically, PFS ensures that the compromise of a single key permits access only to data that is protected by it, not necessarily to the entire communication. To achieve this, PFS ensures that a key used to protect a transmission cannot be used to generate additional keys. In addition, if the key that was used was derived from specific keying material, that material cannot be used to generate other keys.

**Master key PFS**
In Windows Server 2003 IPSec, you can configure the number of times quick mode SAs can be created based on a single main mode SA. If you enable master key PFS, the IKE allows only a single quick mode SA for each main mode SA. By default, master key PFS is disabled, so there is no limit to the number of quick mode SAs that can be created from one main mode SA. To derive a new quick mode SA, a new main mode negotiation is performed, which includes a new Diffie-Hellman exchange and a new authentication process.

**Session key PFS**
Whenever a quick mode SA requires renegotiation, IKE determines whether a session key PFS is specified in the corresponding filter rule. If it is, IKE additionally generates a new Diffie-Hellman key and exchanges it with the IKE peer during quick mode negotiation. By performing another Diffie-Hellman key exchange, IKE provides additional cryptographic strength to quick mode key generation beyond that already contributed by the main mode SA. Performing additional Diffie-Hellman exchanges requires additional computational resources and might affect IPSec performance.

**IPSec Driver Processes**
The IPSec driver does not participate in IP packet processing until the first time the Policy Agent informs the driver that there is an active IPSec policy. If no IPSec policy is active, the IPSec driver does not participate in inbound and outbound IP traffic processing.

**IPSec Driver Responsibilities**
The IPSec driver is responsible for the following:

- Maintaining the SAD and SPD.
- Checking each IP packet to determine whether it matches a policy filter. When a match is found and an SA must be created, the IPSec driver invokes the IKE module. After the IKE module completes its negotiations, an SA is returned to the IPSec driver and stored in the SAD.
- Implementing the IPSec policy as specified in the SA (for example, using a specific hashing method for outbound packets, verifying the integrity of inbound packets, and using a specific method for encrypting and decrypting).
- Tracking the length of time a specific key is in use and requesting a new key from IKE as necessary.

- Tracking the number of bytes that have been transformed (that is, hashed or encrypted) for each SA and requesting a new key from the IKE module if the byte count allowed by the SA is exceeded.

- For each secured inbound packet that contains an AH or ESP header, parsing the packet for the SPI to determine the SA.

- For each non-secured inbound packet, checking the filter list in the SPD to determine whether the packet is permitted or discarded:

    - The filter list can contain an inbound permit filter if the corresponding filter action is set to **Permit** or **Negotiate security** and either the **Accept unsecured communication, but always respond with IPSec** or **Allow unsecured communication with non IPSec-aware computer** options are enabled. The IPSec driver sends unmodified permitted packets to the TCP/IP driver for additional processing.

    - The packet is discarded either because the filter action is set to Block or the filter action is set to Negotiate security and unsecured communications are not allowed.

- Handling hardware offload of cryptographic functions by skipping cryptographic processing on packets processed by offload network adapters and managing offloaded SAs.

- Handling network layer issues such as path maximum transmission unit (PMTU) discovery.

- Creating the SPI that the responder uses to identify the appropriate SA for an inbound packet.

- Deleting expired SAs.

- Providing the implementation of the AH and ESP protocols.

  For outbound traffic that must be secured; the IPSec driver, based on the parameters of the SA, calculates and places the AH or ESP or both headers and trailer on the IP packet before sending it to the TCP/IP driver. For inbound traffic that contains an AH or ESP header, the IPSec driver processes the header and, if it is valid, sends the authenticated and decrypted packet without the AH or ESP headers and trailer back to the TCP/IP driver.

**IPSec Driver Communication**

The following types of communications occur between the Policy Agent, IPSec driver, and IKE module:

- The Policy Agent adds a set of filters to the IPSec driver. Each filter is accompanied by a policy identifier (a GUID) and an index. The index indicates to IPSec what weight to assign to the filter. A lower index indicates higher precedence and higher weight.

- When the Policy Agent deletes a set of filters, it deletes all associated outbound SAs first and then allows the inbound SAs to expire.

- The Policy Agent can receive a set of usage statistics from the IPSec driver. These statistics include the number of packets sent and received for both AH and ESP protocols, the number of SAs, the number of rekeys, and the number of bad packets.

- The IKE module adds SAs as the result of successful negotiation of keys.

- The IKE module can expire a specified SA.

**Packet Processing**

The IPSec driver receives the active IP filter list from the Policy Agent, as shown in the following illustration, and then attempts to match every inbound and outbound packet against the filters in the list.

### IPSec Driver Matching an IP Filter List

When a packet matches a filter, the IPSec driver applies the filter action. When a packet does not match any filters, the IPSec driver passes the packet back without modification to the TCP/IP driver to be received or transmitted.

If the filter action permits transmission, the packet is received or sent with no modifications. If the action blocks transmission, the packet is discarded. If the action requires the negotiation of security, main mode and quick mode SAs are negotiated.

The negotiated quick mode SA and keys are used with both outbound and inbound processing. The IPSec driver stores all current quick mode SAs in a database. The IPSec driver uses the SPI field to match the correct SA with the correct packet.

When an outbound IP packet matches the IP filter list with an action to negotiate security, the IPSec driver queues the packet and then notifies IKE, which begins security negotiations with the destination IP address of that packet. If several outbound packets are going to the same destination and match the same filter before IKE has finished the negotiation, then only the last packet sent is saved.

The following sections describe the basic inbound packet and outbound packet processing that the IPSec driver performs in transport mode.

**Inbound packet processing**

The following figure illustrates this process.

**Basic Inbound Packet Process**

**Note**

- The inbound packet process applies only to local host unicast traffic (traffic with the unicast destination address of the host) when there is an active IPSec policy.

Basic inbound packet processing for transport mode occurs in the following sequence:

1. IP packets are sent from the network interface to the TCP/IP driver.

2. The TCP/IP driver sends the IP packet to the IPSec driver.

3. If the inbound packet is IPSec-protected, the IPSec driver looks up the SA in the SAD.

4. If the inbound packet is not IPSec-protected, the IPSec driver checks the packet for a filter match by looking up the filters in the SPD.

5. After the IPSec-protected inbound packet is authenticated and decrypted, the AH or ESP or both headers are removed and the packet is sent to the TCP/IP driver. If a packet that is not IPSec-protected is permitted by policy, that packet is sent

to the TCP/IP driver.

6. The TCP/IP driver performs IP packet processing as needed and sends the application data to the TCP/IP application.

Detailed inbound packet processing for transport mode occurs in the following sequence:

1. The TCP/IP driver sends the unicast packet to the IPSec driver.

2. If the packet is ISAKMP, the unmodified packet is sent back to the TCP/IP driver.

   **Note**

   - To modify the default filtering behavior for Windows Server 2003 IPSec, you can use the Netsh IPSec context or modify the registry. For more information, see "Default exemptions to IPSec filtering" later in this section.

3. If hardware offload processing was performed, the IPSec driver checks to determine whether the hardware processing was successful.

4. If the hardware processing was not successful, an event is logged and the packet is discarded.

5. The packet is parsed to determine whether an AH or ESP header or both are present.

6. If the packet does not contain an AH or ESP header, the packet is compared to the filter list for a match.

7. If a filter match is not found, the unmodified packet is sent to the TCP/IP driver.

8. If a filter match is found, the IPSec driver attempts to find an SA based on the packet contents.

9. If an SA is not found, the matching filter is checked to determine if it is an inbound permit filter.

10. If the matching filter is an inbound permit filter, the unmodified packet is sent to the TCP/IP driver.

11. If the matching filter is not an inbound permit filter, the packet is discarded.

12. If an SA is found, it is checked to determine whether it is a soft SA. A soft SA is one in which the **Negotiate security** filter action is enabled, but there is no authentication or encryption being performed because the computer with which communication occurs is not running IPSec. This process is also known as fallback to clear. Even though the packet is not being protected, an SA without an AH or ESP header is still maintained in the SAD. Soft SAs and fallback to clear are possible only when **Allow unsecured communication with non IPSec-aware computer** is selected on the **Security methods** tab in the properties of a filter action.

13. If the SA is a soft SA, the unmodified packet is sent to the TCP/IP driver.

14. If the SA is not a soft SA, the packet is discarded.

15. If the packet contains an AH or ESP header (or both), the header is parsed for the SPI.

16. The SPI is used to look up the SA in the SAD.

17. If the SA corresponding to the SPI is not found in the SAD, a Bad SPI event is logged and the packet is discarded.

18. If the SA corresponding to the SPI is found in the SAD, the current time is used to update the SA's last used time. The time is used for aging the SA.

19. The SA is checked to determine whether cryptographic processing for the SA was offloaded to hardware. For packets that

have been processed by hardware offload, steps 20 and 21 are skipped.

20. The packet is authenticated or decrypted or both. This process involves verifying the HMAC in the AH or ESP header, processing the other fields in the AH and ESP headers and trailer, and decrypting the ESP payload.

21. If cryptographic processing is unsuccessful, an event is logged and the packet is discarded.

22. The AH or ESP headers and ESP trailer are removed.

23. If the SA for this packet is a tunnel SA (using either AH or ESP tunnel mode), the decapsulated packet is reinjected into the TCP/IP driver and the original packet is discarded. By reinjecting the decapsulated packet, the TCP/IP driver treats it as if it were received from the network adapter.

24. If the SA for this packet is not a tunnel SA, the IP packet, with the AH and ESP headers removed, is sent back to TCP/IP driver for additional processing.

**Outbound packet processing**

Basic outbound packet processing is shown in the following figure.

**Basic Outbound Packet Process**

Basic outbound packet processing for transport mode occurs in the following sequence:

1. Application data is sent to the TCP/IP driver from the TCP/IP application.

2. The TCP/IP driver sends an IP packet to the IPSec driver.

3. The IPSec driver checks the packet for a filter match by looking up the filters in the SPD.

4. The IPSec driver checks the packet for an active SA by looking up the SAs in the SAD. Based on the SA, the traffic is authenticated or encrypted or both.

5. If the traffic must be protected and there is not an SA, the IPSec driver requests that IKE create the appropriate SAs. The IP packet is then held until the SA is established and can be IPSec framed.

6. The IP packet is sent back to the TCP/IP driver.

7. The TCP/IP driver sends the IP packet to the network interface.

Detailed outbound packet processing for transport mode occurs in the following sequence:

1. The TCP/IP driver sends the unicast outbound packet to the IPSec driver.

2. If the packet is ISAKMP, the unmodified packet is sent back to the TCP/IP driver.

3. The IPSec driver attempts to find a filter that matches the packet. If a filter is not found, the unmodified packet is sent

back to the TCP/IP driver.

4. If a filter match is found, the IPSec driver attempts to find an SA that matches the packet.

5. If an SA is not found, the filter action is checked. If the filter action is set to **Negotiate security**, the IPSec driver requests that the IKE module negotiate the appropriate SAs.

6. If the IKE negotiation is successful, the IKE module informs the IPSec driver of the new SA and the IPSec driver looks up the SA again.

7. If the IKE negotiation is not successful, the packet is discarded.

8. If the filter action is set to **Permit**, the unmodified packet is sent back to the TCP/IP driver. Otherwise, the packet is discarded.

9. If an SA is found in the SAD, the current time is used to update the SA's last used time. The time is used for aging the SA.

10. The SA is checked to determine whether it is about to expire. If the SA is about to expire, the IPSec driver informs the IKE module to initiate a quick mode or Phase 2 rekey of the quick mode SA.

11. The SA is checked to determine whether it has expired. If the SA has expired, the packet is discarded.

12. The Don't Fragment (DF) flag in the IP header of the packet is checked. If the DF flag is set to 1, the size of the IP packet with the proposed AH or ESP or both headers and trailer is calculated.

13. If the size of the IP packet with the proposed IPSec overhead is larger than the path maximum transmission unit (PMTU) for the destination IP address, the IPSec driver indicates a packet-too-large condition for the packet and the unmodified packet is sent back to the TCP/IP driver. The packet-too-large condition allows the TCP/IP driver to either adjust the PMTU for the destination or, in the case of transit traffic, inform the sending host with an Internet Control Message Protocol (ICMP) Destination Unreachable-Fragmentation Needed and DF Set message that includes the new PMTU. The packet is eventually discarded by the TCP/IP driver.

14. If the DF flag is not set to 1, or if it is set to 1 and the additional IPSec overhead is not greater than the current PMTU for the destination, blank AH or ESP both headers and trailer are constructed (based on the settings for the SA).

15. The IPSec driver checks to determine whether the hardware offload is capable of offloading the SA for this packet. If so, the IPSec driver checks to determine whether the SA for the packet was offloaded to the hardware.

16. If the SA was offloaded to the hardware, an offload status is set on the packet and the modified packet with blank AH or ESP or both headers and trailer is sent to the TCP/IP driver.

17. If the SA has not been offloaded to the hardware, the IPSec driver accesses NDIS with instructions to add the SA to the hardware offload network interface.

18. If hardware offload is not enabled or the SA has not been offloaded to the hardware, the IPSec driver performs the cryptographic processing and adds the appropriate values in the fields of the AH or ESP or both headers and trailer.

19. The IPSec driver sends the modified packet to the TCP/IP driver.

**Default exemptions to IPSec filtering**

In Windows Server 2003, the default filtering exemptions have been removed for Kerberos, Resource Reservation Setup Protocol (RSVP), and multicast and broadcast traffic, but remain for ISAKMP traffic, and inbound multicast and broadcast traffic.

To modify the default filtering behavior for Windows Server 2003 IPSec, you can use the Netsh IPSec context or modify the registry.

To modify the default filtering behavior using Netsh, use the following command:

```
netsh ipsec dynamic set config ipsecexempt value={ 0 | 1 | 2 | 3}
```

Depending on which exemptions you want, specify the appropriate values as follows:

- A value of **0** specifies that multicast, broadcast, RSVP, Kerberos, and ISAKMP traffic are exempt from IPSec filtering. This is the default filtering behavior for Windows 2000 (with Service Pack 3 and earlier service packs) and Windows XP.

  **Note**

  - Use this setting only if it is required for compatibility with Windows 2000 and Windows XP. If Kerberos traffic is exempted from filtering, an attacker can bypass other IPSec filters by using either UDP or TCP source port 88 to access any open port. Many port scan tools will not detect this because these tools do not allow setting the source port to 88 when checking for open ports.

- A value of **1** specifies that Kerberos and RSVP traffic are not exempt from IPSec filtering (multicast, broadcast, and ISAKMP traffic are exempt).

- A value of **2** specifies that multicast and broadcast traffic are not exempt from IPSec filtering (RSVP, Kerberos, and ISAKMP traffic are exempt).

- A value of **3** specifies that only ISAKMP traffic is exempt from IPSec filtering. This is the default filtering behavior for Windows Server 2003, Windows 2000 (with Service Pack 4 and later service packs) and Windows XP (with Service Pack 1 and later service packs).

If you change the value for this setting, you must restart the computer for the new value to take effect.

**To modify the default filtering behavior by using the registry**

1. In Regedit, under the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\IPSEC** key, add a new DWORD entry named **NoDefaultExempt**.

2. Assign this entry any value from **0** through **3**.

3. Restart the computer.

The filtering behaviors for each value are equivalent to those noted above for the **netsh ipsec dynamic set config ipsecexempt value=***x*command.

The following table summarizes the equivalent filters that are implemented if all default exemptions to IPSec filtering are enabled (that is, if **NoDefaultExempt** is **0**). When the IP address is specified, the subnet mask is 255.255.255.255. When the IP address is **Any**, the subnet mask is 0.0.0.0.

**Equivalent Filters When NoDefaultExempt=0**

| Source Address | Destination Address | Protocol | Source Port | Destination Port | Filter Action |
|---|---|---|---|---|---|
| My IP Address | Any IP Address | UDP | Any | 88 | Permit |
| Any IP Address | My IP Address | UDP | 88 | Any | Permit |
| Any IP Address | My IP Address | UDP | Any | 88 | Permit |
| My IP Address | Any IP Address | UDP | 88 | Any | Permit |
| My IP Address | Any IP Address | TCP | Any | 88 | Permit |
| Any IP Address | My IP Address | TCP | 88 | Any | Permit |

| | | | | | |
|---|---|---|---|---|---|
| Any IP Address | My IP Address | TCP | Any | 88 | Permit |
| My IP Address | Any IP Address | TCP | 88 | Any | Permit |
| My IP Address | Any IP Address | UDP | 500 | 500 [1] | Permit |
| Any IP Address | My IP Address | UDP | 500 | 500 | Permit |
| My IP Address | Peer IP Address | UDP | 4500 | 4500 [2] | Permit |
| Peer IP Address | My IP Address | UDP | 4500 | 4500 | Permit |
| My IP Address | Any | 46 (RSVP) | | | Permit |
| Any IP Address | My IP Address | 46 (RSVP) | | | Permit |
| Any IP Address | <multicast> [3] | | | | Permit |
| My IP Address | <multicast> | | | | Permit |
| Any IP Address | <broadcast>[4] | | | | Permit |
| My IP Address | <broadcast> | | | | Permit |
| <All IPv6 protocol traffic> [5] | | | | | Permit |

[1]In order for IPSec transport mode to be negotiated through an IPSec tunnel mode SA, ISAKMP traffic cannot be exempted if it needs to pass through the IPSec tunnel first.

[2] When IPSec NAT-T is performed, the filter exemption for UDP port 4500 is automatically generated based on the source and destination IP addresses used during the initial part of the IKE negotiation on UDP port 500. This dynamic permit filter for port 4500 is displayed in the IP Security Monitor snap-in, under **Quick Mode\Specific Filters**, and in the output for the **netsh ipsec dynamic show qmfilter** command.

[3]Multicast traffic is defined as the class D range, with a destination address range of 224.0.0.0 with a 240.0.0.0 subnet mask, which corresponds to the range of addresses from 224.0.0.0 to 239.255.255.255.

[4]Broadcast traffic is defined as a destination address of 255.255.255.255 (the limited broadcast address) or as having the host ID portion of the IP address set to all 1's (the subnet broadcast address).

[5]IPSec does not support filtering for IP version 6 (IPv6) packets, except when IPv6 packets are encapsulated with an IPv4 header.

Windows Server 2003 IPSec does not support specific filters for broadcast protocols or ports, nor does it support multicast groups, protocols, or ports. Because IPSec does not negotiate security for multicast and broadcast traffic, these types of traffic are dropped if they match a filter with a corresponding filter action to negotiate security. A filter with a source address of **Any IP Address** and a destination address of **Any IP Address** can block or permit all multicast and broadcast traffic. By default (and if **the NoDefaultExempt** registry key is set to a value of **2** or **3**), outbound multicast or broadcast traffic will be matched against a filter with a source address of **My IP Address** and a destination address of **Any IP Address**. More specific unicast IP address filters that block, permit, or negotiate security for unicast IP traffic should be configured in the same IPSec policy to achieve appropriate security.

**Hardware acceleration (offloading)**

Hardware acceleration is accomplished by offloading specific processing tasks that are normally completed by an operating system component to the network adapter. Some network adapters can perform IPSec cryptographic functions, such as encryption and decryption of data and the calculation and verification of message authentication codes.

When the NDIS interface binds, the offload capability of the network interface is queried. During outbound packet processing, after an SA is created a check is made to ensure that the network interface can offload cryptographic functions, support transport-over-tunnel functionality, and support IP header options. If not, the packet cannot be offloaded. A check is also made to determine whether the SA for the packet being offloaded is a soft SA. A soft SA is an SA in which no authentication or encryption is being performed because the computer with which communication occurs is not running IPSec. Because no AH

or ESP headers need to be processed, hardware offloading is unnecessary.

If hardware offloading is enabled, a check is made per packet to determine whether the SA for an outbound packet has already been offloaded to the offload adapter. If so, the existing offloaded SA is used. If the SA is not yet offloaded and the offload has not previously failed for this SA, an attempt is made to offload the SA. However, the attempt to offload the SA is made asynchronously. The IPSec driver does not wait for the SA offload to be successful before continuing to process the packet. This causes the first packet to always be cryptographically processed by the IPSec driver, with the cryptographic processing of following packets occurring on the hardware offload network adapter.

Typically, IPSec network offload adapters do not accelerate the IKE negotiation. However, some SSL offload adapters might be capable of processing the IKE Diffie-Hellman calculation in hardware. To determine whether your SSL offload adapter can do so, see the manufacturer's documentation.

Windows 2000, Windows XP, and Windows Server 2003 provide hardware acceleration APIs in the Windows Driver Development Kit (DDK) as part of TCP/IP Task Offload. For more information about these APIs, see *Task Offload* on MSDN.

**Network Ports and Protocols Used by IPSec**
The following table lists the network ports and protocols used by IPSec.

### IPSec Port and Protocol Assignments

| Protocol | Protocol ID | UDP | TCP |
|---|---|---|---|
| ESP | 50 | N/A | N/A |
| AH | 51 | N/A | N/A |
| ISAKMP | N/A | 500 (4500) | N/ A |

The following sections describe how to configure routers, firewalls, or other filtering devices to ensure that traffic that is sent over IPSec protocols can pass through these devices. Additional considerations for IPSec NAT traversal are also described.

**Firewall Filters**
In order for IPSec-secured communications to take place through a firewall or other filtering device, you must configure the firewall to permit IPSec traffic on UDP source and destination port 500 (ISAKMP) and IP Protocol 50 (ESP). You might also need to configure the firewall to permit IPSec traffic on IP protocol 51 (AH) to permit troubleshooting by IPSec administrators and to allow the traffic to be inspected while it is still IPSec-encapsulated.

Ensure that the firewall filter can permit or track fragments for ISAKMP. IKE with certificate or Kerberos authentication requires ISAKMP packets to be fragmented because the ISAKMP protocol uses UDP. ISAKMP messages that are larger than the local interface MTU are automatically fragmented by IP. If only certificate authentication is used, Windows Server 2003 implements a method to avoid IKE message fragmentation. When certificate authentication is used for communication between computers running Windows Server 2003 IPSec and Windows XP IPSec or Windows 2000 IPSec, fragmentation is required.

You must also allow ISAKMP to be initiated from either a source or destination IP address. RFC 2408 specifies that the ISAKMP protocol must be able to negotiate security in either direction. Stateful filtering that allows only one computer to initiate IKE to a responder typically times out and deletes the stateful inbound filter in the firewall. As a result, IKE cannot rekey IPSec security associations, and IPSec connectivity is lost.

**IPSec NAT-T**
In Windows 2000 and Windows XP, if traffic between the client and a server must pass through a network address translator (NAT), then IPSec cannot secure the traffic (the IKE negotiation will fail when translated by a NAT). Windows Server 2003 provides support for version 2 of a new IETF Internet draft called IPSec NAT-T. IPSec NAT-T allows IPSec ESP packets in either transport mode or tunnel mode to pass through NATs that allow UDP traffic. In this design, IKE automatically detects NATs and uses UDP-ESP encapsulation on UDP port 4500 to enable traffic to pass through a network address translator. The Windows Server 2003 implementation of IPSec NAT-T also supports PMTU discovery for UDP-ESP encapsulation. This new functionality allows you to secure servers running Windows Server 2003, when clients are behind a network address translator. IPSec NAT-T does not support the use of AH across network address translators.

If you are using IPSec NAT-T to secure a server, it is recommended that you do not create UDP port 4500 filters in the IPSec policy that is assigned to the server. The IPSec driver recognizes UDP port 4500 traffic and detects the associated UDP-ESP quick mode SA. However, if you are using firewalls or filtering routers to filter traffic for the IPSec-secured server, then you must configure the firewalls or filtering routers to permit the UDP-ESP traffic.

To configure firewalls or filtering routers to permit traffic on UDP source and destination port 4500, use the following settings to create a filter called "Permit IPSec NAT-T ISAKMP traffic on UDP port 4500":

- Source address = *SpecificIPAddress*
- Destination address = *SpecificIPAddress*
- Protocol = UDP
- Source port = **Any** or **4500** (The network address translator might translate source port 4500 to a different source port)
- Destination port = 4500

On computers that are running Windows 2000 or Windows XP, you can install an update package that allows L2TP/IPSec clients that are behind network address translators to use IPSec NAT-T. The NAT-T functionality provided in this update package meets the specifications of IIETF RFC 3193, "Securing L2TP using IPSec," and version 2 of the "UDP Encapsulation of IPSec Packets" and "Negotiation of NAT-Traversal in the IKE" Internet drafts and is compatible with Windows Server 2003 IPSec NAT-T. However, using IPSec in general transport mode for NAT-T is not supported on computers running Windows XP or Windows 2000, even when this update is installed, because PMTU discovery is not provided by UDP-ESP traffic. For more information about the IPSec update package for Windows 2000 and Windows XP, see article 818043, "L2TP/IPSec NAT-T Update for Windows XP and Windows 2000," in the Microsoft Knowledge Base.

**Related Information**
The following RFCs and Internet Drafts are relevant to IPSec. To find the RFCs, type the appropriate RFC number in the IETF RFC Database. To find the Internet Drafts, type the appropriate keyword in the IETF Internet Drafts Database.

- RFC 2401: Security Architecture for the Internet Protocol
- RFC 2402: IP Authentication Header
- RFC 2406: IP Encapsulating Security Payload (ESP)
- RFC 2408: Internet Security Association and Key Management Protocol (ISAKMP)
- RFC 2409: The Internet Key Exchange (IKE)
- UDP Encapsulation of IPSec Packets (draft-ietf-ipsec-udp-encaps-02.txt)

Negotiation of NAT-Traversal in the IKE (draft-ietf-ipsec-nat-t-ike-02.txt)

# IPSec Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPSec Tools and Settings**

**In this section**

- IPSec Tools
- IPSec Registry Entries
- Related Information

Use the following Internet Protocol security (IPSec) tools and registry setting to enable, configure, and manage IPSec on a computer running the Microsoft Windows Server 2003 operating system.

**IPSec Tools**

To manage IPSec policy in Windows Server 2003, you use three tools: the IP Security Policy Management snap-in, the Netsh IPSec context, and the Resultant Set of Policy (RSoP) snap-in. To monitor IPSec performance, you use the IP Security Monitor snap-in. If you need additional troubleshooting functionality, you can use audit logging and detailed IKE logging in Event Viewer and Network Monitor.

As the following table shows, several of the tools that you used to create and manage IPSec policies in previous versions of the Microsoft Windows operating system have been changed, replaced, or are no longer available in Windows Server 2003.

**IPSec Tool Changes in Windows Server 2003**

| Tool | Where It Was Previously Available | Changes in Windows Server 2003 |
|---|---|---|
| IPSeccmd | Support Tools folder of the Microsoft Windows XP operating system CD | Not included in Windows Server 2003. Use the Netsh IPSec context instead. |
| IPSecmon.exe | Microsoft Windows 2000 | Replaced by the new IP Security Monitor snap-in. |
| IPSecpol.exe | *Microsoft Windows 2000 Server Resource Kit* | Not included in Windows Server 2003. |
| Netdiag.exe | Support Tools folder of the Windows Server 2003 operating system CD | No longer includes IPSec functionality. Use the Netsh IPSec context instead. |

Despite these changes, you can share IPSec policies created on computers running the Windows XP, Windows 2000, and Windows Server 2003 operating systems among any of those operating systems.

**IP Security Policy Management Snap-In**

**Category**

The IP Security Policy Management snap-in is included in Windows Server 2003.

**Version compatibility**

The IP Security Policy Management snap-in is available with the Microsoft Windows XP, Windows 2000 Server, and Windows Server 2003 operating systems.

To create and manage IPSec policy, you primarily use the IP Security Policy Management snap-in that is available in the Microsoft Management Console (MMC). You can use IP Security Policy Management to create, modify, and store local IPSec policies or IPSec policies based on the Active Directory directory service. Additionally, you can use IP Security Policy Management to modify IPSec policy on remote computers.

To manage local IPSec policy, you can use either IP Security Policy Management or the command line, depending on your deployment needs. It is recommended that you use IP Security Policy Management to manage IPSec policy for Active Directory-based IPSec policy,

You use different methods to access IP Security Policy Management, depending on whether the IPSec policy is Active Directory-based or local.

To access Active Directory-based IPSec policy, do either of the following on the computer from which you want to manage policy:

- Start IP Security Policy Management from the appropriate organizational unit (OU) in Active Directory (Group Policy).
- Add IP Security Policy Management for Active Directory-based IPSec policy to MMC.

To access local IPSec policy for a computer, do any of the following on the computer for which you want to manage policy:

- Start IP Security Policy Management from Local Security Policy.
- Add IP Security Policy Management for local IPSec policy to MMC.
- Add Group Policy Object Editor for local IPSec policy to MMC.

To create an IPSec policy, a user or process must be logged on to the computer as a member of the Domain Admins group or the local Administrators group or must be running with local system privileges.

For more information about Group Policy settings, see "Group Policy Settings Reference for Windows Server 2003" in the Tools and Settings Collection.

**Resultant Set of Policy (RSoP) Snap-In**
**Category**
RSoP is included as part of the operating system.

**Version compatibility**
Logging mode is available on Windows XP and later operating systems. Planning mode requires that you have a Windows Server 2003 computer as a domain controller.

To view IPSec policy assignments for a computer or for members of a Group Policy container, use the RSoP addition to Group Policy. You can use information about IPSec policy assignments to troubleshoot policy precedence issues and to plan your deployment.

To view IPSec policy assignments in RSoP, you must first open the RSoP MMC console, and then run a query. RSoP provides two types of queries: logging mode queries (for viewing IPSec policy assignments for a computer) and planning mode queries (for viewing IPSec policy assignments for members of a Group Policy container).

For more information about RSoP, see “How Core Group Policy Works” in Core Group Policy Technical Reference.

**Logging mode queries**
To view all of the IPSec policies that are assigned to an IPSec client, you run an RSoP logging mode query. When you run a logging mode query, RSoP retrieves policy information from the Windows Management Instrumentation (WMI) repository on the target computer, and then displays this information in the RSoP console. In this way, RSoP provides a view of the policy settings that are being applied to a computer at a given time.

The query results show the precedence of each IPSec policy assignment, so that you can quickly determine which IPSec policies are assigned but are not being applied and which IPSec policy is being applied. The RSoP console also displays detailed settings (the filter rules, filter actions, authentication methods, tunnel endpoints, and connection type) for the IPSec policy that is being applied.

**Planning mode queries**
To view all of the IPSec policies that are assigned to members of a Group Policy container, you run an RSoP planning mode query. A planning mode query can be useful if, for example, you are planning a company reorganization and you want to move computers from one OU to a new OU. By supplying the appropriate information and then running a planning mode query, you can determine which IPSec policies are assigned but are not being applied to the new OU and which IPSec policy is being applied. In this way, you can identify which policy would be applied if you were to move the computers to the new OU. As with logging mode queries, when you run a planning mode query, the RSoP console displays detailed policy settings for the IPSec policy that is being applied.

When you run a planning mode query, RSoP retrieves the names of the target user, computer, and domain controller from the WMI repository on the domain controller. WMI then uses the Group Policy Data Access Service (GPDAS) to create the policy settings that would be applied to the target computer, based on the RSoP query settings that you entered. RSoP reads the policy settings from the WMI repository on the domain controller, and then displays this information in the RSoP console user

interface.

**IP Security Monitor Snap-In**
**Category**
IP Security Monitor is part of the operating system.

**Version compatibility**
In Windows 2000, IP Security Monitor was implemented as an executable program (IPSecmon.exe). In Windows XP and Windows Server 2003, IP Security Monitor is implemented as an MMC console. In Windows Server 2003, IP Security Monitor includes enhancements that allow you to:

- Monitor IPSec information for your local computer and for remote computers.
- View details —, including the policy name, description, date last modified, store, path, OU, and Group Policy object name — about active IPSec policies.
- View main mode and quick mode generic filters and specific filters.
- View main mode and quick mode statistics.
- Customize refresh rates and use Domain Name System (DNS) name resolution for filter and security association output.
- Search for specific main mode or quick mode filters that match any source or destination IP address, a source or destination IP address on your local computer, or a specific source or destination IP address.

**Netsh.exe: Netsh**
**Category**
Netsh is a command-line tool.

**Version compatibility**
Although you can use netsh commands with both Windows 2000 Server and Windows Server 2003, specific IPSec-related capabilities were added in Windows Server 2003.

The Netsh commands for IPSec provide a fully equivalent alternative to the console-based management and diagnostic capabilities provided by the IP Security Policy Management and IP Security Monitor consoles. You can use Netsh commands for IPSec to script IPSec policy creation, display details about IPSec policies, and change the IPSec configuration for troubleshooting. In addition, administering IPSec from the command line is useful when you want to extend the security and manageability of IPSec. For example, you can use Netsh commands for IPSec to enable IPSec driver event logging, set default traffic exemptions, and configure computer startup security.

For more information about using Netsh IPSec, see the "Command-Line Reference" in the Tools and Settings Collection.

**Eventvwr.msc: Audit Logging in Event Viewer**
**Category**
Event Viewer is part of the operating system.

**Version compatibility**
Event Viewer is available with Windows XP, Windows 2000 Server, and Windows Server 2003.

You can view the success or failure of Internet Key Exchange (IKE) negotiations in the Event Viewer security log. To view these events, enable success or failure auditing for the **Audit logon events** audit policy for your domain or local computer.

To disable audit logging, see "DisableIKEAudits" in IPSec Registry Entries.

**Eventvwr.msc: Detailed IKE Logging in Event Viewer**
**Category**
Event Viewer is part of the operating system.

**Version compatibility**
Event Viewer is available with Windows XP, Windows 2000 Server, and Windows Server 2003.

Enabling audit logging for IKE events and viewing the events in Event Viewer is the fastest and simplest way to troubleshoot failed main mode or quick mode negotiations. However, some scenarios might require a more detailed analysis of the IKE main mode negotiation and quick mode negotiations for troubleshooting. If the audit failure events do not provide enough information, you can enable tracing for IKE negotiations. The IKE tracing log is a very detailed log intended for troubleshooting

IKE interoperability under controlled circumstances. Expert knowledge of the Internet Security Association and Key Management Protocol (ISAKMP) RFC 2408 and IKE RFC 2409 is required to interpret this log.

The IKE tracing log appears as the *systemroot*\Debug\Oakley.log file. The log has a fixed size of 50,000 lines and will overwrite as necessary. Each time the IPSec service is started, a new Oakley.log file is created and the previous version of the Oakley.log file is saved as Oakley.log.sav. When the Oakley.log file becomes full, it is saved as Oakley.log.bak, and a new Oakley.log file is created.

Many IKE negotiations can occur simultaneously. Therefore, to capture a more easily interpreted log, minimize the number of negotiations and log for as short a period of time as possible.

In Windows Server 2003, you can enable or disable the IKE tracing log dynamically while the IPSec service is running. You do this by using Netsh IPSec. For more information about how to enable or disable the IKE tracing log, see "Command-Line Reference" in the Tools and Settings Collection.

**Netmon.exe: Network Monitor**
**Category**
Network Monitor is available in Microsoft Systems Management Server or with Windows 2000 Server and Windows Server 2003.

**Version compatibility**
You can use Network Monitor to capture and view packets in Windows XP, Windows 2000, or Windows Server 2003.

To view IPSec and other network communication, you can install and use Network Monitor.

### Note

- You can use the version of Network Monitor that is provided with Windows Server 2003 to view only the network traffic that is sent to or from the computer on which Network Monitor is installed. To view network traffic that is sent to or from another computer and is routed through your computer (using the Routing and Remote Access service), you must use the version of Network Monitor that is provided with Systems Management Server.

The version of Network Monitor that is provided with Windows Server 2003 includes parsers for the ISAKMP (IKE), Authentication Header (AH), and Encapsulating Security Payload (ESP) protocols. The Network Monitor parsers for ESP can parse inside the ESP packet only if null-encryption is being used and the full ESP packet is captured. Network Monitor cannot parse the encrypted portions of IPSec-secured ESP traffic when encryption is performed in software. However, if encryption is performed by an IPSec hardware offload network adapter, the ESP packets are decrypted when Network Monitor captures them and, as a result, they can be parsed and interpreted into the upper-layer protocols. If you need to diagnose ESP software-encrypted communication, you must disable ESP encryption and use ESP-null encryption by changing the IPSec policy on both computers.

**IPSec Registry Entries**
In Windows Server 2003, you can use the Netsh IPSec command-line tool to perform many of the tasks that you might have performed previously by modifying the registry.

When you enable success or failure auditing for the **Audit logon events** audit policy, IPSec records the success or failure of each main mode and quick mode negotiation and the establishment and termination of each negotiation as separate events. Keep in mind, however, that enabling this type of auditing can cause the security log to fill with IKE events. In Windows 2000, you cannot disable auditing of IKE events. In Windows Server 2003, however, you can disable auditing of IKE events by modifying the registry.

The following information is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows Server 2003 tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**DisableIKEAudits**
**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Lsa\Audit\

**Version compatibility**
Windows Server 2003

When you enable success or failure auditing for the **Audit logon events** audit policy, IPSec records the success or failure of each main mode and quick mode negotiation and the establishment and termination of each negotiation as separate events. However, enabling this type of auditing can cause the security log to fill with IKE events. For example, for servers that are connected to the Internet, attacks on the IKE protocol can fill the security log with IKE events. IKE events can also fill the security log for servers that use IPSec to secure traffic to many clients. To avoid this, you can disable auditing for IKE events in the security log by modifying the registry.

To disable auditing of IKE events in the security log, you must first create the **DisableIKEAudits** key and set the registry setting to a value of **1**.After making this change to the registry, you must either restart the computer or stop and then restart the IPSec service by running the **net stop policyagent** and **net start policyagent** commands at the command prompt.

**Note**

- Stopping and restarting the IPSec service can disconnect all of the computers that are using IPSec from the computer on which the service is stopped and it can prevent further communication with that computer. If you restart the IPSec service immediately, the retransmit behavior of TCP might cause the TCP-based communication to resume after new IKE and IPSec Security Associations (SAs) are established.

For more information about this registry entry, see the "Registry Reference for Windows Server 2003" in the Tools and Settings Collection.

**Related Information**

The following resources contain additional information that is relevant to this section.

# PKI Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**PKI Technologies**

Organizations need enhanced security for data and strong credentials for identity management. You can use certificates to secure data and manage identification credentials from users and computers both within and outside your organization.

A public key infrastructure (PKI) is the combination of software, encryption technologies, processes, and services that enable an organization to secure its communications and business transactions. The ability of a PKI to secure communications and business transactions is based on the exchange of digital certificates between authenticated users and trusted resources.

You can design a PKI solution to meet the following security and technical requirements of your organization:

- **Confidentiality.** You use a PKI to encrypt data that is stored or transmitted.
- **Integrity.** You use a PKI to digitally sign data. A digital signature helps you identify whether another user or process modified the data.
- **Authenticity.** A PKI provides several authenticity mechanisms. Authentication data passes through hash algorithms, such as Shivest Hash Algorithm 1 (SHA1), to produce a message digest. The message digest is then digitally signed by using the sender's private key to prove that the message digest was produced by the sender.
- **Nonrepudiation.** When data is digitally signed, the digital signature provides proof of the integrity of the signed data and proof of the origin of the data. A third party can verify the integrity and origin of the data at any time. This verification cannot be refuted by the owner of the certificate that digitally signed the data.

**PKI Technologies Architecture**

The architecture of a PKI involves implementing various interdependent technologies and processes to make it possible to issue, validate, renew, and revoke certificates. These technologies include:

- One of more servers running Certificate Services and that provide certificate enrollment, revocation and other certificate management services.
- Active Directory directory service or another directory service that provides account management, policy distribution, and certificate publication services.
- Domain controllers that can authenticate end users and computers when they request certificates.
- Domain client computers and users, who request, receive, and use certificates for specific purposes. Although certificates can also be used by services and by non-domain clients, in most Windows PKI environments, domain users and computers are the primary recipients and users of certificates. In some cases, the domain client can be a subordinate CA that requests and receives a certificate authorizing it to issue certificates of its own.

The following figure illustrates the architecture of PKI technologies.

**PKI Technologies Architecture**

**PKI Technologies Components**

The key technology components of a PKI and their relation to the PKI architecture diagram are described in the following table.

**Components of a PKI**

| Components | Description |
|---|---|
| Certificates | Provide the foundation of a PKI. Digital certificates are electronic credentials that are associated with a public key and a private key that an organization uses to authenticate users. Certificates are created on servers running Certificate Services and stored on clients and in a directory such as Active Directory. |
| Certificate templates | Can be used to define the content and purpose of a digital certificate, including issuance requirements; implemented extensions, such as application policy or extended key usage; and enrollment permissions for certificates that a CA issues. Certificate templates are stored in the Active Directory and used by enterprise CAs to provide the default attributes for a certificate. |
| Certificate Services | The part of the core operating system that allows a business to act as its own CA, and issue and manage digital certificates. Certificate Services includes tools to manage issued certificates, publish CA certificates and CRLs, configure CAs, import and export certificates and keys, and recover archived private keys. |
| CAs | Servers on which Certificate Services has been configured to issue, validate, and manage certificates. Windows Server 2003 supports multiple levels of a CA hierarchy and a cross-certified trust network. This includes offline and online CAs. |
| Certificate Revocation Lists | List of certificates that a CA considers no longer usable. Certificates have a specified lifetime, but CAs can reduce this lifetime by a process known as certificate revocation. Publishers can use any kind of directory service, including X.500, Lightweight Directory Access Protocol (LDAP), or directories in a specific operating system, including Active Directory, to store CRLs. Publishers can also publish CRLs on Web servers. |
| Certificate policy and practice statements | The two documents that outline how a CA and its certificates are to be used, the degree of trust that can be placed in these certificates, legal liabilities if the trust is broken, and so on. These documents can also define or impact PKI designs, operations, and usage, including how a CA is configured, how client requests are processed, and guidelines and procedures for revoking certificates. |
| Certificate policies | Configurable limitations on the scope of a certificate. Certificate policies can be implemented as required and allowed certification path length, the range of namespaces that are permitted or excluded by a qualified subordinate CA, the extent to which an organization trusts the identity presented in a certificate, and the applications that can be used in conjunction with certain certificates. |
| Certificate and CRL repositories | A directory service or other location where certificates are stored and published. In a Windows Server 2003 domain environment, the Active Directory is the most likely publication point for certificates issued by Windows Server 2003–based CAs. |
| PKI-enabled applications | Examples of PKI-enabled applications include: Encrypting File System (EFS), Microsoft Internet Explorer, Microsoft Money, Internet Information Services (IIS), Routing and Remote Access, Microsoft Outlook, and Microsoft Outlook Express. Also included are a variety of third-party applications that work with Windows 2000 and Windows Server 2003 Certificate Services. |

**PKI Technologies Scenarios**

A PKI consists of one or more CAs that play specific roles. One or more CAs of each type can be combined in a CA hierarchy.

**Roles in a CA Hierarchy**

Each CA in a CA hierarchy is assigned a role, which is determined by the CA's location in the CA hierarchy. Common roles in a

CA hierarchy include a root CA, a policy CA, and an issuing CA.

**Root CAs**
A root CA is the highest CA in a CA hierarchy and is the trust point for all certificates that are issued by the CAs in the CA hierarchy. If a user, computer, or service trusts a root CA, they implicitly trust all certificates that are issued by all other CAs in the CA hierarchy.

A root CA is different from all other CAs in that it issues its own certificate. This means that the Issuer and Subject fields of the certificate contain the same distinguished name. A root CA only issues certificates to other CAs that are directly subordinate to it.

**Policy CAs**
A policy CA is typically located on the second-tier of a CA hierarchy, directly beneath the root CA. In this scenario, the root CA is often referred to as a parent CA, because the root CA issued a Subordinate Certification Authority certificate to the policy CA. In fact, any CA that issues a certificate to another CA is referred to as a parent CA. The CA that receives the certificate from a parent CA is known as a subordinate CA.

The role of a policy CA is to describe the policies and procedures that an organization implements to secure its PKI, the processes that validate the identity of certificate holders, and the processes that enforce the procedures that manage certificates. A policy CA issues certificates only to other CAs. The CAs that receive these certificates must uphold and enforce the policies that the policy CA defined.

It is not mandatory to use policy CAs unless different divisions, sectors, or locations of your organization require different issuance policies and procedures. However, if your organization requires different issuance policies and procedures, you must add policy CAs to the hierarchy to define each unique policy. For example, an organization can implement one policy CA for all certificates that it issues internally to employees and another policy CA for all certificates that it issues to non-employees.

**Issuing CAs**
An issuing CA is typically located on the lowest tier of a CA hierarchy. An issuing CA issues certificates to other computers, users, network devices, services, or other issuing CAs. An issuing CA is always online.

The parent CA for an issuing CA can be a root CA, a policy CA or another issuing CA. The issuing CA must enforce the policies and procedures that are described in the policy CA above the issuing CA in the CA hierarchy.

**Types of CA Hierarchies**
You can use one of two CA models: a root hierarchy or a cross-certification trust. Windows Server 2003 networks recognize and support both models.

**Root Hierarchies**
In a root CA hierarchy, all of the CAs in the organization's CA hierarchy are chained to a common root CA. The following figure illustrates a root CA hierarchy.

**Root CA Hierarchy**

A root CA hierarchy:

- Enhances security and scalability. It protects the upper layers of the CA hierarchy from network attacks by removing the upper layers of the CA hierarchy from the network.

- Provides flexible administration to the CA hierarchy. You can use role separation to delegate CA management to separate administration groups in an organization.

- Supports commercial CAs.All commercial CAs — such as VeriSign, GTE, Thawte, and RSA — implement trusted root CA hierarchies.

- Supports most applications.Applications such as Microsoft Internet Explorer and Netscape Communicator support certificates that root CA hierarchies issue, as do IIS and Apache Web servers.

**Cross-Certification Trusts**

In a cross-certification trust, a CA in one organization's root CA hierarchy issues a subordinate CA certificate to a CA in another organization's CA hierarchy. The following figure illustrates a cross-certification hierarchy.

**Cross-Certification Trust**

A cross-certification trust:

- Provides interoperability between businesses and between products. When cross-certification is implemented, the certificates are logically chained to the trusted root CA of the organization that is evaluating the presented certificate.

- Joins disparate PKI domains. You can issue a Cross Certification Authority certificate from any CA in your organization's hierarchy to any CA in a partner organization's CA hierarchy.

- Assumes complete trust of a foreign CA hierarchy. Cross-certification does not enforce any constraints on the certificates that a partner organization issues. You must implement qualified subordination to implement constraints on those certificates.

# CA Certificates Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Certification authority (CA) certificates are certificates issued by a CA to itself or to a second CA for the purpose of creating a defined relationship between the two CAs. A certificate that is issued by a CA to itself is referred to as a trusted root certificate because it is intended to establish a point of ultimate trust for a CA hierarchy. Once the trusted root has been established, it can be used to authorize subordinate CAs to issue certificates on its behalf. Although the relationship between CAs is most commonly hierarchical, CA certificates can also be used to establish trust relationships between CAs in two different public key infrastructure (PKI) hierarchies. In all of these cases, the CA certificate is critical to defining the certificate path and usage restrictions for all end entity certificates issued for use in the PKI.

**In this subject**

- How CA Certificates Work
- CA Certificates Tools and Settings

# What Are CA Certificates?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Certification authority (CA) certificates are certificates that are issued by a CA to itself or to a second CA for the purpose of creating a defined relationship between the two CAs.

A certificate that is issued by a CA to itself is referred to as a trusted root certificate, because it is intended to establish a point of ultimate trust for a CA hierarchy.

Once the trusted root has been established, it can be used to authorize subordinate CAs to issue certificates on its behalf.

Although the relationship between CAs is most commonly hierarchical, CA certificates can also be used to establish trust relationships between CAs in two different public key infrastructure (PKI) hierarchies.

In all of these cases, the CA certificate is critical to defining the certificate path and usage restrictions for all end entity certificates issued for use in the PKI.

**Problems Solved by CA Certificates**

When an end entity uses a certificate, a trust relationship must be verified between the end entity certificate and the root CA. This trust relationship between a root CA and an end entity certificate is verified by validating the contents of all of the certificates in the certificate chain up to the root CA.

The guidelines and procedures that have been established for the PKI define the trust. This includes the ability of end entity certificates to be used for certain purposes and prevented from being used for other purposes. These guidelines and procedures are implemented in a number of ways. For example, the trust and the security of the PKI can be established in two ways:

- The steps taken to ensure the physical security of the server that hosts the CA.
- The manner in which administrative roles for the CA are delegated.

However, the appropriate configuration of CA certificates for the organization's needs is one of the most powerful tools that an organization has to implement appropriate PKI security.. CA certificates contain special configuration data that regulate the CAs to which they are issued. These configuration options can:

- Define the organizational namespace in which certificates issued by the subordinate CA can be issued and trusted.
- Specify the acceptable uses of certificates issued by the subordinate CA.
- Define the issuance guidelines that must be followed in order for a certificate issued by the subordinate CA to be considered valid.
- Create a managed trust between separate certification hierarchies.

**Core CA Certificate Use Scenarios**

Trust and acceptable use are integrally connected: How much you trust a certificate should help you decide whether it is acceptable for a predetermined use at a specific time in a specific location.

This is the most basic security and business principle in PKI deployment: you must create defined trust relationships within an enterprise.. Once this is done, you can use defined trusts to enable certificate types of connections while limiting others. For example, they can:

- Prevent certificates from being used with unintended applications.
- Apply consistent certificate issuance policies.
- Apply consistent name formatting in issued certificates.

- Prevent the implementation of unauthorized subordinate CAs.

The following are some of the trust scenarios that can be enabled by properly configured CA certificates:

- Simple trust within an enterprise PKI
- Cross trust between two enterprise CAs (restricted)
- Bridge trust for multiple enterprise PKIs (unrestricted)
- Certificate trust continuity when the certificate policy changes

**Simple Trust Within an Enterprise**

Simple trusts between CAs in a single PKI are the most common type of certificate trust relationships. They impose clear hierarchical roles and relationships between the root CA, intermediate policy CAs, the CAs that issue end entity certificates (if any), and the end-entity certificates themselves.

The following diagram illustrates a simple PKI trust hierarchy in a single organization.

**Cross Trust Between Two CAs**

Cross trust between two CAs allows an organization to extend a simple PKI trust hierarchy to secondary PKI trust hierarchies within the same organization or within other organizations. You can implement cross trust by using special CA certificates called *cross certificates* and a strategy called *qualified subordination*. Qualified subordination allows you to place certificate issuance constraints on subordinate CAs and to place usage constraints on the certificates they issue. With qualified subordination, you can focus subordinate CAs according to specific certification needs and administer your public key infrastructure (PKI) more efficiently. With qualified subordination, each CA in a cross trust relationship can define and implement rules that do the following:

- Define the namespaces for which your PKI hierarchy will issue and accept trusted certificates
- Specify the acceptable uses of certificates issued by a cross-certified subordinate CA
- Define what issuance practices must be followed for a certificate issued by the qualified subordinate CA to be considered valid.

For example, suppose that, due to a merger, Organization 1 wants to share certain certificate-protected resources with users in the engineering department of Organization 2. They can accomplish this by creating a cross trust with a specific CA in Organization 2, but limit the locations and applications in organization 1 for which Organization 2's certificates can be used.

These cross CA trusts are one-directional. If Organization 2 wants to grant Organization 1 certificate users privileges within Organization 2, they must establish a separate cross trust in order to enable this certificate use.

The following figure illustrates one typical cross CA trust relationship. There are two-way trust relationships between the CAs in both Organization 1 and Organization 2, but trust between the two organizations is managed using two separate one-way trusts, so that each organization can determine the degree and type of trust it wants to share with the other organization.

Cross certificates restrict the certificates that are acceptable to your organization. They can be issued by either the qualified subordinate CA or by CAs that chain through the qualified subordinate CA,. The configuration options that you apply in the cross certificates between the two organizations allow you to:

- Limit trust to all CAs in your organization
- Limit trust to specific CAs in your organization.
- Restrict the name space available to certificate holders from the other organization
- Add new CAs to an existing CA hierarchy
- Apply application policy that defines the purposes for which certificates issued by a subordinate CA can be used
- Apply policy constraints
- Map CA policy in one organization to CA policy in another organization
- Create trust between two organizations
- Create trust between multiple organizations

**CA Certificate Dependencies and Interactions**

A number of factors can impact interoperability between a Windows Server 2003 CA and the CAs of other organizations. The interoperability of Windows Server 2003 PKIs with non-Microsoft PKIs is dependent on how the following features and standards are implemented in both PKIs:

- Standards support
- Algorithm and key length support
- CRL distribution points
- Authority information access (AIA)
- Authority key identifier (AKI)
- Certificate extensions
- Extended key usage (EKU)
- Directory integration

You must determine whether the other PKIs with which you need to establish trust support these features and standards, and how you can accommodate differences.

**Standards Support**

A number of technical standards provide a basis for interoperability between Windows Server 2003 and other PKI applications. To promote non-Microsoft interoperability with the Windows Server 2003 application programming interface (API), Microsoft

supports the following standards:

- **Public Key Infrastructure for X.509 Certificates (PKIX)**. Defines interoperable PKI standards for the Internet.
- **X.509**. Describes the standard format of a certificate.
- **Public-Key Cryptography System (PKCS)**. Provides a standard for public key message exchanges.
- **Transport Layer Security (TLS)**. Provides a secure and authenticated channel between hosts on the Internet above the transport layer.
- **Secure/Multipurpose Mail Extensions (S/MIME)**. Serves as a standard for secure e-mail across the Internet.
- **Kerberos authentication protocol**. Provides a symmetric key framework for authentication in large networks.
- **Personal Computer/Smart Card (PC/SC)**. Serves as a standard for integrating smart cards and smart card readers.

Most PKI vendors have adopted many or all of these PKI standards. Different vendors, however, can implement the standards in different ways. While it might be possible to link external PKI implementations to yours, this might involve making some changes to your existing design. For this reason, it is strongly recommended that you evaluate the external PKI to determine whether it meets all your critical requirements.

**Hardware Support**

Windows Server 2003 uses CryptoAPI to abstract hardware-based key management from applications, and it uses the PC/SC standard instead of PKCS #11 to communicate with smart cards and readers. Many non-Microsoft CAs have their own cryptographic APIs and use PKCS #11 to interface to hardware tokens such as smart cards. Because the Windows 2000 and Windows Server 2003 operating systems require hardware devices to support Plug and Play and power management features, and PC/SC includes support for these ease-of-use features, Windows Server 2003 does not support PKCS #11.

### Note

- The Windows Server 2003 PKI can use non-Microsoft cryptographic service providers (CSPs), and can enroll users for certificates that have keys that were generated by non-Microsoft CSPs.

**Algorithm and Key Length Support**

Windows 2000 and Windows Server 2003 support several well-known cryptographic algorithms that are also supported by other PKI products. Key length, in turn, is determined in part by the cryptographic algorithm that you select. When you install a Windows Server 2003 CA, you can select CA key lengths from 384 bits to 16,384 bits, depending on the CSP that you select. In a typical deployment, user certificates have 1,024-bit keys and root CAs have 4,096-bit keys.

In general, the lengths of public and private keys do not impact interoperability, as long as both environments support a common range of key lengths. If one PKI supports large public keys and another does not, however, the two cannot exchange symmetric keys or sign and verify data.

### Note

- While key exchange and digital signature operations performed between PKIs do not require the same public and private key lengths, symmetric key algorithms do. In addition, if different key lengths are used, both key lengths must be supported in both environments.

When PKIs do not support the same key lengths, some applications cannot decrypt data that other applications have encrypted. In addition, the PKIs might not be able to establish secure communications channels between applications if the applications cannot agree on symmetric key lengths, as required by protocols such as Secure Sockets Layer (SSL) and TLS.

If a PKI uses public key cryptography based on an algorithm such as RSA, all PKI operations can be accomplished with only one key pair. However, single key pairs might not meet the security requirements of your organization or its choice of algorithm. For this reason, Windows Server 2003 supports both single key pairs and dual key pairs. A good PKI is flexible enough to allow as many or as few key pairs as are required by applications.

If one PKI operates according to the number of keys that applications use, it can impact interoperability with other PKIs. For

example, an e-mail application could sign a message with a signature-only key and include the associated certificate in a message sent to a recipient without also sending an encryption certificate as part of the message. The recipient might then be unable to discover the encryption certificate of the sender to reply with an encrypted message back to the sender.

**CRL Distribution Points**
With certificate revocation lists (CRLs), the optional CRL distribution point (CDP) extension in a certificate identifies how revocation information for the certificate can be obtained. If a CRL distribution point is not always available, certificate chain building can be delayed, causing inconvenience for the user. If a CRL is not available at the distribution point that has been specified in the certificate, CRL retrieval might even fail and the certificate will be considered invalid.

You need to compare any non-Microsoft CRL support with the Windows Server 2003 CRL support. For example, the non-Microsoft PKIs might not support the Windows Server 2003 CRL process, which includes the use of delta CRLs. Conversely, the Windows Server 2003 PKI might not support the methods of the non-Microsoft PKI for processing CRL information. Also, a few non-Microsoft PKIs support partitioned CRLs, which most PKIs, including Windows Server 2003 PKIs, do not support.

**Authority Information Access**
The Authority Information Access (AIA) extension is a pointer to the most currently published CA parent certificate of a CA. The Windows Server 2003 PKI uses this extension to assist in building trust chains to validate client certificates.

Some non-Microsoft PKIs do not provide the AIA extension. In this case, parent certificates must be distributed to domain clients so that the certificates are available before the chain building process begins. Cross certificates must also be available locally on domain clients, because there is no information in a certificate that specifies where it can be found.

**Authority Key Identifier**
The Authority Key Identifier (AKI) extension provides a means to identify the public key of the CA that validates the signature on a CRL. This identification is based on either the subject key identifier (SKI) or the issuer name and serial number from the certificate that is issued by the CRL issuer. The AKI extension is useful in cases when a CRL issuer has more than one signing key.

An organization that expects its PKI certificates to be used by other Windows Server 2003 PKIs must populate the Authority Key Identifier extension with a unique key identifier and an issuer name and serial number. The Windows Server 2003 PKI attempts to construct certificate chains by using the issuer name and serial number in the AKI first, and then the subject key identifier.

**Certificate Extensions**
Not all certificate extensions are universally recognized. If a CA does not recognize a certificate extension in a request and it has been marked critical, it rejects the certificate. Unless you intend to limit the use of the certificate to a specific application that understands the critical extension, avoid putting critical extensions in certificates because it limits interoperability.

**Extended Key Usage**
The Extended Key Usage (EKU) extension indicates the purposes for which the public key that is contained in the certificate can be used. The Windows Server 2003 PKI uses the EKU extension to indicate certificates that support special functions, such as Internet protocol security (IPSec) and encrypting file system (EFS) file encryption backup. The EKU extensions of other organizations may be used for different purposes.

**Directory Integration**
Windows Server 2003 PKI certificates can be published to any directory or repository, although the default CA exit module only supports Active Directory. However, by default, a Windows Server 2003 PKI relies on Active Directory and LDAP for authentication, including smart card logons and certificate autoenrollment, as well as for certificate management.

With Microsoft Certificate Services, certificates issued by a non-Microsoft CA can be associated with a Windows Server 2003 user account stored in Active Directory. This is possible because applications such as Internet Explorer and Internet Information Services (IIS) can be used to authenticate a user to an account stored in Active Directory, based on the user principal name (UPN) information in a certificate.

The account to which the certificate maps provides information about user access rights on the server. This is an extremely powerful feature for Web-based applications and non-Microsoft CAs because it combines strong authentication by means of public key technology with the native authorization model of Windows Server 2003. For example, to enable extranet and remote access scenarios without requiring the application and certificate to manage access rights, administrators can use certificates from partner companies and map them to accounts in Active Directory by means of one-to-one or many-to-one mappings.

# How CA Certificates Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Certification authority (CA) certificates are certificates that are issued by one CA to another CA. These CA certificates become a part of the certificate trust hierarchy, the certificate path from end-entity certificates to the trusted root CA certificate.

The first CA certificate issued in a public key infrastructure (PKI) is a root certificate, issued by a CA to itself. Once a root CA has been created, it can be used to issue, sign, and validate CA certificates that are issued to other CAs.

Most commonly, root CAs are used to issue CA certificates to subordinate CAs in a PKI hierarchy. These subordinate CAs, in turn, can issue their own CA or end-entity certificates.

However, CA certificates can also be used to establish trust between two or more PKI hierarchies. CA certificate-based trust relationships can connect PKIs in one organization, in two organizations, or spanning multiple organizations.

Because of their critical role in establishing trust between CAs and in the certificate validation process, CA certificates are extremely powerful and critical elements of an organization's security strategy. For this reason, CA certificates are typically configured with a variety of policy constraints to strictly define their acceptable use and to prevent their unacceptable use.

The information in the CA Certificates Technical Reference is interrelated with the information in the Certificate Services Technical Reference. The information in these two Technical Reference documents should be taken together to gain a full understanding of how Certificate Services can be implemented in Microsoft Windows 2000 and Windows Server 2003 environments.

**Ideal Environment for CA Certificates**
In a PKI, trust is established when a valid certification path can be traced from an end-entity certificate to an issuing CA and ending with a trusted root certificate. Trust in CA certificates is established by carefully defining and controlling:

- Where and how certificates can be used.
- The applications that can be configured to use certificates.
- Requirements that must be met before a certificate is issued.
- Acceptable formats for subject names in certificates.
- Equivalence between certificate policies in multiple organizations.

For more information about the mechanisms that are available to define and configure CA certificate restrictions, see the following section, "CA Certificate Architecture."

**CA Certificate Architecture**
In many ways, the architecture of CA certificates is identical to the architecture of end-entity certificates. However, CA certificates also have some unique features.

**CA Certificate Shared Features**
All certificates that are issued in Windows Server 2003 and earlier PKIs are structured to comply with standards established by the Public-Key Infrastructure (X.509) Working Group (PKIX) of the Internet Engineering Tasks Force (IETF). The following figure shows the contents of X.509 version 3 certificates, as implemented in Windows Server 2003.

**Structure of an X.509 Certificate**

X.509 version 3 certificates are the current certificate format in a Windows Server 2003 PKI. Version 3 certificates support the following fields that have been supported since X.509 version 1:

- **Subject.** Provides the name of the computer, user, network device, or service that the CA issues the certificate to. The subject name is commonly represented by using an X.500 or Lightweight Directory Access Protocol (LDAP) format.

- **Serial Number.** Provides a unique identifier for each certificate that a CA issues.

- **Issuer.** Provides a distinguished name for the CA that issued the certificate. The issuer name is commonly represented by using an X.500 or LDAP format. For a root CA, the Issuer and Subject are identical. For all other CA certificates and for end entity certificates, the Subject and Issuer will be different.

- **Valid From.** Provides the date and time when the certificate becomes valid.

- **Valid To.** Provides the date and time when the certificate is no longer considered valid.

  **Note**

  - The date when an application or service evaluates the certificate must fall between the Valid From and Valid To fields of the certificate for the certificate to be considered valid.

- **Public Key.** Contains the public key of the key pair that is associated with the certificate.

  In addition to the fields defined in X.509 version 1, X.509 version 3 certificates include optional fields or extensions that provide additional functionality and features to the certificate. These extensions are not necessarily included in each certificate that a CA issues:

- **Subject alternative name.** A subject can be presented in many different formats. For example, if the certificate must include a user's account name in the format of an LDAP distinguished name, e-mail name, and a user principal name (UPN), you can include the e-mail name or UPN in a certificate by adding a subject alternative name extension that includes these additional name formats. Subject alternative name is only used in end entity certificates, not in CA certificates.

- **Basic constraints.** This X509 version 3 extension is used to distinguish between end-entity certificates and CA certificates. There are still some PKI clients today that do not recognize basic constraints, which can make it possible for an end-entity to act as a CA. Windows Server 2003 and Windows 2000 operating systems honor basic constraints in accordance with Internet Engineering Task Force (IETF) Request for Comments (RFC) 2459 and will reject CA certificates that do not contain this extension.

- **Name constraints.** This extension restricts the namespaces that are permitted or excluded by a qualified subordinate CA and its subordinates when issuing certificates.

- **Policies.** Defines the list of acceptable issuance and application policies for certificate usage. These policies are identified in the certificate by object identifiers (also known as OIDs).

- **Policy mapping.** Allows a policy from one domain to be mapped onto a policy of another domain.

- **Policy constraints.** Restricts the subordination levels in a certificate hierarchy to which a policy is applied. These extensions are used in conjunction with issuance and application policies only.

- **Application policy.** Defines which applications can be used in conjunction with certain certificates.

- **Application policy mapping**. Identifies equivalence between the application policies of two organizations that cross certify by using certificate application policies.

- **Cross certificate distribution points. I**dentifies where cross certificates related to a particular certificate can be obtained and how often the cross certificates at that location are updated.

- **CRL distribution points (CDP).** Provides one or more URLs where the application or service can retrieve a certificate revocation list (CRL) from. Used when an application or service must determine whether a certificate has been revoked before its validity period has expired.

- **Authority Information Access (AIA).** Provides one or more URLs from where an application or service can retrieve the issuing CA certificate. Used to validate the certificate of the CA that issued the certificate — also referred to as the parent CA — for revocation and validity.

- **Enhanced Key Usage (EKU).** Defines which applications can be used in conjunction with certain certificates. Because some implementations of public key infrastructure (PKI) applications might not understand application policies, both application policies and enhanced key usage sections appear in certificates issued by a Microsoft CA

Many of these extensions are configured using the Certification Authority snap-in, Certreq.exe, and Certutil.exe, which are described in the CA Certificate Tools section. They are also discussed in greater detail in the Certificate Services Technical Reference. Other extensions can be configured by creating CAPolicy.inf and Poliy.inf files that must be installed on a CA as part of the CA setup and renewal process. These extensions and their configuration options are discussed in greater detail in the following section.

#### CA Certificate Extensions

Many people assume that simply accepting the default configuration options presented by the Setup user interface when configuring a new root CA or a subordinate CA automatically provides a degree of security appropriate for their requirements. In fact, few organizations have identical security requirements.

The CA setup routines only present a portion of the security options that can be used to configure new root and subordinate CAs. Many end-entity certificate configuration options can be included in certificate requests. However, many of the most important configuration constraints must exist on the server hosting the CA before the CA is installed or renewed. These CA-based certificate constraints make it possible to address a variety of security needs and concerns. These CA certificate-based constraint extensions are configured using two files, CAPolicy.inf for root CAs and Policy.inf for subordinate CAs.

**Note**

- Some of these extensions can also be configured using the command line tools Certutil.exe and Certreq.exe. For a complete understanding of the capabilities of Certutil and Certreq, see the Windows Server 2003 Help.

The following section will describe all the options available in these two files so that you can create CAPolicy.inf and Policy.inf files tailored to your specific needs.

#### Overview of CAPolicy.inf and Policy.inf

A CAPolicy.inf file is a configuration file that defines the extensions, constraints, and other configuration settings that are applied to a root CA certificate and all certificates issued by the root CA. The CAPolicy.inf file must be installed on a host server before the setup routine for the root CA begins. When the security restrictions on a root CA are to be modified, the root certificate must be renewed and an updated CAPolicy.inf file must be installed on the server before the renewal process begins.

A Policy.inf file is a configuration file that defines the constraints that are applied to a subordinate CA certificate and all certificates issued by the subordinate CA. The constraints can include basic constraints, name constraints, application policies, and certificate policies. If a subordinate CA is being used to issue cross certificates connecting two different PKIs, these restrictions serve an essential role in ensuring that the cross certification process does not detract from security.

CAPolicy.inf and Policy.inf files:

- Are created and defined manually by an administrator.

- Are utilized during the creation of root and subordinate CA certificates.

- Are defined on the signing CA where you sign and issue the certificate, not the CA where the request is generated.

There are, however, important differences between CAPolicy.inf and Policy.inf files. For example, CAPolicy.inf files must be placed in the *Systemroot* folder before installation begins. Policy.inf, on the other hand, can exist in any folder on the requesting computer. In addition, the Policy.inf file can use any file name, as long as the syntax is correct.

CAPolicy.inf and Policy.inf files make it possible to specify and configure a wide variety of CA attributes and options. This makes it very difficult to define a default template that administrators should use for all purposes. Therefore, the following section will describe all the options in order to enable you to create an .inf file tailored to your specific needs.

The following terms are used to describe the .inf file structure:

- A *section* is an area in the .inf file that covers a logical group of keys. Section names in .inf files are identified by appearing in brackets. Many, but not all, sections in an .inf file are used to configure certificate extensions.
- A *key* is the name of an entry. It appears to the left of the equal sign.
- A *value* is the parameter. It appears to the right of the equal sign.

In the following example, [RequestAttributes] is the section, AttributeName1 is the key, and AttributeValue1 is the value:

```
[RequestAttributes]
AttributeName1 = AttributeValue1
```

The following table describes the possible sections of CAPolicy.inf and Policy.inf files. It is followed by a more detailed discussion of the configuration options that can be configured using each section of these files.

| **Section** | **Explanation** | **Applies to** |
|---|---|---|
| [Version] | Identifies the file as an .inf file. | Setup and renewal of root and subordinate CAs |
| [RequestAttributes] | Defines the certificate template to use when creating new certificates. | Setup and renewal of root and subordinate CAs |
| [NameConstraintsExtension] | Defines the permitted and excluded namespaces for certificates issued by a subordinate CA. | Setup and renewal of root and subordinate CAs |
| [PolicyExtension] | Lists user-defined policies | Setup and renewal of root and subordinate CAs |
| [Policy MappingsExtension] | List of user-defined policy mappings. | Setup and renewal of root and subordinate CAs |
| [PolicyConstraintsExtension] | Specifies the depth of the CA hierarchy that requires and inhibits policy mapping. | Setup and renewal of root and subordinate CAs |
| [ApplicationPolicyExtension] | Defines the applications or services a certificate can be used for. An alternate to the Enhanced Key Usage extension | Setup and renewal of root and subordinate CAs |
| [ApplicationPolicyMappingsExtension] | Lists user-defined application policy mappings. | Setup and renewal of root and subordinate CAs |
| [ApplicationPolicyConstraintsExtension] | Defines the depth of the CA hierarchy that requires and inhibits policy mapping. | Root and subordinate CAs |
| [BasicConstraintsExtension] | Sets the maximum subordinate CA path length | Root and subordinate CAs |
| [CrossCertificateDistributionPointsExtension] | Identifies where cross certificates related to a particular certificate can be obtained and how often that location is updated. | Primarily on subordinate CAs that are used to issue cross certificates. |
| [EnhancedKeyUsageExtension] | Defines the applications or services a certificate can be used for. | An alternate to the Application Policy extension |
| [AuthorityInformationAccess] | Specifies the authority information access points . | Initial setup and renewal of a root CA |
| [CRLDistributionPoints} | Used to specify CRL distribution points (CDPs) | Initial setup and renewal of a root CA |
| [certsrv_server] | Used to specify renewal key length, the renewal validity period, and the certificate revocation list (CRL) validity period | New CA setup and CA renewal. |

| | | |
|---|---|---|
| [NewRequest] | Used .inf files that serve as templates for new certificate requests. | New CA setup and CA renewal. |
| [RequestAttribute] | Used in conjunction with [NewRequest] to define additional attributes associated with template-based certificate requests. | New CA setup and CA renewal. |

The policy constraint options that you use, and where you choose to implement them, depends on your unique requirements.

**Note**

- The use of each policy option can be configured as mandatory (Critical = True, Critical=Yes, or Critical=0) or optional (Critical = False, Critical=No, Critical=1). If an extension is marked as critical and the validating computer cannot parse the extension, it must reject the certificate chain. These values are not case sensitive.

**Version**

The version section identifies the file as an .inf file.

If present, Version must contain the Signature key. The Signature key must be equal to the fixed string "$Windows NT$"

```
Signature= "$Windows NT$"
```

**Request Attributes**

Request attributes are used to pass significant name and value pairs to the policy module of a CA. Any pairs of significant can be passed to a policy module, including pairs that are of use to a customer policy module developed specifically for an organization. For example, request attributes can be used to specify the certificate template to use when creating a new certificate, such as:

```
CertificateTemplate = CrossCA
```

In addition, it can also be used to predefine attributes and values associated with any new certificate, in the format:

```
AttributeName1 = AttributeValue1
AttributeName2 = AttributeValue2
```

**Name Constraints**

Name Constraints is an optional extension that allows organizations to designate which namespaces are either permitted or excluded for certificates issued by a subordinate CA. When you create a new CA, you can define name constraints for the CA by configuring CAPolicy.inf. These name constraints apply to all certificates that are issued in the PKI. Similarly, when you create a Cross Certification Authority certificate, you define name constraints in the Policy.inf file to apply to all certificates issued in the second PKI that will be considered valid in your PKI hierarchy.

**Note**

- Name constraint validation is performed on the CA, not on the client. However, your clients must run Windows XP or Windows Server 2003 in order to use name constraints.

When a CA that is configured with name constraints receives a request, it compares the names present in the subject and the subject alternate name fields of the request to the configured name constraints, to determine whether the namespace is permitted or excluded.

The following table includes examples of permitted and excluded name constraint settings.

| Element | Description | Sample Values |
|---|---|---|
| NameConstraints<br><br>Excluded Name Constraints Extension | Identifies whether permitted name types and excluded name types have been configured. | Include = NameConstraintsPermitted<br><br>Exclude = NameConstraintsExcluded |

| | | |
|---|---|---|
| [NameConstraintsPermitted] | List of user-defined permitted name formats. | DNS = .corp.contoso.com<br><br>email = @contoso.com<br><br>email = @exchange.contoso.com<br><br>UPN = .corp.contoso.com<br><br>UPN = @corp.contoso.com<br><br>DIRECTORYNAME = "DC=com, DC=Contoso, DC=Corp"<br><br>DIRECTORYNAME = "C=US, S=WA, L=Redmond, O=Contoso"<br><br>DIRECTORYNAME = "O=Contoso, OU=NorthAmerica" |
| [NameConstraintsExcluded] | List of user defined excluded name types | DNS = .development.contoso.com<br><br>email = @development.contoso.com<br><br>UPN = .development.contoso.com<br><br>UPN = @development.contoso.com<br><br>DIRECTORYNAME = "DC=com, DC=Contoso, DC=Development"<br><br>DIRECTORYNAME = "C=US, O=Contoso, OU=Development" |

Before deploying a PKI, organizations need to decide which individual clients and business units are able to enroll for and use certain certificates.

For many organizations, the selected users, computers, and services are members of specific Active Directory domains and subdomains.

Name constraints can be based on any of the following types of name formats:

- X.500 directory name
- DNS domain name
- Universal Resource Identifier (URI)
- E-mail and user principal name
- Internet protocol (IP) address

Additional name constraint forms may be enforced using the Other Name forms, which are identified by name and object identifier that are encoded with UTF8 or ASN.1. Other Names forms can be used to represent names that are outside of the standard name types, such as Rfc822Name, DNS, or X.500 Directory Name. Other Names consist of an object identifier and a binary large object. The most common Other Name is the Universal Principal Name (UPN), which has the constant OID_NT_PRINCIPAL_NAME as the object identifier. The version 2 "Directory E-mail Replication" template certificates and the Version 1 "Domain controller" certificates have a subjectaltname extension that contains the constant OID_NTDS_REPLICATION as other name type and the globally-unique identifier (GUID) representation of the domain controller as the binary large object. In Windows 2000, only the UPN was present in the other name constraint. However, in Windows Server 2003 operating systems, the other name constraint has been expanded to support even the domain controller GUIDs. The following is the syntax where the first part is the object identifier, followed by a qualifier identifying the encoding of the following data as UTF8, octet, or ASN.1:

```
OtherName=1.2.3.4.99.100,{utf8}ssss
OtherName=1.2.3.4.99.101,{octet}ABCD
OtherName=1.2.3.4.99.102,"{asn}BAgAAQIDBAUGBw=="
OtherName=1.3.6.1.4.1.311.25.1
```

One scenario where this might be useful is when you have cross-forest smartcard logon, wherein the other domain has Windows 2000 domain controllers. In this case, you can provide an additional name constraint as "OtherName=1.3.6.1.4.1.311.25.1" to allow all Domain E-Mail Replication certificates and restrict the namespace using the DNS name constraint. It is technically possible to restrict the GUID of a domain controller as another name but that would not be a generic constraint but a specific constraint to only one domain controller.

**Relative Distinguished Name Constraints**

Relative distinguished names are used to identify the names of objects stored in directories, such as Active Directory or X.500 directories.

Using relative distinguished name constraints allows you to restrict a qualified subordinate CA to issue certificates only to specific users or computers in Active Directory by using the object's relative distinguished name. The distinguished name can be very specific, where the permitted or excluded relative distinguished name refers to a specific object, or the distinguished name can be a wildcard value that references all the objects within a specific container, domain, or organizational unit.

The name constraint must be included in either the Policy.inf file used to create a qualified subordinate CA or in the CAPolicy.inf file used when installing a new subordinate CA. The following table shows some examples of LDAP name constraints and defines what objects the constraints refer to.

| Relative Distinguished Name Constraint | Includes |
|---|---|
| DC=example,DC=contoso,DC=com | All objects in the example.contoso.com domain |
| CN=Users,DC=example,DC=Contoso,DC=com | All objects in the Users container in the example.contoso.com domain |
| CN=Brian Komar,CN=Users,DC=contoso,DC=com | The user object Brian Komar in the Users container in the contoso.com domain |
| OU=Marketing,DC=Contoso,DC=Com | All objects in the Marketing organizational unit (OU) of the Contoso.com domain |
| CN=Servers,CN=Sites,CN=Configuration,DC=Contoso,DC=Com | All domain controllers in the contoso.com forest |
| OU=Domain Controllers, DC=Tacoma,DC=Contoso,DC=Com | All domain controllers in the tacoma.contoso.com domain. |

The range of characters in the allowed name constraint is defined by the relative distinguished name type. Most relative distinguished names (such as O=, OU=,CN=, and so on) support international (UTF8) characters, where relative distinguished names that include (DC=,C=,email, and so on) support on IA5 character types. A relative name constraint will appear in either the permitted or excluded name constraints using the following format:

```
DIRECTORYNAME = "DC=NWtraders, DC=com"
```

**DNS Name Constraints**

You can apply the DNS namespaces that your network uses for name resolution as name constraints for a qualified subordinate CA. When the qualified subordinate CA receives a certificate request, it compares the DNS name that is associated with the computer requesting the certificate to its DNS name constraints and decides whether or not to issue a certificate.

DNS name constraints compare any DNS names that are contained in certificate requests to the list of permitted and excluded DNS name constraints. As with LDAP distinguished name constraints, the name in the certificate request must match one of the permitted names for the certificate to be issued.

The DNS domain names that are accepted by the subordinate CA must follow the standard DNS naming conventions as specified in RFCs 1034 and 1035, and are listed in either the Policy.inf or CAPolicy.inf file used. Therefore, the DNS name constraint cannot contain international character sets. For more information about RFCs 1034 and 1035 see the entries in the IETF RFC Database.

When configuring a DNS name constraint, you can either designate a specific DNS host name, for example, host.example.contoso.com, or you can designate a DNS namespace. For example, the DNS name constraint .example.contoso.com indicates all hosts that have a DNS name that ends with example.contoso.com. The preceding period (.) indicates that any DNS name that ends with example.contoso.com matches the name constraint.

**Note**

- This does not include a host that does not have a period preceding example.contoso.com. For example, the host named ourexample.contoso.com would not result in a match when compared to the name constraint .example.contoso.com.

The following table demonstrates the results for submitted DNS names against configured DNS name constraints.

| Submitted DNS Name | DNS Name Constraint | Evaluation |
|---|---|---|
| www.example.contoso.com | .example.contoso.com | Match |
| www.south.example.contoso.com | .example.contoso.com | Match |
| example.contoso.com | .example.contoso.com | No Match |
| Ourexample.contoso.com | example.contoso.com | No Match |
| www.example.contoso.com | example.contoso.com | Match |

**Uniform Resource Identifier Constraints**

Uniform Resource Identifiers (URIs) are used to identify resources on the Internet by means of identifiers such as URL, FTP, HTTP, telnet,

mailto, news, and gopher. URLs in CAPolicy.inf should use the replaceable parameter syntax that also appears in the **Extensions** tab of the Certification Authority snap-in. If you don't use the replaceable parameter syntax, then CDP and AIA extensions in renewed CA root certificates might point to the same location that was specified in the previous CA root certificate.

When validating the URI names in a certificate request, the qualified subordinate CA ignores the protocol element in the URI, such as http:// or ftp://, and uses only the domain or host names.

The URI naming conventions supported for name constraints must follow the syntax specified in RFC 2396. For more information about name constraints, see RFC 2396 in the IETF RFC Database.

When a qualified subordinate CA validates a URI name, it ignores the protocol element in the URI. For example, if the submitted URI is http://www.example.contoso.com and the URI name constraint is URL=ftp://.example.contoso.com, the actual comparison performed is between the host name www.example.contoso.com and the name constraint .example.contoso.com. In this case, the result would be a match, even though the protocols differ.

As with DNS constraints, a URI constraint can reference either a host or a domain. If a preceding period is included in the URI constraint, the domain name must include the entire suffix defined in the name constraint. For example, if the URI constraint is .example.contoso.com, then matches are achieved for west.example.contoso.com and for east.example.contoso.com.

The most frequent application of URI name constraints is the validation of certificate requests for Web Server certificates, where the Web servers URL is submitted in the certificate request. For example, if the Web Server certificate request has a name of http://www.contoso.com and the qualified subordinate CAs permitted URI name constraint is URL=http://www.contoso.com, then this URI constraint would permit the certificate request for the Web Server certificate.

A URI name constraint will appear in either the permitted or excluded name constraints using the following format:

```
URL = "http://.contoso.com"
```

**RFC 822, E-mail, and UPN Constraints**

You can specify RFC 822, e-mail and UPN name constraints for an individual subject, such as person@example.contoso.com, or you can specify constraints for all subjects whose e-mail names or UPNs end in a specific name, such as @example.contoso.com. Typically, you need to specify e-mail or UPN name constraints for all subjects whose e-mail addresses and UPNs end in a specific name.

RFC 822 and e-mail constraints must follow RFC 822 naming conventions and use IA5 encoding of character strings. User Principal Names (UPNs) use the same syntax but are encoded using UTF8. Although RFC 822 names, UPNs, and e-mail addresses share the same syntax, you must provide separate examples in the name constraints listing of Policy.inf to differentiate between requests using e-mail addresses and requests using UPN names.

The following table shows some examples of RFC 822, e-mail, and UPN constraints and how they are evaluated.

| Submitted Address | UPN/E-Mail Constraint | Evaluation |
|---|---|---|
| jsmith@nwtraders.com | jsmith@nwtraders.com | Match |
| bjsmith@nwtraders.com | jsmith@nwtraders.com | Match |
| jsmith@nwtraders.com | @nwtraders.com | Match |
| jbsmith@nwtraders.com | bjsmith@nwtraders.com | No Match |

**Note**

- UPN name constraints should always be entered as two separate entries in the list of name constraints. One entry should include the at sign (@, such as in @nwtraders.com); the second entry should replace the at sign with a period (.), so this entry would be .nwtraders.com. This format allows for the possibility of having a UPN of subdomain.nwtraders.contoso.

**IP Address Constraints**

IP address constraints allow you to specify either specific IP addresses or ranges of IP addresses that a CA can successfully receive certificates from a qualified subordinate CA. The format of the IP addresses in the constraints must follow either RFC 791 (for IPv4 addresses) or RFC 2460.

When a certificate request is received by a qualified subordinate CA, the source IP address in the certificate request is compared to the IP address constraints to determine if the IP address is permitted or excluded by the name constraints.

To specify a range of IP addresses, you must specify both the IP address and associated subnet mask in each constraint. For example, if you wanted to create an IP address constraint for the 192.168.3.0 network, the constraint would be 192.168.3.0/255.255.255.0.

An IP address constraint will appear in either the permitted or excluded name constraints using the following format:

```
IPADDRESS = 192.168.3.0/255.255.255.0
IPADDRESS = 192.168.2.254/255.255.255.255
IPADDRESS = 172.16.8.0/255.255.248.0
```

The first constraint includes all computers in the 192.168.3.0 network. The second constraint is a host-specific constraint that only includes the host with IP address 192.168.2.254. The final constraint is a Classless Internet Domain Routing (CIDR) example that includes all hosts with addresses between 172.16.8.1 and 172.16.15.254.

Name constraints can be configured to result in the following outcomes:

- **Permitted.** The certificate request contains all names that are listed as permitted in the CA name constraints extension of the issuer.
- **Not permitted.** The certificate request contains a name that is not listed as permitted in the name constraints extension of the issuer.
- **Excluded.** The certificate request contains a name that is listed as excluded in the name constraints extension of the issuer.

When name constraints are added to a CA certificate, the following rules are applied to the subject name and alternate subject name fields:

- **Excluded namespaces take precedence over permitted namespaces.** A qualified subordinate CA will not issue a certificate to a user within an excluded namespace even if the user is also within a permitted namespace. For example, a user might be within the permitted Active Directory namespace **.xyz.com** but also within the excluded DNS namespace **.uvw.xyz.com**. The excluded DNS namespace overrides the permitted Active Directory namespace and the certificate request of the user fails.
- **If the name constraints extension exists in a CA certificate, all name constraints must be present in the appropriate format.** Any name formats that are not included are considered to be wildcards that match all possibilities. For example, if the DNS name constraint is absent, the entry is treated as DNS="".

  **Note**

  - You can disable this requirement by modifying the following registry setting: **HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\SystemCertificates\Root\ProtectedRoots** . For more information, see "CA Certificate Tools and Settings."
- **All name constraints are considered, even if they are not specified.** No precedence is applied to the listed name constraints. For this reason, name constraints that are not present are treated as wildcards. For example if you only restrict the DNS name space, the Name Constraints extension sets the remaining name constraints to allow all name spaces.
- **Name constraints are applied to the Subject Name extension and any existing Subject Alternate Name extensions.** For example, if a user can be identified by a DNS domain name and an alternate e-mail name, name constraints apply to both.
- **Name constraints apply to all names contained in a certificate request.** Each name in the subject or subject alternate name extensions must match at least one of the name constraints listed for that name type. A certificate request that includes a subject name or subject alternate name that does not match a listed name type is rejected.
- **Name constraints are not case sensitive.** The comparison is not case-sensitive if the name or part of the name is encoded with an IA5 string. If it is encoded as a Unicode or UTF8 string, the comparison will be a binary match of the content.
- **A qualified subordinate CA's name constraints cannot permit names excluded by its parent CA.** For example, if the parent CA excludes the DNS name .contoso.com, then its qualified subordinate CA cannot permit the DNS sub-domain .example.contoso.com.
- **Constraints apply only when the namespace types specified as name constraints are present in the certificate request.** If no namespace of the specified types is in the certificate request, the certificate is acceptable. For example, a CA is configured with the following name constraints:

```
[NameConstraintsExtension]
Include = NameConstraintsPermitted
Exclude = NameConstraintsExcluded

[NameConstraintsPermitted]
DirectoryName = "DC=Contoso, DC=Com"
email = @contoso.com
UPN = .contoso.com
UPN = @contoso.com

[NameConstraintsExcluded]
```

In this configuration, if the CA receives a request with the e-mail name of user1@northwindtraders.com, the request would be rejected.

Likewise, the request would be rejected if the subject alternate name contained user1@northwindtraders.com while the subject name contained CN=user1,OU=Contractors,DC=Contoso,DC=Com. Remember that all subject names must match the name constraints for a certificate to be issued. The default policy as mentioned previously requires all names to be defined unless otherwise configured on the certification authority.

**Note**

- If you do not specify permitted or excluded names, you are creating a wildcard (*) name constraint for those name constraint formats.

When the name constraint processing is completed, the validation process will result in one of the following outcomes:

- **Permitted.** The end certificate contains a name that is listed as permitted in an issuer's name constraints extension.
- **Not permitted**. The end certificate contains a name that is not listed as permitted in an issuers name constraints extension.
- **Excluded**. The end certificate contains a name that is listed as excluded in an issuer's name constraints extension.
- **Not Defined**. The issuer certificate does not list a constraint for a specific name type, such as Directory Name or IP Address.

**Note**

- Windows Server 2003 CAs will have constraints set to permit all namespaces for a particular name type, unless specified otherwise in the name constraints extension in the Policy.inf

**Policy**

You can use issuance policies to define the extent to which your organization trusts the identity presented in a certificate. For example, you can set an issuance policy stipulating that you only trust certificates that were issued during a face-to-face meeting with a network administrator, such as when a smart card certificate is issued.

**Note**

- *Issuance policy* is the Microsoft term for Certificate Policies defined in part 4.2.1.5 in RFC 2459 and is contained in the certificatePolicies extension of a certificate.

An object identifier must describe every issuance policy that you define. The inclusion of an issuance policy object identifier in an issued certificate indicates that the certificate was issued in a manner that meets the issuance requirements associated with the issuance policy object identifier.

**Note**

- Issuance policy is only available on Windows Server 2003 CAs. Windows 2000 does not provide issuance policy.

The following table includes examples of issuance policy settings.

| Element | Description | Sample Values |
|---|---|---|
| [PolicyStatementExtension] | Lists the policies that have been defined by the organization, and whether they are optional or mandatory | Policies = MediumAssurancePolicy, LowAssurancePolicy, RequireCertificatePolicy |

| | | |
|---|---|---|
| [MediumAssurancePolicy] | Requires that each policy that is included must be identified by an object identifier. In addition, a Notice or URL key can be included for each policy. | OID = 1.3.6.1.4.1.311.21.8.1308480216.1095248452.3429159812.3095816201.1472143667.3857372322<br><br>Notice = "Legal policy statement text" |
| [LowAssurancePolicy] | Requires that each policy that is included must be identified by an object identifier. In addition, a Notice or URL key can be included for each policy. | OID = 1.3.6.1.4.1.311.21.8.1308480216.1095248452.3429159812.3095816201.1585704526.3613270325<br><br>URL = "http://http.site.com/some where/default.asp"<br><br>URL = "ftp://ftp.site.com/some where else/default.asp"<br><br>Notice = "Limited use policy statement text."<br><br>URL = "ldap://ldap.site.com/some where else again/default.asp" |
| [RequireCertificatePolicy] | Requires that each policy that is included must be identified by an object identifier. In addition, a Notice or URL key can be included for each policy. | OID = 1.3.6.1.4.1.311.21.15<br><br>URL = http://extra.site.com/Extra Policy/default.asp<br><br>[oidpolicy]<br><br>OID = 1.3.6.1.4.1.311.21.55 |
| [LegalPolicy] | Requires that an organization's legal policy documents must be identified with at least one object identifier, and zero or more Notice and URL keys. Legal policy statements usually need to be identified in all certificates an organization issues or accepts. | OID = 1.3.6.1.4.1.311.21.43<br><br>Notice = "Legal policy statement text" |

| | | |
|---|---|---|
| [LimitedUsePolicy] | Used by many organizations to limit the allowed uses of certificates they issue or accept. These usage limitations can be identified with at least one object identifier and 0 or more Notice and URL keys. | OID = 1.3.6.1.4.1.311.21.47<br><br>URL = "http://http.site.com/some where/default.asp"<br><br>URL = "ftp://ftp.site.com/some where else/default.asp"<br><br>Notice = "Limited use policy statement text."<br><br>URL = "ldap://ldap.site.com/some where else again/default.asp" |
| [ExtraPolicy] | Used by organizations to define additional policies beyond legal and use restrictions. These can also be defined with at least one object identifier and 0 or more Notice and URL keys. | OID = 1.3.6.1.4.1.311.21.53<br><br>URL = http://extra.site.com/Extra Policy/default.asp |

You can use a specific certificate template to define one or more issuance policy object identifiers that need to be included in any certificates issued. Windows Server 2003 includes four predefined issuance policies:

- **All Issuance (2.5.29.32.0).** The all issuance policy indicates that the issuance policy contains all other issuance policies. Typically, this object identifier is only assigned to CA certificates. A root CA automatically implies that all issuance policies are defined.

  **Note**

  - The x.y.z portion of the object identifier in these examples is a randomly-generated numeric sequence that is unique for each Windows Server 2003 forest.

- **Low Assurance (1.3.6.1.4.1.311.21.8.** *x.y.z.* **1.400).** The low assurance object identifier represents certificates that are issued with no additional security requirements.

- **Medium Assurance (1.3.6.1.4.1.311.21.8** *.x.y.z.* **1.401).** The medium assurance object identifier represents certificates that have additional security requirements for issuance. For example, a smart card certificate that is issued in a face to face meeting with a smart card issuer might be considered a medium assurance certificate and contain the medium assurance object identifier.

- **High Assurance (1.3.6.1.4.1.311.21.8** *.x.y.z.* **1.402).** The high assurance object identifier represents certificates that are issued with the highest security. For example, the issuance of a key recovery agent certificate might require additional background checks and a digital signature from a designated approver, because a person holding this certificate can recover private key material from a Windows Server 2003, Enterprise Edition CA.

In addition, you can create your own object identifiers to represent custom issuance policies. For example, two organizations that are involved in a purchaser and seller relationship can define custom object identifiers to represent digital signature certificates for specific purchase amounts. In such a case, an object identifier can be defined for purchase between $100,000 and $500,000 and another object identifier can be defined for purchases greater than $500,000. Applications can then use these object identifiers to recognize whether a person had the appropriate signing authority for a specific volume purchase.

You can provide additional information about the issuance policies implemented at a CA by configuring policy qualifiers. Policy qualifiers

provide information directly, or provide links to information, that describe the purpose of the issuance policy. The following code shows both formats of the policy qualifier:

```
[LegalPolicy]
OID = 1.3.6.1.4.1.311.21.43
Notice = "Legal policy statement text"
URL = "http://www.example.contoso.com/policy/isspolicy.asp"
```

When viewing the certificate in an application, a person can follow the URL and read the description of the issuance policy in a Web browser. If a text message is used as a policy qualifier, the application will display the message.

It is recommended that URLs rather than notice text be implemented for certificate practice statements. This allows practice statements to be modified without having to re-issue the CA certificate. In addition, URLs do not dramatically increase the size of certificates compared to notice text.

**Policy Mappings**

You can use policy mappings to explicitly state the comparability of certificate policies in two PKI hierarchies. Policy mapping is commonly used to cross-certify two PKIs, such as between two organizations.

In many cases, the administrators of two PKIs define their own policies and object identifiers. In some cases, these policies are identical, but in most cases there are small differences between them. For example, one organization might stipulate that one physical form of identification is sufficient to grant a certificate request, while a second organization requires three forms of physical identification to grant a similar request. In these cases, you need to negotiate with the administrators of the other PKI to define terms of equivalence before the cross-certified relationship can be established. This is called policy mapping.

Policy mapping enables interoperability between two organizations that apply similar issuance and application policies, but have deployed different object identifiers.

The following table includes examples of policy mappings.

| Element | Description | Sample Values |
|---|---|---|
| [PolicyMappingsExtension] | Each entry maps one foreign policy object identifier to a local policy object identifier. | 1.3.6.1.4.1.311.21.53 = 1.2.3.4.87<br><br>1.3.6.1.4.1.311.21.54 = 1.2.3.4.89 |

The first object identifier is foreign, the second is local. If the policy object identifier (for example, 1.2.3.4) of one company represents a specific function, and the policy object identifier of another company (for example, 11.22.33.44) represents the same function, they can be mapped, so that 11.22.33.44 and 1.2.3.4 are interchangeable.

The qualified subordinate CA that contains this mapping is called the *issuer CA* and the subordinate CA whose policies have been mapped is called the *subject CA*. In mapping some or all of the policies of the subject CA to the policies of the issuer, the issuer CA effectively subordinates the subject CA. The result of this mapping is that users and computers in the issuer CA trust hierarchy can use their own certification paths to validate certificates from users and computers in the subject CA trust hierarchy. The separate trust hierarchy can be within the same intranet or in separate PKI environments over an extranet.

Policy mappings can be applied by:

- Identifying the trust hierarchies that are to be linked with a trust relationship.
- Establishing equivalence in the assurance levels that are used by the two trust hierarchies involved in the trust relationship.
- Obtaining the issuance and application policy object identifiers used in both trust hierarchies involved in the trust relationship.
- Mapping the issuance and application policy object identifiers in the separate trust hierarchies, and defining policy constraints in the CA certificate request for the qualified subordinate CA that you are installing in your trust hierarchy.
- Installing the qualified subordinate CA with the policies, policy mappings, and policy constraints in your trust hierarchy.

**Policy Constraints**

The policy constraints extension specifies the depth of the CA hierarchy that requires and inhibits policy mapping. Require policy constraints define the levels of a PKI hierarchy where foreign certificates with mapped policy can be used. Inhibit policy constraints specify the boundaries beyond which these certificates cannot be used.

The following table includes examples of policy constraints settings.

| Element | Description | Sample Values |
|---|---|---|
| [PolicyConstraintsExtension] | Specifies the depth of the CA hierarchy that requires policy mapping | RequirePolicyMapping = 3 |

| | | |
|---|---|---|
| | Specifies the depth of the CA hierarchy that inhibits policy mapping. | InhibitPolicyConstraints = 5 |

You can refine policy mapping by setting parameters for how the issuance policy defined in qualified subordination affects other CAs below the qualified subordinate CA. These parameters can help to limit unplanned trust relationships. The following two settings define this relationship:

- **Require explicit policy.** Specifies the number of certificates that can exist in the hierarchy below a certificate before an explicit policy must exist. For example, if the explicit policy is configured with a setting of 3, the defined issuance policy must exist for three layers of the hierarchy. The CA on which the qualified subordination is defined is the first level.

- **Inhibit policy mapping.** Specifies the number of additional certificates that can appear in the path before policy mapping is no longer permitted. For example, an inhibit policy mapping value of 3 restricts the policy mapping to only three levels of CAs below the qualified subordinate CA.

**Application Policy**

Certificates provide important information that is not specific to an application. However, you might need to define which applications can be used in conjunction with certain certificates. Application policy allows you to ensure that certificates are only used with the applications that you specify.

Application policies included in certificates allow applications to determine if a certificate can be used when authenticating a user, encrypting data, or signing a device driver. An application can be coded to only accept certificates that contain specific application policies. When the application receives signed information from a user, the application will review the certificate associated with the private key used to sign the information and verify that the certificate chain has the required object identifier as a valid application policy.

Each application policy has one object identifier, and can include Notice and URL keys, as in the examples in the following table.

| Element | Description | Sample Values |
|---|---|---|
| [ApplicationPolicyStatementExtension] | Specifies the application policies that apply to the specified certificates. | Policies = AppLegalPolicy, AppLimitedUsePolicy, AppExtraPolicy, AppOIDPolicy |
| [AppLegalPolicy] | Specifies specific legal requirements and implications of the certificate. The notice spells out these legal requirements and implications in terms understandable by the user. | OID = 1.3.6.1.4.1.311.21.54<br><br>Notice = "Application Legal policy statement text" |
| [AppLimitedUsePolicy] | Many certificates will be issued for restricted uses, such as for signing purchase orders up to a certain value. The sample URLs would provide explanatory text for these usage restrictions. | OID = 1.3.6.1.4.1.311.21.58<br><br>URL = "http://http.contoso.com/application some where/default.asp"<br><br>URL = "ftp://ftp.contoso.com/application some where else/default.asp"<br><br>Notice = "Application Limited use policy statement text."<br><br>URL = "ldap://ldap.contoso.com/application some where else again/default.asp" |
| [AppExtraPolicy] | Many certificates will be issued for restricted uses, such as for signing purchase orders up to a certain value. The sample URLs would provide explanatory text for these usage restrictions. | OID = 1.3.6.1.4.1.311.21.64<br><br>URL = http://extra.contoso.com/Application Extra Policy/default.asp |
| [Appoidpolicy] | An optional format to use for an application policy. | OID = 1.3.6.1.4.1.311.21.66 |

Application policy is Microsoft-specific and is treated much like Extended Key Usage. Because some implementations of PKI applications might not understand application policies, both application policies and enhanced key usage sections appear in certificates issued by a Microsoft CA.

If a certificate has an extension containing an application policy and also has an EKU extension, the EKU extension is ignored. If, however, a certificate has only an EKU extension, the EKU extension is treated like an application policy extension. If a certificate has an application policy extension and an EKU property, the effective policy for the certificate is the common policy between the EKU property object identifiers and the application policy object identifiers.

**Note**

- You can view all defined application policy object identifiers in the Certificate Templates console. To do this, in the console tree, right-click **Certificate Templates** and click **View Object Identifiers**.

After you define the object identifiers for your organization's certificate policies, obtain the complementary object identifiers from the partner organization. Obtain the partner's object identifiers because the object identifiers differ between the two organizations.

The following Application Policy object identifiers are recognized by Windows Server 2003.

- Server Authentication (1.3.6.1.5.5.7.3.1)
- Client Authentication (1.3.6.1.5.5.7.3.2)
- Code Signing (1.3.6.1.5.5.7.3.3)
- Secure E-mail (1.3.6.1.5.5.7.3.4)
- IP Security End System (1.3.6.1.5.5.7.3.5)
- IP Security Tunnel Endpoint (1.3.6.1.5.5.7.3.6)
- IP Security User (1.3.6.1.5.5.7.3.7)
- Time Stamping (1.3.6.1.5.5.7.3.8)
- IP Security IKE Intermediate (1.3.6.1.5.5.8.2.2)
- All Application Policies (1.3.6.1.4.1.311.10.12.1)
- Microsoft Trust List Signing (1.3.6.1.4.1.311.10.3.1)
- Qualified Subordination (1.3.6.1.4.1.311.10.3.10)
- Key Recovery (1.3.6.1.4.1.311.10.3.11)
- Document Signing (1.3.6.1.4.1.311.10.3.12)

**Note**

- A list of available object identifiers can be viewed in the **Certificate Templates** console. To do this, in the console tree, right-click **Certificate Templates** and click **View Object Identifiers**. Alternatively, custom application policy object identifiers can be defined and used in custom-developed applications.

**Application Policy Mappings**

When qualified subordination is configured between two CAs that use certificate application policies, you must map the object identifiers between the two organizations in the policy file that you create. Application policy mapping ensures that only authorized application policy object identifiers from a partner organization are allowed in certificates that the partner organization issues. Application policy mapping associates the partner organization's application policy object identifiers with application policy object identifiers that are defined in your organization's PKI.

The following example shows how application policy mappings are configured in CAPolicy.inf or a Policy.inf file. Each entry maps one foreign application policy object identifier to one local application policy object identifier. The first object identifier is foreign, the second is local.

| Element | Description | Sample Values |
|---|---|---|
| [ApplicationPolicyMappingsExtension] | List of user defined application policy mappings. | 1.3.6.1.4.1.311.21.64 = 1.2.3.4.98<br><br>1.3.6.1.4.1.311.21.65 = 1.2.3.4.100 |

**Application Policy Constraints**

The application policy constraints extension specifies the depth of the CA hierarchy that requires and inhibits policy mapping. Require application policy constraints define the levels of a PKI hierarchy where foreign certificates with mapped policy can be used. Inhibit application policy constraints specify the boundaries beyond which these certificates cannot be used.

Policy qualifiers are typically URLs that provide information directly or provide links to information that describe the purpose of the certificate policy. The following table shows examples of application policy constraints:

| Element | Description | Sample Values |
|---|---|---|
| [ApplicationPolicyConstraintsExtension] | Defines the depth of the CA hierarchy that requires application policy mapping | RequirePolicyMapping = 6 |
| | Defines the depth of the CA hierarchy that inhibits policy constraints | InhibitPolicyConstraints = 10 |

**Basic Constraints**

A basic constraint defines which CAs your organization trusts in a partner's CA hierarchy by limiting the path length for a certificate chain.

The following table shows examples of basic constraints:

| Element | Description | Sample Values |
|---|---|---|
| [BasicConstraintsExtension] | Defines the path limits for validating certificate chains. | PathLength = 3 |
| [EnhancedKeyUsageExtension] | | OID = 1.3.6.1.5.5.7.3.4 Secure E-mail<br>OID = 1.3.6.1.5.5.7.3.1 Server Authentication |

Basic constraints allow an application to determine whether a certificate is a CA certificate, which can then be used by the certificate chain engine to build certification paths, or an end-certificate, which cannot.

You can also use basic constraints to limit the maximum number of CA certificates that can be included in a CA path. For example, setting a path length of 0 in the basic constraints section of the CAPolicy.inf file allows only certificates issued by that specific CA to be included in the CA path. A path length of 2 allows only a total of three CA certificates in a certification path. In the latter case, any certification paths that include more than three CAs are discarded.

Use basic constraints if you do not want to trust additional CAs that are created lower in the CA hierarchy of your organization. You can also use basic constraints in cross-certified relationships if you trust your business partner and the certificates from all their existing CAs, but you do not want to trust certificates from any additional CAs that they authorize.

**Cross Certificate Distribution Points**

The cross certificate distribution point (CCDP) extension identifies where cross certificates related to a particular certificate can be obtained and how often that location is updated. Windows XP and later operating systems use this extension for the discovery of cross-certificates that might be used during the path discovery and chain building process.

**Note**

- The CCDP extension is unique to Windows CAs.

The following table shows examples of configuration options for cross certificate distribution point extensions.

| Element | Description | Sample Values |
|---|---|---|
| CrossCertDistPoints | One or more locations where the cross certificates related to a particular certificate can be found. | URL = http://%1/Public/My CA.crt<br>URL = ftp://contoso.com/Public/MyCA.crt<br>URL = file://\\%1\Public\My CA.crt |
| syncDeltaTime | An optional integer field that specifies the delta between when this location will be refreshed. If syncDeltaTime is present, CrossCertDistPointNames must also be present. | SyncDeltaTime = 24 |

This extension should be non-critical, but support for this extension by CAs and applications is recommended.

**Enhanced Key Usage**

Application policies are sometimes called *extended key usage* or *enhanced key usage*. Because some implementations of PKI applications might not understand application policies, both application policies and enhanced key usage sections appear in certificates issued by a Microsoft CA.

If a certificate has an extension containing an application policy and also has an EKU extension, the EKU extension is ignored. If, however, a certificate has only an EKU extension, the EKU extension is treated like an application policy extension. If a certificate has an application policy extension and an EKU property, the effective policy for the certificate is the common policy between the EKU property object identifiers and the application policy object identifiers.

This section can be used during CA setup or CA certificate renewal, but is only used if you are setting up a root CA or renewing a root CA certificate. The Enhanced Key Usage extension for a subordinate CA is determined by the CA which issued the subordinate CA's certificate. An example of this section is:

```
[EnhancedKeyUsage]
OID=1.2.3.4.5
OID=1.2.3.4.6
```

**Authority Information Access**
You can specify the authority information access points in CAPolicy.inf. This section is only used if you are setting up a root CA or renewing a root CA certificate. Subordinate CA authority information access extensions are determined by the CA which issued the subordinate CA's certificate. This section can be used during CA setup or CA certificate renewal.

Multiple URLs are supported. HTTP, FILE, FTP, and LDAP URLs are supported. If no URLs are specified (in other words, if the Authority Information Access section is empty), the default Authority Information Access extension will be suppressed.

The syntax is: `[AuthorityInformationAccess]URL="http://CompanyWebSite/Public/myCA.crl"`

**CRL Distribution Points**
You can specify CRL distribution points (CDPs) in CAPolicy.inf. Any CDP in CAPolicy.inf will take precedence for certificate verifiers over the CDP's specified in the CA policy module.

Some additional notes about the CRL section:

- Multiple URLs are supported.
- HTTP, file, FTP, and LDAP URLs are supported.
- This section can be used during CA setup or CA certificate renewal.
- This section is only used if you are setting up a root CA or renewing a root CA certificate. Subordinate CA CRL distribution point extensions are determined by the CA that issued the subordinate CA's certificate.
- URLs with spaces must be surrounded by quotes.
- If no URLs are specified (in other words, if the CRL Distribution Point section is empty), the default CRL Distribution Point extension will be suppressed.

If you want to specify the CDP using CAPolicy.inf, a sample of the syntax is:

```
[CRLDistributionPoint]
URL="http://CompanyWebSite/Public/myCA.crl"
```

Replacement tokens are used to retain the configuration of distribution points flexible. You can use replacement tokens in the CAPolicy.inf file and in the Certification Authority MMC in CA Extensions.

A replacement token consists of the percent sign and a number. This behavior occurs if you use replacement tokens in the Certificate Services MMC or if you use them in a Certutil.exe command. If replacement tokens are used in a batch file, and you use the percent sign (%), you must use another escape sign when needed, because the Windows shell typically interprets a percent sign as a command-line parameter.

The mapping of replacement tokens is different in versions of Windows later than Windows 2000 Server. You can use the following tokens for CRLDistributionPoint, AuthorityInformationAccess, and CrossCertificateDistributionPointsExtension URLs. The following table describes the replacement token options for Windows 2000 and Windows Server 2003.

| **Token name** | **Description** | **Windows 2000 map value** | **Windows Server 2003 map value** |
|---|---|---|---|
| ServerDNSName | The DNS name of the CA server | %1 | %1 |
| ServerShortName | The NetBIOS name of the CA server | %2 | %2 |
| CaName | The name of the CA | %3 | %3 |
| Cert_Suffix | The renewal extension of the CA | %4 | Not applicable. |
| CertificateName | | Not applicable. | %4 |
| Domain_Name | The location of the domain root in Active Directory | %5 | N/A |
| (Not used) | | N/A | %5 |
| ConfigurationContainer | The location of the configuration container in Active Directory | %6 | %6 |

| | | | |
|---|---|---|---|
| CATruncatedName | The "sanitized" name of the CA, 32 characters with a hash on the end | %7 | %7 |
| CRLNameSuffix | The renewal extension for the CRL | %8 | %8 |
| DeltaCRLAllowed | | | %9 |
| CDPObjectClass | | | %10 |
| CAObjectClass | | | %11 |

The Certification Server setup process replaces all %number% sequences with the appropriate value.

**certsrv_server**

Another section of CApolicy.inf that is not used frequently is [certsrv_server], which is used to specify renewal key length, the renewal validity period, and the certificate revocation list (CRL) validity period for a CA that is being renewed or installed.

Options that can be configured in this section include:

- **RenewalKeyLength**, which sets key size for renewal only. This is only used when CA renewal generates new keys.
- **RenewalValidityPeriod** and **RenewalValidityPeriodUnits**, which establish the lifetime of new root CA certificate when renewing the old CA certificate.
- **CRLPeriod** and **CRLPeriodUnits**, which establish the validity period for the full CRL, while **CRLDeltaPeriod** and **CRLDeltaPeriodUnits** establish the validity period for the delta CRL.
- **RenewalKeyLength**, **RenewalValidityPeriod** and **RenewalValidityPeriodUnits**, which are only processed when the CA is being renewed.
- **LoadDefaultTemplates**, which is not processed when the CA is a subordinate CA.

An example would be:

```
[certsrv_server]
RenewalKeyLength=2048
RenewalValidityPeriod=Years
RenewalValidityPeriodUnits=5
CRLPeriod=Days
CRLPeriodUnits=2
CRLDeltaPeriod=Hours
CRLDeltaPeriodUnits=4
```

**NewRequest**

The [NewRequest] section is mandatory for an .inf file that acts as a template for a new certificate request. If this section is missing, the following error message is displayed:

**INF file line not found 0xe0000102 (INF: -536870654)**

This section requires at least one key with a value. If this section is empty and has no keys, the following error message is displayed:

**Incorrect function. 0x1 (WIN32: 1)**

The following options can be associated with a new certificate request.

**EncipherOnly**

This parameter has an impact on the functional capabilities of the public-private key pair. If the value is set to **True**, the key can exclusively be used for encryption. If this is set to **False**, the key can be used for encryption and other purposes. This parameter refers only to the key type in CryptoAPI and has only an indirect relationship to the Key Usage extension that might be included in an issued x.509 certificate. The default value of the certificate enrollment control is set to False. This setting only affects AT_KEYEXCHANGE key types and then correspondingly limits the key usage to key encryption or data encryption. The digital signature and non-repudiation key usages will be disallowed.

| **Summary Information** | **Details** |
|---|---|
| Syntax | EncipherOnly={Boolean} |
| Values | **True** or **False** |
| Default value | **False** |
| Sample | EncipherOnly = True |

| | |
|---|---|
| Supported with CA type | Windows 2000<br>Windows Server 2003 |
| Can be manipulated in a pending request | Yes (through the key usage extension) |

**Exportable**

This parameter is ignored when the **UseExistingKeySet** key is set to **True** because you can set the exportable flag only when a new key is created. You cannot change this flag for an existing key. If this attribute is set to **True**, the private key can be exported together with the certificate. To ensure a high level of security, private keys should not be exportable, however in some cases it might be required to make the private key exportable if several computers or users must share the same private key. For example, a Web-server that runs Secure Sockets Layer (SSL) and is published with Microsoft Internet Security and Acceleration Server to the Internet requires a certificate with an exportable key, because the certificate and key must be installed on the Web-server and the computer running ISA Server as well. Also, if you want to manage and back up the keys, they must be exportable to provide for this functionality.

This setting correlates with the template configuration if a Windows Server 2003 enterprise CA is used. A certificate template administrator can explicitly define if private keys should be exportable or not. The template setting for exportable has no effect on the exportability properties of a key generated through the **certreq.exe -new** command.

| **Summary Information** | **Details** |
|---|---|
| Syntax | Exportable = {Boolean} |
| Values | **True** or **False** |
| Default value | **False** |
| Sample | Exportable = **True** |
| Supported with CA type | Windows 2000<br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**KeyContainer**

It is not recommended to set this parameter for new requests where new key material is generated. The key container is automatically generated and maintained by the system.

For requests where the existing key-material should be used, this value can be set to the key-container name of the existing key.

If the **UseExistingKeySet** key is set to **True**, the key container must be set explicitly in the .inf file or in the renewal certificate.

| **Summary Information** | **Details** |
|---|---|
| Syntax | KeyContainer = {Key_containerName} |
| Values | Random string value (GUID) |
| Default value | None |
| Sample | KeyContainer = {C347BD28-7F69-4090-AA16-BC58CF4D749C} |
| Supported with CA type | Windows 2000<br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**KeyLength**

The key length defines the length of the public and private key. The key length has an impact on the security-level of the certificate. Greater key length provides usually a higher security level, however some applications might have limitations regarding the key length.

| **Summary Information** | **Details** |
|---|---|
| Syntax | KeyLength = {integer} |
| Values | Any valid key length that is supported by the cryptographic service provider |
| Default value | 1024 (depends on CSP) |

| | |
|---|---|
| Sample | KeyLength=2048 |
| Supported with CA type | Windows 2000<br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**KeySpec**
KeySpec determines if the key can be used for signatures, for exchange (encryption) or for both. If the **KeySpec** is set to a value of 2, the **EncipherOnly** key is ignored.

| Summary Information | Details |
|---|---|
| Syntax | KeySpec = {integer} |
| Values | AT_EXCHANGE: 1<br>AT_SIGNATURE: 2 |
| Default value | 2 |
| Sample | KeySpec=1 |
| Supported with CA type | Windows 2000<br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**KeyUsage**
Key usage defines what the certificate key should be used for. The value is a bit field that is composed of the key usage flags as they are defined in the Windows Platform Software Development Kit.

### Note

- The key usage extension has an indirect dependency with the extended key usage extension, so these two extensions need to align. For example, if you specify "Encrypting File System" as the extended key usage, you should also specify "Key Encipherment" as the key usage.

To combine multiple key usages, summarize the values of the individual key usages by performing hexadecimal arithmetic. The default key usage is set to **Digital Signature (0x80)** and **Non-Repudiation (0x40)**. The hexadecimal sum of 0x80 and 0x40 results in 0xC0.

The key usage parameter is primarily useful if certificate requests are submitted to stand-alone CAs. Only enterprise CAs have certificate key usages predefined through certificate templates. The key usage extension is set to Critical by default.

| Summary Information | Details |
|---|---|
| Syntax | KeyUsage = {hexadecimal_value} |
| Values | CERT_DIGITAL_SIGNATURE_KEY_USAGE: 0x80<br>CERT_NON_REPUDIATION_KEY_USAGE: 0x40<br>CERT_KEY_ENCIPHERMENT_KEY_USAGE: 0x20<br>CERT_DATA_ENCIPHERMENT_KEY_USAGE: 0x10<br>CERT_KEY_AGREEMENT_KEY_USAGE: 0x08<br>CERT_KEY_CERT_SIGN_KEY_USAGE: 0x04<br>CERT_OFFLINE_CRL_SIGN_KEY_USAGE:0x02<br>CERT_CRL_SIGN_KEY_USAGE: 0x02<br>CERT_ENCIPHER_ONLY_KEY_USAGE: 0x01 |

| | |
|---|---|
| Default value | 0xC0 for AT_SIGNATURE (default)<br>For AT_KEYEXCHANGE, EncipherOnly = TRUE: 0x30<br>For AT_KEYEXCHANGE, EncipherOnly = FALSE: 0xf0 |
| Sample | KeyUsage=0xa0 |
| Supported with CA type | Windows 2000<br>Windows Server 2003 |
| Can be manipulated in a pending request | Yes |

**MachineKeySet**

This key is important when you need to create certificates that are owned by the computer and not a user. The key-material that is generated is maintained in the security context of the security principal (user or computer account) that has created the request. When a CA administrator creates a certificate request on behalf of a computer, the key-material must be created in the machines security context and not the administrators' security context. Otherwise, the computer cannot access its private key, since it would be in the administrator's security context.

You must set this key to **True**, if you are creating requests for domain controllers, Web servers or any other service that runs in the computer's security context.

| **Summary Information** | **Details** |
|---|---|
| Syntax | MachineKeySet = {Boolean} |
| Values | **True** or **False** |
| Default value | FALSE |
| Sample | MachineKeySet = True |
| Supported with CA type | Windows 2000<br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**PrivateKeyArchive**

The PrivateKeyArchive setting works only if the corresponding RequestType is set to CMC**,** because only the CMC request format allows for securely transferring the requester's private key to the CA for key archival. Only the Windows Server 2003 enterprise CA supports private key archival. The Windows Server 2003 enterprise CA must be online and accessible to retrieve the CA encryption certificate directly during this process.

| **Summary Information** | **Details** |
|---|---|
| Syntax | PrivateKeyArchive = {Boolean} |
| Values | **True** or **False** |
| Default value | **False** |
| Sample | PrivateKeyArchive = True |
| Supported with CA type | Windows Server 2003 |
| Can be manipulated in a pending request | No |

**ProviderName**

The provider name is the display name of the certificate service provider (CSP). If you do not know the provider name of the CSP you are using, run certutil –csplist at a command line prompt. The command displays the names of all CSPs that are available on the local system.

| **Summary Information** | **Details** |
|---|---|
| Syntax | ProviderName = {CSP_stringname} |
| Values | The descriptive name of the certificate service provider |

| | |
|---|---|
| Default value | Microsoft Strong Cryptographic Provider |
| Sample | ProviderName=Microsoft RSA SChannel Cryptographic Provider |
| Supported with CA type | Windows 2000<br><br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**ProviderType**

The provider type is used to select specific providers based on specific algorithm capability such as "RSA Full". If you do not know the provider type of the CSP you are using, type certutil –csplist at a command-line prompt. The command displays the provider type of all CSPs that are available on the local system.

| Summary Information | Details |
|---|---|
| Syntax | ProviderType = {integer} |
| Values | The number that describes the provider type |
| Default value | 12 |
| Sample | ProviderType=13 |
| Supported with CA type | Windows 2000<br><br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**RenewalCert**

If a CA administrator needs to renew a certificate that exists on the system where the certificate request is generated, the CA administrator must specify its certificate hash as a value for this key. You can only renew certificates that have not expired. Certificates that have expired cannot be renewed and must be replaced with a new certificate.

**Note**

- If you do not know the certificate hash, use the Certificates MMC Snap-In and look at the certificate that should be renewed. Open the certificate properties and see the **Thumbprint** attribute of the certificate. Certificate renewal requires either a PKCS#7 or a CMC request format.

| Summary Information | Details |
|---|---|
| Syntax | RenewalCert={CertificateHash} |
| Values | The certificate hash of any certificate that is available at the computer where the certificate request is created |
| Default value | Not applicable. |
| Sample | RenewalCert=4EDF274BD2919C6E9EC6A522F0F3B153E9B1582D (You must use double quotes if white space is used between pairs of hexadecimal values) |
| Supported with CA type | Windows 2000<br><br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**Requestername**

The requester name can be specified for certificate requests if the **RequestType** is set to PKCS7 or CMC. If the **RequestType** is set to PKCS10, this key will be ignored. The **Requestername** can only be set as part of the request. CA administrators cannot manipulate the **Requestername** in a pending request.

| Summary Information | Details |
|---|---|
| Syntax | Requestername=samAccountName in Active Directory |

| | |
|---|---|
| Values | The domain name of the user who requested the certificate. |
| Default value | Not applicable. |
| Sample | Requestername = "DOMAINNAME\username" |
| Supported with CA type | Windows 2000 (with a PKCS#7 request type only)<br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**RequestType**

The **RequestType** determines the standard that is used to generate and send the certificate request.

| **Summary Information** | **Details** |
|---|---|
| Syntax | RequestType={string value} |
| Values | CMC<br>PKCS10<br>PKCS10-<br>PKCS7 |
| Default value | PKCS10 |
| Sample | RequestType = CMC |
| Supported with CA type | Windows 2000 (except CMC request type)<br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**Silent**

By default, the **Silent** option gives the CSP access to the interactive user desktop of the CA administrator and request information such as a smartcard personal identification number (PIN) from the CA administrator. If this key is set to **True**, the CSP must not interact with the desktop and will be blocked from displaying any user interface to the CA administrator.

| **Summary Information** | **Details** |
|---|---|
| Syntax | Silent={Boolean} |
| Values | **True** or **False** |
| Default value | **False** |
| Sample | Silent = **True** |
| Supported with CA type | Windows 2000<br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**Subject**

Several applications rely on the subject information in a certificate. Thus, it is recommended to specify a value for this key. If the subject is not set here, you should include a subject name as part of the Subject Alternate Name certificate extension.

| **Summary Information** | **Details** |
|---|---|
| Syntax | Subject={String} |
| Values | Relative distinguished name string values |
| Default value | Not applicable. |

| | |
|---|---|
| Sample | Subject=CN=computer1.contoso.com<br><br>Subject=CN=John Smith,CN=Users,DC=Contoso,DC=com x |
| Supported with CA type | Windows 2000<br><br>Windows Server 2003 |
| Can be manipulated in a pending request | Yes |

**UseExistingKeySet**

The *UseExistingKeySet* parameter is used to specify that an existing key pair should be used in building a certificate request. If this key is set to **True**, you must also specify a value for the *RenewalCert* key or the **KeyContainer** name. You must not set the key to *Exportable* because you cannot change the properties of an existing key. In this case, no key-material is generated when the certificate request is built.

| Summary Information | Details |
|---|---|
| Syntax | UseExistingKeySet={Boolean} |
| Values | **True** or **False** |
| Default value | **False** |
| Sample | UseExistingKeySet=**True** |
| Supported with CA type | Windows 2000<br><br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**UserProtected**

If this key is set to **True**, a password must be set and typed in whenever a private key is used. The CA administrator can choose to protect the key with a password when the key is generated or choose to display a password dialog box only when the key is used within an application.

| Summary Information | Details |
|---|---|
| Syntax | UserProtected={Boolean} |
| Values | **True** or **False** |
| Default value | **False** |
| Sample | UserProtected=**True** |
| Supported with CA type | Windows 2000<br><br>Windows Server 2003 |
| Can be manipulated in a pending request | No |

**[RequestAttributes]**

This section is used in conjunction with the **New Request** attribute to define additional attributes associated with the certificate request. All keys from this section can be specified as part of the `certreq -submit -attrib` command. For example, instead of specifying the CertificateTemplate in the .inf instruction file, a CA administrator could enter the following at a command-line prompt:

```
certreq -submit -attrib "CertificateTemplate:Domaincontroller" dcname.req
```

**CertificateTemplate**

The value of this key instructs the CA which certificate template to use when processing the certificate request. The name must be specified as the common name of the certificate template or the object identifier of the template, not the template display name.

| Summary Information | Details |
|---|---|
| Syntax | CertificateTemplate = {Templatename} |
| Values | Any valid certificate template name |
| Default value | Not applicable. |
| Sample value | Critical = “DomainController” |

| | |
|---|---|
| Can be manipulated in a pending request | Yes |

**SAN**

The subject alternate name (SAN) can be specified in various ways. An SPN is specified as a UPN value.

| Summary Information | Details |
|---|---|
| Syntax | SAN = "{tag}={value}&{tag}={value}]..."<br><br>Always include double quotes around values |
| Values | A list of valid subject alternate name extension tags.<br><br>*email, upn, dns, guid, url, ipaddress, oid*<br><br>Alternatively, any valid object identifier can be specified. |
| Default value | Not applicable. |
| Sample value | See the following table for sample values. |
| Can be manipulated in a pending request | Yes |

The value is a string type by default but can be prefixed with a tag in section brackets ({}) that determines the data type of the value explicitly as exemplified in the following table:

| SAN string: | Explanation |
|---|---|
| 2.5.29.17={octet}MBmCF1cySzMtQk8tREMuY29udG9zbzluY29t | An ASN.1 string is put into the SAN as with one or several encoded extensions.<br><br>The octet is a wrapper around a base64 string that is encoded in binary format |
| 1.2.3.4={utf8}SomeReadableText | An ASN.1 string is put into the SAN as with one or several encoded extensions.<br><br>The value is a string encoded with a UTF8 wrapper. |
| 2.5.29.17={asn}=3019821757 | An ASN.1 string is put into the SAN as with one or several encoded extensions. |
| email=John.Smith@contoso.com | The user's e-mail address is put into the SAN. |
| dns=w2k3bodc.contoso.com | The DNS name is set to computers FQDN. |
| dn="CN=W2K3BODC,OU=Domain Controllers,DC=contoso,DC=com" | The distinguished name is set to the domain controller's distinguished name. |
| url="http://www.contoso.com/default.html" | The URL is set to an HTTP URL. |
| ipaddress=172.134.10.134 | The IP is put into the SAN. |
| oid=2.5.29.17 | A given object identifier is put into the SAN. |
| upn=John.Smith@contoso.com | The UPN name represents the user. |
| guid=f7c3ac41-b8ce-4fb4-aa58-3d1dc0e36b39 | A GUID is put into the SAN. |

**Combining Extensions**

Many of the configuration options in the CA certificate extensions that are described above overlap. For example, you might need to decide whether to configure certain policy restrictions in the Policy Extension or in the Application Policy Extension. In addition, with many of these extensions and restrictions, organizations might need to decide whether to implement them at the root CA level or in a subordinate CA.

As a general rule, policy should be configured as high in the PKI hierarchy as possible. However, it is rare to put constraints in the root CA certificate itself. Instead, if a policy applies to the entire PKI, such policy constraints should be applied at the root level, when the CA certificate for a subordinate CA is created.

Policies that apply only to a portion of the PKI can be applied by establishing multiple subordinate policy CAs below the root CA.

Policy constraints are the most useful of the constraint options, both internally and externally. Name and path constraints might not provide you with sufficient protection in certain cross-certified relationships if the security standards of your business partners are not as strong as yours. For example, Organization A might have a policy that all user certificates must be approved manually by an administrator, while

Organization B approves certificate requests automatically as long as the user has an e-mail account. The security administrators for Organization A must ensure that the certificates that users in Organization B use to access resources meet the higher security standards that are necessary in Organization A. They can accomplish this by using policy constraints.

You can use name constraints to limit unplanned domain-based trusts. If your organization has more than one domain — such as contoso.com and subdomain.contoso.com — you might only want cross-certificates to map to CAs in the contoso.com domain and not to CAs in the subdomain.contoso.com domain. On the other hand, if you have five different domains and want your cross-certificates to apply to three of them, path constraints provide a more flexible solution.

Use path constraints if transitive trusts create problems for your organization — for example, if you have an environment in which users can freely install subordinate CAs and you do not have strong security guidelines governing CA creation and management.

Use policy mapping if the organization that you are cross-certifying with has policies that are similar to those of your organization. Policy mapping is less useful when the policies of your organization are stricter than the policies of the other organization, or vice versa. If this is the case, use policy constraints to restrict your trust relationship instead of using policy mapping.

**CA Certificate Processes and Interactions**

Two types of processes and interactions are associated with CA certificates:

- Processes and interactions that are common to end entity certificates as well as CA certificates.
- Processes and interactions that are unique to CA certificates.

All certificates are validated essentially the same way -- by a series of checks involving

- **Certificate discovery.** The process of collecting CA certificates from Group Policy, Enterprise Policy, and AIA pointers in issued certificates, and the process of enrolling certificates.
- **Path validation.** The process by which public key certificates and their issuer certificates are processed in a hierarchical fashion until the certificate chain terminates at a trusted, self-signed certificate. Typically, this is the root CA certificate.
- **Revocation checking.** Each certificate in the certificate chain is verified to ensure that none of the certificates are revoked. The revocation checking can take place either in conjunction with the chain building process or after the chain is built.

For more information about these processes, see "How Certificates Work" in the Technical Reference.

Where CA certificates differ significantly from end entity certificates is how they are created, and the relationships between them established, from the trusted root CA certificate to subordinate CA certificates and cross certificates. The following sections describe these processes:

- How root CA certificates are created.
- How root CA certificates are renewed.
- How cross certificates are created.
- How subordinate CA certificates are created.
- How policies are applied for qualified subordination.

**How Root CA Certificates are Created**

The creation of a root CA certificate is inseparable from the process of setting up Certificate Services on the first CA in a PKI hierarchy. Certificate Services provides components that process subsequent certificate requests and enable you to manage certificate use. The root certificate, on the other hand, provides the foundation and establishes the basic rules that government certificate issuance and use. Where the root certificate defines standards for what is acceptable and unacceptable in the PKI hierarchy, Certificate Services applies those standards throughout its processes.

An issued certificate typically inherits properties from a certificate template that is provided by the issuing CA. (Some examples are certificate lifetime, the distribution point of the CRL, and other parameters.) Since the root CA requires a certificate for itself, the root CA must self-sign the root CA certificate because there is no parent CA that could issue the CA certificate.

Before the CA certificate is generated, you must have completed any custom configuration of the CAPolicy.inf file that is relevant to the CA certificate. The CAPolicy.inf file should contain all configuration information that is required to generate the self signed CA certificate according to the organization's needs.

**Process for Creating Root CA Certificates**

To ensure that the CAPolicy.inf file is correctly processed:

- The ASCII text file must be available on the local computer before the CA setup procedure starts or before CA certificate renewal is attempted.
- The file must be placed in the *Systemroot* folder on the local computer on which the CA is installed.

For the specific syntax, see "CA Certificate Physical Structure," in this document.

**Note**

- There is no syntax or error-checking message mechanism if the CAPolicy.inf file is not in the correct format.

The public and private keys are then generated by the CSP. If you use the default CSP, the keys are written to the local computer's key store. If you did not use a hardware security module (HSM), the key is generated by CryptoAPI and is stored in the profile of the system account on the local computer. The length of time that is required to generate the key depends on both the size of the key that is generated and the CPU performance of the local computer. If an HSM is installed and selected, the key is generated in the HSM and stored according to the HSM specific architecture. Since no certificate templates are available on a stand-alone CA server that is a member of a workgroup, the CA certificate needs to be built from configuration information in the registry.

The following default key usage extension values are added to the CA certificate:

- Digital signature
- Certificate signing
- Certificate offline CRL signing
- Certificate CRL signing

However, if a root CA is installed on a computer that is running either a Windows 2000 or a Windows Server 2003 operating system, and that computer is a domain member, the CA inherits the Enhanced Key Usage extension settings from the CA template in Active Directory, even if the CA is installed as a stand-alone CA. If no Active Directory is available, the Enhanced Key Usage settings are also taken out of the configuration that is available in the registry.

**How Root CA Certificates are Renewed**

Root CA certificates need to have a longer lifetime than any other certificates in a PKI hierarchy. However, even root CA certificates will expire eventually. If they are not renewed, then every other certificate in the hierarchy is invalidated as well.

In addition, root CA certificates can be renewed before this is necessary in order to:

- Change the key used by the CA. (This is used in case of actual or suspected compromise.)
- Add certificate policies to the CA for qualified subordination.
- Change the CDP or Authority Information Access (AIA) paths.
- Partition a CRL.

Note that it is good practice to change the CA key at each renewal

Before the renewal process begins, the CAPolicy.inf file must be edited to reflect any changes, such as using a larger encryption key.

**Note**

- With root CA certificates, you cannot change the cryptographic service provider, reduce the key size, or shorten the validity period.

This updated information is then combined with the unchanged configuration information in the expiring root CA certificate to create the renewed root CA certificate, as illustrated in the following figure.

**Process for Renewing Root CA Certificates**

Both the expiring root CA certificate and the renewed root CA certificate continue to play critical roles in the PKI hierarchy:

- The original root CA certificate remains the ultimate foundation of trust for the hierarchy, and helps to validate the certificate chains for all certificates that have been issued under the original hierarchy.
- The renewed root CA certificate provides the foundation of trust for all certificates that are issued in the hierarchy from the renewal date forward.

To support both of these scenarios, by default, the root CA renewal process creates a pair of cross CA certificates that establish the trust relationship between the original and renewed root certificate:

- One verifies that the original root CA certificate trusts the renewed CA certificate
- The second verifies that the renewed CA certificate trusts the original root certificate.

The following figure illustrates this relationship.

**How Root CA Certificates Use Cross Certificates**

**Note**

- Although the certificates linking the original and renewed root certificate are referred to as cross certificates, they are not the same as the cross certificates used to establish trust between two separate PKI hierarchies.

Stand-alone CAs generate self -signed cross certificates when CA keys are changed. A cross certificate is generated for each key transition, for the period where the lifetimes of each root certificate overlap.

**How Subordinate CA Certificates Are Created**

The process for creating subordinate CA certificates in many ways resembles the process for creating a root CA certificate. Policy.inf must be in place on the server before you start Certificate Services setup, and the configuration data in Policy.inf is combined with configuration options that you select during Certificate Services setup.

At this point the two processes diverge, and the setup code for a subordinate CA generates a subordinate CA certificate request, which must be processed on the parent CA. After the parent CA has processed the request and generated the subordinate CA certificate, it can be transferred using the Certification Authority snap-in or Certutil.exe onto the subordinate CA. The following figure illustrates this process.

**Process for Creating Subordinate CA Certificates**

The process for obtaining a subordinate CA certificate from the root CA differs, depending on whether the parent CA is available online.

- If a parent CA is available online, the request can be sent directly to the root CA over the network.
- If a parent CA is not available online, the request must be saved to a file, which must be physically transferred to the parent CA to be processed.

At a minimum, the parent CA should provide a file that contains the subordinate CA's newly-issued certificate and, preferably, its full certification path. If a subordinate CA certificate does not include the full certification path, you must install the parent CA's certificate in the Intermediate Certification Authorities certificate store of the computer (if the parent CA is not a root CA), as well as the certificates of any other intermediate CA in the chain. You must also install the certificate of the root CA in the chain into the Trusted Root Certification Authorities store. These certificates should be installed in the certificate store before the CA certificate is installed on the new subordinate CA so that the new subordinate CA can build a valid CA chain when it starts.

**How Policies Are Applied for Qualified Subordination**

You can use CA certificates to implement qualified subordination, the process used to clearly define which certificates issued in one CA hierarchy are trusted in another CA hierarchy. Qualified subordination, which is also commonly called cross certification, can be used to link PKIs when two organizations merge or following an acquisition, or to facilitate closer business relationships between two organizations such as joint development agreements or consulting arrangements.

Qualified subordination is applied by issuing CA certificates from a CA in one PKI to a CA in a second PKI in order to establish a one-way trust relationship. If a CA in the second PKI issues a similar CA certificate to a CA in the first PKI, there will be a two-way trust relationship between the two hierarchies. Most likely, administrators in each hierarchy would configure these cross certificates using basic, policy, naming, and application constraints to limit which certificates are accepted from the other PKI, and the purposes for which they can be used.

**Note**

- In Windows 2000 operating systems, true cross-certification of CA hierarchies is not possible. Instead, you can define Certificate Trust Lists (CTLs) that trust specific CAs and use restricted certificates.

For example, consider the two PKIs illustrated in the following figure.

**How Cross Certificates Establish Trust Between PKI Hierarchies**

In this example, cross certificates are issued by Subordinate CA 2 to Subordinate CA A, which makes it possible for user certificates issued by Issuing CA A to be used in the PKI anchored by Root CA 1, and by Subordinate CA A to Subordinate CA 2, which makes it possible for certificates issued by Issuing CA 1 to be used in the PKI anchored by Root CA 2.

Cross CA certificates such as this can also be issued from one root CA to a second root CA, by a root to a subordinate CA, by a subordinate CA to a root, or by a third "bridge" root CA to a root or subordinate CA in each of the organizations that wish to have a cross relationship. However, in any of these cases, it is likely that various name and policy constraints will be used to define and limit the usage of certificates issued in the partner's CA hierarchy.

The key to understanding the use of cross certificates is that when a certificate issued by Issuing CA 1 is presented for use in the root CA 2 hierarchy, it is not validated against root CA 2. Instead, its certificate validation chain now includes the Sub CA A cross certificate, Subordinate CA 2, and Root CA 1. However, the cross certificate itself also must be validated, so the user certificate still ends up being validated for use --indirectly, in the case of the partner organization) for use.

To prevent undesired trust from being established, you can use:

- Basic constraints. These define which CAs your organization trusts in a partner's CA hierarchy by limiting the path length for a certificate chain.. For example, in the cross certificate issued by Subordinate CA 2, basic constraints could prevent the acceptance and use of certificates issued by any CAs beyond Subordinate CAB — or certificates issued by Subordinate CA B itself.

- Name constraints. These prevent acceptance of certificates from the other organization in undesired namespaces. For example, if Subordinate CA 1 serves certificate requests for users and computers in a domain for a separate division of the organization, it would be undesirable for certificates issued in Organization A for use in a relationship with the organization supported by Subordinate CA 2 to be used elsewhere in the organization.

- Application constraints. These prevent the use of the partner organization's certificates from being used for unapproved purposes. The cross certificate issued by Subordinate CA A might specify that certificates issued in the partner organization can only be used for e-mail signing, or for computer authentication, and specifically exclude other uses, such as key recovery.

- Policy constraints. These define the level of trust or assurance associated with the partner organization's certificates. In many organizations, certificates can have significant legal implications, such as for signing purchase orders up to, but not exceeding, certain amounts. For example, Sub CA Cross Certificate can include a policy constraint specifying that certificates issued in the partner organization can only used to sign purchase orders up to $1,000. In a case such as this, it would likely also be valuable to include a policy mapping to an Organization 2 policy defining policy limits, such as legal liability, associated with certificates issued in the Root CA 2 hierarchy.

# CA Certificates Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- CA Certificate Tools
- CA Certificate Registry Entries
- CA Certificate Group Policy Settings

**CA Certificate Tools**
The following tools are associated with CA certificates.

**Certreq.exe: Certreq**

**Category**
Certreq ships with the Windows Server 2003 operating system tools and with the Windows Server 2003 Adminpak.

**Version Compatibility**
Certreq is compatible with Windows Server 2003 and Windows 2000 Server, and can be used to manage the certificate containers for users, computers, and services on computers running Windows 2000, Windows XP, and Windows Server 2003.Certreq enables you to submit, retrieve, create, and accept certificate requests that are sent to a Windows Server 2003 CA. You can also use Certreq to create and sign cross-certificate requests. You can also place the Certreq command syntax in a batch file to script certificate requests.

To find more information about Certreq, see "Command Line References" in Tools and Settings Collection.

**Certutil.exe: Certutil**

**Category**
Certutil is a command-line program that is installed as part of Certificate Services and with the Windows Server 2003 Adminpak.

**Version Compatibility**
Certutil can be used on Windows 2000 Server CAs and Windows Server 2003 CAs.

You can use Certutil to extract and display CA configuration information, configure Certificate Services, back up and restore CA components, and verify certificates, key pairs, and certificate chains.

To find more information about Certutil, see "Command Line References" in Tools and Settings Collection.

**Certsrv.msc: Certification Authority Snap-in**

**Category**
The Certification Authority snap-in ships with Windows 2000 Server and Windows Server 2003.

**Version Compatibility**
The Certification Authority snap-in is compatible with Windows Server 2003 and Windows 2000 Server.

The Certification Authority snap-in can be used to manage multiple CAs. It allows you to perform a variety of administrative tasks including:

- Starting and stopping the CA.
- Backing up and restoring the CA.
- Changing exit and policy modules.
- Viewing the CA certificate.

- Installing or reinstalling a CA certificate for the CA.
- Setting security permissions and delegating administrative control for the CA.
- Revoking certificates.
- Viewing or modifying CRL distribution points.
- Publishing CRLs and scheduling CRL publication.
- Configuring the types of certificates that are to be issued by the CA.
- Viewing information about certificates that have been issued.
- Viewing information about certificates that have been revoked.
- Viewing pending certificate requests.
- Approving or denying pending certificate requests.
- Viewing failed certificate requests.
- Renewing the CA's certificate.

**CA Certificate Registry Entries**

CA certificate-related registry entries correlate to the physical view of the certificate-related data that can be viewed by using the Certificates snap-in.

The registry settings in this section are a subset of the registry settings in "Certificate Services Tools and Settings." This subset makes it possible to monitor and manage key configuration options associated with CA certificates.

The following registry keys are associated with CA certificates that were distributed via Group Policy:

- **HKEY_CURRENT_USER\Software\Microsoft\SystemCertificates**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\SystemCertificates**

The following registry keys are associated with CA certificates that were not distributed via Group Policy:

- **HKEY_CURRENT_USER\Software\Policies\Microsoft\SystemCertificates**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\EnterpriseCertificates**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\SystemCertificates**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\CertSvc**

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as MMC, to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_Current_User\Software\Microsoft\SystemCertificates**

**HKEY_Current_User\Software\Microsoft\SystemCertificates** contains registry settings for user certificates that have been distributed by means other than Group Policy. These keys also contain registry settings relating to the CA certificates that

support the user certificates.

The majority of the registry subkeys under SystemCertificates contain binary large objects that pertain to:

- **Certificates.** These entries identify the certificates associated with the registry entry.
- **CRLs.** These entries identify the certificate revocation lists (CRLs) associated with the registry entry.
- **CTLs.** These entries identify the certificate trust lists (CTLs) associated with the registry entry.

The following registry subkeys are located under SystemCertificates. Additional subkeys — which might appear under some registry subkeys — appear below under the registry subkey that they correspond to.

These subkeys appear under SystemCertificates:

**AuthRoot**

**Registry path**
**HKEY_Current_User\Software\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**AuthRoot** contains data about certificates, CRLs, and CTLs from non-Microsoft root CAs.

**CA**

**Registry path**
**HKEY_Current_User\Software\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**CA** contains data about certificates, CRLs, and CTLs from intermediate CAs.

**Root**

**Registry path**
**HKEY_Current_User\Software\ Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Root** contains data about trusted root CA certificates, CRLs, and CTLs.

**trust**

**Registry path**
**HKEY_Current_User\Software\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Trust** contains data about enterprise trust certificates, CRLs, and CTLs.

**HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates**
**HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates** contains registry settings for user certificates that have been distributed by using Group Policy. These keys also contain registry settings relating to the CA certificates that support the user certificates.

The majority of the registry entries contain binary large objects that pertain to:

- **Certificates.** These entries identify the certificates associated with the registry entry.
- **CRLs.** These entries identify the CRLs associated with the registry entry.

- **CTLs.** These entries identify the CTLs associated with the registry entry.

The following registry entries are located under SystemCertificates Additional subkeys — which might appear under some registry subkeys — will be detailed below under the registry subkeys that they correspond to.

**AuthRoot**

**Registry path**
**HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**AuthRoot** contains data about certificates, CRLs, and CTLs from non-Microsoft root CAs.

**CA**

**Registry path**
**HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**CA** contains data about certificates, CRLs, and CTLs from intermediate CAs.

**root**

**Registry path**
**HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Root** contains data about trusted root CA certificates, CRLs, and CTLs.

**trust**

**Registry path**
**HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Trust** contains data about enterprise trust certificates, CRLs, and CTLs

**HKEY_Local_Machine\Software\Microsoft\EnterpriseCertificates**
**HKEY_Local_Machine\Software\Microsoft\EnterpriseCertificates** contains registry settings for computer certificates that are downloaded from the Active Directory by the auto enrollment feature.

**AuthRoot**

**Registry path**
**HKEY_Current_User\Software\Microsoft\EnterpriseCertificates\AuthRoot**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**AuthRoot** contains data about certificates, CRLs, and CTLs from non-Microsoft root CAs.

**CA**

**Registry path**
**HKEY_Current_User\Software\Microsoft\EnterpriseCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**CA** contains data about certificates, CRLs, and CTLs from intermediate CAs.

**NTAuth**

**Registry Path**
**HKEY_Local_Machine\Software\Microsoft\EnterpriseCertificates\NTAuth**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Any CA that issues smart card logon or domain controller certificates must publish its CA certificate into the **NTAuth** store in Active Directory. Windows 2000 and Windows 2003 CAs automatically publish their CA certificates in Active Directory. Certificates published by third parties must be imported into the **NTAuth** store. After you put the non-Microsoft CA in the **NTAuth** store, domain-based Group Policy adds this registry key to all computers in the domain.

For more information about the **NTAuth** store, see "How Certificate Services Works" in the Windows Server 2003 Technical Reference.

**Root**

**Registry path**
**HKEY_Current_User\Software\ Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Root** contains data about trusted root CA certificates, CRLs, and CTLs.

**trust**

**Registry path**
**HKEY_Current_User\Software\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Trust** contains data about enterprise trust certificates, CRLs, and CTLs.

**HKEY_Local_Machine\Software\Microsoft\SystemCertificates**
**HKEY_Local_Machine\Software\Microsoft\SystemCertificates** contains registry settings for computer certificates that have been distributed by means other than Group Policy. These keys also contain registry settings relating to the CA certificates that support the computer certificates.

**AuthRoot**

**Registry path**
**HKEY_Local_Machine\Software\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**AuthRoot** contains data about certificates, CRLs, and CTLs from non-Microsoft root CAs.

**CA**

**Registry path**
**HKEY_Local_Machine\Software\Microsoft\SystemCertificates\CA**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**CA** contains data about certificates, CRLs, and CTLs from intermediate CAs.

**ROOT**

**Registry path**
**HKEY_Local_Machine\Software\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**ROOT** contains data about trusted root CA certificates, CRLs, and CTLs.

**trust**

**Registry path**
**HKEY_Local_Machine\Software\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Trust** contains data about enterprise trust certificates, CRLs, and CTLs.

**HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates**
**HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates** contains registry settings for computer certificates that have been distributed using Group Policy. These keys also contain registry settings relating to the CA certificates that support the computer certificates.

The majority of registry entries contain binary large objects that pertain to:

- **Certificates.** These entries identify the certificates associated with the registry entry.
- **CRLs.** These entries identify the CRLs associated with the registry entry.
- **CTLs.** These entries identify the CTLs associated with the registry entry.

The following registry entries are located under **SystemCertificates**. Additional subkeys — which might appear under some registry subkeys — will be detailed below under the registry subkeys that they correspond to.

**AuthRoot**

**Registry path**
**HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**AuthRoot** contains data about certificates, CRLs, and CTLs from non-Microsoft root CAs.

**ca**

**Registry path**
**HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Ca** contains data about certificates, CRLs, and CTLs from intermediate CAs.

**Certificates**

**Registry path**
**HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\SystemCertificates\Root\Certificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Certificates** contains a unique key for each root CA certificate that is based on the hash of the certificate.

**ProtectedRoots**

**Registry path**
**HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\SystemCertificates\Root\ProtectedRoots**

**Version**

Windows Server 2003 and Windows XP Professional Service Pack 2

**ProtectedRoots** can be used to:

1. Disable user root store trust. This prevents CryptoAPI applications from using the user root store in building trusted certificate chains.

2. Disable user root store changes. This prevents users from adding root CAs to the user trusted root store. This value can also be set through Group Policy in Windows Server 2003.

3. Disable user root store purge. This prevents the user from removing root CAs from the user trusted store that are also in the local computer trusted root store.

4. Disable the requirement for NTAuth policy processing. This disables the requirement for an issuing CA to be present in the NTAuth store of the local computer. This value can be set using Group Policy.

5. Disable name constraint enforcement for undefined name types. By default, Windows XP Professional with Service Pack 2 and Windows Server 2003 reject undefined name types in a name constraint validation. Setting this value forces the acceptance of all name forms that are not explicitly defined.

### Note

- The option to disable name constraint enforcement is not configurable using Group Policy.

**Root**

**Registry path**
**HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Root** contains data about trusted root CA certificates, CRLs, and CTLs.

**Trust**

**Registry path**
**HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates**

**Version**
Windows Server 2003, Windows XP, and Windows 2000

**Trust** contains data about enterprise trust certificates, CRLs, and CTLs.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\CertSvc**
The registry entries in this hive correlate to CA certificate configuration information that can be configured and viewed using the Certificates and Certification Authority snap-ins, as well as the Certutil command-line tool.

**CertSvc\Configuration\CAName**
The registry settings in this hive contain information relating to the configuration of the certification authority (CA) installed on the server.

**CACertFileName**

**Registry Path**
**\CertSvc\Configuration** *CAName*\ **CACertFileName**

**Version**
Windows Server 2003 and Windows 2000 Server

On subordinate CAs, this setting identifies the name and location of the root certificate.

**CACertHash**

**Registry Path**
**\CertSvc\Configuration** *CAName*\ **CACertHash**

**Version**
Windows Server 2003 and Windows 2000 Server

On subordinate CAs, this setting identifies the hash algorithms — SSH-1, for example — that are used for all CA certificates.

**CACertPublicationURLs**

**Registry Path**
**\CertSvc\Configuration** *CAName*\ **CACertPublicationURLs**

**Version**
Windows Server 2003 only

This setting identifies the URL of the authority information access point where a client can find a CA certificate. Because the authority information access point is the location of the certificate that was used to sign the certificate, and because a root CA issues the CA certificate to itself, you should leave this setting blank for the root CA.

**CAKeyUsage**

**Registry Path**
**\CertSvc\Configuration** *CAName*\ **CAKeyUsage**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting makes it possible to disable the digital signature key usage on stand-alone CAs. By default, a stand-alone CA certificate will contain digital signature, certificate signing, and CRL signing key usage values.

### Note

- Enterprise CAs enforce the key usage based on the subordinate CA template settings.

**CAServerName**

**Registry Path**
**\CertSvc\Configuration** *CAName*\ **CAServerName**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting records the DNS name of the server on which the CA is running.

**CAType**

**Registry Path**
**\CertSvc\Configuration** *CAName*\ **CAType**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting records whether the CA is a root, enterprise, or stand-alone CA.

**CommonName**

**Registry Path**
\ **CertSvc\Configuration** \ *CAName*\ **CommonName**

**Version**
Windows Server 2003 and Windows 2000 Server

The common name becomes part of the certificate issuer name and is also part of the CRL and AIA if replacement tokens are used. The common name must not exceed 64 characters in length.

### Note

- Each space in the name will actually use three characters in the total length because of how escape characters are written (%20).

#### CRLFlags

**Registry Path**
\ **CertSvc\Configuration** \ *CAName*\ **CRLFlags**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting allows you to manage cross CA certificate creation. By default, cross CA certificates are generated using predefined extensions in the registry. If desired, this setting can be used to generate cross certificates using the Cross CA certificate template instead. This setting can also be used to disable automatic cross CA certificate generation. .

#### CRLPublicationURLs

**Registry Path**
\ **CertSvc\Configuration** \ *CAName*\ **CRLPublicationURLs**

**Version**
Windows Server 2003 and Windows 2000 Server

Configuring this setting ensures that the correct CRL and AIA information is embedded in each issued certificate so that the certificate's signature and revocation status can be verified.

For all CA types (online or offline, root or subordinate, enterprise or stand-alone), the configuration of the AIA extension and the CRL distribution point extension is critical. If they are not configured correctly or if they contain invalid extensions, there may be unexpected problems. For example, smart card login attempts may not work, there may be invalid e-mail digital signatures, or there may be Web sites that are not trusted.

### Note

- Changes to CRL distribution points and AIA extensions take effect only after the CA is restarted, and the extensions appear in certificates issued only after the changes are applied. The CRL and AIA configuration processes are different on computers that are running Windows Server 2003 and Windows 2000 Server.

#### DSConfigDN

**Registry Path**
\ **CertSvc\Configuration** \ *CAName*\ **DSConfigDN**

**Version**
Windows Server 2003 and Windows 2000 Server

The distinguished name in DSConfigDNidentifies the namespace of the domain that the CA belongs to. When a root  CA is configured as a stand-alone CA, the distinguished name should be the same as the namespace that will be used for the enterprise CA. The distinguished name becomes part of the certificate issuer name and is also part of the CRL and AIA if replacement tokens are used. It is also used by several variables that are used to set the CRL and AIA.

### Note

- After you use this command to change the registry key, a new CRL and any new CA certificates that are issued must be republished. Only new certificates that are issued after you use the previous command will have this information available. It is important to note that you must reissue and republish any subordinate CA certificate if it was issued before you changed the registry key.

#### EnforceX500NameLengths

**Registry Path**
**\CertSvc\Configuration** *CAName*\ **EnforceX500NameLengths**

**Version**

Windows Server 2003 and Windows 2000 Server

This setting makes it possible for certificates issued by the CA to bypass X.500 naming restrictions. Windows Server 2003 CAs enforce X.500 naming standards by default. It is possible that deep organizational unit (OU) paths might exceed normal length restrictions. If your organization's PKI does not need to be compatible with a non-Microsoft PKI, you can configure this registry setting to bypass the X.500 name length restriction.

**HighSerial**

**Registry Path**
**\CertSvc\Configuration** *CAName*\ **HighSerial**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting can be used to enable alternate forms of fixed length serial number generation. In Windows 2000 CAs, two types of fixed-length serial numbers are generated. In a Windows Server 2003 CA, three types of fixed-length serial numbers are generated. The default and alternate forms are the same as in Windows 2000. The alternate forms can be used to work around serial number encoding issues in certain non-Microsoft PKI applications.

### Note

- Any length hexadecimal string can be set in the registry (but there must be an even number of digits). The number of bytes used from the registry will be reduced if it would overflow a total of 19 bytes for the serial number. The high byte is manipulated as described previously to avoid problems with certain non-Microsoft applications. The IETF standards specify a maximum of 20 byte serial numbers.

**SubjectTemplate**

**Registry Path**
**\CertSvc\Configuration** *CAName*\ **SubjectTemplate**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting contains an ordered list of the subject relative distinguished name elements that are allowed in the **Subject** field of certificates issued by the CA.

This setting can only be set to a small, fixed list of relative distinguished name elements supported by the CA. If, during request processing, a listed relative distinguished name field is empty, or if the field is not populated by the request **Subject** field or by the policy module, the element will not be included. If the registry value is completely empty, the binary subject encoding from the request is passed through to the issued certificate unmodified.

**CertSvc\Configuration\CAName\CSP**

**Provider**

**Registry Path**
**HKLM\System\CurrentControlSet\Services\CertSvc\Configuration** \ *CAName*\ **CSP\Provider**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting lists the CSP that is used to generate the CA certificate key material.

**Hash Algorithm**

**Registry Path**
**HKLM\System\CurrentControlSet\Services\CertSvc\Configuration\\CAName** *CSP*\ **HashAlgorithm**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting identifies the hash algorithm that is used for hashing and signing CA certificate contents.

**CertSvc\Configuration\CAName\PolicyModules**

**Active**

**Registry Path**
**CertSvc\Configuration** *CAName*\ **PolicyModules\Active**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting lists the active policy modules.

**CertSvc\Configuration\CAName\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy**

**DisableExtensionList**

**Registry Path**
**CertSvc\Configuration** *CAName*\
**PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\DisableExtensionList**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting disables the adding of a certificate extension to a certificate that is included by default in certificates issued by an enterprise CA. An example of such a certificate extension could be the S/MIME capabilities extension.

**EditFlags**

**Registry Path**
**CertSvc\Configuration** *CAName*\ **PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\EditFlags**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting enables you to identify the critical and non-critical extensions associated with policy modules, such as enabling basic constraints. The flags that can be configured include:

- **EDITF_ATTRIBUTEENDDATE.** Controls certificate validity time by certificate request. This feature is disabled by default for enterprise CAs, and enabled by default for stand-alone CAs.

  **Note**

  - Although the validity period of a certificate is normally set by the CA, the CA can be configured in a way that allows the request to specify the validity period. This CA configuration option can only reduce the validity period of certificates to be issued by a request.

- **EDITF_ENABLEAKIISSUERNAME.** Used to enable or disable the issuer name and issuer serial number.

  **Note**

  - You should disable the issuer name and issuer serial number if you renew CA keys when you renew CA certificates or plan to use cross-certificates.

**EnableEnrolleeRequestExtensionList**

**Registry Path**
**CertSvc\Configuration** *CAName*\
**PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\EnableEnrolleeRequestExtensionList**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting lists the object identifiers (also known as OIDs) of the rules extensions that are defined by the organization that must appear in the issued certificate. These settings apply to all requests submitted to a stand-alone CA, and to requests submitted to an enterprise CA that use a template which specifies that the request must supply the subject information.

**EnableRequestExtensionList**

**Registry Path**
**CertSvc\Configuration** *CAName*\ **PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\EnableRequestExtensionList**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting lists the object identifiers of the rules extensions defined by the organization that must appear in the issued certificate. By default, extensions that are in the submitted request are added to the CA's database, but are marked as disabled, so they will not appear in the issued certificate.

**RequestDisposition**

**Registry Path**
**CertSvc\Configuration** *CAName*\ **PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\RequestDisposition**

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to specify what the policy module should do with incoming and resubmitted requests. Options include:

- Process all certificate requests that meet applicable policy and template processing requirements.
- Place all initial certificate requests in a pending queue, and process all certificate requests that are resubmitted by an administrator, assuming the requests meet applicable policy and template processing requirements.

**RevocationType**

**Registry Path**
**CertSvc\Configuration** *CAName*\ **PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\RevocationType**

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to specify an alternative certificate revocation service to function with a Windows Server 2003 CA. This setting enables CRL URLs from the following: Lightweight Directory Access Protocol (LDAP), File Transfer Protocol (FTP), and file locations; CDP extensions; and Active Server Page (ASP)-based revocation.

**RevocationURL**

**Registry Path**
**CertSvc\Configuration** *CAName*\ **PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\RevocationURL**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the URL for an alternative certificate revocation service that has been configured to function with a Windows Server 2003 CA.

The replacement variables that can be used in the revocation URL are listed in the following table.

**Registry Variables for Alternative Revocation Services**

| Alternative Revocation Service | Registry Variable |
|---|---|
| SERVERDNSNAME | 1 |
| SERVERSHORTNAME | 2 |
| SANITIZEDCANAME | 3 |
| CERTFILENAMESUFFIX | 4 |

| | |
|---|---|
| DOMAINDN | 5 |
| CONFIGDN | 6 |
| SANITIZEDCANAMEHASH | 7 |
| CRLFILENAMESUFFIX | 8 |
| CRLDELTAFILENAMESUFFIX | 9 |
| DSCRLATTRIBUTE | 10 |
| DSCACERTATTRIBUTE | 11 |
| DSUSERCERTATTRIBUTE | 12 |
| DSKRACERTATTRIBUTE | 13 |
| DSCROSSCERTPAIRATTRIBUTE | 14 |

In order for the revocation service to function, the application, service, or account connecting to this URL must have Read permissions in the Certification Authority snap-in. If IIS is using a local account, follow the steps for enabling anonymous access in IIS and allowing Anonymous Read access to the CA.

### Note

- Enabling Anonymous Read access to the CA might expose privacy or security risks.

#### SubjectAltName

**Registry Path**
**CertSvc\Configuration** *CAName*\ **PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\SubjectAltName**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting uses an organizational unit for the SubjAltName extension of an issued certificate. This setting is almost never used.

#### SubjectAltName2

**Registry Path**
**CertSvc\Configuration** *CAName*\ **PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\SubjectAltName2**

**Version**
Windows Server 2003 and Windows 2000 Server

This setting makes it possible for a stand-alone CA to place the e-mail address of the authenticated user making the certificate request in the SubjAltName extension of an issued certificate. This setting is rarely used.

#### CA Certificate Group Policy Settings

The following public key Group Policy settings are associated with CA certificates:

- **Trusted Root Certification Authorities** for adding trusted root CA certificates to the Trusted Root Certification Authorities store.

- **Enterprise Trust** for configuring certificate trust lists.

#### Trusted Root Certification Authorities

When you install an enterprise root CA or a stand-alone root CA, the certificate of the CA is added automatically to the Trusted Root Certification Authorities Group Policy object for the domain. You also can add certificates for other root CAs to the Trusted Root Certification Authorities Group Policy object.

Trusted Root Certification Authorities Group Policy can be configured in the following location in the Group Policy MMC snap-

in:

Computer Configuration/Windows Settings/Security Settings/Public Key Policies/Trusted Root Certification Authorities

The root CA certificates that you add become trusted root CAs for computers within the scope of the Group Policy object. For example, if you want to use a non-Microsoft CA as a root CA in a certification hierarchy, you must add the certificate for the non-Microsoft CA to the Trusted Root Certification Authorities Group Policy object.

To add a certificate for the root CA to the Trusted Root Certification Authorities Group Policy, in the **Public Key Policies** node, right-click **Trusted Root Certification Authorities**, click **All Tasks**, and then click **Import**. When the Certificate Import Wizard appears, use the wizard to import a certificate file for the certificate of the root CA and add it to Group Policy. The certificate is added to the **Trusted Root Certification Authorities** store of all computers within the scope of Group Policy the next time it is refreshed on each computer.

You can also use Trusted Root Certification Authorities Group Policy to control the changes users can make to trusted root CA options.

To modify these settings, right-click **Trusted Root Certification Authorities**, and then click **Properties**.

To prevent users making any changes to the trusted root CA store, you can clear the **Allow users to select new root Certification Authorities (CAs) to trust** check box.

To limit client trust of alternative certificate stores, under **Client computers can trust the following certificate stores**, select one of the following options:

- **Third-Party Root Certification Authorities and Enterprise Root Certification Authorities**
- **Enterprise Root Certification Authorities**

In addition, the following settings under **To perform certificate-based authentication of users and computers, CAs must meet the following criteria:** can be used to manage certificate-based authentication by certificate holders:

- **Registered in Active Directory only**
- **Registered in Active Directory and compliant with name constraints requirements for user principal names (UPNs)**

**Note**

- For more information about importing non-Microsoft root CA certificates, see the information for **HKEY_Local_Machine\Software\Microsoft\EnterpriseCertificates\NTAuth**, earlier in this document.

#### Certificate Trust Lists

You can create certificate trust lists (CTLs) to trust specific CAs and to restrict the uses of certificates issued by the CAs. For example, you might use a CTL to trust certificates that are issued by a commercial CA and restrict the permitted uses for those certificates. You might also use CTLs to control trust on an extranet for certificates that are issued by CAs that are managed by your business partners. You can configure CTLs for computers and for users.

Before administrators can create CTLs, they must have a valid trust list signing certificate — such as the Administrator certificate or the Trust List Signing certificate that is issued by enterprise CAs. The trust list signing private key for the administrator is used to sign the CTL for integrity. If the trust list signing certificate for an administrator is invalid, all CTLs that have been created and signed by that administrator also are invalid.

Certificate Trust List Group Policy is configured as part of Public Key Policies\Enterprise Trust in the Security Settings of the Group Policy object for a user or computer in a domain, site, or OU. Certificate Trust List Group Policy can be configured in the following location in the Group Policy MMC snap-in:

Computer Configuration/Windows Settings/Security Settings/Public Key Policies/Enterprise Trust

You use the Certificate Trust Wizard to configure Certificate Trust List Group policy.

To activate the wizard, right-click **Enterprise Trust**, click **New** and then click **Certificate Trust List**. The wizard enables you to configure the following options:

- **Valid duration.** An optional lifetime for the CTL. If you do not specify a lifetime, the CTL expires when the trust list signing certificate expires.

- **Designate Purposes.** Enables you to restrict the purposes for which certificates are trusted. The CTL establishes trust only for certificates that are valid for the selected purposes. A certificate might support all of the listed purposes.

- **Add Purpose.** Enables you to add purposes to the **Designate Purposes** box. This also requires you to enter an object identifer for the new purpose.

- **Current CTL Certificates.** Displays the certificates of the root CAs that are to be trusted by this CTL. Certificates with certification paths to the root CA are trusted for all designated purposes specified by the CTL.

- **Add from Store.** Adds a root certificate from the Trusted Root Certification Authorities store.

- **Add from File.** Adds a root CA's certificate from a file.

- **Remove.** Deletes the certificate that is selected in the **Current CTL Certificates** box.

- **View Certificate.** Enables you to view the certificates that are selected in the **Current CTL Certificates** box.

- **Use this certificate.** Displays the trust list signing certificate for the private key that is to be used to sign the CTL.

- **Select from Store.** Adds a trust list signing certificate from the Personal store for the administrator.

- **Select from File.** Adds the trust list signing certificate from a file.

- **View Certificate.** Enables you to view the certificate listed in the **Use this certificate** box.

- **Add a timestamp to the data.** Adds a timestamp to the CTL. The timestamp is used to determine the valid lifetime of the CTL. If a timestamp is not used, the computer clock is used instead.

- **Timestamp service URL.** Identifies the location of the timestamp service that is to be used for the timestamp.

- **Friendly Name.** The optional name that appears in the Microsoft Management Console when the CTL is displayed.

- **Description.** An optional description to describe the CTL.

# Certificates Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Digital certificates are electronic credentials that are used to certify the online identities of individuals, computers, and other entities on a network. Digital certificates function similarly to identification cards such as passports and drivers' licenses. They are issued by certification authorities (CAs) that must validate the identity of the certificate holder, both before the certificate is issued and when the certificate is used. Common uses include business scenarios requiring authentication, encryption, and digital signing.

# What Are Certificates?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What Are Certificates?**

**In this section**

- Uses of Certificates
- Certificate Dependencies
- Related Information

Digital certificates are electronic credentials that are used to certify the identities of individuals, computers, and other entities on a network.

Digital certificates function similarly to identification cards such as passports and drivers' licenses. For example, passports and drivers' licenses are issued by recognized government authorities, whereas digital certificates are issued by recognized certification authorities (CAs).

When someone requests a passport or driver's license, the government authority verifies the identity of the requester, certifies that the requester meets all requirements to receive the card, and then issues the card. Before a certificate can be issued, a CA or CA administrator must verify the requester's identity, determine that they meet all requirements to receive the certificate, and then issue the certificate.

Like an identification card such as a driver's license or passport, a digital certificate can be used to verify the identity of its owner. When the certificate is presented to others, they help verify the identity of its owner based on the quality of the contents of the certificate:

- Personal information that helps identify the owner.
- The signature of the issuing authority. For digital certificates, the issuing authority is the CA.
- Information needed to identify and contact the issuing authority.

In addition, the quality of a certificate is enhanced if it:

- Is designed to be tamper-resistant and difficult to counterfeit.
- Is issued by an authority that can revoke the certificate at any time (for example, if the employee to whom the certificate was issued is no longer employed by the organization).
- Can be checked for revocation by contacting the issuing authority.

**Uses of Certificates**

Private and public networks are being used with increasing frequency to communicate sensitive data and complete critical transactions. This has created a need for greater confidence in the identity of the person, computer, or service on the other end of the communication. In addition, these valuable communications must be protected while they are on the network. Although accounts and passwords provide a certain level of assurance in the identity of the entity on the other end of the network, they offer little or no protection while data is in transit. In comparison, digital certificates and public key encryption provide an enhanced level of authentication and privacy to digital communications.

Certificates and certificate services from numerous vendors are being used to strengthen the security of a variety of applications and user scenarios. Windows Server 2003 Certificate Services makes possible strong security based on public key encryption that can enhance a variety of internal and external applications for your organization, including:

- Authentication.

- Encryption.
- Data integrity.

**Authentication**

Authentication is crucial to secure and reliable communication. Each party to a communication must be able to prove their own identity to those with whom they communicate, and in turn must be able to verify the identity of the parties at the other end of the communication.

This process can be challenging when both parties are in the same location. Authentication of identity on a network can be even more difficult because the communicating parties do not physically meet as they communicate. This makes it potentially easier for an unethical person to intercept messages that are meant to be private or to pretend that they are another person or entity.

Digital certificates and public key encryption provide an enhanced means of verifying identity, which makes it difficult for an entity to impersonate another entity. Digital certificates help verify identity because the data in a certificate includes the public cryptographic key from the certificate subject's public and private key pair. A message signed with its sender's private key can be verified by the message's recipient as authentic by using the sender's public key, which can be found on a copy of the sender's certificate. Verifying a signature by using a public key from a certificate proves that the signature was produced using the certificate subject's private key. If the sender has been vigilant and has kept the private key secret, the receiver can be confident in the identity of the message sender.

A few of the ways certificates are used to provide authentication are:

- Authentication of a user to a secure Web site via the Transport Layer Security (TLS) or the Secure Sockets Layer (SSL) protocol.
- Authentication of a server to a user via TLS.
- Logging on to a Windows Server 2003 domain.
- Authentication of a client on a wireless network.
- Authentication of a client across the Internet to create a virtual private network (VPN).
- Internet Protocol security (IPSec).

**Encryption**

Communications over a network, such as the Internet, are subject to possible monitoring by unknown and, perhaps, malicious users. Public networks are treacherous for unencrypted sensitive information because anyone can access the network and analyze the data being transmitted between two points. Even private local area networks (LANs) are vulnerable to determined efforts by intruders to acquire physical access to the network. Consequently, if sensitive information is transmitted between computing devices on any type of network, users will almost certainly want to use some sort of encryption to keep their data private.

Encryption is the process of disguising a message or data in such a way as to hide its substance. It can be thought of as locking something valuable into a strongbox with a key. Conversely, decryption can be compared to opening the box and retrieving the valuable item. On computers, sensitive data in the form of e-mail messages, files on a disk, and files being transmitted across the network can be encrypted by using a key. Encrypted data and the key used to encrypt data are both unintelligible.

Public key encryption is not used to encrypt large amounts of data; instead, data is typically protected with a private key and that private key in turn is encrypted with the public key of the recipient of the data. The encrypted secret key will then be transmitted to the recipient along with the encrypted data. The recipient will use the private key to decrypt the secret key. The secret key will then be used to decrypt the message itself.

Certificates enable privacy for data that is transmitted using a number of different methods. Some of the commonly used privacy-enabling protocols that use certificates are:

- Secure Multipurpose Internet Mail Extensions (S/MIME).

- TLS.
- Encrypting File System (EFS)

**Data Integrity**
An increasing number of digital documents require strong evidence that the data has not been altered since it was signed and confirmation of the identity of the person or entity who signed the data. A digital signature helps ensure the integrity and origin of data, which are essential for secure e-commerce transactions.

Digital signatures are typically used when data is distributed in plaintext, or unencrypted, form. In these cases, although the sensitivity of the message itself might not warrant encryption, there could be a compelling reason to ensure that the data is in its original form and has not been sent by an impostor. In a distributed computing environment, plaintext can conceivably be read or altered by anyone on the network who has access to it, whether authorized or not.

**Certificate Dependencies**
To use certificates in Windows Server 2003, you need to set up a public key infrastructure (PKI), which consists of one or more CAs that are linked in a hierarchy. These CAs and the PKI are required to manage certificate issuance, validation, renewal, and revocation in one or more organizations.

You can use a third-party PKI with Windows Server 2003, or you can establish your own PKI based on Windows Server 2003 Certificate Services.

If you are using Active Directory to manage user and computer accounts on the network, your enterprise CAs can use information contained in Active Directory — such as user account names, security group memberships, and certificate templates — to simplify certificate enrollment, renewal, revocation, and validation.

In addition, Active Directory stores public key Group Policy for distribution to all computers that are within the scope of a Group Policy object. Public key Group Policy enables you to control which CAs are to be trusted in the enterprise, specify alternative EFS recovery agents, and configure automatic enrollment and renewal of certificates for computers running Windows 2000, Windows XP, and Windows Server 2003 — all from a central administration point.

Active Directory also supports mapping certificates to network user accounts for authenticating clients and controlling access to network resources. Using smart cards for the user logon process is a special case of certificate mapping that extends the Kerberos v5 authentication protocol to include authentication of users on the basis of certificates and private keys that are stored on smart cards. Using smart cards for the user logon process provides enhanced security for user authentication and a single set of user credentials for logging on locally or remotely over a network.

The following figure illustrates the role of domain client certificates in an Active Directory environment.

**Domain Client Certificates in Active Directory**

# How Certificates Work

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Certificates Work**

**In this section**

- Certificate Architecture
- Certificate Processes and Interactions
- Related Information

Digital certificates are electronic credentials that are used to assert the online identities of individuals, computers, and other entities on a network. Digital certificates function similarly to identification cards such as passports and drivers licenses. They are issued by certification authorities (CAs) that must validate the identity of the certificate-holder both before the certificate is issued and when the certificate is used. Common uses include business scenarios requiring authentication, encryption, and digital signing.

The following sections provide an in-depth view of how certificates work in an optimal environment. An optimal environment for certificates includes the following:

- A public key infrastructure (PKI) that has been designed, planned, and deployed with appropriate security measures to minimize the risk that CAs can be compromised.
- Certificate configurations have been planned so that only intended users can initiate certificate use, and certificates can only be used for the purposes intended.

**Certificate Architecture**

A digital certificate binds a user, computer, or service's identity to a public key by providing information about the subject of the certificate, the validity of the certificate, and applications and services that can use the certificate. Certificates issued in Windows Server 2003 and earlier PKIs are structured to meet these objectives based on standards established by the Public-Key Infrastructure (X.509) Working Group (PKIX) of the Internet Engineering Tasks Force (IETF). The following figure shows the contents of X.509 version 3 certificates as implemented in Windows Server 2003.

**X.509 Version 3 Certificate**

X.509 version 3 certificates are the current certificate format in a Windows Server 2003 PKI. Version 3 certificates support the following fields that have been supported since X.509 version 1:

- **Subject.** Provides the name of the computer, user, network device, or service that the CA issues the certificate to. The

subject name is commonly represented by using an X.500 or Lightweight Directory Access Protocol (LDAP) format.

- **Serial Number.** Provides a unique identifier for each certificate that a CA issues.
- **Issuer.** Provides a distinguished name for the CA that issued the certificate. The issuer name is commonly represented by using an X.500 or LDAP format.
- **Valid From.** Provides the date and time when the certificate becomes valid.
- **Valid To.** Provides the date and time when the certificate is no longer considered valid.

  **Note**

  - The date when an application or service evaluates the certificate must fall between the Valid From and Valid To fields of the certificate for the certificate to be considered valid.

- **Public Key.** Contains the public key of the key pair that is associated with the certificate.

In addition to the version 1 fields, X.509 version 3 certificates include extensions that provide additional functionality and features to the certificate. These extensions are optional and are not necessarily included in each certificate that the CA issues:

- **Subject alternative name.** A subject can be presented in many different formats. For example, if the certificate must include a user's account name in the format of an LDAP distinguished name, e-mail name, and a user principal name (UPN), you can include the e-mail name or UPN in a certificate by adding a subject alternative name extension that includes these additional name formats.
- **CRL distribution points (CDP).** When a user, service, or computer presents a certificate, an application or service must determine whether the certificate has been revoked before its validity period has expired. The CDP extension provides one or more URLs where the application or service can retrieve the certificate revocation list (CRL) from.
- **Authority Information Access (AIA).** After an application or service validates a certificate, the certificate of the CA that issued the certificate — also referred to as the parent CA — must also be evaluated for revocation and validity. The AIA extension provides one or more URLs from where an application or service can retrieve the issuing CA certificate.
- **Enhanced Key Usage (EKU).** This attribute includes an object identifier (OID) for each application or service a certificate can be used for. Each OID is a unique sequence of numbers from a worldwide registry.
- **Certificate policies.** Describes what measures an organization takes to validate the identity of a certificate requestor before it issues a certificate. An OID is used to represent the validation process and can include a policy-qualified URL that fully describes the measures taken to validate the identity.

**Certificate Templates**

Windows 2000 and Windows Server 2003 Enterprise CAs use certificate templates, stored in the Active Directory directory service, to provide the default attributes for a certificate. These attributes include authorized uses for the certificate, the cryptographic algorithms used with the certificate, the format of the subject, the public key length, issuance requirements, and the certificate lifetime.

Certificate templates are configured on an enterprise CA and are applied to accept or reject incoming certificate requests. Only enterprise CAs can issue certificates based on certificate templates. Certificate template information is stored in Active Directory in the container

`CN=Certificate Templates,CN=Public Key Services,CN=Services,CN=Configuration, DC=` *ForestRootNameDN*

where *ForestRootNameDN* is the LDAP distinguished name of the forest root domain.

Computers running Windows Server 2003 support two types of certificate templates: version 1 and version 2. Servers running Windows 2000 only support the issuance of certificates that are based on version 1 certificate templates.

When the first enterprise CA is installed in the forest, version 1 templates are created by default. Unlike version 2 templates,

these cannot be modified or removed. In Windows 2000, certificate management was very limited because only the templates' security permissions could be set.

Version 1 templates are provided for backward compatibility, and support many general needs for subject certification. For example, there are certificates that allow Encrypting File System (EFS) encryption, client authentication, smart card logon, or server authentication.

Version 2 certificate templates allow you to define specific attributes for certificates that meet your organization's business needs. Version 2 template definitions are stored in Active Directory, although you can create and modify version 2 templates at any computer running Windows Server 2003 or Windows XP Professional with the Windows Server 2003 Administration pack installed. Certificates based on version 2 templates can only be issued by a CA running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition.

**Types of Certificate Templates**

Only a few certificate templates are assigned to a fresh CA installation by default. Several predefined certificate templates and custom certificate templates must be assigned explicitly if needed.

There are two categories of certificate templates: certificate templates issued to users and certificate templates issued to computers. Only computers can use certificates that are issued to computers; likewise, only users can use certificates that are issued to users. Another way to distinguish between certificate templates is based on how they are used:

- **Single function.** A certificate template can be highly restricted and only be used for a single function. For example, you can use a Basic EFS certificate template only to encrypt and decrypt files that are protected by using EFS.

- **Multiple functions.** You can use a certificate template for multiple functions. For example, you can use a user certificate template to encrypt and decrypt files, authenticate with a server, and send and receive secure e-mail by using the same certificate.

After the upgrade to Windows Server 2003 certificate templates is completed, the following preconfigured certificate templates are listed in the Certificate Templates Microsoft Management Console (MMC).

**Windows Server 2003 Certificate Templates**

| Name | Description | Key Usage | Subject Type | Published to Active Directory |
|---|---|---|---|---|
| Administrator | Allows trust list signing and user authentication | Signature and encryption | User | Yes |
| Authenticated Session | Subject can authenticate to a Web server | Signature | User | No |
| Basic EFS | Used by EFS to encrypt data | Encryption | User | Yes |
| CA Exchange | Used to store keys that are configured for private key archival | Encryption | Computer | No |
| CEP Encryption | Allows the holder to act as a registration authority (RA) for simple certificate enrollment protocol (SCEP) requests | Encryption | Computer | No |
| Code Signing | Used to digitally sign software | Signature | User | No |
| Computer | Allows a computer to authenticate itself on the network | Signature and encryption | Computer | No |
| Cross-Certification Authority | Used in cross-certification and qualified subordination | Signature | CrossCA | Yes |
| Directory E-mail Replication | Used to replicate e-mail within Active Directory | Signature and encryption | DirEmailRep | Yes |

| | | | | |
|---|---|---|---|---|
| Domain Controller | All-purpose certificates held by domain controllers | Signature and encryption | DirEmailRep | Yes |
| Domain Controller Authentication | Used to authenticate Active Directory computers and users | Signature and encryption | Computer | No |
| EFS Recovery Agent | Allows the subject to decrypt files previously encrypted with EFS | Encryption | User | No |
| Enrollment Agent | Used to request certificates on behalf of another subject | Signature | User | No |
| Enrollment Agent (Computer) | Used to request certificates on behalf of another computer subject | Signature | Computer | No |
| Exchange Enrollment Agent (Offline request) | Used to request certificates on behalf of another subject and supply the subject name in the request | Signature | User | No |
| Exchange Signature Only | Used by Microsoft Exchange Key Management Service to issue certificates to Exchange users for digitally signing e-mail | Signature | User | No |
| Exchange User | Used by Microsoft Exchange Key Management Service to issue certificates to Exchange users for encrypting e-mail | Encryption | User | Yes |
| IPSEC | Used by IP Security (IPSec) to digitally sign, encrypt, and decrypt network communication | Signature and encryption | Computer | No |
| IPSEC (Offline request) | Used by IP Security (IPSec) to digitally sign, encrypt, and decrypt network communication when the subject name is supplied in the request | Signature and encryption | Computer | No |
| Key Recovery Agent | This certificate can recover private keys archived on the certification authority. | Encryption | KRA | Yes |
| Root Certification Authority | Used to prove the identity of the root certification authority | Signature | CA | Yes |
| Router (Offline request) | Used by a router when requested through SCEP from a CA that holds a CEP Encryption certificate | Signature and encryption | Computer | No |
| Smartcard Logon | Allows the holder to authenticate using a smart card | Signature and encryption | User | No |
| Smartcard User | Allows the holder to authenticate and protect e-mail using a smart card | Signature and encryption | User | Yes |
| Subordinate Certification Authority | Used to prove the identity of the root certification authority, issued by the parent or root certification authority | Signature | CA | Yes |
| Trust List Signing | The holder can digitally sign a trust list. | Signature | User | No |
| User | Certificate to be used by users for e-mail, EFS, and client authentication | Signature and encryption | User | Yes |
| User Signature Only | Allows users to digitally sign data | Signature | User | No |

| | | | | |
|---|---|---|---|---|
| Router (Offline request) | Used by a router when requested through SCEP from a CA that holds a CEP Encryption certificate | Signature and encryption | Computer | No |
| Smartcard Logon | Allows the holder to authenticate using a smart card | Signature and encryption | User | No |
| Smartcard User | Allows the holder to authenticate and protect e-mail using a smart card | Signature and encryption | User | Yes |
| Subordinate Certification Authority | Used to prove the identity of the root certification authority, issued by the parent or root certification authority | Signature | CA | Yes |
| Trust List Signing | The holder can digitally sign a trust list. | Signature | User | No |
| User | Certificate to be used by users for e-mail, EFS, and client authentication | Signature and encryption | User | Yes |

**Certificate Template Options**

The following sections detail the specific information that can be configured for a version 2 certificate template by using the Certificate Templates Microsoft Management Console (MMC) snap-in.

**Note**

- Because certificate templates exist only once within a forest, all changes made to the templates apply on a forest-wide level. If several CAs exist within one forest, templates can be assigned to CAs. Nevertheless, all CAs within a forest use one set of templates.

The **General** tab is the first tab that appears when a certificate template is duplicated. The **General** tab allows administrators to configure the following attributes of the certificate template:

- **Template display name,** The display name shown in the Certificate Templates, Certificates, and Certification Authority snap-ins.

- **Template name.** The name of the certificate template object created in the CN=Certificate Templates,CN=Public Key Services,CN=Services,DC=*ForestRootDomain* container.

- **Validity period.** Defines the validity period for an issued certificate. The validity period must not be greater than the validity period of the CA's certificate.

- **Renewal period.** The time before the validity period expires when the certificate will be renewed, if reenrollment is supported for the certificate template. By default, the minimum renewal period is 80 percent of the certificate lifetime or 6 weeks, whichever is greater.

- **Publish options.** Determines whether the certificate can be published to Active Directory. Certificates are published as an attribute of the security principal contained in the subject of the issued certificate.

- **Reenrollment option.** If the certificate template is published to Active Directory, this prevents reenrollment if a valid certificate of the same certificate template exists for the security principal indicated in the subject attribute of the certificate.

  **Note**

  - Re-enrollment settings mainly affect auto-enrollment design in a Windows Server 2003 network.

**Request Handling**

The options on the **Request Handling** tab define the purpose of the certificate template, the supported cryptographic service providers (CSPs), minimum key length, exportability, auto-enrollment settings, and whether strong private key protection should be required.

#### Certificate Purposes

The certificate purpose defines the intended primary use of the certificate. The certificate purpose can be one of four settings:

- **Encryption.** A certificate with this purpose will contain cryptographic keys for encryption and decryption.
- **Signature.** A certificate with this purpose will contain cryptographic keys for signing data only.
- **Signature and encryption.** A certificate with this purpose covers all primary uses of a certificate's cryptographic key, including encryption of data, decryption of data, initial logon, or digitally signing data.
- **Signature and smartcard logon.** A certificate with this purpose allows for initial logon with a smart card, and digitally signing data; it cannot be used for data encryption.

#### Archive Settings

When subject's lose their private keys due to the user profile becoming corrupted or being lost, or when a computer is stolen, any information that was persistently encrypted by using the corresponding public key is inaccessible. To help avoid this, Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition make it possible for a subject's encryption keys to be archived in the CA database when certificates are issued. If subject's lose their encryption keys, the information can be retrieved from the database and securely provided to the subject's. This allows the encrypted information to be recovered instead of lost.

### Note

- Signing keys cannot be archived. If signing keys are lost, the user must request a new set of signing keys.

The following key archival settings are defined on the **Request Handling** tab:

- **Archive subject's encryption private key.** If the issuing Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition CA is configured for key archival, the subject's encryption key will be archived.
- **Allow private key to be exported.** When this option is specified, the subject's private key can be exported for backup or transportation.
- **Deleting revoked or expired certificates (do not archive).** If a certificate is renewed with autoenrollment due to expiration or revocation, the previously issued certificate is removed from the subject's certificate store. By default, the certificate is archived.
- **Include symmetric algorithms allowed by the subject.** When the subject requests the certificate, they can supply a list of supported symmetric algorithms. This option allows the issuing CA to include those algorithms in the certificate, even if they are not recognized or supported by that server. The algorithms are used by applications like secure e-mail.

To enable key archival and recovery, the following configuration options must be set in the certificate template and at the Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition CA:

- The specific certificate template must be configured to allow key archival.
- One or more key recovery agents must be identified on the CA, and key recovery agent certificates must be issued to those agents.
- Key archival must be configured on the CA.

#### User Input Settings

The **Request Handling** tab also allows several user input settings to be defined for a certificate template. These settings can be used to implement strong private key protection. These settings include:

- **Enroll subject without requiring any user input.** This option allows auto-enrollment without any user interaction and is the default setting for both computer and user certificates. This option must not be enabled for computer certificates.

- **Prompt the user during enrollment.** Although useful when testing initial auto-enrollment deployments, typically, this option is disabled. By disabling this option, users do not have to provide any input for the installation of a certificate based on the certificate template.

- **Prompt the user during enrollment and require user input when the private key is used.** This option enables the user to set a strong private key protection password on the user's private key when the key is generated, and requires the user to use it whenever the certificate and private key are used. This option must not be enabled for computer certificates or smart card user certificates.

  **Note**

  - To enable smart card auto-enrollment, the **Prompt the user during enrollment** check box must be selected so that the user is prompted to insert the smart card in the smart card reader when required.

**Other Request Handling Settings**

In addition to key archival settings, some general options that affect all certificates, including those that do not enable key archival, can be defined. These include:

- **Minimum key size.** This specifies the minimum size, in bits, of the key that will be generated for this certificate.

- **Cryptographic service providers.** This is a list of CSPs that will be used to enroll certificates for the given template. The list is compiled from all CSPs that are available on the computer that is used to maintain the certificate template. Selecting one or more CSPs configures the certificate to only work with those CSPs. If you do not select a specific CSP, the certificate enrollment will work with any installed CSP, but will use the first CSP from the enumeration list. The CSP must be installed on the client workstation for the CSP to be used during enrollment. If a specific CSP is chosen and not available on a client computer, enrollment will fail. If you need to restrict the CSP choice to a specific third party CSP, you must have the CSP installed on the computer that is used to configure the certificate template.

  **Note**

  - For more information, see "CSPs" later in this section.

**Subject Name**

When configuring a certificate template, subject name guidelines must be defined. The subject name of a certificate identifies the user, computer, or service that the certificate represents. This is included in the issued certificate template and must uniquely identify the subject. The subject name can either be built automatically during the certificate request by using the authentication name of the subject or explicitly defined by the subject and included in the certificate request. Windows obtains the attributes as defined in the CA's registry from Active Directory for automatic building. To provide the name manually, the subject supplies that information in the certificate request, for example by using the Web-based enrollment pages.

A number of options can be included with the subject name, in addition to specific configuration settings for the subject name when the subject name is built from Active Directory information during the certificate request process. The format of the subject name can be defined as:

- **None.** Does not enforce any name format for this field.

- **Common name.** The CA creates the subject name from the common name (CN) of the requestor obtained from Active Directory. These should be unique within a domain, but might not be unique within an enterprise.

- **Fully distinguished name.** The CA creates the subject name from the fully distinguished name obtained from Active Directory. This guarantees that the name is unique within an enterprise.

In addition, you can choose to include the e-mail name in the subject name. This information is populated from the e-mail attribute of an account, and is included with either the CN or fully distinguished name as part of the subject name.

In addition to the subject name, you can also choose which name formats are included in the alternate subject name attributes of issued certificates. The alternate subject name formats that are available include:

- **E-mail name.** If the e-mail name field is populated in the Active Directory user object, that e-mail name will be used for user accounts.

  **Note**

  - The e-mail name is required for user certificates. If the e-mail name is not populated for a user in Active Directory, the certificate request by that user will fail.

- **Domain Name System (DNS) name.** The FQDN of the subject that requested the certificate is used for computer accounts.

- **User principal name (UPN).** The UPN is part of the Active Directory user object and will be used for user accounts.

- **Service principal name (SPN).** The SPN is part of the Active Directory computer object and will be used for computer accounts.

Usually, a subject cannot request a certificate that uses a nonmatching subject name. For example, user1@example.com would not be allowed to request a certificate with a subject name of user2@example.com.

The only subject that can request a certificate for another user is one who holds a certificate based on the Enrollment Agent template. That subject can request certificates on behalf of any other subject. For example, an enrollment agent can request Smart Card User or Smart Card Logon certificates on behalf of other users.

The only case in which a subject can request a certificate with a different subject name is when the request holds a certificate based on the Enrollment Agent template. The Enrollment Agent template allows a subject to request a certificate on behalf of another subject.

#### Issuance Requirements

The **Issuance Requirements** tab allows higher assurance-level certificates to be placed in a pending state until the certificate is reviewed before it is issued. The following settings configure the authentication and signature requirements for issuance certificates that are based on a template:

- **CA certificate manager approval.** All certificate requests are placed into the pending container of the CA for a certificate manager to issue or deny. Any defined certificate manager can issue or deny a certificate request of this type.

- **This number of authorized signatures.** This setting requires the Certificate Management Messages over CMS (CMC) certificate request to be digitally signed by one or more authorized parties before it can be issued.

  **Note**

  - Defining the number of authorized signatures enables several other configuration parameters.

- **Policy type required in signature.** This option is only enabled when the **This number of authorized signatures** value is set. This option defines which specific application policy, issuance policy, or both are required in the signing certificate. This is how the CA determines whether the signature is appropriate for authorizing the issuance of the subject's certificate.

- **Application policy.** This option specifies the application policy that must be included in the signing certificate used to sign the certificate request. It is enabled when **Policy type required in signature** is set to either **Application policy** or **Both application and issuance policy**.

- **Issuance policy.** This option specifies the issuance policy that must be included in the signing certificate used to sign the certificate request. This option is enabled when **Policy type required in signature** is set to either **Issuance policy** or **Both application and issuance policy**.

#### Superseded Templates

The **Superseded Templates** tab allows existing certificate templates to be superseded with a modified version 2 certificate template. The following scenarios are supported:

- A version 2 certificate template can supersede a version 1 certificate template.
- A version 2 certificate template can supersede a version 2 certificate template.
- A common version 2 certificate template can supersede multiple existing certificate templates.

#### Extensions

The **Extensions** tab allows an administrator to define specific application policies, issuance policies, certificate subject types, and key usage attributes for a certificate template. The following sections detail the specifics on each form of extension defined in a certificate template.

#### Application Policies

Application policies are settings that inform a target that the subject holds a certificate that can be used to perform a specific task. They are represented in a certificate by an OID that is defined for a given application. This OID is included in the issued certificate. When a subject presents its certificate, the certificate can be examined by the target to verify the application policy and determine whether the subject can perform the requested action.

The following table shows some of the more commonly used application policies and their related OIDs.

**Commonly Used Application Policies and OIDs**

| Application Policy | OID |
|---|---|
| Client Authentication | 1.3.6.1.5.5.7.3.2 |
| CA Encryption Certificate | 1.3.6.1.4.1.311.21.5 |
| Smart Card Logon | 1.3.6.1.4.1.311.20.2.2 |
| Document Signing | 1.3.6.1.4.1.311.10.3.12 |
| File Recovery | 1.3.6.1.4.1.311.10.3.4.1 |
| Key Recovery | 1.3.6.1.4.1.311.10.3.11 |
| Microsoft Trust List Signing | 1.3.6.1.4.1.311.10.3.1 |
| Qualified Subordination | 1.3.6.1.4.1.311.10.3.10 |
| Root List Signer | 1.3.6.1.4.1.311.10.3.9 |
| Encrypting file system | 1.3.6.1.4.1.311.10.3.4 |

By restricting which application policies are defined in a certificate template, a certificate cannot be used for undesired transactions. For example, a certificate with the Secure E-mail OID cannot be used for client authentication.

Because some implementations of PKI applications might not understand application policies, both application policies and EKU fields appear in certificates that a Microsoft CA issues. EKU is similar to application policy in that EKU also defines the functions of certificate.

#### Certificate Policies

Certificate policies, also referred to as issuance policies, define the measures that are used to identify the subject of the certificate and thereby define the level of assurance for an issued certificate. For example, your organization might require a face-to-face meeting before the certificate is issued to provide for a higher level of assurance for the issued certificate.

**Note**

- Certificate policies refer to the certificate policies extension identifier described in RFC 2459.

Issuance policies are represented in a certificate by an OID that is defined at the CA. This OID is included in the issued certificate. When a subject presents its certificate, the certificate can be examined by the target to verify the issuance policy and determine whether that level of issuance policy is sufficient for the subject to perform the requested action.

The following table describes the three default certificate policy OIDs included in Windows Server 2003.

**Default certificate policy OIDs in Windows Server 2003.**

| OID type | Description |
|---|---|
| Low assurance | Provides no additional mechanism to identify the subject of the certificate. For example, a certificate that is issued based only on the credentials provided can be a low assurance certificate. |
| Medium assurance | Requires additional validation of the certificate's subject. For example, a smart card certificate might require an administrator to have a face-to-face meeting with an employee before issuing the smart card to an employee. |
| High assurance | Requires research into the subject's identity. For example, a high assurance certificate might require that an organization perform a background check on an employee before issuing the certificate. |

**Note**

- The low, medium, and high assurance OIDs are unique for each Active Directory forest.

One or more issuance policies can be set for a certificate template. Because these issuance policies are simply text labels with an associated OID, no options are associated with them. The only special issuance policy is **All issuance policies**, which indicates that this policy includes all others. This is normally reserved for certificates held by CAs.

Issuance policies are often used when configuring qualified subordination (cross-certification) between PKI hierarchies to ensure that certificates that are recognized by another organization's PKI meet your organization's issuance requirements.

You can also configure a certificate template to increase the issuance security of a certificate by requiring the user or computer to provide additional forms of identification for the certificate request. The additional forms of identification can include providing photo identification, meeting face to face with a local registration authority, or signing the certificate request with a previously issued signing certificate. These can be implemented by using the following issuance options:

- **Certificate Manager Approval.** This setting sets all certificate requests to a pending state until a certificate manager issues or denies the certificate request. The certificate manager must first validate the identity of the certificate requestor before issuing or denying the certificate request. In some cases, the certificate manager will record any forms of identification that the user presents into a custom certificate issuance database application.

- **Signing Requests.** An existing certificate can sign a certificate request to increase the issuance security. You can configure a certificate template to require a signature by using a certificate request with a specific application policy OID, certificate policy OID, or combination of application and certificate policy OIDs. The assumption here is that the possession of the private key associated with the signing certificate increases the issuance security of the certificate request.

**Certificate Template Information**

The certificate template information, also referred to as the certificate subject type, defines the purpose of a certificate template. Six subject types are recognized by Windows Server 2003 CAs:

- Key recovery agent
- Directory e-mail replication
- Cross-certified CA
- CA
- Computer
- User

The certificate template information extension cannot be edited. If an administrator requires a specific subject type to be applied to a certificate, the administrator should clone from a certificate template that includes the required subject type.

**Key Usage**
A certificate enables the subject to perform a specific task. To help control the usage of a certificate outside its intended purpose, restrictions are automatically placed on certificates. Key usage is a restriction method that determines what a certificate can be used for. It allows the administrator to issue certificates that can only be used for specific tasks or certificates that can be used for a broad range of functions. If no key usage is specified, the certificate can be used for any purpose.

For signatures, key usage can be limited to one or more of the following purposes:

- Digital signature
- Signature is a proof of origin (nonrepudiation)
- Certificate signing
- CRL signing

For encryption key usage, the following options are available:

- Key exchange without key encryption
- Key exchange only with key encryption

**Security**
The **Security** tab allows you to define the discretionary access control list (DACL) for a specific certificate template. The permissions that can be assigned to a certificate template include:

- **Full Control.** This permission allows a security principal to modify all attributes of a certificate template, including the permissions for the certificate template.
- **Read.** This permission allows a security principal to see the certificate template when enrolling for certificates. It is required for a security principal to enroll or auto-enroll a certificate; it is required by the certificate server to find the certificate templates in Active Directory.
- **Write.** This permission allows a security principal to modify the attributes of a certificate template, including the permissions assigned to the certificate template.
- **Enroll.** This permission allows a security principal to enroll for a certificate based on the certificate template. To enroll for a certificate, the security principal must also have Read permissions for the certificate template.
- **Autoenroll.** This permission allows a security principal to receive a certificate through the auto-enrollment process. Auto-enrollment permissions require that the user has both Read and Enroll permissions in addition to the Auto-enroll permission.

  **Note**

  - It is recommended that certificate template permissions be assigned only to global groups or universal groups. Because the certificate template objects are stored in the Configuration naming context, you cannot assign permissions using domain local groups. To simplify administration, it is never recommended to assign certificate template permissions to individual user or computer accounts.

**Certificate Template Objects Defined in the Windows Schema**
The Certificate Templates container contains the certificate templates that are defined within an Active Directory forest. Each certificate template is of the class pKICertificate.

Each template is stored in the following location in the Configuration naming context:

```
CN=<name of template>,CN=Certificate Templates,CN=Public Key
Services,CN=Services,CN=Configuration,DC= ForestRootDomain
```

The following version 1 attributes are defined in the Active Directory schema.

**Version 1 Attributes**

| Attribute Name | Description |
|---|---|
| cn | Common name of the certificate type |
| distinguishedName | The common name of the certificate type |
| displayName | The display name of a certificate type |
| pKIExtendedKeyUsage | An array of extended key usage object identifiers (OIDs) for a certificate type |
| pKIDefaultCSPs | The list of default CSPs for this certificate type |
| pKICriticalExtensions | The list of critical extensions |
| revision | The major version of the template |
| templateDescription | The description of the template |
| flags | General enrollment flags (see below) |
| pKIDefaultKeySpec | |
| NTSecurityDescriptor | Security Descriptor name |
| pKIKeyUsage | Key Usage extension |
| pKIMaxIssuingDepth | Basic Constraints |
| pKIExpirationPeriod | Certificate validity period |
| pKIOverlapPeriod | Certificate renewal period |

The following version 2 attributes are defined in the Active Directory schema.

**Version 2 Attributes**

| Attribute name | Description |
|---|---|
| msPKI-Template-Schema-Version | The schema version of the template |
| msPKI-Template-Minor-Revision | The minor version of the template |
| msPKI-RA-Signature | The number of RA signatures required on a request referencing this template |
| msPKI-Minimal-Key-Size | The minimal key size required |
| msPKI-Template-Cert-Template-OID | The OID of this template |
| msPKI-Supersede-Templates | The OID of the template that this template supersedes |
| msPKI-RA-Policies | The RA issuer policy OIDs required in certificates used to sign a request |

| | |
|---|---|
| msPKI-RA-Application-Policies | The RA application policy OIDs required in certificates used to sign a request |
| msPKI-Certificate-Policy | The certificate issuer policy OIDs are placed in the OID_CERT_POLICIES extension by the policy module |
| msPKI-Certificate-Application-Policy | The certificate application policy OIDs are placed in the OID_APPLICATION_CERT_POLICIES extension by the policy module |
| msPKI-Enrollment-Flag | Enrollment flags (see below) |
| msPKI-Private-Key-Flag | Private key flags (see the following section) |
| msPKI-Certificate-Name-Flag | Subject name flags (see the following section) |

**Flags**

The following enrollment flags are defined in the Active Directory schema.

**Enrollment Flags**

| Flag | Description |
|---|---|
| CT_FLAG_INCLUDE_SYMMETRIC_ALGORITHMS<br>0x00000001 | Include the S/MIME symmetric algorithms in the requests |
| CT_FLAG_PEND_ALL_REQUESTS<br>0x00000002 | All certificate requests are pended |
| CT_FLAG_PUBLISH_TO_KRA_CONTAINER<br>0x00000004 | Publish the certificate to the key recovery agent (KRA) container in the Active Directory |
| CT_FLAG_PUBLISH_TO_DS<br>0x00000008 | Publish the resultant certificate to the userCertificate property on the user object in the Active Directory |
| CT_FLAG_AUTO_ENROLLMENT<br>0x00000020 | This certificate can be issued through auto-enrollment |
| CT_FLAG_PREVIOUS_APPROVAL_VALIDATE_REENROLLMENT<br>0x00000040 | A previously issued certificate will validate subsequent enrollment requests |
| CT_FLAG_DOMAIN_AUTHENTICATION_NOT_REQUIRED<br>0x00000080 | Domain authentication is not required |
| CT_FLAG_USER_INTERACTION_REQUIRED<br>0x00000100 | User interaction is required to enroll using auto-enrollment |
| CT_FLAG_ADD_TEMPLATE_NAME<br>0x00000200 | Add the szOID_CERTTYPE_EXTENSION (template name) extension Note: This flag will only be set on version 1 certificate templates and only for Windows 2000 CAs |
| CT_FLAG_REMOVE_INVALID_CERTIFICATE_FROM_PERSONAL_STORE<br>0x00000400 | Remove invalid (expired or revoked) certificates from the personal store on local client computers during auto-enrollment |

The following subject name flags are defined in the Active Directory schema.

**Subject Name Flags**

| Flag | Description |
| --- | --- |
| CT_FLAG_ENROLLEE_SUPPLIES_SUBJECT<br>0x00000001 | The enrolling application must supply the subject name |
| CT_FLAG_ENROLLEE_SUPPLIES_SUBJECT_ALT_NAME<br>0x00010000 | The enrolling application must supply the subjectAltName in the certificate request |
| CT_FLAG_SUBJECT_REQUIRE_DIRECTORY_PATH<br>0x80000000 | The subject name should be the full distinguished name (DN) based on the Active Directory path |
| CT_FLAG_SUBJECT_REQUIRE_COMMON_NAME<br>0x40000000 | The subject name should be the common name |
| CT_FLAG_SUBJECT_REQUIRE_EMAIL<br>0x20000000 | The subject name must include the e-mail name |
| CT_FLAG_SUBJECT_REQUIRE_DNS_AS_CN<br>0x10000000 | The subject name must include the DNS name as the common name |
| CT_FLAG_SUBJECT_ALT_REQUIRE_DNS<br>0x08000000 | The subject alternative name must include the DNS name |
| CT_FLAG_SUBJECT_ALT_REQUIRE_EMAIL<br>0x04000000 | The subject alternative name must include the e-mail name |
| CT_FLAG_SUBJECT_ALT_REQUIRE_UPN<br>0x02000000 | The subject alternative name must include the UPN |
| CT_FLAG_SUBJECT_ALT_REQUIRE_DIRECTORY_GUID<br>0x01000000 | The subject alternative name must include the directory GUID (used by domain controllers) |
| CT_FLAG_SUBJECT_ALT_REQUIRE_SPN<br>0x00800000 | The subject alternative name must include the service principal name (SPN) |
| CT_FLAG_SUBJECT_ALT_REQUIRE_DIRECTORY_GUID<br>0x01000000 | The subject alternative name must include the directory GUID |
| CT_FLAG_SUBJECT_ALT_REQUIRE_SPN<br>0x00800000 | The subject alternative name requires SPN |

The following private key flags are defined in the Active Directory schema.

**Private Key Flags**

| Flag | Description |
| --- | --- |
| CT_FLAG_ALLOW_PRIVATE_KEY_ARCHIVAL<br>0x00000001 | Archival of the private key is allowed or required |
| CT_FLAG_EXPORTABLE_KEY<br>0x00000010 | Mark the private key as exportable |

The following general flags are defined in the Active Directory schema.

**General Flags**

| Flag | Description |
|---|---|
| CT_FLAG_MACHINE_TYPE<br>0x00000040 | This is a machine certificate |
| CT_FLAG_IS_CA<br>0x00000080 | This is a CA certificate |
| CT_FLAG_IS_CROSS_CA<br>0x00000800 | This is a cross-CA certificate |
| CT_FLAG_IS_DEFAULT<br>0x00010000 | Default certificate type that is set on all version 1 templates that cannot be modified |
| CT_FLAG_IS_MODIFIED<br>0x00020000 | The certificate type has been modified (read only) |
| CT_MASK_SETTABLE_FLAGS<br>0x0000ffff | Flag that can be set for general flags |

**CSPs**

Microsoft CryptoAPI provides a secure interface to the installable CSP modules that perform all cryptographic operations and manage private keys for all Windows Server 2003 cryptographic services, including Certificate Services.

Vendors can develop hardware or software CSPs that support a wide range of cryptographic operations and technologies. However, Microsoft must certify and digitally sign all CSPs. CSPs do not work in Windows Server 2003 unless they have been digitally signed by Microsoft.

**Note**

- For more information about obtaining a Microsoft digital signature for a CSP, see the Platform Software Development Kit (SDK) on MSDN.

Windows Server 2003 includes the following Microsoft CSPs:

- **Microsoft Base Cryptographic Service Provider:** The Base CSP provides a broad set of basic cryptographic functions. It is not subject to United States government cryptography export restrictions and can be exported to other countries (subject to general United States export restrictions in addition to the import restrictions of other countries). The Base CSP uses Rivest-Shamir-Adelman (RSA) technology, which is licensed from RSA Data Security, Inc.

- **Microsoft Strong Cryptographic Service Provider:** The Strong CSP is an extension of the Base CSP available with Windows 2000 and Windows Server 2003. It supports all the algorithms in the Enhanced CSP, but the key lengths are the same as in the Base CSP. It supports RSA, Data Encryption Standard (DES), 3DES, RC2, and RC4 in addition to (Message-Digest Algorithm) MD5 and Secure Hash Algorithm 1 (SHA1).

- **Microsoft Enhanced Cryptographic Service Provider:** The Enhanced CSP provides the same capabilities as the Base CSP, but enforces stronger security by supporting longer key lengths and additional cryptographic algorithms. The Enhanced CSP also uses RSA technology.

The following table highlights differences between the Base CSP and the Enhanced CSP. The public key lengths shown in the table are the default key lengths.

**Comparison of Microsoft Base CSP and Microsoft Enhanced CSP**

| Algorithm | Base CSP | Strong CSP | Enhanced CSP |
|---|---|---|---|

| | | | |
|---|---|---|---|
| RSA public key signature algorithm | Key length: 512 bits. | Key length: 1,024 bits. | Key length: 1,024 bits. |
| RSA public key exchange algorithm | Key length: 512 bits. | Key length: 1,024 bits. | Key length: 1,024 bits. |
| RC2 block encryption algorithm | Key length: 40 bits. | Key length: 128 bits. | Key length: 128 bits. Salt length: Settable. |
| RC4 stream encryption algorithm | Key length: 40 bits. | Key length: 128 bits. | Key length: 128 bits. Salt length: Settable. |
| DES | Key length: 56 bits. | Key length: 56 bits. | Key length: 56 bits. |
| Triple DES (2-key) | Not supported. | Key length: 112 bits. | Key length: 112 bits. |
| Triple DES (3-key) | Not supported. | Key length: 168 bits. | Key length: 168 bits. |
| SHA1 | Key length: 160 bits. | Key length: 160 bits. | Key length: 160 bits. |
| Message Digest 2 (MD2) | Key length: 128 bits. | Key length: 128 bits. | Key length: 128 bits. |
| Message Digest 4 (MD4) | Key length: 128 bits. | Key length: 128 bits. | Key length: 128 bits. |
| Message Digest 5 (MD5) | Key length: 128 bits. | Key length: 128 bits. | Key length: 128 bits. |
| SSL3 (SHAMD5) | Key length: 288 bits. | Key length: 288 bits. | Key length: 288 bits. |
| Message Authentication Code (MAC) | Key length: 512 bits. | Key length: 1,024 bits. | Key length: 1,024 bits. |

Public keys used with the Base, Strong, and Enhanced CSPs for digital signatures can be up to 16,384 bits long. However, the public keys used for key encryption and key exchange (to protect secret keys) are limited to a maximum of 1,024 bits for the Base and Strong CSPs, and 16,384 bits for the Enhanced CSP. In addition, the symmetric keys for the encryption algorithms in the Base CSP are limited to shorter key lengths, resulting in significantly weaker cryptographic security. Overall, the key lengths and the encryption algorithms in the Enhanced CSP provide far stronger cryptographic security.

For the Base, Strong, and Enhanced CSP, public keys used for signing or key exchange can be a minimum of 384 bits long. However, public keys of at least 1,024 bits are recommended, unless they adversely affect computer performance.

The default public key length of the Strong and Base CSPs is 512 bits, and the default public key length of the Enhanced CSPs is 1,024 bits. Windows Server 2003 Certificate Services uses the default public key lengths of the CSP, although any key length the CSP supports can be configured.

The Strong and Enhanced CSPs are compatible with the Base CSP except that the CSPs can generate only RC2 or RC4 keys of the default key length. The default symmetric key length for RC2 and RC4 in the Base CSP is 40 bits. The default symmetric length for RC2 and RC4 in the Strong and Enhanced CSP is 128 bits. Therefore, the Enhanced CSP cannot create keys with Base CSP–compatible key lengths. However, the Strong and Enhanced CSPs can import RC2 and RC4 keys of up to 128 bits. Therefore, the Strong and Enhanced CSPs can import and use 40-bit keys that were generated by using the Base CSP.

Other Microsoft CSPs include:

- **Microsoft Base DSS Cryptographic Service Provider.** This CSP provides data signing and signature verification capability by using the SHA and Digital Signature Algorithm (DSA).

- **Microsoft Base DSS and Diffie-Hellman Cryptographic Service Provider.** This CSP provides a superset of the DSS Cryptographic Provider and also supports Diffie-Hellman key exchange, hashing (message digests), data signing, and signature verification by using the SHA and DSA algorithms.

- **Microsoft Base DSS and Diffie-Hellman/Schannel Cryptographic Service Provider.** This CSP offers various cryptographic services that are required for data integrity, session key exchange, and authentication during secure Web communications by using the SSL and Transport Layer Protocol (TLS) protocols.

- **Microsoft RSA/Schannel Cryptographic Provider:** This CSP is similar to the Microsoft Base DSS and Diffie-Hellman/Schannel Cryptographic Provider in that it works with SSL3 and TLS1, but uses the RSA suite of algorithms rather than Diffie-Hellman.

- **Smart Card Cryptographic Service Providers:** Windows Server 2003 includes smart card CSPs from a number of vendors, including Schlumberger, Gemplus, and Infineon.

**Local Certificate Storage**
In Windows Server 2003, public-key objects such as certificates, CRLs, and certificate trust lists (CTLs) are stored in certificate stores for use by users, services, and computers. The Windows Server 2003 certificate stores include physical stores and logical stores.

Physical certificate stores can be local or remote:

- Local objects are stored in the registry of the computer.

- The user object in Active Directory has a virtual store on the userCertificate attribute,

Many public key objects in the physical stores are shared among users, services, and computers through the use of logical certificate stores. These logical certificate stores group certificates together in logical, functional categories for users, computers, and services and provide pointers to the physical certificate stores. The use of logical certificate stores eliminates the need to store duplicates of common public key objects, such as trusted root certificates, CTLs, and CRLs for users, computers, and services.

However, some certificates, CTLs, or CRLs are issued for use only by an individual service, user, or local computer. Therefore, users, computers, and services also have individual stores that provide a place to store certificates, CTLs, or CRLs that are not shared in common. For example, a user can request and obtain a certificate or a CRL, which appears in the individual's logical store and is physically stored in the user's unique certificate store in the registry. Such individual user certificates and CRLs are not shared with local computers or with services.

In addition, some public-key objects, such as trusted root certificates and CTLs, can be distributed through Public Key Group Policy. Public key objects that are distributed through Group Policy are stored in special areas of the registry and appear in the logical stores for users, computers, and services. When you use Group Policy, separate CTLs can be created for users and computers. The CTLs for users are not shared with services or the computer. However, the CTLs for computers are shared with users and services.

The logical certificate stores include the following categories for users, computers, and services:

- **Personal** Contains individual certificates for the user, service, or computer. For example, when an enterprise CA issues you a User certificate, the certificate is installed in the Personal store for your user account.

- **Trusted Root Certification Authorities** Contains certificates for root CAs. Certificates with a certification path to a root CA certificate are trusted by the computer for all valid purposes of the certificate.

- **Disallowed Certificates** These are certificates that a user has explicitly decided not to trust using either Software Restriction policy or by clicking "Do not trust this certificate" when the decision is presented in an e-mail application or a Web browser.

- **Third-Party Root Certification Authorities** Trusted root certificates from certification authorities other than Microsoft and your organization.

- Enterprise Trust Contains CTLs. Certificates with a certification path to a CTL are trusted by the computer for purposes specified in the CTL.

- **Intermediate Certification Authorities** Contains certificates for CAs that are not trusted root certificates (for example, certificates of subordinate CAs), but that are required to validate certification paths. This store also contains CRLs for use by the user, service, or computer, and cross certificates..

- **Active Directory User Object** Contains certificates that are published in Active Directory for the user. This store appears in the Certificates snap-in for users only, not for computers or services.

- **Request** Contains pending or rejected certificate requests. This store appears only in the Certificates snap-in after a certificate request has been made for the user, computer, or service.

- **SPC** Contains certificates for software publishers that are trusted by the computer. Software that has been digitally

signed by publishers with certificates in this store is downloaded without prompting the user. By default, this store is empty. When Microsoft Internet Explorer downloads software that has been signed by a software publisher for the first time, users are prompted to choose whether they want to trust all software that is signed by this publisher. If a user chooses to trust all software signed by the publisher, the publisher's software publisher certificate (SPC) is added to the SPC store. This store appears in the Certificates snap-in for the local computer only, not for users or services.

- **Trusted People** Certificates issued to people or end entities that are explicitly trusted. Most often these are self-signed certificates or certificates explicitly trusted in an application such as Microsoft Outlook.

- **Other People** Certificates issued to people or end entities that are implicitly trusted. These certificates must be part of a trusted certification hierarchy. Most often these are cached certificates for services like Encrypting File System, where certificates are used for creating authorization for decrypting an encrypted file.

- **Certificate Enrollment Requests** Pending or rejected certificate requests.

- **Server Authentication** Certificates that server programs use to authenticate themselves to clients.

- **Client Authentication** Certificates that client programs use to authenticate themselves to servers.

- **Code Signing** Certificates associated with key pairs used to sign active content.

- Secure E-mail Certificates associated with key pairs used to sign e-mail messages.

- **Encrypting File System** Certificates associated with key pairs that encrypt and decrypt the symmetric key used for encrypting and decrypting data by the encrypting file system.

- **File Recovery** Certificates associated with key pairs that encrypt and decrypt the symmetric key used for recovering encrypted data by the encrypting file system.

  **Note**

  - Other applications can also create their own certificate stores.

Changes to the logical certificate stores are made to the appropriate physical stores that are located in either the registry or Active Directory. Because you use only the logical certificate store for a user, service, or computer, you do not have to track where the certificates are actually stored or edit the registry to manage the certificate stores. However, it is a good idea to track changes made to the physical and logical stores; this information can be useful when you try to determine why certificate-enabled actions succeed or fail.

**Viewing Physical and Logical Stores**

Certificate management tools distinguish between the physical structure of certificate stores and their logical abstraction. The logical abstraction, which simplifies the physical structure, was implemented to group certificates by function or purpose and to enable administrators to understand certificate stores in a simpler way.

A number of tools are available to view the physical and logical stores:

- Internet Explorer shows only the logical certificate stores.

- The Certificates snap-in shows the logical structure by default; however, it is possible to view the physical structure. On the **View** menu, click **Options**, and then click **Show the following: Physical certificate stores**.

- The Registry Editor (Regedit.exe) displays only the physical certificate store structure.

- The Certutil command-line tool (Certutil.exe) refers to certificate stores by labels that are equal to the store names in the registry or LDAP directory.

  **Note**

- For more information about the certificate management tools and registry stores for certificates, CRLs, and CTLs, see "Resource Kit Tools" in Tools and Settings Collection.

**Private Keys Stored in User Profiles**
Users' private keys are stored on the local file system in the following locations:

- $:\Documents and Settings\%UserName%\Application Data\Microsoft\Crypto\RSA
- $:\Documents and Settings\%UserName%\Application Data\Microsoft\Crypto\DSS

Computer private keys are stored on the local file system in the following locations:

- $:\Documents and Settings\All users\Application Data\Microsoft\Crypto\RSA\Machine Keys
- $:\Documents and Settings\All users\Application Data\Microsoft\Crypto\DSS\Machine Keys

The **Security** properties page indicates who can access this private key.

Windows associates certificates with their owner. By default, every subject that has permissions to log on to the computer or run as a service owns a set of certificate stores.

The number of certificates per store is limited only by memory and hard disk space. For certificates that are stored in the registry, the limiting factor is the total size of the registry. For information about the physical store location, see the individual store description later in this section.

**Personal Certificates Stored in User Profiles**
Certificates that are stored in the personal certificate store belong to the current user. These certificates in appear in the file system in:

```
%USERPROFILE%\Application Data\Microsoft\Systemcertificates\My
```

Access to the personal certificate store is restricted to the user who owns the certificate.

The personal store receives certificates from auto-enrollment or when a user requests a certificate manually. If a user imports a personal certificate, the certificate is stored in the Personal container.

This store maintains certificates of any type. A user who owns an S/MIME certificate, an EFS, certificate and a client-authentication certificate, for example, will see these certificates in his or her personal certificate store.

For roaming profiles, the users certificates are located on the share that hosts the user's profile. Because user certificates and private keys are part of the user's profile, this information is transmitted over the network when a roaming profile is read from or written to the server share.

**Certificate Processes and Interactions**
Certificates are credentials, and like other forms of credentials they need to be created before they can be used. After they have been created, there needs to be a means of validating their authenticity and verifying that they can be used for the desired purpose. After certificates have been created and validation processes are in place, certificates can be used for the following basic cryptographic operations:

- Public key encryption
- Message digest functions
- Digital signing

**How Certificates Are Created**
Certificates are issued by a CA, which can be any trusted service or entity willing to verify and validate the identities of those to whom it issues certificates and their association with specific keys. Companies might issue certificates to employees, schools might issue certificates to students, and so on. Of course, a CA's public key must be trustworthy or the certificates it issues will not be trusted. Because anyone can become a CA, certificates are only as trustworthy as the authority that issues the underlying keys.

The following six steps describe the process of requesting and issuing a certificate.

1. Generate a key pair The applicant generates a public and private key pair or is assigned a key pair by some authority in his or her organization.

2. Collect required information The applicant collects whatever information the CA requires to issue a certificate. The information could include the applicant's e-mail address, birth certificate, fingerprints, notarized documents — whatever the CA needs to be certain that the applicant is who he or she claims to be. CAs with stringent identification requirements produce certificates with high assurance — that is, their certificates generate a high level of confidence. CAs themselves are said to be of high, medium, or low assurance.

3. Request the certificate The applicant sends a certificate request, consisting of his or her public key and the additional required information, to the CA. The certificate request, which is signed with the client's public key, can also be encrypted by using the CA's public key. Many requests are made by using e-mail, but requests can also be sent by postal or courier service — for example, when the certificate request itself must be notarized.

4. Verify the information The CA applies whatever policy rules it requires to verify that the applicant should receive a certificate. As with identification requirements, a CA's verification policy and procedures influence the amount of confidence generated by the certificates it issues.

5. Create the certificate The CA creates and signs a digital document containing the applicant's public key and other appropriate information. The signature of the CA authenticates the binding of the subject's name to the subject's public key. The signed document is the certificate.

6. Send or post the certificate The CA sends the certificate to the applicant or posts the certificate in a directory, as appropriate.

**How Certificates Are Validated**

Before it trusts certificates, Windows performs a validation check to ensure that certificates are valid and that they have a valid certification path.

The status of a public key certificate is determined through three distinct, but interrelated, processes implemented in CryptoAPI:

- Certificate discoveryThe process of collecting CA certificates from Group Policy, Enterprise Policy, and AIA pointers in issued certificates, and the process of enrolling certificates.

- Path validationThe process by which public key certificates and their issuer certificates are processed in a hierarchical fashion until the certificate chain terminates at a trusted, self-signed certificate. Typically, this is a root CA certificate.

- Revocation checkingEach certificate in the certificate chain is verified to ensure that none of the certificates are revoked. The revocation checking can take place either in conjunction with the chain building process or after the chain is built.

**Chain Building**

Chain building is the process of building a trust chain, or certification path, from the end certificate to a root CA that is trusted by the security principal.

The chain-building process will validate the certification path by checking each certificate in the certification path from the end certificate to the root CA's certificate. The certificates are retrieved from the Intermediate Certification Authorities store, the Trusted Root Certification Authorities store, or from a URL specified in the AIA attribute of the certificate. If CryptoAPI discovers a problem with one of the certificates in the path, or if it cannot find a certificate, the certification path is discarded as a nontrusted certification path.

To improve performance, CryptoAPI will store subordinate CA certificates in the Intermediate Certification Authorities store so that future requests for the certificate can be satisfied from the store, rather than accessing the certificate through a URL.

**Certificate Storage**

Windows Server 2003 and Windows XP store certificates locally on the computer or hardware device that requested the certificate, or — in the case of a user — on the computer or device that the user used to request the certificate. There are

separate stores known as the machine store, used by the computer, and the user store or My store used by the currently logged-on user. A certificate store will often contain numerous certificates, possibly issued from a number of different CAs.

Certificate chains are formed by looking at certificates available in multiple certificate stores. The certificate chain engine must determine what scope of certificate stores to search when building certificate chains. By default, the chain engine searches the ROOT, TRUST, CA, and MY certificate stores.

In addition to the default stores, the certificate chain engine can be configured to use different stores, such as restricted root, restricted trust, restricted other, and additional stores. For example, the Trusted People store is used by both Outlook and EFS when searching for certificates. Alternatively, an application can create its own store for certificate storage or even call additional revocation providers registered with CryptoAPI.

**Purpose**
The certificate chain engine builds all possible certificate chains. The entire graph of certificate chains is constructed and then ordered by the "quality" of the chain. The best-quality chain for a given end certificate is returned to the calling application as the default chain.

Each chain is built by using a combination of the certificates available in the certificate stores and certificates available from published URL locations. Each certificate in the chain is assigned a status code. The status code indicates whether the individual certificate is:

- Signature-valid Is the signature valid?
- Time-valid Are the certificate start and expiration dates properly configured, has the start date not occurred yet, or has the certificate expired?
- Expired Has the certificate expired?
- Revoked Has the certificate been revoked?
- Time-nested Have any of the certificates that are higher in the PKI hierarchy expired?
- Any other restrictions on the certificate For example, is the certificate being used for a purpose other than has been intended?

Each status code has a precedence assigned to it. For example, an expired certificate has a higher precedence than a revoked certificate. This is because an expired certificate should not be checked for revocation status.

If different status codes are assigned to the certificates in a certificate chain, the status code with the highest precedence is applied to the certificate chain and propagated into the certificate chain status.

**Path validation**
For each certificate in the chain, the certificate chain engine must select a certificate of the issuing CA. This process, known as path validation, is repeated until a self-signed certificate is reached (typically, this is a root CA certificate). CryptoAPI treats root certificates as the absolute determinant of trust in trust decisions.

There are different processes that can be used to select the certificate for an issuing CA. The actual process that is used is based on whether the certificate currently being investigated has the Authority Key Identifier (AKI) extension defined. Inspection of the AKI extension will lead to one of three matching processes being implemented:

- Exact match If the AKI extension contains the issuer's user name and issuer serial number, only certificates that match on user name and serial number will be chosen in the chain-building process. As a further test, the issuer name on the issued certificate must match the subject name on the issuer certificate.
- Key match If the AKI extension only contains public key information, only certificates that contain the indicated public key in the Subject Key Identifier (SKI) extension will be chosen as valid issuers.

  **Note**

  - The public key information in the AKI extension and in the SKI extension is the hash of the public key. Therefore, both hashes must have been calculated by using the same algorithm. Otherwise, no key match will be

determined even though the public key used for the hashes matches. The default hash algorithm used by the Microsoft CA and CryptoAPI is SHA-1 when no SKI exists in the certificate. However, when an SKI exists, both MD5 and SHA-1 algorithms are supported, but the AKI and SKI must use the same algorithm.

- Name match. If no information exists in the AKI, or if the AKI does not exist in the certificate, the certificate will be marked as "name match." In name matching, the subject name of a certificate must match the issuer name in the current certificate in order for the certificate to be chosen as a valid issuer. Because the data is stored in a binary format, the name-matching process is case-sensitive.

In all cases, even if a matching certificate is not found in the store, the current certificate will still be marked as "exact match", "key match" or "name match," because this describes the attempted match rather than the attained match.

**Caching**

To increase performance, the certificate chain engine uses a least recently used (LRU) caching scheme. This scheme creates a cache entry for each certificate it encounters as it builds the certificate chain. Each cache entry includes the status of the certificate, so the best certificate chain can be built from cached items on subsequent calls to the chaining API without having to determine the status of each certificate again. After a certificate has been added to the cache, it will not be removed until it expires or is revoked.

During the path validation process, valid cached certificates will always be selected. If valid cached certificates are not found, a store search will be performed. For issuer certificates and CRLs, URL retrieval can be required to download the certificates and CRLs from the distribution point indicated in the URL.

All certificates are stored in the cache when the certificates are selected from a store or from a URL. The only difference is the location where the cached certificates are stored. Certificates can be stored in the following locations:

- CA store All certificates retrieved from any WinHTTP-supported URLs via the AIA extension are cached in the CA store.

- Local file system If the retrieval URL begins with LDAP, FTP, or HTTP, the certificate (or CRL) is also cached in the local file system.

In some cases, the certificate might be cached in all three locations. For example, when a certificate is retrieved from an HTTP URL, the certificate will be cached in memory, the CA store, and in the local file system.

**Revocation**

The certificate chain engine performs basic revocation checking during chain building, but the process differs between Windows 2000 and Windows 2003 and Windows XP.

For Windows 2000, post-processing revocation is used. This means that the CRL checking is performed after the chain is built. The certificate chain engine will check each certificate in the chain to determine whether the certificate has been revoked and the reason for the revocation.

Windows XP and Windows Server 2003 use revocation checking while building the certificate chain. Rather than waiting until the chain is built, each certificate is examined as the chain is built. If a revoked certificate is discovered in the chain, the chain is assigned a lower quality value.

### Note

- The existence of a revoked certificate in a certificate chain does not preclude the chain from being presented to the calling application as the best-quality certificate chain. The best-quality chain might not necessarily be a trustworthy chain.

**Certificate path validation**

The path validation process ensures that a valid certification path can be established for a given end certificate. A valid certification path is defined as an end-user certificate that can be traced along a certificate chain to a trusted root CA. Each CA certificate in the path must be discovered and subsequently validated until a final authority such as a root CA is obtained. During the validation process, a certificate can be deemed invalid (or not trusted) for many reasons. The reasons include:

- The time period configured in the certificate is not valid. This occurs when the start and expiration dates are improper, have not occurred yet, or are expired.

  **Note**

    - An expired CA certificate in the certification path reduces the quality of the path, but it does not invalidate the path. In a Windows Server 2003 PKI, a certification path can be valid as long as the CA certificate was valid at the time the certificate was issued. For example, a third-party CA might issue a certificate with a lifetime that extends past the CA's certificate's expiration date. After the CA's certificate expires, the certification path for the certificate is still valid and the certificate is trusted as long as all other validation criteria are met. In Windows 2000, however, CryptoAPI enforces time nesting rules by default where a child certificate must have a validity period shorter than the parent. Signatures, however, might be considered valid past the date of the certificate lifetime.

- The certificate is unrecognized. If the certificate format is improper, does not conform to the X.509 version 1 through version 3 standard for digital certificates, the certificate is discarded.

- The information in certificate fields is improper or incomplete.

- The certificate's digital thumbprint and signature fail the integrity check, indicating that the certificate has been tampered with or corrupted.

- The certificate's status was determined to be revoked.

- The issuing CA is not in either a trusted certification hierarchy or a CTL.

- The root CA for the certification path is not in the Trusted Root Certification Authorities store.

- The certificate is not permitted for the intended use as specified in a CTL.

- The certificate contains a critical extension that is not understood by the application.

**Critical extensions**
The CryptoAPI engine does not enforce critical extensions in certificates, only CRLs. The CryptoAPI engine and programming model place the burden of parsing critical extensions on the calling application; therefore, an application must understand and enforce the critical extension when evaluating a certificate. The CryptoAPI revocation provider, however, does evaluate critical extensions in CRLs and therefore would reject a CRL with a critical extension that is not known or understood.

**Certificate status checking**
All certificates in a certificate chain can be processed to verify that none of the certificates has been revoked. Certificate chain validation is, of course, optional from an application standpoint and might not be enforced by CryptoAPI. Windows by default checks certificate revocation status via CRLs, because the CRL processing engine is the native revocation provider included with CryptoAPI. When this functionality has been invoked, each certificate in the certificate chain is checked against the CRL published in the CRL Distribution Point (CDP) extension in the certificate. If the certificate is found to be included in the CRL, the certificate is then considered revoked. Additionally, third-party revocation providers can be registered with CryptoAPI to add support for additional protocols that check revocation status including Online Certificate Status Protocol (OCSP), Simple Certificate Validation Protocol (SCVP), and XML Key Management Specification (XKMS).

When a certificate's status is verified by using a CRL, several steps must be performed by an application to check the status of the certificates in the certificate chain. These steps are performed against each certificate in the chain. These steps include:

1. Verify the signature of the CRL. The CRL must be signed so that the application can determine whether it trusts the CRL issuer to issue CRLs.

   **Note**

   - Windows Server 2003, Windows 2000, and Windows XP can only verify a CRL that was signed by the same private key used to sign the issued certificate. These versions of Windows do not support CRLs signed by an entity other than the CA that signed the issued certificate.

2. Verify that the CRL has not expired. A CRL is considered expired if the current date is later than the date contained in the next update field of the CRL. If the certificate that is being checked has expired, the application must verify that the CRL's

issue date follows the effective date of the certificate, but precedes the certificate's expiration date.

3. Search the list of revoked certificates to verify that either the target certificate is not included or its revocation date is later than the effective date.

When a third-party revocation provider supporting OCSP has been registered, an OCSP responder will be used for certificate status checking; in this case, the process is slightly modified.

1. Verify that the response indicates the certificate is valid. A valid response indicates that the certificate has not been revoked.

2. Verify the signature on the OCSP response. This activity includes developing and processing a path that establishes that the certificate issuer or a trust point trusted the responder for the express purpose of issuing responses.

Neither Windows XP nor Windows 2000 contains an OCSP client component by default. However, a third-party OCSP client can be installed as a revocation provider to CryptoAPI. OCSP responders can be located by using the AIA extension in the certificate as defined by RFC 2459. The Windows Server 2003 CA supports the OCSP responder location to be included in the AIA extension of certificates. Multiple revocation providers can be added to CryptoAPI depending on revocation requirements. For additional information about revocation providers, see the Platform SDK on MSDN.

No matter what process is used to verify certificate validity, if the status check fails any of the above checks for any certificate in the certificate chain, the certificate chain will be rejected.

**Basic constraint validation**
Basic constraints give an administrator the ability to designate whether an issued certificate is a CA certificate or an end certificate. This validation is used to verify that a CA certificate can be used by the certificate chain engine to build certification paths.

An additional use of the basic constraint extension is to limit the maximum number of CA certificates that can be included under a given CA. For example, a path length of zero only allows end certificates to be issued by that specific CA. Likewise; a path length of two in the basic constraints extension will only allow three CA certificates in a certification path. In this example, any certification paths discovered with more than three CAs in the path will be discarded.

**Name constraint validation**
A CA certificate can contain name constraints that are applied to all certificate requests made to the CA. Each request is compared to the list of permitted and excluded constraints to determine whether the certificate should be considered permitted, not permitted, excluded, or not defined.

### Note

- Name constraint validation can only be performed by Windows XP and Windows Server 2003 clients. Name constraints are not evaluated by Windows 2000 clients. If you require that name constraints be applied, you can indicate that the extensions are critical, which should result in the chain being discarded by an application conforming to RFC 2459.

For example, a permitted constraint could allow all DNS names that end in contoso.com. This would include DNS names such as contoso.com and xcontoso.com. If you only wanted DNS names from the contoso.com DNS name space, you could use the permitted constraint .contoso.com. This constraint would permit x.contoso.com but exclude xcontoso.com.

When name constraints are present in a CA certificate, the following rules are applied to the subject name and alternate subject name entries.

- If the name constraints extension exists in a CA certificate, all name constraints should be present in the extension. Any name constraints that are not included are considered wildcards that will match all possibilities. For example, if the DNS name constraint were absent, the entry would be treated as DNS=.

- All name constraints will be considered. There is no precedence applied to the listed name constraints. It is for this reason that name constraints that are not present are treated as wildcards.

- An excluded name constraint will take precedence over a permitted name constraint

- Name constraints are applied to the subject name extension and any existing subject alternate name extensions.

- Name constraints apply to all names contained in an end certificate. Each name in the subject or subject alternate name extensions should match at least one of the name constraints listed for that name type. A subject name or subject alternate name that does not match a listed name type will be rejected. Note that most client name spaces are not included in a CA certificate and generally do not apply.

- Name constraints are case-sensitive if the names are stored in ASCII or Unicode format.

Name restrictions must be enforced across the following alternative name information entries in the subject name: Other Name (NT Principal Name only); RFC 822 Name; DNS Name; URL; Directory Name, and IP address.

When the certificate chain engine validates an end certificate for name constraints, it will arrive at one of the following results:

- **Permitted** The end certificate contains a name that is listed as permitted in an issuer's name constraints extension.

- **Not permitted** The end certificate contains a name that is not listed as permitted in an issuer's name constraints extension.

- **Excluded** The end certificate contains a name that is listed as excluded in an issuer's name constraints extension

- **Not Defined** The issuer certificate does not list a constraint for a specific name type (such as Directory Name or IP Address)

**Policy constraint validation**

A policy constraint allows a CA administrator to ensure that specific constraints are met when a certificate is issued or used by an application. The policy constraint ensures that all certificates issued by the CA implement the required policy constraints.

By definition, a root CA implements all policies. This applies to both enterprise and standalone CAs. At some point down the hierarchy, a CA can have one or more policies defined. After a CA certificate is encountered with any policy OIDs, all certificates below that CA in the hierarchy must also have a subset of those policy OIDs. A certificate chain with no valid policy set will be considered invalid, whereas one with no policy OIDs at all will be considered valid and matching the "any policy" OID. The above is valid only for application policies and not issuance polices. The absence of the certificatePolicies extension in a CA other than the root CA implies that there is no issuance policy.

There are two policies currently used with a Windows Server 2003 CA: issuance policy and application policy. The policy applied to a certificate affects how the validity of a certificate chain is determined.

**Issuance policy**

Issuance policies, referred to as the certificate policies extension in RFC 2459, allow a CA administrator to define the circumstances and requirements for certificate issuance. The assurances required for certificate issuance can vary based on certificate templates. An issuance policy defines a set of administrative rules that must be followed when issuing a certificate. The rules are defined in the certificate by an OID defined by the CA. Each certificate issued by the CA will include the OID. The OID is not defined in the CA, but instead in the certificate template.

### Note

- Issuance policy is only available to Windows Server 2003 and Windows XP clients. Issuance policy is not recognized by Windows 2000 clients.

When an entity presents a certificate to an application, the application can examine the certificate to verify the issuance policy and determine if the issuance policy is sufficient to perform the action requested by the subject.

Currently, two types of constraints are defined: **Require explicit policy** and **Inhibit policy mapping**.

- **Require explicit policy** specifies the number of certificates that can exist in the hierarchy below the current certificate before an explicit policy must exist.

- **Inhibit policy mapping** specifies the number of additional certificates that can appear in the path before policy mapping is no longer permitted.

Policies can also be mapped to other policies on a one-to-many basis. Policy mapping allows interoperability between two organizations that implement similar policies, but have deployed different OIDs. If one company's policy OID (for example, 1.2.3.4) stands for a specific function and another company's policy OID (for example, 11.22.33.44) stands for the same function, these two OIDs can be mapped. In this example, 11.22.33.44 can be mapped to 1.2.3.4.

**Application policy**

Certificates provide key information that is not specific to an application; however, the ability to decide which certificates can be used for certain functions is important. Application policy allows you to issue certificates widely and restrict their usage to only their intended purposes.

Application policies are settings that inform a target that the subject holds a certificate that can or cannot be used to perform a specific task. They are represented in a certificate by an OID that is defined by the CA. This OID is included in all issued certificates. When a subject presents its certificate, it can be examined by the target to verify the application policy and determine if it can perform the requested action.

Application policy is Microsoft-specific and is treated much like EKU

- If a certificate has an extension containing an application policy and has an EKU extension, the EKU extension is ignored.
- If there is only an EKU extension, it is treated like an application policy extension.

If there is an application policy extension (and no EKU extension) and an EKU property on the certificate, the intersection of the EKU property OIDs and the application policy OIDs is taken and the result is the effective policy for the certificate.

If the application policy extension is absent, CryptoAPI will function like any other RFC 2459–compliant client. If it is present, CryptoAPI will implement the application policy rules. It is recommended that implementers make the extension non-critical extension so that its presence should be benign to other clients.

**Note**

- Policy mapping can only be used with the application policy extension. If the EKU extension is used, policy mapping is not possible because EKU does not support policy mapping. Non-Windows clients and applications might not understand this extension or use it as designed.

**Basic Cryptographic Operations**

A certificate contains information that identifies the certificate's owner (called the subject) as an entity on the network. A certificate also contains the owner's public key. Furthermore, a certificate identifies the CA (called the issuer) that issued the certificate.

A CA uses its private key to digitally sign each certificate it issues. To create the digital signature, the CA generates a message digest from the certificate, encrypts the digest with its private key, and includes the digital signature as part of the certificate. Anyone can use the message digest function and the CA's public key to verify the certificate's integrity. If a certificate becomes corrupted or someone tampers with it, the message digest for the altered certificate does not match the digest in the CA's digital signature. The following figure shows how a certificate is signed by the issuing CA.

**Digital Signature for a Certificate**

Information contained in the Subject Public-Key Value field of X.509 version 3 certificates specifies the cryptography operations for which the public key and private key set can be used. Public key security systems commonly support the following basic cryptography operations:

- Digital signing of electronic data to verify data origin and the integrity of data.
- Secret key encryption to protect symmetric secret encryption transmitted and shared over networks.

The following table briefly describes the certificate purposes.

**Basic Cryptographic Operations**

| Cryptographic Operations | Intended use |
|---|---|
| Signature | Data signing, authentication, nonrepudiation |
| Encryption | Data encryption and decryption |
| Signature and encryption | Data encryption and decryption, digital data signing, authentication |
| Signature and smart card logon | Smart card logon, digital data signing |

The public key and private key set can be used to provide a variety of specific security functions for information security technologies. These specific functions of certificates are listed in the keyUsage and EKU extensions. Common specific security functions for public key technology include the following:

- Secure mail to provide authentication, confidentiality, integrity, and nonrepudiation for e-mail communications.
- Secure Web communications to provide authentication, integrity, and confidentiality between Web clients and servers.
- Code signing to provide integrity and nonrepudiation for executable code to be distributed on the Internet or intranets.
- Local network logon or remote access logon to authenticate users of network resources.
- IPSec authentication to authenticate clients that do not use Kerberos authentication or shared secret passwords for IPSec communications.

**Public Key Encryption**

In public key encryption, different keys are used to encrypt and decrypt information. The first key is a private key (a key that is known only to its owner), while the second key — called the public key — can be made known and available to other entities on the network.

The two keys are different but complementary in function. For example, a user's public key can be published in a certificate in a directory so that it is accessible to other people in the organization. The sender retrieves the recipient's certificate from Active Directory, retrieves the public key from the certificate, and then encrypts their communication by using this public key. Information that is encrypted with the public key can be decrypted only by using the corresponding private key of the set, which remains with its owner. The following figure shows basic encryption and decryption with asymmetric keys.

**Encryption and Decryption with Asymmetric Keys**

Public key encryption plays an increasingly important role in providing strong, scalable security on intranets and the Internet. Public key encryption is commonly used to perform the following functions:

- Encrypt symmetric secret keys to protect the symmetric keys during exchange over the network or while being used, stored, or cached by operating systems.
- Create digital signatures to provide authentication and nonrepudiation for online entities.
- Create digital signatures to provide data integrity for electronic files and documents.

The RSA digital signature process also uses private keys to encrypt information to form digital signatures. For RSA digital signatures, only the public key can decrypt information encrypted by the corresponding private key of the set.

**Message Digest Functions**

Message digest functions, also called hash functions, are frequently used in conjunction with asymmetric keys to further strengthen public key encryption. Message digests are commonly 128 bits to 160 bits in length and provide a unique digital identifier for each digital file or document. Two copies of a document will have the same message digest, but if even one of the bits for the document changes, the message digest changes. The following figure shows the basic message digest process.

**Example of the Message Digest Process**

Message digests are commonly used in conjunction with public key technology to create digital signatures or "digital thumbprints" that are used for authentication, integrity, and nonrepudiation. Message digests also are commonly used with digital signing technology to provide data integrity for electronic files and documents.

For example, to provide data integrity for e-mail messages, message digests can be generated from the completed mail message, digitally signed with the originator's private key, and then transmitted with the messages. The recipient of the message can then do the following to check the integrity of the message:

- Use the same message digest function to compute a digest for the message.
- Use the originator's public key to verify the signed message digest.
- Compare the new message digest to the original digest.

If the two message digests do not match, the recipient knows the message was altered or corrupted. The following figure shows a basic integrity check process with a digitally signed message digest.

**Example of an Integrity Check with a Digitally Signed Message Digest**

Because the message digest is digitally signed with the sender's private key, it is not feasible for an intruder to intercept the message, modify it, and create a new valid encrypted message digest to send to the recipient.

**Digital Signatures**

A common use of public key encryption is to provide digital signatures. Just as handwritten signatures or physical thumbprints

are commonly used to uniquely identify people for legal proceedings or transactions, so digital signatures are commonly used to identify electronic entities for online transactions. A digital signature uniquely identifies the originator of digitally signed data and also ensures the integrity of the signed data against tampering or corruption.

One possible method for creating a digital signature is for the originator of data to create the signature by encrypting all of the data with the originator's private key and enclosing the signature with the original data. Anyone with the originator's public key can decrypt the signature and compare the decrypted message to the original message. Because only someone with the private key can create the signature, the integrity of the message is verified when the decrypted message matches the original. Even if an intruder intercepts and alters the original message while it is in transit, the intruder cannot create a new valid signature. If an intruder alters the signature during transit, the signature will not be properly verified and therefore will be invalid.

However, encrypting all data to provide a digital signature is impractical for three reasons:

- The cipher text signature is the same size as or greater than the corresponding plaintext, so message sizes are doubled, which consumes large amounts of bandwidth and storage space.

- Public key encryption places heavy computational loads on computer processors, so network and computer performance can be significantly degraded.

- Encrypting the entire contents of information produces large amounts of ciphertext, which can be used for cryptanalysis attacks, especially known plaintext attacks (where certain parts of the encrypted data, such as e-mail headers, are known beforehand to the attacker).

Digital signature algorithms use more efficient methods to create digital signatures. The most common types of digital signatures today are created by signing message digests with the originator's private key to create a digital thumbprint of the data. Because only the message digest is signed, the signature is usually much shorter than the data that was signed. Therefore, digital signatures place a relatively low load on computer processors during the signing process, consume insignificant amounts of bandwidth, and produce small amounts of ciphertext for cryptanalysis.

# Certificates Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Certificate Tools and Settings**

**In this section**

- Certificate Tools
- Certificate Registry Entries
- Certificate Group Policy Settings

**Certificate Tools**

The following tools are associated with certificates.

**Certmgr.msc: Certificates Snap-in**

**Category**

Certificates is a Microsoft Management Console (MMC) snap-in that ships with Windows Server 2003 and Windows 2000 Server.

**Version compatibility**

Certificates is compatible with Windows Server 2003 and Windows 2000 Server, and can be used to manage the certificate stores for users, computers, and services on computers running Windows Server 2003, Windows XP, and Windows 2000.

You can use Certificates to:

- View information about certificates, such as certificate contents and the certification path.
- Import certificates into a certificate store.
- Move certificates between certificate stores.
- Export certificates and, optionally, export private keys (if key export is enabled).
- Delete certificates from certificate stores.
- Request certificates from an enterprise certification authority (CA) for the Personal certificate store.

  **Note**

  - The ability to perform some tasks will depend on the capabilities of the PKI configuration and environment.

To find more information about the “Certificates” snap-in, see “Certificates” on Microsoft TechNet.

**Certtempl.msc: Certificate Templates Snap-in**

**Category**

Certificate Templates is an MMC snap-in that ships with Windows Server 2003.

**Version compatibility**

Certificate Templates only runs on Windows XP and Windows Server 2003, but can be used to manage certificate templates in a Windows 2000 Active Directory environment.

Certificate Templates enables administrators to duplicate, rename, and manage certificate templates. In Windows Server 2003, Certificate Templates also enables you to modify existing certificate template properties — such as certificate validity period, renewal period, cryptographic service providers (CSPs), key size, and key archival.

In addition, administrators or users with the appropriate permissions can use Certificate Templates to establish and apply enrollment policies (including autoenrollment), issuance policies, and application policies.

For more information about the Certificate Templates snap-in, see "Certificate Templates How to" on Microsoft TechNet.

**Certreq.exe: Certreq**

**Category**
Certreq is a command-line tool that ships with the Windows Server 2003 operating system tools and with the Windows Server 2003 Adminpak

**Version compatibility**
Certreq is compatible with Windows Server 2003 and Windows 2000 Server, and can be used to manage the certificate stores for users, computers, and services on computers running Windows Server 2003, Windows XP, and Windows 2000.

Certreq enables you to submit, retrieve, create, and accept certificate requests that are sent to a Windows Server 2003 CA. You can also use Certreq to create and sign requests for cross-certificates. You can also place the Certreq command syntax in a batch file to script certificate requests.

To find more information about Certreq, see "Command-Line References" in Tools and Settings Collection.

**Certutil.exe: Certutil**

**Category**
Certutil is a command-line tool that is installed as part of Certificate Services.

**Version compatibility**
Certutil can be used on Windows Server 2003 and Windows 2000 Server CAs.

You can use Certutil to extract and display CA configuration information, configure Certificate Services, back up and restore CA components, and verify certificates, key pairs, and certificate chains.

To find more information about Certutil, see "Command-Line References" in Tools and Settings Collection.

**Certificate Registry Entries**
Certificate-related registry entries correlate to the physical view of the certificate-related data that can be viewed by using the Certificates snap-in.

The following registry keys are associated with certificates:

- HKEY_Current_User\Software\Microsoft contains data about user certificates that have not been distributed by using Group Policy.
- HKEY_Current_User\Software\Policies\Microsoft contains data and settings for user certificates that have been distributed by using Group Policy.
- HKEY_Local_Machine\Software\Microsoft contains data about computer certificates that have not been distributed using Group Policy.
- HKEY_Local_Machine\Software\Policies\Microsoft contains data and settings for computer certificates that have been distributed by using Group Policy.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as MMC, to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_Current_User\Software\Microsoft**
HKEY_Current_User\Software\Microsoft contains registry settings for user certificates that have been distributed by means other than Group Policy. These settings are stored in the following subkeys:

- HKEY_Current_User\Software\Microsoft\Cryptography

- HKEY_Current_User\Software\Microsoft\SystemCertificates

**HKEY_Current_User\Software\Microsoft\Cryptography**
The following registry entries are located under HKEY_Current_User\Software\Microsoft\Cryptography.

**Autoenrollment**

**Registry path**
HKEY_Current_User\Software\Microsoft\Cryptography\

**Version**
Windows Server 2003, Windows 2000, and Windows XP

This setting is used to manage event logging and cached directory service data when user certificate autoenrollment has been enabled.

**AEExpress**

**Registry path**
HKEY_Current_User\Software\Microsoft\Cryptography\Autoenrollment

**Version**
Windows Server 2003 and Windows XP

You can add AEExpress on a per-user basis if the default 60-second delay is not desired. With this registry setting, the autoenrollment balloon UI appears at each logon or Group Policy refresh interval.

### Note

Using this subkey in a normal production environment is not recommended. If it is used, it must be created on a per-user basis. Computer certificates do not support user interaction and should not be configured to require this setting.

**HKEY_Current_User\Software\Microsoft\SystemCertificates**
The following registry subkeys are located under SystemCertificates. The majority contain binary large objects that pertain to:

- **Certificates.** These entries identify the certificates associated with the registry entry.
- **CRLs.** These entries identify the certificate revocation lists (CRLs) associated with the registry entry.
- **CTLs.** These entries identify the certificate trust lists (CTLs) associated with the registry entry.

Additional subkeys — which might appear under some registry subkeys — will be detailed below under the registry subkeys that they correspond to.

**ACRS**

**Registry path**
HKEY_Current_User\Software\Microsoft\SystemCertificates

**Version**
Windows 2000 and Windows XP

Automatic Certificate Request Settings (ACRS) in Group Policy is used by Windows 2000 to specify certificates to autoenroll. This registry setting has been replaced in Windows XP and Windows Server 2003 by certificate template autoenrollment. ACRS is still available for backward compatibility, but is not supported for user certificates.

**AddressBook**

**Registry path**
HKEY_Current_User\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

AddressBook contains data about certificates, CRLs, and CTLs relating to people. Unlike certificates registered in the

TrustedPeople container, these certificates are not explicitly trusted.

**AuthRoot**

**Registry path**
HKEY_Current_User\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

AuthRoot contains data about certificates, CRLs, and CTLs from non-Microsoft root CAs.

**CA**

**Registry path**
HKEY_Current_User\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

CA contains data about certificates, CRLs, and CTLs from intermediate CAs.

**Disallowed**

**Registry path**
HKEY_Current_User\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Disallowed contains data about disallowed certificates. For example, this store will contain data about certificates that have been rejected as untrustworthy during the Authenticode software installation process.

**My**

**Registry path**
HKEY_Current_User\Software\ Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

My contains data about a user's personal certificates. However, physical storage of this data for the user, which is viewable by using the Certificates snap-in, has been moved to the following Documents and Settings folder:

Application Data\Microsoft\SystemCertificates

**REQUEST**

**Registry path**
HKEY_Current_User\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows 2000, and Windows XP

REQUEST contains data about pending certificate requests. When a pending certificate request has been approved or rejected, this registry data is removed. Data about pending certificate requests is also stored for the user in the following Documents and Settings folder:

Application Data\Microsoft\SystemCertificates\My

**Root**

**Registry path**
HKEY_Current_User\Software\ Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Root contains data about trusted root CA certificates, CRLs, and CTLs.

**trust**

**Registry path**
HKEY_Current_User\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Trust contains data about enterprise trust certificates, CRLs, and CTLs.

**TrustedPeople**

**Registry path**
HKEY_Current_User\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

TrustedPeople contains data about certificates from other users where there is explicit trust.

**TrustedPublisher**

**Registry path**
HKEY_Current_User\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

TrustedPublisher contains data about certificates that have been explicitly accepted as trustworthy. For example, it will contain data about certificates that are accepted as trustworthy during the Authenticode software installation process.

**HKEY_Current_User\Software\Policies\Microsoft**
HKEY_Current_User\Software\Policies\Microsoft contains registry settings for user certificates that have been distributed by using Group Policy. These settings are stored in the following subkeys:

- HKEY_Current_User\Software\Policies\Microsoft\Cryptography
- HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**HKEY_Current_User\Software\Policies\Microsoft\Cryptography**
This set of registry entries is used when Group Policy-based autoenrollment is used to manage the availability of user certificates.

**Autoenrollment**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\Cryptography

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Autoenrollment implements Group Policy for autoenrollment of user certificates.

**AEEventLogLevel**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\Cryptography\Autoenrollment\

**Version**
Windows Server 2003 and Windows XP

AEEventLogLevel enables enhanced logging of autoenrollment processes for users.

**HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates**
The following registry entries are located under SystemCertificates. The majority contain binary large objects that pertain to:

- **Certificates.** These entries identify the certificates associated with the registry entry.
- **CRLs.** These entries identify the CRLs associated with the registry entry.
- **CTLs.** These entries identify the CTLs associated with the registry entry.

Additional subkeys — which might appear under some registry subkeys — will be detailed below under the registry subkeys that they correspond to.

**AddressBook**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

AddressBook contains data about certificates, CRLs, and CTLs relating to other people. Unlike certificates registered in the TrustedPeople container, these certificates are not explicitly trusted.

**AuthRoot**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

AuthRoot contains data about certificates, CRLs, and CTLs from third-party root CAs.

**CA**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

CA contains data about certificates, CRLs, and CTLs from intermediate CAs.

**Disallowed**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Disallowed contains data about disallowed certificates. For example, it will contain data about certificates that are rejected as untrustworthy during the Authenticode software installation process

**EFS**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

EFS contains data about certificates enabling the encrypting file system for the user.

**root**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Root contains data about trusted root CA certificates, CRLs, and CTLs.

**trust**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Trust contains data about enterprise trust certificates, CRLs, and CTLs

**TrustedPeople**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

TrustedPeople contains data about certificates from other users where there is explicit trust.

**TrustedPublisher**

**Registry path**
HKEY_Current_User\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

TrustedPublisher contains data about certificates that have been explicitly accepted as trustworthy. For example, this store will contain data about certificates that are accepted as trustworthy during the Authenticode software installation process.

**HKEY_Local_Machine\Software\Microsoft**
HKEY_Local_Machine\Software\Microsoft contains registry settings for computer certificates that have been distributed by means other than Group Policy. These settings are stored in the following subkeys:

- HKEY_Local_Machine\Software\Microsoft\Cryptography
- HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**HKEY_Local_Machine\Software\Microsoft\Cryptography**

**AutoEnrollment**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\Cryptography

**Version**
Windows Server 2003 and Windows XP

This setting is used to manage event logging level and cached directory service data when computer certificate autoenrollment has been enabled.

**Calais**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\Cryptography

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Calais contains settings that enable various vendors' smart cards and smart card readers.

**Defaults**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\Cryptography

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Contains information about different specific and generic CSPs listed in the Provider and Provider Types categories.

**IEDirtyFlags**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\Cryptography

**Version**
Windows versions prior to Windows 2000

This legacy setting was used to record certificates and keys that are incompletely removed from Internet Explorer.

**OID**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\Cryptography

**Version**
Windows Server 2003, Windows XP, and Windows 2000

OID is the hive used by the CryptRegisterOIDFunction, CryptRegisterDefaultOIDFunction, and CryptRegisterOIDInfo application programming interfaces (APIs) to register data.

**Protect**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\Cryptography

**Version**
Windows Server 2003, Windows XP, and Windows 2000

You can use Protect to define providers for use with the ProtectedStorage service.

**RNG**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\Cryptography

**Version**
Windows Server 2003, Windows XP, and Windows 2000

RNG is used by the Windows Random Number Generator to enhance random number generation from one computer startup to another.

**Services**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\Cryptography

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Services identifies the predefined physical stores for certificates associated with Windows services.

**HKEY_Local_Machine\Software\Microsoft\SystemCertificates**

**AddressBook**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

AddressBook contains data about certificates, CRLs, and CTLs relating to other people. Unlike certificates registered in the TrustedPeople container, these certificates are not explicitly trusted

**AuthRoot**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

AuthRoot contains data about certificates, CRLs, and CTLs from non-Microsoft root CAs.

**CA**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

CA contains data about certificates, CRLs, and CTLs from intermediate CAs.

**Disallowed**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Disallowed contains data about disallowed certificates. For example, it will contain data about certificates that are rejected as untrustworthy during the Authenticode software installation process.

**My**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

My contains data about the certificates, CRLs, CTLs, and private keys associated with a computer account.

**Recovery**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003 and Windows XP

Recovery stores the certificate for a user's password reset disk.

**REQUEST**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

REQUEST contains data about pending certificate requests. When a pending certificate request has been approved or rejected, this registry information is removed.

**ROOT**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

ROOT contains data about trusted root CA certificates, CRLs, and CTLs.

**SPC**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Not supported

SPC is a legacy registry store that was used by Internet Explorer 3.0 for migrating Software Publisher Certificates. It is no longer used.

**trust**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Trust contains data about enterprise trust certificates, CRLs, and CTLs.

**TrustedPeople**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

TrustedPeople contains data about certificates from other users where there is explicit trust.

**TrustedPublisher**

**Registry path**
HKEY_Local_Machine\Software\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

TrustedPublisher contains data about certificates that have been explicitly accepted as trustworthy. For example, this store will contain data about certificates that are accepted as trustworthy during the Authenticode software installation process.

**HKEY_Local_Machine\Software\Policies\Microsoft**
HKEY_Local_Machine\Software\Policies\Microsoft contains registry settings for computer certificates that have been distributed by using Group Policy. These settings are stored in the following subkeys:

- HKEY_Local_Machine\Software\Policies\Microsoft\Cryptography
- HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**HKEY_Local_Machine\Software\Policies\Microsoft\Cryptography**

**Autoenrollment**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\Cryptography

**Version**
Windows Server 2003 and Windows XP

Autoenrollment implements Group Policy for autoenrollment of computer certificates. The default autoenrollment behavior is as follows:

Approximately 60 seconds after logon, the balloon UI is displayed. If no user interaction is explicitly defined on the certificate template, no UI will be displayed to the user. This delay is incorporated to enable speedy application and shell response times during the logon and starting of the client computer.

**AEEventLogLevel**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\Cryptography\Autoenrollment

**Version**
Windows Server 2003 and Windows XP

AEEventLogLevel enables enhanced logging of autoenrollment processes for computers.

**HKEY_Local_Machine\Software\Policies\Microsoft\System Certificates**
The following registry entries are located under SystemCertificates. The majority contain binary large objects that pertain to:

- **Certificates.** These entries identify the certificates associated with the registry entry.
- **CRLs.** These entries identify the CRLs associated with the registry entry.
- **CTLs.** These entries identify the CTLs associated with the registry entry.

Additional subkeys — which might appear under some registry subkeys — will be detailed below under the registry subkeys that they correspond to.

**ACRS**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows 2000 and Windows XP

Automatic Certificate Request Settings (ACRS) in Group Policy is used by Windows 2000 to specify certificates to autoenroll. This registry setting has been replaced in Windows XP and Windows Server 2003 by certificate template autoenrollment; however, ACRS is still supported for backward compatibility.

**AddressBook**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

AddressBook contains data about certificates, CRLs, and CTLs relating to other people. Unlike certificates registered in the TrustedPeople container, these certificates are not explicitly trusted.

**AuthRoot**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

AuthRoot contains data about certificates, CRLs, and CTLs from non-Microsoft root CAs.

**ca**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Ca contains data about certificates, CRLs, and CTLs from intermediate CAs.

**Disallowed**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Disallowed contains data about disallowed certificates. For example, it will contain data about certificates that are rejected as untrustworthy during the Authenticode software installation process.

**EFS**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

EFS contains data about certificates, CRLs, and CTLs that enable the use of Encrypting File System (EFS) on the computer.

**Root**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Root contains data about trusted root CA certificates, CRLs, and CTLs.

**Trust**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

Trust contains data about enterprise trust certificates, CRLs, and CTLs.

**TrustedPeople**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

TrustedPeople contains data about certificates from other users where there is explicit trust.

**TrustedPublisher**

**Registry path**
HKEY_Local_Machine\Software\Policies\Microsoft\SystemCertificates

**Version**
Windows Server 2003, Windows XP, and Windows 2000

TrustedPublisher contains data about certificates that have been explicitly accepted as trustworthy. For example, it will contain

data about certificates that are accepted as trustworthy during the Authenticode software installation process.

**Certificate Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with certificates.

**Group Policy Settings Associated with Certificates**

| Group Policy Setting | Description |
|---|---|
| Computer Configuration\Windows Settings\Security Settings\Public Key Policies\Autoenrollment | Can be used to enroll certificates automatically, renew expired certificates, update pending certificates, and remove certificates that have been revoked. In addition, this setting can be used to block certificate autoenrollment. |
| Computer Configuration\Windows Settings\Security Settings\Public Key Policies\Encrypting File System | Can be used to add or create a data recovery agent for use with EFS. |
| Computer Configuration\Windows Settings\Security Settings\Public Key Policies\Automatic Certificate Request Settings | Can be used to configure automatic certificate request settings for a specific certificate template for a domain by using the Automatic Certificate Request Setup Wizard. The request will be processed automatically at the first occurrence of any of the following: a user logs on, Group Policy is refreshed, or a computer joins the domain and is subject to a Group Policy setting. |
| Computer Configuration\Windows Settings\Security Settings\Public Key Policies\Trusted Root Certification Authorities | Can be used to add a new trusted root CA certificate to a Group Policy object (GPO) for a domain. For a root CA certificate to be imported, the root certificate must be in a PKCS #12 file, in a PKCS #7 file, or in binary-encoded X.509 v3 certificate files. |
| Computer Configuration\Windows Settings\Security Settings\Public Key Policies\Enterprise Trust | Can be used to add a new enterprise trust policy to a GPO for a domain. You do this by using the Certificate Trust List Wizard to create a new CTL for the GPO or assigning an existing CTL to the GPO. Acceptable file formats from which you can import a certificate are:<br>• X.509 v3 certificate files (.cer, .crt)<br>• PKCS #7 files (.spc, .p7b)<br>• Microsoft serialized certificate stores (.sst) |

To find more information about these Group Policy settings, see “Group Policy Settings Reference” in the Tools and Settings Collection.

# Certificate Services Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In order to realize the enhanced security made possible by certificates, organizations need a cost-effective, efficient, secure way to manage the distribution and use of certificates. In the Microsoft Windows Server 2003 operating system, you use Certificate Services to distribute certificates to users, computers, and services. Certificate Services enables you to configure certificates, establish and verify the identity of certificate holders, set policies that control how a certificate is to be used, revoke certificates if they should no longer be considered valid, and publish certificate revocation lists (CRLs) that help users verify a certificate's status.

**In this subject**

- What Is Certificate Services?
- How Certificate Services Works
- Certificate Services Tools and Settings

# What Is Certificate Services?

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Common Certificate Services Scenarios
- Technologies Related To Certificate Services
- Certificate Services Dependencies
- Related Information

Windows Server 2003 Certificate Services provides customizable services for creating and managing public key certificates used in software security systems employing public key technologies.

Organizations use certificates to enhance security by binding the identity of a person, device, or service to a corresponding private key. However, in order to realize the enhanced security made possible by certificates, organizations need a cost effective, efficient, secure way to manage the distribution and use of certificates.

A server configured as a certification authority (CA) provides the management features needed to regulate certificate distribution and use. A CA:

- Configures the format and content of certificates and issues certificates to users, computers, and services.
- Establishes and verifies the identities of certificate holders.
- Sets policies that control how certificates are to be used.
- Revokes certificates if they should no longer be considered valid and publishes certificate revocation lists (CRLs) to be used by certificate verifiers.
- Logs all request, issuance, renewal, and revocation transactions.

Certificate Services is the Windows Server 2003 service that provides the core functionality for Windows Server 2003 CAs. Certificate Services provides customizable services for managing certificates for a particular CA and for the enterprise.

**Common Certificate Services Scenarios**

Managing certificates and CAs involves the following processes:

- **Issuing certificates to users and computers.** The issuance process includes obtaining and validating information about the intended recipient of the certificate, placing policy restrictions designated by the organization in certificates that are issued, and publishing the certificates to a directory.
- **Managing certificate lifetimes.** Because all certificates have a limited life, certificates need to be renewed or allowed to expire. The renewal process is similar to the issuance process, but typically involves fewer security checks. Thus, when an organization develops its renewal strategy, it should balance security concerns against potential disruptions to users.
- **Revoking certificates and verifying revocation status.** Some certificates need to be invalidated before their expiration date. Effective certificate revocation and revocation verification processes are critical to the security of an organization's public key infrastructure (PKI).

For a more detailed technical description of these processes, see "How Certificate Services Works."

**Issuing Certificates to Users and Computers**

A certificate can be used to authenticate the identity of the computer or user that owns the certificate, as well as to encrypt or sign data. Because of this, the certificate issuer must ensure that certificate holders are known entities and meet certain criteria.

In Windows Server 2003, identity verification can be based on:

- Manual verification of a client's credentials by a Certificate Manager.
- Automatic approval based on credentials in Active Directory directory service.

When identity verification is complete, a certificate is constructed based on the certificate policy set by the CA administrator.

Certificate policies are sets of rules that are used when processing certificate requests, issuing certificates, revoking certificates, and publishing certificate revocation lists (CRLs). Certificate policies constitute a combination of administrative policies and configuration settings on the CA:

- **Administrative policies.** For example, an administrative policy might grant commercial certificates only if applicants present identification in person. Another administrative policy might grant credentials based on e-mail requests.
- **Configuration settings on the CA.** When you install Certificate Services, the CA is configured with a default set of rules and settings. These define CA-specific settings such as the CA's certificate, the CA's default issuance behavior, and the CA's key recovery agents. Along with the CA, you can also install a number of preconfigured certificate templates, which define what information a certificate request must have and how to process incoming requests for a certificate based on a particular template.

The combination of applying CA settings and certificate template settings, plus the defined administrative guidelines, are documented in the certificate policy and practice statements that govern the operation of a CA.

When a certificate request has been processed and the certificate has been created, it needs to be published and made available for use. At this point, Certificate Services returns the certificate to the client to be placed in the client's certificate store on the local computer, and data about the certificate is recorded in the certificates database on the CA. In addition, the certificate can be published to Active Directory to make it more accessible to others.

**Managing Certificate Lifetimes**

All certificates have a limited lifetime that needs to be defined by an administrator in a certificate template before the first certificate is issued. The certificate lifetimes that an administrator defines can have an impact on the security of a PKI for the following reasons:

- Over time, encryption keys become more vulnerable to attack. In general, the longer amount of time that key pairs are in use, the greater the risk that keys can be compromised.
- When a CA certificate expires, all certificates that are issued by that CA for validation also expire. This is known as time nesting.

End-entity certificates expire when the issuing CA certificate reaches the end of its lifetime, unless:

- The end-entity certificate is renewed and linked to a CA certificate with a longer lifetime.
- The end-entity certificate was revoked before the CA certificate expiration date is reached.

**Revoking Certificates and Verifying Revocation Status**

Unlike a certificate that reaches the end of its lifetime and is not renewed, a certificate might need to be designated unusable before its lifetime is complete. This is done by a process called revocation.

A certificate manager should revoke a certificate if the recipient of the certificate breaks the rules that are defined in the certificate practice statement or if the private key that is associated with the certificate is compromised. For example, a rule might specify that certificates can only be issued to a current employee of the organization or to an employee who performs a specific task. If that employee leaves the organization or is reassigned, the certificate should be revoked. Similarly, a certificate should be revoked if the private key associated with the certificate has been compromised. In either case, the goal is to prevent unapproved use of the certificate and its associated key.

**Note**

- Even when a certificate has been revoked, it is up to the party relying on the certificate to decide whether to accept or reject the certificate for an intended purpose. For example, some parties would accept an expired passport as proof of a bearer's identity, although they would not allow an expired passport to be used to cross a national border.

Verifying revocation status is an important corollary to certificate revocation. When a certificate is issued and used, certificate policies determine whether a certificate requester or certificate user meets the criteria set for the certificate. However, when revocation verification takes place and a certificate is determined to have been revoked, all other certificate policy verifications are overridden. Because a certificate that was valid yesterday might not be acceptable today, the revocation verification process is critical to the integrity of the PKI.

#### Technologies Related to Certificate Services

Certificate Services is an enabling technology that can be used in a wide variety of applications. For example, it can be used to enhance the security of technologies such as:

- **Authentication.** Certificates and Certificate Services extend and enhance, rather than replace, the security provided by password-based authentication.

- **Access control.** Certificates and Certificate Services make it possible to limit user access to highly sensitive data.

- **Digital signing.** Certificates and Certificate Services make it possible to positively identify a user who modifies data by applying digital signatures to files and documents.

- **Wireless networking.** Certificates and Certificate Services can be used to enhance the authentication process for wireless clients and deter unauthorized users from accessing a wireless network or from viewing data as it crosses between wireless access points and client computers.

- **Virtual private networks (VPNs).** Certificates and Certificate Services can be used to authenticate clients that are allowed to initiate VPN connections to an organization's network. In addition, certificates and Certificate Services can be used to deter unauthorized users from viewing or intercepting data as it crosses the public Internet through a VPN connection.

Because Certificate Services is an enabling technology, technology strategists should consider the business problems faced by their organizations to determine how Certificate Services can help solve those problems.

#### Certificate Services Dependencies

Using Certificate Services in Windows involves three types of dependencies:

- What Windows version you are using.

- Whether the computer is joined to a domain, and the version of Active Directory that the organization is using.

- Whether the organization's PKI will be linked to any other organization's PKI.

#### Windows Version Dependencies

In Windows Server 2003, Certificate Services includes a number of new and enhanced features. Windows Server 2003 Enterprise Edition includes some enhanced features that are not available with Windows Server 2003 Standard Edition. In addition, using Windows XP Professional clients enhances an organization's ability to take advantage of many of these new features.

Many features and capabilities require that you run Windows Server 2003 on the server and run Windows XP Professional on the client. The following table illustrates key differences in capabilities that are available in environments using different client and server operating systems.

**Feature Dependencies in Certificate Services**

| | Version 2 Templates | Key Archival and Recovery | Autoenrollment | Delta CRL | Qualified Subordination |
|---|---|---|---|---|---|
| Description | New features and options including customizable enrollment, validity, issuance, application, and key usage policies | Archival and recovery of private keys associated with a certificate request | Enables the issuance of certificates to computers and users | Lists of certificates whose status has changed since the last full (base) CRL was compiled can be published more frequently with less impact on network capacity. | Administrator can add restrictions to a CA certificate. These restrictions are translated into certificate extensions within issued certificates. |
| Windows Server 2003 Enterprise Edition | Enterprise CA only | Yes | User and computer | Yes | Yes |
| Windows Server 2003 Standard Edition | | | Computer only | Yes | Yes |
| Windows 2000 Server | | | Computer only | | |
| Windows XP Professional client with Windows 2000 Server CA | | | Computer only | | |
| Windows XP Professional client with Windows Server 2003 CA | Yes | Yes | User and computer | Yes | Yes |
| Windows 2000 Professional client with a Windows 2000 Server CA | | | Computer only | | |
| Windows 2000 Professional client with a Windows Server 2003 CA | By Web enrollment support only | By Web enrollment support or programmatic script | Computer only | | |

**Active Directory Dependencies**

If you are using Active Directory to manage user and computer accounts on the network, your enterprise CAs can use information contained in Active Directory — such as user account names, security group memberships, and certificate templates — to simplify certificate enrollment, renewal, revocation, and validation.

The Active Directory schema in Windows Server 2003 has been enhanced to enable a number of new Certificate Services capabilities — version 2 templates, key recovery and archival, and delta CRLs, for example — that were described in the previous section.

In addition, Active Directory stores public key Group Policy for distribution to all computers that are within the scope of the policy. Public key Group Policy enables you to control which CAs are to be trusted in the enterprise, to specify alternative Encrypting File System (EFS) recovery agents, and to configure automatic enrollment and renewal of certificates for computers running Windows 2000, Windows XP, and Windows 2003 — all from a central administration point.

Active Directory also supports mapping certificates to network user accounts for authenticating clients and controlling access to network resources. Using smart cards for the user logon process is a special case of certificate mapping that extends the Kerberos V5 authentication protocol to include authentication of users on the basis of certificates and private keys that are stored on smart cards. Using smart cards for the user logon process provides enhanced security for user authentication and a single set of user credentials for logging on locally or remotely over a network.

The Active Directory schema in Windows Server 2003 has been enhanced to enable a number of new Certificate Services capabilities — for example, version 2 templates, key recovery and archival, and delta CRLs — that were described in the previous section.

**Non-Microsoft Dependencies**

Windows Server 2003 Certificate Services is based on common industry standards defined by the Internet Engineering Task Force (IETF) Public Key Infrastructure (PKIX) working group and others. Windows Server 2003 Certificate Services supports the following industry standards:

- **RFC 2313 (PKCS #1).** A method for encrypting data using Rivest-Shamir-Adleman (RSA) public key cryptography.
- **RFC 2527.** A framework for creating certificate policies and certification practice statements for CAs and PKIs.
- **RFC 2528.** Representation of Key Exchange Algorithm (KEA) Keys in Internet X.509 Certificates.
- **RFC 2559.** Addresses operational protocols that make it possible to retrieve data regarding X.509 certificates and CRLs from an LDAP directory.
- **RFC 2560.** Guidelines for support of Online Certificate Status Protocol (OCSP).

  **Note**

  - This requires the use of non-Microsoft OCSP software.
- **RFC 2585.** Specifies the conventions for using the File Transfer Protocol (FTP) and the Hypertext Transfer Protocol (HTTP) to obtain certificates and CRLs from PKI repositories.
- **RFC 2587.** Defines auxiliary object classes that need to be supported in an LDAP schema to support PKIX requirements.
- **RFC 2255.** Guidelines for formatting LDAP URLs. Clarifies how LDAP URLs are resolved.
- **RFC 2797.** Defines a certificate management protocol using Certificate Management Messages over CMS.
- **RFC 3280.** Formatting of X.509 v3 certificates and X.509 v2 CRLs for use on the Internet.

In addition, Windows Server 2003 Certificate Services also supports industry standards that enable the following:

- **Transport Layer Security (TLS).** Provides a secure and authenticated channel between hosts on the Internet above the transport layer.
- **Secure Multi-purpose Internet Mail Extensions (S/MIME).** Serves as a standard for secure e-mail across the Internet.
- **Kerberos V5 authentication protocol.** Provides a symmetric key framework for authentication in networks.

A PKI based on Certificate Services can generally be linked to an external organization's PKI, even if the external PKI is not based on Certificate Services, so long as the external PKI supports the above standards. A detailed comparison of how each PKI implements these standards is generally required in order to determine compatibility.

# How Certificate Services Works

Updated: September 22, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Certificate Services Architecture
- Certificate Services Protocols
- Certificate Services Interfaces
- Certificate Services Physical Structure
- Certificate Services Processes and Interactions
- Related Information

Certificate Services provides customizable services for issuing and managing certificates used in software security systems employing public key technologies. You can use Certificate Services to:

- Create certification authorities (CAs) which will receive certificate requests.
- Verify the information in a certificate request.
- Verify the identity of the certificate requester.
- Issue and renew certificates.
- Revoke certificates.
- Publish certificate revocation lists (CRLs).

Additionally, in Windows Server 2003, you can use Certificate Services to:

- Enroll users for certificates from the CA using the Web, or the Microsoft Management Console (MMC) Certificates snap-in, or transparently through autoenrollment.
- Take advantage of programmatic and command-line scripting to perform common tasks such as enrollment processing.
- Help simplify — by using certificate templates and CA policy — the choices a certificate requester has to make when requesting a certificate.
- Take advantage of the Active Directory directory service to publish trusted root certificates, publish issued certificates, and publish CRLs.
- Implement the ability to log on to an Active Directory domain using a smart card.

An optimal environment for Certificate Services includes one or more servers running Certificate Services. The servers running Certificate Services have been planned and deployed to enable:

- Efficient verification of certificates through a process called chain building. With the chain-building process, all certificates in a CA hierarchy are verifiable and lead to a root CA that provides an ultimate anchor of trust.

- Security of all CAs in the hierarchy by means of proper configuration and delegation of administrative responsibilities. In addition, it might be desirable to take the root CA offline in order to more stringently protect the hierarchy from compromise.

- Well defined processes and procedures for validating certificate requests and renewals, as well as for revoking certificates.

The following sections provide an in-depth view of how Certificate Services works in an optimal environment.

**Certificate Services Architecture**
In order to properly configure and manage Certificate Services, you need to understand its major components, the parameters of those components, and dependencies. The following figure shows a functional block diagram of how Certificate Services is implemented in Windows Server 2003.

**Windows Server 2003 Certificate Services Functional Diagram**

The Certificate Services engine, exit modules, and policy modules of Windows Server 2003 Certificate Services work in conjunction with CryptoAPI to perform a variety of tasks, which include:

- Submitting certificate requests (client module).

- Processing certificate requests (Certificate Services engine).

- Verifying whether requesters are qualified to receive certificates (policy module).

- Creating and issuing certificates for qualified requesters (Certificate Services engine).

- Generating a private key and distributing it to the requester's protected certificate store (CryptoAPI and cryptographic service providers).

- Managing the private key for all cryptography operations (CryptoAPI).

- Distributing the certificates that are issued to qualified clients and, optionally, publishing certificates to Web pages, public folders, or Active Directory (exit module).

- Publishing periodic CRLs to Active Directory and, optionally, to Web pages or public folders (exit module).

- Storing all certificate transactions for the audit trail (certificates database).

  **Note**

  - In Windows Server 2003, all cryptographic functions and private key management are performed by CryptoAPI in conjunction with cryptographic service providers (CSPs). CryptoAPI also manages any interactions with hardware security modules (HSMs), if present. Any system service or application can request cryptographic services by using CryptoAPI.

The following sections describe these Certificate Services components:

- Client module
- Certificate Services engine
- Policy module
- Exit module
- Certificates database
- CryptoAPI

**Client Module**
The client module is the software that is used by the end user to generate a certificate request, send the request, and receive the finished certificate. Windows Server 2003 Certificate Services provides CA services for X.509 v3 certificate clients. It supports all Windows clients, as well as any other clients that can generate X.509 v3–compliant certificate requests.

**Certificate Services Engine**
The Certificate Services engine, whose file name is Certsrv.exe, is the core component of Certificate Services. The engine acts as a broker for all requests it receives from clients and regulates the flow of information between the other components during the processing of a request and the generation of a certificate. At each stage of processing, the engine interacts with the various modules to ensure appropriate action is taken based on the state of the request.

The Certificate Services engine supports the following CA operations:

- Issuance
- Publication
- Revocation
- CRL maintenance
- Other operations useful for certificates, such as key archival

Certificate Services operates in two modes: enterprise and stand-alone. In both modes, Certificate Services performs two main operations: receiving requests and publishing requests. Requests are received by a Distributed Component Object Model (DCOM) interface that clients call to submit requests. Requests are published by a number of different methods, including:

- Stand-alone Web enrollment with IIS and Certificate Services
- Enterprise Web enrollment with IIS and Certificate Services
- Enterprise enrollment with an enrollment agent
- Enterprise direct enrollment

These enrollment methods are described later in this section.

**Request Handling**
The default entry module processes these types of requests:

- Public Key Cryptography Standard (PKCS) #10 certificate requests
- Certificate Management protocol using CMS made through remote procedure calls (RPCs) or HTTP

The entry module is a dynamic-link library (DLL) that cannot be customized. Windows Server 2003 services usually use RPCs to submit certificate requests to enterprise CAs. However, the Web Enrollment Support pages use HTTP to submit certificate requests to CAs.

Intermediary applications can be written to handle certificate requests from different types of clients, across multiple transports, or according to policy-specific criteria. IIS is one intermediary application that accepts HTTP-based requests and makes DCOM calls on behalf of users to the CA interfaces. Intermediaries can also check on the status of a previously submitted request and obtain the Certificate Services configuration information.

Certificate requests to Certificate Services are placed in a pending queue until they are approved or denied by the policy module.

**Note**

- You can develop custom certificate enrollment applications that submit RPC or HTTP requests to Certificate Services. For more information about developing custom applications for Windows Server 2003 Certificate Services and about the required certificate request format, see "Using Certificate Enrollment Control" in the Cryptography collection of the Microsoft Platform SDK on MSDN.

**Policy Module**

After Certificate Services has parsed a certificate request, it loads the policy module and tells it where to find the request. The default policy module then examines the request, validating the different fields against its policy.

The policy module contains the set of rules governing issuance, renewal, and revocation of certificates. This policy is created from hard-coded values, registry settings, and — in the enterprise mode — certificate templates. Certificate Services provides a callback interface for the policy module. The callback interface enables the module to request information about a certificate request from the certificates database.

**Note**

- The policy module does not directly access the request; all access is through the Certificate Services engine.

The policy module determines whether a certificate request is approved, denied, or queued (left pending) for an administrator to approve or deny issuance. It does this by verifying the information in the request against various sources, such as a directory service, an external legacy database, or information from an outside authority. In addition, the policy module can send alerts to the appropriate administrator if manual (offline) approval of the request is required.

You can create custom policy modules to insert additional certificate attributes and extensions that might be required by a client application. Extension handlers work in tandem with the policy module to set rules extensions on a certificate. Each extension handler acts as a template for the rules extensions that should appear in a certificate. The policy module must load the appropriate extension handler when it is needed. For example, information such as a job title and a signing limit can be inserted and used by an online purchasing form to determine whether the user can sign for the amount requested.

The policy module can use additional information included in the certificate request to incorporate requested attributes in the issued certificate. For example, certificate requests to stand-alone CAs must include all information about the requested certificate. Therefore, the policy module incorporates this information into each issued certificate. However, enterprise CAs use certificate templates to specify certificate attributes, so certificate requests to enterprise CAs require less information.

After it has validated all the fields, the policy module will create some of the necessary certificate fields, such as the validity period, and determine whether the request should be approved or denied. The policy module then notifies the Certificate Services engine of the result.

Windows Server 2003 Certificate Services includes default policy modules for enterprise and stand-alone CAs. In addition, you can build custom policy modules to address special needs.

**Enterprise CA policy**

By default, an enterprise CA policy always issues a certificate or denies a request immediately. Enterprise CA policy uses Active Directory to determine the identity of the requester, and then automatically determines whether the requester has security permissions to receive a certificate of the type being requested. However, on a per-template basis, you can specify that certificate requests are directed to a pending queue so that an administrator can approve or deny them.

**Stand-alone CA policy**

By default, stand-alone CA policy sends certificate requests to a pending queue so that an administrator can approve or deny them. If you prefer, you can configure stand-alone CA policy to automatically approve all certificate requests. However, because

a stand-alone CA does not verify the identity of requesters in Active Directory, there is no automatic means to verify the identity and validity of the certificate requester. Therefore, if a stand-alone CA is configured to approve certificate requests automatically, it can pose a significant security risk.

**Custom policy modules**
Policy module settings are fully customizable. You can customize policy enforcement by:

- Modifying the installed policy module using the Certification Authority snap-in to create a custom policy module that then makes an explicit call to the default policy module.
- Developing your own policy modules.
- Acquiring a non-Microsoft policy module when one is available.

After you customize the policy module, you can configure Certificate Services to only call the new policy module.

For more information about how to customize policy modules, see "Certificate Enrollment Control" in the Cryptography collection of the Microsoft Platform SDK on MSDN.

**Exit Module**
After the Certificate Services engine has signed and published either a newly created certificate or new CRL, it notifies the exit module of this event. The engine provides a callback interface for the exit module, which allows the exit module to query the certificates database about issued certificates and other data. Exit modules publish completed certificates and CRLs through a number of transports or protocols. For more information, see "Certificate Services Protocols" later in this document.

### Note

- CA administrators can add in additional responses to notifications by creating a custom exit module. One example might be: Call this pager when a certificate with the user name of the CEO is issued.

The exit module packages the issued certificate in the appropriate transport mechanism or protocol and distributes it to the location specified in the request. Certificate requests can specify that the certificate be distributed to Lightweight Directory Access Protocol (LDAP) directory services, file systems, or URLs. The exit module also delivers CRLs to CRL distribution points.

By default, the server notifies each exit module installed on the server whenever a certificate or CRL is published. The default enterprise exit module publishes certificates and CRLs to Active Directory. The default stand-alone exit module publishes certificates and CRLs to the local file system.

Because Windows Server 2003 Certificate Services supports multiple exit modules, you can use the certification authority snap-in to install multiple exit modules for a CA. For example, you can install exit modules that post certificates to legacy open database connectivity (ODBC) databases or to non-Microsoft LDAP directory services.

As with policy module settings, exit module settings are fully customizable. For more information about customizing exit modules, see "Writing Custom Exit Modules" in the Cryptography collection of the Microsoft Platform SDK on MSDN.

**Certificates Database**
The certificates database records all certificate transactions. The certificates database:

- Tracks each certificate request, the requester, and whether the request was granted or denied.
- Records information for the issued certificate, such as the private key, serial number and expiration date.
- Provides a complete audit trail for each certificate from request to expiration.
- Flags and tracks certificates that are revoked by CA administrators.

You can use the Certification Authority snap-in to manage the audit trail.

### Note

- To audit CA activity, use the Certification Authority snap-in and Event Log.

For more information about the certificates database, see “Certificate Services Physical Structure” later in this document.

**CryptoAPI**
Certificate Services uses CryptoAPI for all cryptographic operations, including key generation and exchange, data encryption and decryption, hashing, digital signatures, and signature verification.

CryptoAPI is a generic application programming interface to cryptographic modules, called cryptographic service providers (CSPs). These CSPs are modular in nature and are replaceable by system administrators. During installation, the CA administrator can choose which CSP Certificate Services will use. For most default installations of Windows Server 2003 and Certificate Services, this will be the Microsoft RSA-enhanced provider.

CryptoAPI can also be configured with a hardware-based CSP. If a hardware-based CSP is installed, the CA Administrator can configure Certificate Services to use this CSP.

**Note**

- CSPs cannot access any CryptoAPI interfaces and operate on Windows unless they have received a digital signature from Microsoft. The CSP digital signature is verified each time the CSP is loaded, and each time it attempts to access the CryptoAPI interface. If the signature verification fails, no cryptographic functions are accessible to applications.

Applications can use the functions in CryptoAPI without needing information about the underlying security implementation, just as an application can use a graphics library without needing information about the particular graphics hardware configuration.

**Certificate Services Protocols**
Two protocols, DCOM and LDAP, provide key Certificate Services functionality.

Certificate Services uses the DCOM protocol for enrollment. Certificate Services performs two main operations: receiving requests and publishing requests. Requests are received by a DCOM interface that clients call to submit requests. Requests are published by a number of different methods, which are discussed in How Certificate Enrollment and Renewal Requests are Processed later in this document.

In the enterprise mode, both Certificate Services and clients use a directory service, such as Active Directory, to provide and access services for a domain. Both Certificate Services and clients retrieve templates from Active Directory. Certificate Services also accesses Active Directory by LDAP to verify the client and to store and retrieve certificates.

In addition, Certificate Services can distribute certificates through any transport mechanism. That is, it can accept certificate requests from an applicant and post certificates to the applicant through HTTP, RPC, disk file, or custom transport.

**Certificate Services Interfaces**
Certificate Services publishes the following external DCOM interfaces:

- **ICertRequest and ICertRequest2.** These interfaces accept requests for new and existing certificates.

- **ICertAdmin and ICertAdmin2.** These interfaces provide administrative functions, including request management (modification, denial, resubmission, and revocation), importing certificates, key archival, CRL management, server configuration, user role retrieval, and certificate data retrieval.

- **ICertView and ICertView2.** These interfaces allow properly authorized clients to create a customized or complete view of the Certificate Services certificates database.

- **ICertPassage.** The ICertPassage RPC protocol provides an interface to a CA for submitting a PKCS #10 request and receiving a certificate in a PKCS #7 response.

  **Note**

  - ICertPassage has been superseded in Windows Server 2003 by ICertRequest, but is still used by Windows 2000 clients.

Access to these interfaces is available to developers through licensable APIs. Each of these published interfaces has one of four terminating interfaces inside Certificate Services:

- **ICertRequestD and ICertRequestD2**
- **ICertAdminD and ICertAdminD2**

Certificate Services also uses five internal interfaces, which are not accessible to developers:

- **ICertPolicy.** Certificate Services determines whether to deny, send to a pending queue, or issue a certificate request through this interface, by calling the policy module.
- **ICertServerPolicy.** The policy module queries and modifies certificate request data through this interface.
- **ICertExit.** Certificate Services notifies any exit modules through this interface upon certificate or CRL issuance.
- **ICertServerExit.** An exit module can query the Certificate Services engine about issued certificates through this interface.
- **ICertDB.** Certificate Services uses this interface to access the certificates database.

The following figure shows the relationship between the published external interfaces, the terminating interfaces, and the internal interfaces for Windows Server 2003 Certificate Services.

**Certificate Services Interfaces**

**Certificate Services Physical Structure**

When people think of Certificate Services physical structure, they typically think in terms of the number of servers running Certificate Services, how these servers are linked, whether these servers are dedicated exclusively to Certificate Services or perform multiple functions, and so on. Many of these issues are addressed in PKI design documents. For more information about these issues, see "PKI Technologies."

The physical structure of Certificate Services itself can best be described in terms of where certificates and certificate-related data are stored. Certificate Services uses a number of places to store certificates and configuration data:

- **The certificates database and CA log file**
- **The registry**
- **Active Directory**
- **The file system**

Identical or closely related certificate data can appear in several — even in all — of these locations. For example, parts of the configuration information from the configuration container in Active Directory are replicated to the clients certificate store. Certificates that are stored in the Active Directory Configuration container are deployed to all clients across the forest. And, if a certificate is registered in the Configuration container and the domain security Group Policy object (GPO), a certificate can appear twice on the client.

**Certificates Database**

Certificate Services uses an Extensible Storage Engine (ESE) database to store all certificate requests in any status, all issued certificates, certificate extensions, certificate attributes, and CRLs. The database is composed of four tables: the Request and Certificates table, the Extensions table, the Attributes table, and the CRL table.

These tables maintain status information (receipt, parsing, authorization, signing, and dispatch) as the service processes a certificate request. When Certificate Services receives a request, it creates a row in the certificates database and begins to parse the request and verify the request signatures.

The database also stores all certificates and CRLs issued by the service so that administrators can track, audit, and archive service activity. As Certificate Services parses a certificate request, it fills in the fields of the certificates database from the fields in the request. After the request has been fully parsed, the policy module is notified and the context handle corresponding to the request is passed as a parameter. In addition, the database is used by the Certificate Services engine to store pending revocations before publishing them in a CRL.

Because the certificates database is a transaction database, it includes certificate log files, which record all certificate transactions. By default, the certificates database and the CA log files are installed at the following location:

*systemroot*\system32\certlog

You can choose another location to install either the certificates database or the CA log files — including installing the database and log files separately on different drives — when you are installing a CA.

**Note**

- There is a one-to-one mapping between the tables in the certificates database.

The following table describes the contents of the certificates database.

**Schema of the Certificates Database**

| Column Name | Localized Name | Type | Maximum Length |
|---|---|---|---|
| Request.RequestID | Request ID | Long | 4 -- Indexed |
| Request.RawRequest | Binary Request | Binary | 65536 |
| Request.RawArchivedKey | Archived Key | Binary | 65536 |
| Request.KeyRecoveryHashes | Key Recovery Agent Hashes | String | 8192 |
| Request.RawOldCertificate | Old Certificate | Binary | 16384 |
| Request.RequestAtributes | Request Attributes | String | 32768 |
| Request.RequestType | Request Type | Long | 4 |
| Request.RequestFlags | Request Flags | Long | 4 |
| Request.StatusCode | Request Status Code | Long | 4 |
| Request.Disposition | Request Disposition | Long | 4 -- Indexed |
| Request.DispositionMessage | Request Disposition Message | String | 8192 |
| Request.SubmittedWhen | Request Submission Date | Date | 8 |
| Request.ResolvedWhen | Request Resolution Date | Date | 8 -- Indexed |
| Request.RevokedWhen | Revocation Date | Date | 8 |
| Request.RevokedEffectiveWhen | Effective Revocation Date | Date | 8 -- Indexed |
| Request.RevokedReason | Revocation Reason | Long | 4 |

| | | | |
|---|---|---|---|
| Request.RequesterName | Requester Name | String | 2048 -- Indexed |
| Request.CallerName | Caller Name | String | 2048 |
| Request.SignerPolicies | Signer Policies | String | 8192 |
| Request.SignerApplicationPolicies | Signer Application Policies | String | 8192 |
| Request.Officer | Officer | Long | 4 |
| Request.DistinguishedName | Request Distinguished Name | String | 8192 |
| Request.RawName | Request Binary Name | Binary | 4096 |
| Request.Country | Request Country/Region | String | 8192 |
| Request.Organization | Request Organization | String | 8192 |
| Request.OrgUnit | Request Organization Unit | String | 8192 |
| Request.CommonName | Request Common Name | String | 8192 |
| Request.Locality | Request City | String | 8192 |
| Request.State | Request State | String | 8192 |
| Request.Title | Request Title | String | 8192 |
| Request.GivenName | Request First Name | String | 8192 |
| Request.Initials | Request Initials | String | 8192 |
| Request.SurName | Request Last Name | String | 8192 |
| Request.DomainComponent | Request Domain Component | String | 8192 |
| Request.EMail | Request E-mail Address | String | 8192 |
| Request.StreetAddress | Request Street Address | String | 8192 |
| Request.UnstructuredName | Request Unstructured Name | String | 8192 |
| Request.UnstructuredAddress | Request Unstructured Address | String | 8192 |
| Request.DeviceSerialNumber | Request Device Serial Number | String | 8192 |
| RequestID | Issued Request ID | Long | 4 -- Indexed |
| RawCertificate | Binary Certificate | Binary | 16384 |
| CertificateHash | Certificate Hash | String | 128 -- Indexed |
| CertificateTemplate | Certificate Template | String | 254 -- Indexed |
| EnrollmentFlags | Template Enrollment Flags | Long | 4 |
| GeneralFlags | Template General Flags | Long | 4 |
| SerialNumber | Serial Number | String | 128 -- Indexed |
| IssuesrNadeID | Issuer Name ID | Long | 4 |
| NotBefore | Certificate Effective Date | Date | 8 |
| NotAfter | Certificate Expiration Date | Date | 8 -- Indexed |

| | | | |
|---|---|---|---|
| SubjectKeyIdentifier | Issued Subject Key Identifier | String | 128 |
| RawPublicKey | Binary Public Key | Binary | 4096 |
| PublicKeyLength | Public Key Length | Long | 4 |
| PublicKeyAlgorithm | Public Key Algorithm | String | 254 |
| PublicKeyAlgorithmParameters | Public Key Algorithm Parameters | Binary | 4096 |
| UPN | User Principal Name | String | 2048 -- Indexed |
| DistinguishedName | Issued Distinguished Named | String | 8192 |
| RawName | Issued Binary Name | Binary | 4096 |
| Country | Issued Country/Region | String | 8192 |
| Organization | Issued Organization | String | 8192 |
| OrgUnit | Issued Organization Unit | String | 8192 |
| CommonName | Issued Common Name | String | 8192 -- Indexed |
| Locality | Issued City | String | 8192 |
| State | Issued State | String | 8192 |
| Title | Issued Title | String | 8192 |
| GivenName | Issued First Name | String | 8192 |
| Initials | Issued Initials | String | 8192 |
| SurName | Issued Last Name | String | 8192 |
| DomainComponent | Issued Domain Component | String | 8192 |
| EMail | Issued E-mail Address | String | 8192 |
| StreetAddress | Issued Street Address | String | 8192 |
| UnstructuredName | Issued Unstructured Name | String | 8192 |
| UnstructuredAddress | Issued Unstructured Address | String | 8192 |
| DeviceSerialNumber | Issued Device Serial Number | String | 8192 |

**Registry**

Certificate Services uses the registry to store all of its configuration data, as well as other data. This registry key is:

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\CertSvc

For more information about relevant registry settings, see "Certificate Services Tools and Settings."

**Active Directory**

Various PKI-related containers such as certification authorities, enrollment services, templates, object identifiers (OIDs), and the authority information access and CRL distribution point extensions are created when the first enterprise CA is created in a forest. The permissions on the containers are also set at that time. These containers are replicated to every domain controller within a forest.

Installing an enterprise CA creates the following containers.

**"Trusted root CA and CRL distribution point containers"**

Before you can install an issuing CA, you must publish the root CA's certificate to the Active Directory trusted root CA container, and publish the root CA's CRL to the Active Directory CRL distribution point container. This will cause all domain

members (including the issuing CA) to import the root CA's certificate into their own root stores and will enable them to verify the revocation status of any certificates issued by the root CA. The common name of the trusted root CA container is:

CN=Certification Authorities,CN=Public Key Services,CN=Services,CN=Configuration,DC=

The common name of the CRL distribution point container is:

CN=CDP,CN=Public Key Services,CN=Services,CN=Configuration,DC=

**Authority information access container**
The authority information access container is the publication point for the most currently published CA certificates for root and intermediate CAs. The authority information access extension in a certificate identifies the location of the authority information access container, which helps clients find CA certificates dynamically during chain building.

The common name of the authority information access container is:

CN=AIA,CN=Public Key Services,CN=Services,CN=Configuration,DC=

**NTAuthCertificates container**
Publishing CA certificates to the NTAuthCertificates leaf object indicates that these CAs are trusted to both:

- Issue authentication (logon) certificates for any user in the forest.
- Enable logon for smart cards, IIS mapping, and Extensible Authentication Protocol-Transport Layer Security (EAP-TLS).

The common name of the NTAuthCertificates leaf object is:

CN=NTAuthCertificates,CN=Public Key Services,CN=Services,CN=Configuration,DC=?

**Certificate Templates container**
Installing the first enterprise CA in the forest also installs 29 certificate template objects in Windows Server 2003 or 24 certificate template objects in Windows 2000. The common name for the Certificate Templates container is:

CN=Certificate Templates,CN=Public Key Services,CN=Services,CN=Configuration,DC=

For more information about certificate templates in Windows Server 2003 and Windows 2000, see the "Certificates Technical Reference."

**OID container**
Windows Server 2003 adds an object identifier (OID) container to the configuration container. Because OIDs are not hard-coded in version 2 templates, the OID container is required to work with version 2 templates. The common name for the OID container is:

CN=OID,CN=Public Key Services,CN=Services,CN=Configuration,DC=

Windows Server 2003 includes four predefined issuance policy OIDs:

- **All issuance (2.5.29.32.0).** The all issuance policy OID indicates that the issuance policy contains all other issuance policies. Typically, this object identifier is only assigned to CA certificates.
- **Low assurance (1.3.6.1.4.1.311.21.8. *x.y.z.* 1.400).** The low assurance OID is used to represent certificates that are issued with no additional security requirements.

  **Note**

  - The *x.y.z* portion of the OID is a randomly generated numeric sequence that is unique for each Windows Server 2003 forest.
- **Medium assurance (1.3.6.1.4.1.311.21.8. *x.y.z* .1.401).** The medium assurance OID is used to represent certificates that have additional security requirements for issuance. For example, a smart card certificate that is issued in a face-to-face meeting with a smart card issuer might be considered a medium assurance certificate and contain the medium assurance object identifier.
- **High assurance (1.3.6.1.4.1.311.21.8. *x.y.z* .1.402).** The high assurance OID is used to represent certificates that are

issued with the highest security. For example, the issuance of a key recovery agent certificate might require additional background checks and a digital signature from a designated approver because a person holding this certificate can recover private key material from a Windows Server 2003, Enterprise Edition CA.

**Key recovery agent container**

Key recovery agent certificates are published to the key recovery agent container in Active Directory when enrollment occurs. Because a CA can issue multiple key recovery agent certificates, each key recovery agent certificate will be added to the multi-valued user attribute of the CA object.

The common name for the key recovery agent container is:

CN=KRA,CN=Public Key Services,CN=Services,CN=Configuration,DC=

### Note

- The key recovery agent container only appears under Windows Server 2003.

**File System**

By default, the only directory in the file system that is used by Certificate Services is *systemdir*\CertLog. This is where the certificates database and request logs are stored. Some organizations prefer to create two separate directories, one for the database and one for the log files.

Certificate Services and its associated tools produce several logs which can be used for troubleshooting:

- Certificate Services logs to *systemroot*\certsrv.log (when debug logging is enabled).
- Certutil.exe logs to *systemroot*\certutil.log.
- Certification Authority snap-in logs to windir\certmmc.log.

Certificates and CRLs also are stored on the local file system. During the installation of the root CA, the root certificate is saved to the following shared folders:

- \\Localhost\Certenroll
- \\Locahost\Certconfig
- The SystemCertificates\My folder of the local computer, which is located at:

  \\Documents and Settings*username*\Application Data\Microsoft\SystemCertificates\My
- The trusted root certification authorities container in the local computer registry, which is located at:

  HKEY_Local_Machine\Software\Microsoft\SystemCertificates\Root

The initial CRL is published in the following shared folders:

- \\Localhost\Certenroll
- The intermediate certification authorities container in the registry of the local computer.

The CA certificate of a stand-alone CA is stored in the following shared folders:

- \\Localhost\Certenroll
- \\Locahost\Certconfig

#### Contents of the CertConfig and CertEnroll Shared Folders

More than one certificate file exists in the \CertConfig and \CertEnroll shared folders after a period of time. If the CA name is used as part of a file name, the sanitized CA name adds additional escape characters in order to accommodate any extended ASCII characters in the file name. The escape characters appear in the file name as %20.

The following table explains the certificate file name extensions and their purposes.

**Certificate Paths and File Name Extensions**

| Sample File Name | Description |
|---|---|
| \\Localhost\CertConfig\Certsrv.txt | This is the configuration file for the CA. |
| \\Localhost\CertConfig\Certsrv.bak | If the CA is reinstalled, the original CA configuration file is renamed with the .bak extension. |
| \\Localhost\CertConfig\SubCAname.req<br>\\Localhost\CertConfig\SubCAname(1).req | Request file that is used to generate the CA certificate. Request files are used only for subordinate CAs. Request files are generated with the same base file name suffix as certificates. |
| *systemroot*\\SubCAname.req<br>*systemroot*\\SubCAname(1).req | If no shared folder was created during the CA setup procedure and Active Directory is used to publish the CA's configuration information, request files are written to the systemroot drive instead of to the \\Localhost\CertConfig file. |
| \\Localhost\CertConfig\CAname.crt<br>\\Localhost\CertEnroll\CAname.crt | This is the concatenated name of the original root CA certificate. |
| \\Localhost\CertConfig\CAname(1).crt<br>\\Localhost\CertEnroll\CAname(1).crt | When a root CA certificate is renewed, the version number (in parentheses) is appended to the certificate name. |
| \\Localhost\CertConfig\CAname(0-1).crt<br>\\Localhost\CertEnroll\CAname(0-1).crt<br>\\Localhost\CertConfig\CAname(1-0).crt<br>\\Localhost\CertEnroll\CAname(1-0).crt | When a root certificate is renewed, a cross-certificate is automatically created from the old root certificate, which is trusted by all clients, to the new root certificate, which is not yet trusted. If the old root certificate is version 0 and the new root is version 1, the CA name is appended with the version number of the old root certificate and the version number of the new root certificate (in parenthesis and separated by a dash). If the cross-certificate provides cross trust from the new to the old CA certificates, then the order of the numbers in parenthesis is reversed. |
| \\Localhost\CertEnroll\CAname.crl | This is the name format for the original base revocation list for a CA. |
| \\Localhost\CertEnroll\CAname(1).crl | When an updated base CRL is created, the updated version is indicated in parentheses. Thus, (1) indicates the first updated base CRL. |
| \\Localhost\CertEnroll\Caname+.crl | A plus sign is added to the base CRL name to indicate that this is a delta CRL. |

As illustrated in this table, an important function of the CertConfig and CertEnroll shared folders is to provide links between original and renewed root certificates, and original and updated CRLs. For root certificates, these links are provided by cross-certificates. The cross-certificates are automatically generated when Certificate Services starts after renewing a root CA certificate with a new key. Cross-certificates are not created for subordinate CAs, nor are they created when a root certificate is renewed with the same key. If you upgrade from Windows 2000 Server after renewing a root CA certificate with a new key, the cross-certificate is generated the first time that Certificate Services starts after you upgrade to Windows Server 2003.

#### Certificate Services Processes and Interactions

Certificates are a powerful security technology. Therefore, it is important to understand and carefully manage the processes performed by Windows Server 2003 Certificate Services. These processes are described in the following subsections:

- **How certificates are created.** This describes the core functioning of Windows Server 2003 Certificates Services.

- **Certificate enrollment and renewal.** Beyond the basic process associated with the creation of a new certificate, there can be significant differences in how enrollment and renewal are handled, depending on whether a stand-alone or enterprise CA is being used, whether manual or autoenrollment is used, and which versions of the operating system are involved.

- **How certificates are revoked.** In Windows Server 2003, certificate revocation and management have been enhanced with the addition of delta CRLs.

- **How key pairs are stored.**

  **Note**

  - Another important closely related process, certificate validation, is described in "How Certificates Work."

**How Certificates Are Created**

Certificates are created only after a certificate request has been successfully processed. The process of validating or denying a certificate request involves all of the key components of Windows Server 2003 Certificate Services:

- The Certificates Services engine
- Policy module
- Exit module
- Certificates database

In addition, significant roles are played by the client requesting the certificate, CryptoAPI, and, typically, a directory such as Active Directory. The following figure illustrates these components and their relation to each other.

**Components Involved in Certificate Creation**

The following steps are involved in creating a certificate:

**Note**

- This process applies to most common PKCS #10 requests or Certificate Management protocol using CMS requests.

1. When a user initiates a certificate request, Enrollment Control (Xenroll.dll) uses a cryptographic service provider (CSP) on the client's computer to generate a public key and private key pair for the user.

2. After a key pair has been generated, Xenroll builds a certificate request based on a certificate template.

3. The user's public key is sent with the user's identifying information to the Certificate Services engine.

4. Meanwhile, a copy of the request is placed in the request folder for the requester. In the case of a user, this folder is:

   C:\Documents and Settings*username*\Application Data\Microsoft\SystemCertificates\Request\

5. The CA authenticates the user.

6. The Certificate Services engine passes the request to the policy module, which might perform an additional access check

by querying Active Directory or another reliable source such as IIS.

7. The policy module also checks the registry for a list of certificate templates for the CA. The policy module checks the list for version numbers to verify that it has the most recent versions of all certificate templates. If the request references a more recent version of the certificate template than is currently available, the request fails.

8. If the access check is successful, the Certificate Services engine creates a new row in the Request and Certificates table of the certificates database. A request ID is entered into the database to help track the request.

9. Additional attributes of the certificate request, such as the extensions associated with the request, are entered into the appropriate fields in the database.

10. The Certificate Services engine validates the digital signature used to sign the certificate request. This validation process involves comparing all the certificates in the chain leading up to the root CA to a reliable source, such as Active Directory or IIS. This validation process also involves confirming that none of the certificates in the chain has been revoked.

11. The policy module applies a certificate template to fill out the data associated with the request. This process adds information such as usage restrictions and validity periods, as well as subject name format, to the data in the original request. Some of this data is fixed and therefore copied directly from the template, some comes from the certificate request, and some is constructed on a per user basis (concatenating the friendly name of the user into common name format, for example).

    **Note**

    - When a certificate is being renewed, data that is not being modified is simply reused.

12. If a certificate template has been set to pending, an administrator must verify related information in the request — such as the identity of the requester — which is not controlled by the policy module.

13. The policy module returns the request to the Certificate Services engine, noting whether the request should be issued, should be denied, or is pending.

14. If the request has been approved, the Certificate Services engine constructs the certificate with the appropriate subject, validity period, and extensions.

15. The Certificate Services engine encodes, signs, and validates the certificate from information in the database to verify that the certificate is valid for the entire certificate chain and all defined purposes, and performs another revocation check before it issues the certificate.

16. The issued certificate is sent to the exit module, which saves the certificate to the certificates database and, depending on the template configuration, publishes it to the directory service.

    **Note**

    - If this is a local forest, the certificate is published to the user object. If this is a forest trust, the certificate is published to the contact object.

17. The exit module constructs and signs a response, which is returned to Xenroll.dll on the client. This response can include:

    - A CMS response.

    - A certificate BLOB.

    - A message indicating whether the certificate request has been approved, has been denied, or is pending.

- An error message.
- Request ID.

Xenroll places the certificate in the following folder:

C:\Documents and Settings*username*\Application Data\Microsoft\SystemCertificates\My\Certificates

**Certificate Enrollment and Renewal**
Certificate enrollment and renewal in PKIs based on Windows Server 2003 Certificate Services varies depending on:

- The types of enrollment.
- The types of clients.
- Optional components involved in the enrollment and renewal process.

**Types of Enrollment**
Certificate Services supports three certificate enrollment and renewal methods:

- Autoenrollment
- Manual
- Custom

The methods used to process certificate enrollment and renewal will vary depending on the level of verification the CA must perform to authenticate the certificate requester's identity.

Some enrollment and renewal requests can be approved or denied quickly by configuring the CA to simply verify whether the requester has a valid e-mail address or is a member of a domain.

If the certificate request involves a high-security application, on the other hand, an authorized enrollment agent might have to verify the requesters identity through other agencies or by conducting background checks, In such situations, manual certificate enrollment and renewal processes would be appropriate.

The enrollment and renewal options available to you will depend on the types of clients and CAs that you have.

**Autoenrollment**
Autoenrollment provides a quick and simple way to issue user and computer certificates and to benefit from applications that can use PKI.

Automatic certificate enrollment and renewal can be configured using the Automatic Certificate Request Setup Wizard (only for Windows Server 2003 and Windows XP user and computer certificates). Certificate autoenrollment also works in a Windows Server 2003 Terminal Services session if you use a Remote Desktop Protocol (RDP) 5.1 client.

On computers that are running Windows XP, you can automatically enroll users and computers for certificates, including smart card–based certificates. In contrast, the Windows 2000 Server family only supports certificate autoenrollment for computer certificates.

Certificate autoenrollment is based on the combination of Group Policy settings and version 2 certificate templates. This combination allows certificate enrollment and renewal in the background for computers and users at any time when you apply Group Policy.

To perform autoenrollment, the certificate requester must be registered and authenticated as either a user or computer in Active Directory.

You can configure computer autoenrollment for computer, domain controller, and IPSec certificates.

Certificate autoenrollment occurs at the end of the logon process. It also occurs every eight hours while a user is logged on. Users can also manually activate or cancel autoenrollment in the Certificates snap-in. When activated, autoenrollment

determines through Active Directory queries whether any certificates need to be autoenrolled for the user or computer. If the computer is not networked, autoenrollment is not activated.

When autoenrollment is activated, Certificate Services first checks for any pending autoenrollment requests. If there are any pending requests, an enterprise CA can return a pending status with the request identifications. Autoenrollment attempts to complete pending request identifications by querying the CA that designated the requests as pending. If the certificate is denied, autoenrollment fails the request and an error is generated in the CA event log. If the certificate still has not been issued after a specified period of time — configurable in the registry — then the request is considered to have failed. If a certificate is issued, then it is added to the following folder:

Documents and Settings*username*\Application Data\Microsoft\SystemCertificates

Certificates that are automatically issued are also automatically renewed from the enterprise CA that issued the certificates. Certificates can be manually renewed with the Certificate Renewal Wizard or through the Certificate Services Web Enrollment Support pages.

You can strengthen the security of autoenrollment by:

- Specifying in the certificate template that an additional signature with a specific OID must be included in the request.
- Requiring that a smart card be used to complete the autoenrollment process.
- Configuring the CA to place incoming requests in a pending queue and defining CA officers to verify and approve pending requests.

**Manual enrollment**
Manual enrollment can be configured using the Certificate Request and Certificate Renewal wizards, or using Windows Server 2003 Certificate Services Web Enrollment Support pages.

**Certificate Request and Certificate Renewal wizards**
You can request or renew certificates for Windows Server 2003 and Windows XP users and computers by using the Certificate Request Wizard and the Certificate Renewal Wizard that are available in the Certificates snap-in. These wizards do not function unless an enterprise CA is online to process and issue certificate requests and renewal requests. The ACLs for the certificate templates determine which user accounts or computer accounts can enroll for the various types of certificates.

You can request or renew certificates with an existing private and public key set or request that certificates be issued or renewed with a new private and public key set. However, do not renew certificates with the same private and public key sets if the maximum safe key lifetime would be exceeded.

**Manual enrollment using Web Enrollment Support**
You can have users submit their certificate requests by using a Web page. When a request is received by a CA, the CA verifies whether the requester is qualified to receive a certificate and then either approves or denies the request.

The Windows Server 2003 Certificate Services Web Enrollment Support pages are composed of Active Server Pages and ActiveX controls that provide a Web-based user interface to a CA. By default, the Web Enrollment Support pages are automatically installed on the computer where the CA is installed, but you can also install the Web Enrollment Support pages on another computer running Windows Server 2003.

You can use the Web Enrollment Support pages to perform the following tasks:

- Request and obtain a basic user certificate.
- Request and obtain other types of certificates by using advanced options.
- Request a certificate by using a certificate request file.
- Renew certificates by using a certificate renewal request file.
- Save a certificate request to a file.
- Save the issued certificate to a file.

- Check on pending certificate requests.
- Retrieve the CA's certificate.
- Retrieve the latest CRL from the CA.
- Enroll for smart card certificates on behalf of other users (for use by trusted administrators).

The Web Enrollment Support pages that are installed for stand-alone CAs are similar to the pages that are installed for enterprise CAs, but they differ in that stand-alone CAs do not use certificate templates. For stand-alone CAs, all information about the certificate, including information about the requester, must be specified in the certificate request. The Web Enrollment Support pages for stand-alone CAs support a number of types of certificates that have much of the same functionality as certificate types that are based on templates.

You can deploy stand-alone CAs and Web Enrollment Support pages to issue most of the types of certificates that enterprise CAs can issue. However, certificates for logging on by using smart cards and for autoenrollment require an enterprise CA to issue and renew the certificates.

**Custom enrollment and renewal applications**
The standard enrollment and renewal methods that are available in Windows Server 2003 can meet a wide range of needs. However, if you have special needs, you can develop custom certificate enrollment and renewal applications. Windows Server 2003 Certificate Services supports industry-standard certificate requests by using remote procedure call (RPC) requests or HTTP requests. You can develop custom applications that make certificate requests to Certificate Services. For more information about developing custom applications with Windows Server 2003 Certificate Services, see "Programming Certificate Services" in the Cryptography collection of the Microsoft Platform SDK on MSDN.

**Client Requirements for Enrollment**
You can enroll version 2 templates with any computer running Windows XP or later through the default enrollment methods, including the Certificates snap-in, autoenrollment, Web Enrollment Support pages, or command-line tools.

A computer running Windows 2000 cannot use the Certificates snap-in to enroll a version 2 template. However, any client that is running Microsoft Internet Explorer 5.01 or later can use a version 2 template to enroll certificates through the Web enrollment methods and a downloaded ActiveX control. To download the ActiveX control on a client computer, it is necessary to log on as an administrator or power user on the local computer. In addition, clients running Windows 2000 can enroll version 2 templates through a connection to a server running Windows Server 2003 that has Terminal Services enabled.

### Note

- An enrollment agent that enrolls certificates that are based on version 2 templates requires either a Windows XP or Windows Server 2003 enrollment station. There is no support to enroll version 2 templates with an enrollment agent on a Windows 2000 enrollment station. Nevertheless, certificates that are based on version 2 templates that have been enrolled through an enrollment agent on either a Windows XP or Windows Server 2003 enrollment station can be used on a Windows 2000 client computer.

If certificates have been enrolled with a Windows 2000 PKI where only version 1 templates were available, there is no immediate need to re-enroll or renew these certificates with version 2 templates.

The following three tables list different enrollment methods that are supported on computers that are running Windows 2000, Windows XP, or the Windows Server 2003 family. You can use scripted enrollment with support of CAPICOM and Xenroll. For more information, see "Programming Certificate Services" in the Cryptography collection of the Microsoft Platform SDK on MSDN.

**Certificate Request Wizard Enrollment**

| | **Version 1 template** | **Version 2 template** |
|---|---|---|
| Self enrollment on a Windows 2000 workstation | Yes | No |
| Self enrollment through a Windows Server 2003 Terminal Server session | Yes | Yes |
| Self enrollment on a Windows XP workstation | Yes | Yes |

| | | |
|---|---|---|
| Enrollment agent on a Windows 2000 workstation | No | No |
| Enrollment agent through a Windows Server 2003 Terminal Server session | No | No |
| Enrollment agent on a Windows XP workstation | No | No |

**Web Enrollment**

| | **Version 1 template** | **Version 2 template** |
|---|---|---|
| Self enrollment on a Windows 2000 workstation | Yes | Yes |
| Self enrollment through a Windows Server 2003 Terminal Server session | Yes | Yes |
| Self enrollment on a Windows XP workstation | Yes | Yes |
| Enrollment agent on a Windows 2000 workstation | Yes | No |
| Enrollment agent through a Windows Server 2003 Terminal Server session | Yes | Yes |
| Enrollment agent on a Windows XP workstation | Yes | Yes |

**Scripted Enrollment**

| | **Version 1 template** | **Version 2 template** |
|---|---|---|
| Self enrollment on a Windows 2000 workstation | Yes | Yes |
| Self enrollment through a Windows Server 2003 Terminal Server session | Yes | Yes |
| Self enrollment on a Windows XP workstation | Yes | Yes |
| Enrollment agent on a Windows 2000 workstation | Yes | Yes |
| Enrollment agent through a Windows Server 2003 Terminal Server session | Yes | Yes |
| Enrollment agent on a Windows XP workstation | Yes | Yes |

**Note**

- Because a PKI is a forest resource, the Active Directory site structure is not taken into account when any kind of certificate is requested and issued. An Active Directory–integrated certificate requester enumerates all registered enrollment services in Active Directory and sends its request to a CA that can enroll the certificate type that the user wants. The client does not necessarily choose the closest CA, from a network perspective. Because of this, you should verify that the CA deployment ensures that any client has reliable network connectivity with a CA.

#### Client Requirements for Renewal

When a certificate comes to the end of its lifetime, it must be renewed or replaced to ensure that the certificate owner is able to continue with the certificate's purpose.

In certificate renewal, the renewal requester already owns a certificate. The renewal takes the information of the existing certificate into account when the renewal request is submitted. A certificate can either be renewed with a new key or the existing key can be used for the renewed certificate.

If a certificate was enrolled with a version 2 template, it cannot be renewed if it was based on a version 1 template. However, a certificate that was enrolled with a version 1 template can be renewed with a certificate that was made from a version 2 template.

The following three tables list the different certificate renewal methods that are supported on computers that are running Windows 2000, Windows XP, or the Windows Server 2003 family.

**Certificate Renewal Wizard Enrollment**

| | Version 1 templates | Version 2 templates |
|---|---|---|
| Self renewal on a Windows 2000 workstation | Yes | No |
| Self renewal on a Windows 2000 workstation with Windows Server 2003 Terminal Server session | Yes | Yes |
| Self renewal on a Windows XP workstation | Yes | Yes |
| Renewal with an enrollment agent on a Windows 2000 workstation | No | No |
| Renewal with an enrollment agent on a Windows 2000 workstation with Windows Server 2003 Terminal Server session | No | No |
| Renewal with an enrollment agent on a Windows XP workstation | No | No |

**Web Enrollment**

| | Version 1 templates | Version 2 templates |
|---|---|---|
| Self renewal on a Windows 2000 workstation | No | No |
| Self renewal on a Windows 2000 workstation with Windows Server 2003 Terminal Server session | No | No |
| Self renewal on a Windows XP workstation | No | No |
| Renewal with an enrollment agent on a Windows 2000 workstation | No | No |
| Renewal with an enrollment agent on a Windows 2000 workstation with Windows Server 2003 Terminal Server session | No | No |
| Renewal with an enrollment agent on a Windows XP workstation | No | No |

**Scripted Enrollment**

| | Version 1 templates | Version 2 templates |
|---|---|---|
| Self renewal on a Windows 2000 workstation | Yes | Yes |
| Self renewal on a Windows 2000 workstation with Windows Server 2003 Terminal Server session | Yes | Yes |
| Self renewal on a Windows XP workstation | Yes | Yes |
| Renewal with an enrollment agent on a Windows 2000 workstation | No | No |
| Renewal with an enrollment agent on a Windows 2000 workstation with Windows Server 2003 Terminal Server session | No | No |
| Renewal with an enrollment agent on a Windows XP workstation | Yes | Yes |

**Enrollment and Renewal Using Optional Components**

Certificate enrollment and renewal rarely take place without the use of optional components, including Active Directory or another directory service, IIS, or another client acting as an enrollment agent. The following sections discuss the enrollment and renewal process for enterprise and stand-alone CAs where these optional components are being used.

**Enterprise direct enrollment**

The most basic enrollment method in the enterprise mode is direct enrollment. This is where the client makes a DCOM call directly to Certificate Services and passes the request over this call.

The client will have already retrieved any templates from Active Directory, and will have created the request, using an appropriate template. The following figure shows this configuration and the relationships between Certificate Services, Active

Directory, and the client.

**Enterprise Direct Enrollment**

**Enterprise indirect enrollment with enrollment agent**

Another likely enrollment method in enterprise mode is for clients to use an enrollment agent. An enrollment agent is a person who is authorized with a special Enrollment Agent certificate to request certificates on behalf of a client. Most uses of enrollment agents will be for smart card clients, which can store the private key off the computer. The following figure shows this configuration and the relationship between the enrollment agent, Certificate Services, and Active Directory.

**Enterprise Enrollment with Enrollment Agent**

Before any enrollment occurs, the enrollment agent will have retrieved any certificate templates from the registry of the server that hosts the CA. When a user needs to enroll, the enrollment agent uses the certificate template to create a certificate request and signs the request with the Enrollment Agent certificate. The enrollment agent computer then makes an authenticated DCOM call to Certificate Services. The enrollment agent then sends the certificate request over this DCOM call.

Unlike in the Web enrollment configurations, the enrollment agent computer does not impersonate the client. Instead, the DCOM call made to Certificate Services will have the enrollment agent computer as the caller name. This is important to note, because the certificate request will have the client's identifying information, which will not match the DCOM caller name. Certificate Services would normally reject this mismatch. However, the Enrollment Agent certificate used to sign the request contains the Enrollment Agent OID, which is explicitly trusted to issue certificates on behalf of others. As a result, Certificate Services will accept the request.

**Stand-alone Web enrollment**

The most common method of enrollment in the stand-alone mode is by an HTML interface, provided by a set of Web pages running on a server running IIS. This is called Web enrollment.

IIS can be installed on the same computer as Certificate Services or on a separate computer. In either case, when the client needs a certificate and must enroll in a hierarchy, it connects to IIS by HTTP and authenticates to the server in a manner required by IIS. The client then creates a certificate request and sends it over the HTTP connection to the server by way of a remote DCOM interface. This HTTP connection is most often secured by Transport Layer Security (TLS). IIS then receives the

request and passes it by way of a local DCOM interface to Certificate Services.

The following figure shows this configuration and the relationship between IIS, Certificate Services, and the client.

**Stand-alone Web Enrollment**

**Enterprise Web enrollment**
Enterprise mode Web enrollment also can be configured with IIS and Certificate Services running on the same computer or on separate computers.

Before enrollment occurs, the client will have retrieved any certificate templates from Active Directory. When the client needs to enroll, it will make an HTTP connection to IIS and authenticate in some manner. The computer running IIS must be trusted for delegation in Active Directory. This allows IIS to impersonate the client and make an authenticated DCOM call to Certificate Services. IIS then passes the request over this DCOM call.

The following figure shows the relationship between IIS, Certificate Services, and the client.

**Enterprise Web Enrollment**

**How Certificates Are Revoked**
To help maintain the integrity of an organization's public key infrastructure (PKI), the administrator of a CA must revoke the subject's certificate if the subject leaves the organization, if the subject's private key has been compromised, or if some other security-related event dictates that it is no longer desirable to have the subject's certificate considered valid. When a certificate is revoked by a CA, it is added to that CA's certificate revocation list (CRL).

CRLs are complete, digitally-signed lists of unexpired certificates that have been revoked. The CRL is retrieved by clients who can then cache it (based on the configured lifetime of the CRL) and use it to verify certificates presented for use.

Windows Server 2003 Certificate Services supports industry standard X.509 version 2 CRLs. Each CA maintains a CRL for the certificates it issues and publishes the CRL to CRL distribution points, which can include Web pages, network shares, or Active Directory. An X.509 version 3 certificate usually contains the CRL distribution point for its issuing CA.

**Note**

- Non-Microsoft products can use CRLS published by CAs running on Windows operating systems to provide revocation information in other formats, such as Online Certificate Status Protocol (OCSP), Simple Certificate Validation Protocol

(SCVP), and XML Key Management Specification (XKMS).

By default, enterprise CAs publish CRLs once per week to Active Directory. By default, stand-alone CAs publish CRLs once per week to the following folder on the CA server:

*systemroot*\Certsrv\Certenroll

**Delta CRLs**
Microsoft Windows Server 2003 can publish large CRLs, generating large amounts of directory replication traffic. For a CA with a large population of users, this list can become as large as 1 MB. Many applications require up-to-date revocation status information, which requires the CA to publish the CRLs frequently. Even when there are no new revocation changes, the CA has to republish the entire list so that applications have the latest information.

For this reason, a new type of CRL called a delta CRL has been introduced with Windows Server 2003 Certificate Services. Delta CRLs are CRLs that contain the list of changes in revocation status that have occurred since the last base CRL was published.

**Note**

- Delta CRLs are not necessarily relative to the last published CRL, but always relative to a designated base CRL. Delta CRLs are not aggregated, and the client always uses a pair of the latest delta CRL and a valid base CRL.

It is important that a relying party (client) has access to both a base and delta CRL. If the base CRL is not available for the client's, an error will occur with the delta CRL's processing. When an error occurs, the client falls back to the base CRL.

**Reasons for Revocation**
When a certificate is revoked, a certificate issuer can specify why the certificate was revoked. This is done by specifying a revocation reason code. The reason codes are defined by RFC 3280 and include:

- **KeyCompromise.** The token or disk location where the private key associated with the certificate has been compromised and might be in the possession of an unauthorized individual. This can include cases where a laptop is stolen or a smart card is lost.

- **CACompromise.** The token or disk location where the CA's private key is stored has been compromised and might be in the possession of an unauthorized individual. When a CA's private key is revoked, all certificates issued by the CA that have been signed using that private key are considered revoked, as well.

- **AffiliationChanged.** The user has terminated his or her relationship with the organization indicated in the **DistinguishedName** property of the certificate. This reason code is typically used when an individual has been terminated or has resigned from an organization. You do not have to revoke a certificate when a user changes departments, unless your security policy requires that a different certificate be issued by a departmental CA.

- **Superseded.** A replacement certificate has been issued to a user, and the reason does not fall under the previous reasons. This reason code is typically used when a smart card fails, the user forgets a password, or the user has changed their legal name.

- **CessationOfOperation.** If a CA is decommissioned, the CA's certificate should be revoked with this reason code. Do not revoke the CA's certificate if the CA no longer issues new certificates, yet still publishes CRLs for the currently issued certificates.

- **CertificateHold.** A temporary revocation that indicates that a CA will not vouch for a certificate at a specific point in time. After a certificate is revoked with a CertificateHold reason code, the certificate can then be revoked with another reason code, or unrevoked and returned to use.

  **Note**

  - Although CertificateHold allows a certificate to be unrevoked, it is not recommended to place a hold on a certificate, as it becomes difficult to determine if a certificate was valid for a specific time.

- **RemoveFromCRL.** If a certificate is revoked with the CertificateHold reason code, it is possible to unrevoke a certificate. The unrevoking process still lists the certificate in the CRL, but with the reason code set to RemoveFromCRL.

**Note**

- This is specific to the CertificateHold reason and is only used in delta CRLs.

- **Unspecified.** You can revoke a certificate without providing a specific reason code. Although it is possible to revoke a certificate with the Unspecified reason code, this is not recommended, because it does not provide an audit trail as to why a certificate is revoked.

**The Revocation Checking Process**

Prior to checking the status of a certificate, the client checks the certificate to ensure that the certificate is trusted and valid. For more information about how certificate trust is established, see How Certificates Work.

Every issued certificate has a defined period during which the issuing CA will vouch for the validity of the certificate. The validity period is defined in two fields in the issued certificate:

- **NotBefore.** This field defines the date and time on which the certificate's validity period begins.

- **NotAfter.** This field defines the last date on which the certificate is considered valid by the issuing CA. The NotAfter date cannot be set to a date later than the NotAfter date defined in the issuing CA's certificate.

If CRL-based status checking is used and the certificate is found to have a valid time, the presented certificate is examined to see if it contains a CRL distribution point extension. The CRL distribution point extension indicates both the protocol that must be used to retrieve the CRL (HTTP, FTP, LDAP, or FILE) and the location where the CRL is stored (represented as a URL).

Using this information, CryptoAPI searches the local certificate stores and the local cache for any CRL signed by the issuer (that is the CA) of the certificate that is to be validated. A cached version of a current CRL will always be used (so long as it is valid), rather than downloading the same CRL again. The following logic is used to evaluate the CRL:

- If a CRL is found and the certificate's serial number is listed in the CRL, then the certificate will be considered revoked.

- If the CRL is expired and the certificate is listed in the CRL with any reason other than CertificateHold, the certificate will be considered to be revoked and no attempt will be made to retrieve a new CRL.

- If the certificate is not listed in the CRL, or if the reason code is CertificateHold**,** then a new CRL will be retrieved from the URLs listed in the certificate's CRL distribution point extension. The new CRL is fetched only if it is past the NextUpdate field in the currently held CRL. The new CRL is checked to determine if the certificate is revoked. If the original reason was CertificateHold, the CRL is checked to determine if the certificate is unrevoked by looking for the RemoveFromCRL reason code.

- If the CRL cannot be obtained, the client will generate a Server offline error.

**CRL Format**

A version 2 CRL includes the following fields:

- **Version.** The version of formatting used for the CRL.

- **Issuer.** The issuing CA's distinguished name (DN) represented using an X.500 DN such as CN=TestCA,OU=PKI,DC=nwtraders,DC=com.

- **This Update.** The date that this CRL was issued. Universal Time Coordinate (UTC) format is used for dates up to the year 2049. Generalized Time format is used for dates of 2050 and beyond.

- **Next Update.** The date at which the next CRL will be issued. The same date formatting rules are used as for This Update.

- **Revoked Certificates.** A sequence of zero or more revoked certificates with the following fields represented for each revoked certificate.

- **Certificate Serial Number.** The serial number assigned by the issuing CA for each revoked certificate.
- **Revocation Date.** The date at which the revocation took place.
- **CRL Entry Extension.** An optional field that contains version 2 extensions for CRLs that provides additional information about a single CRL entry.
- **ReasonCode.** Identifies the reason for the certificate revocation. Reasons can include: Unspecified, KeyCompromise, CACompromise, AffiliationChanged, Superseded, CessationOfOperation, CertificateHold, and RemoveFromCRL.
- **HoldInstructionCode.** This option, only defined in the PKI x.509 format, indicates the action to be taken if the CertificateHold is entered in the ReasonCode field. This extension is not supported by a Windows Server 2003 CA.
- **InvalidityDate.** The date on which it is known, or suspected, that the private key associated with the certificate was compromised.
- **CertificateIssuer.** An optional field used to indicate the CA that issued the certificate if indirect CRLs are implemented. A Windows Server 2003 CA does not use this extension, but it is supported by Windows XP clients.
- **AuthorityKeyIdentifier.** A numeric representation of the issuer name and serial number from the CRL issuer's certificate that is used in the certification chain building process.
- **IssuerAltName.** An optional field used to associate alternative identities with the issuer. This can contain a DNS name or a Uniform Resource Indicator (URI). A Windows Server 2003 CA does not use this extension, but it is supported by Windows XP clients.
- **CRLNumber.** A monotonically increasing sequence number that indicates the version of the CRL since the first CRL was published.
- **IssuingDistributionPoint.** Identifies the CRL distribution point if CRL partitioning is implemented. For example, the CRL can be partitioned so that end-entity, CA certificate, or specific reason code revocations are published at a specific distribution point. A Windows Server 2003 CA does not use this extension, but it is supported by Windows XP clients.

  **Note**

  - Windows Server 2003 does not support partitioning CRLs by reason code.
- **deltaCRLIndicator.** Indicates that the CRL is a delta CRL. This also specifies the minimum CRL number of base CRL with which the delta CRL can be combined to obtain the complete state of the CA.
- **Signature (Issuer Signature Algorithm).** Identifies the algorithm used to certify the CRL.
- **SignatureValue.** The actual digital signature computed using the indicated Issuer Signature Algorithm on the ASN.1 DER encoded CRL. The value is encoded as a bit string and omits the signature algorithm and SignatureValue fields.

#### CRL Distribution Point Extensions

When a CA issues a certificate, it can place a CRL distribution point extension in the new certificate that points to the relevant CRL for the certificate containing the extension only.

For example, the root CA issues certificates with a CRL distribution point that points only to the root CA's CRL. A first level subordinate CA issues certificates with a CRL distribution point that points only to the first level subordinate CA's CRL. Finally, a second level CA issues certificates with a CRL distribution point that points only to the second level CA's CRL.

**Note**

- For more information, see Trusted root CA and CRL distribution point containers earlier in this subject.

When the default revocation provider is used, the full certificate chain must be built first, then each certificate in the chain is searched for a CRL distribution point extension to fetch a CRL that will prove the revocation status of that one certificate only. The Windows client does not support a certificate status model where one CA can supply information about revoked certificates that were issued by a different CA. This is because the key that was used to sign the certificate in question must be the same key used to sign the CRL that is used to verify revocation status of the certificate.

The CRL distribution point might point to both primary and alternative locations for CRL retrieval. When a client must acquire the latest CRL, the CRL distribution point extension in a certificate is checked and the CRL retrieval is attempted by contacting the URLs in the CRL distribution point extension. If the name resolution of a fully qualified domain name fails, or the CRL is unavailable, the client tries the next CRL distribution point from the CRL distribution point extension field.

**Note**

- If the client is able to resolve the name of the CRL distribution point but the CRL is not physically available, it might take a significant period of time before the timeout threshold is reached. Windows XP provides enhancements in reducing the timeout threshold as well as CRL unavailability detection.

If the CRL distribution point extension is not available in a certificate, then CryptoAPI will only check the local certificate store and cache for a CRL. If a local CRL is available, it will be checked despite the absence of a CRL distribution point extension. However, a specific application must specify whether or not to demand a revocation check of a certificate.

**CRL Publication**

A CRL distribution point URL can specify several protocols for CRL access. These include:

- **HTTP.** HTTP websites can store the updated CRLs.
- **LDAP.** A Lightweight Directory Access Protocol database can contain the updated CRLs.
- **File.** CRLs can be accessed using the Server Message Block (SMB) protocol.
- **FTP.** File Transfer Protocol servers can be used to distribute updated CRLs. The CRL, by default, is published in two locations by a Microsoft enterprise CA:
    - http://*CAName/*certenroll/*CRLName*
    - LDAP:///CN=*CAName*,CN=*CAComputerName*,CN=CDP,CN=Public Key Services,CN=Services,CN=Configuration, DC=*ForestRootDomain*,DC=*TLD*

When a CRL is published, the CRL will take on different names, depending on whether the CA's certificate has been renewed, and whether the existing private keys are re-used when the certificate is renewed. The following table outlines some examples of CRL names that are automatically generated for a Windows Server 2003 CA.

**Auto-generated CRL File Names**

| Scenario | Name of the CRL File | Name of Delta CRL File | CA Version |
|---|---|---|---|
| A certification authority named IssuingCA that has never had its CA certificate renewed | issuingca.crl | issuingca+.crl | 0.0 |
| A certification authority named IssuingCA that has been renewed once with the same key | issuingca.crl | issuingca+.crl | 0.0 |
| A certification authority named IssuingCA that has been renewed once with a new key | issuingca.crl<br>issuingca(1).crl | issuingca+crl<br>issuingca(1)+.crl | 2.2 |
| A certification authority named IssuingCA that has been renewed three times, twice with a new key | issuingca(3).crl | issuingca(3)+.crl | 3.3 |

**How Key Pairs Are Stored**

Windows Server 2003 and Windows XP store a user's public key certificates in the user's personal certificate store. Certificates

are stored in plaintext because they are public information, and they are digitally signed by certification authorities to protect against tampering.

User certificates for each user profile are located in the following folder:

*systemroot*\Documents and Settings*username*\Application Data\Microsoft\SystemCertificates\My\Certificates

These certificates are written to the users personal store in the system registry each time the user logs on to the computer. If roaming profiles are being used, users' certificates are stored on the file server where the roaming user profile is stored

Private keys for the Microsoft RSA-based cryptographic service providers (CSPs), including the Base CSP and the Enhanced CSP, are located in the user profile under:

*systemroot*\Documents and Settings*username*\Application Data\Microsoft\Crypto\RSA

In the case of a roaming user profile, private keys reside in the RSA folder on the file server where the roaming user profile is stored and are downloaded to the user's computer until the user logs off or the computer is restarted.

Because private keys must be protected, all files in the RSA folder are automatically encrypted by using a random symmetric key called the user's master key. The user's master key is 64 bytes in length and is generated by a strong random number generator. 3DES keys are derived from the master key and are used to protect private keys. The master key is generated automatically and is periodically renewed. It encrypts each file in the RSA folder automatically as the file is created.

The Data Protection API automatically encrypts the user's master key or keys. Master keys are stored in the user profile under

*systemroot*\Documents and Settings*username*\Application Data\Microsoft\Protect

For a domain user who has a roaming profile, the master key is located in the user's profile and is downloaded to the user's profile on the local computer until the computer is restarted.

**Certificate Services Key Storage**
Certificate Services must maintain a key pair for signing certificate requests. The public part of that key pair resides in a certificate located in the My folder of the local computer. The private part of that key pair resides in the cryptographic service provider (CSP) containers.

As shown in the following figure, Certificate Services can have multiple certificates that contain the same public key and, thus, use the same private key. The reasons for this might be because of certificate expiration or varying certificate attributes. There can be up to a maximum of 65,536 Certificate Services certificates.

Each private key has only one active base CRL and one active delta CRL that contains revoked certificates that were signed by that key. Expired CRLs can be automatically deleted upon CRL publication if there is an existing, non-expired CRL for that private key.

### Relationship of Certificates, Private Keys, and CRLs

**Key Archival and Key Recovery**
Subjects can lose their private keys in a variety of ways, such as accidental deletion or deliberate misuse. An administrator might also want to recover the key of a particular subject to access data protected by that key. Key recovery can be used whenever the key archival process has stored the subject's private key.

Windows Server 2003, Enterprise Edition can be configured to archive the private key of a specific certificate when the certificate is issued. This private key archive allows the key to be recovered at a later time if the private key is lost. This process is implemented in two separate phases: key archival and key recovery.

The following sections detail how the key archival and key recovery processes work in Windows Server 2003.

**Key Archival Process**

1. The client finds a CA in the Active Directory (enrollment services container in the configuration partition) and makes an authenticated DCOM connection to the CA.

2. The client requests the CA's encryption certificate.

3. The CA sends the encryption certificate to the client.

4. The client validates that the CA's encryption certificate has been signed by the same key as the CA signing certificate and performs a revocation status check. This ensures that only the intended CA can decrypt the certificate request containing the private key.

5. The client encrypts the private key corresponding to the request with the CA encryption certificate public key, builds a Certificate Management protocol using CMS (CMC) request, and sends the full CMC certificate request to the CA.

6. The CA validates that the encrypted private key cryptographically pairs with the public key in the certificate request.

7. The CA validates the signature on the request with the public key in the request.

8. The CA encrypts the private key from the user request with a random 3DES symmetric key and then encrypts the symmetric key with one or more key recovery agent public keys.

9. The CA saves the encrypted key BLOB containing the encrypted private key and the symmetric key encrypted with one or more key recovery agent public keys to the CA database.

10. The CA processes the certificate request normally.

11. The CA responds to the client with a full PKI response in CMC.

    **Note**

    - Only RSA encryption keys can be archived in the CA database. Signature only keys as well as non-RSA key pairs will not be archived. Denied and resubmitted requests will also not archive private keys.

**Key Recovery Process**

Key recovery is initiated by an end-entity that has lost access to a private key. The end-entity is typically a user or an administrator of a computer who notifies a key recovery agent about lost private key material. The key recovery agent must have a key recovery agent certificate that was used to protect the symmetric key on the private key of the user. The key recovery agent can also be a Certificate Manager (an officer on the CA that issued the certificate in question to the user).

**Note**

- Each organization should determine whether key recovery agent and Certificate Manager should be combined into one role or should be separate roles.

The actual key recovery process first retrieves the PKCS #7–encrypted recovery BLOB from the database. The encrypted BLOB is protected by ACLs to ensure that only a valid Certificate Manager is able to copy the BLOB from the database. Encrypted BLOBs in the database contain the issuer name and serial number of each key recovery agent certificate for key recovery agent identification purposes during recovery.

The recovery BLOB consists of wrapping the encrypted PKCS #7 certificate in the database in another signed PKCS #7 certificate. This enables a number of certificates to be included in the recovery BLOB. The returned certificates include the full chain of the user certificate that is to be recovered, the chain of the signing CA certificate (which might differ from the CA certificate under which the user certificate was issued), and the key recovery agent certificates to which the key was encrypted.

**Related Information**

# Certificate Services Tools and Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**In this section**

- Certificate Services Management Tools
- Certificate Services Registry Settings
- Certificate Services Group Policy Settings

**Certificate Services Management Tools**
The following tools are associated with Certificate Services.

**Certreq.exe: Certreq**

**Category**
Certreq ships with the Windows Server 2003 operating system tools and with the Windows Server 2003 Adminpak.

**Version Compatibility**
Certreq is compatible with Windows Server 2003 and Windows 2000 Server, and can be used to manage the certificate containers for users, computers, and services on computers running Windows 2000, Windows XP, and Windows Server 2003.Certreq enables you to submit, retrieve, create, and accept certificate requests that are sent to a Windows Server 2003 CA. You can also use Certreq to create and sign cross-certificate requests. You can also place the Certreq command syntax in a batch file to script certificate requests.

To find more information about Certreq, see “Command Line References” in Tools and Settings Collection.

**Certutil.exe: Certutil**

**Category**
Certutil is a command-line program that is installed as part of Certificate Services.

**Version Compatibility**
Certutil can be used on Windows 2000 Server CAs and Windows Server 2003 CAs.

You can use Certutil to extract and display CA configuration information, configure Certificate Services, back up and restore CA components, and verify certificates, key pairs, and certificate chains.

To find more information about Certutil, see “Command Line References” in Tools and Settings Collection.

**Certsrv.msc: Certification Authority Snap-in**

**Category**
The Certification Authority snap-in ships with Windows 2000 Server and Windows Server 2003.

**Version Compatibility**
The Certification Authority snap-in is compatible with Windows Server 2003 and Windows 2000 Server.

The Certification Authority snap-in can be used to manage multiple CAs. It allows you to perform a variety of administrative tasks including:

- Starting and stopping the CA.
- Backing up and restoring the CA.
- Changing exit and policy modules.
- Viewing the CA certificate.

- Installing or reinstalling a CA certificate for the CA.
- Setting security permissions and delegating administrative control for the CA.
- Revoking certificates.
- Viewing or modifying certificate revocation list (CRL) distribution points.
- Publishing CRLs and scheduling CRL publication.
- Configuring the types of certificates that are to be issued by the CA.
- Viewing information about certificates that have been issued.
- Viewing information about certificates that have been revoked.
- Viewing pending certificate requests.
- Approving or denying pending certificate requests.
- Viewing failed certificate requests.
- Renewing the CA's certificate.

To find more information about the Certification Authority snap-in, see "Use the Certification Authority snap-in" on Microsoft TechNet.

**Certificate Services Registry Entries**
Registry settings in the following hive are associated with Certificate Services:

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\CertSvc

The Certificate Services-related registry entries correlate to CA and certificate configuration information that can be configured and viewed using the Certificates and Certification Authority snap-ins, as well as the Certutil command-line tool. In addition, other Certificate Services-related registry settings correlate to configuration data that can be viewed directly in certificates issued by the CA.

In addition, user root store trust options can be set on client computers in the following location:

HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\SystemCertificates\Root\ProtectedRoots

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as MMC, to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**CertSvc**
The registry settings in this hive are all created automatically as part of Certificate Services.

**Description**

**Registry Path**
\CertSvc\Description

**Version**
Windows Server 2003 and Windows 2000 Server

This setting provides a reader-friendly description of Certificate Services. The default description reads:

"Creates, manages, and removes X.509 certificates for applications such as S/MIME and SSL. If this service is stopped, certificates will not be created. If this service is disabled, any services that explicitly depend on it will fail to start."

**DisplayName**

**Registry Path**
\CertSvc\DisplayName

**Version**
Windows Server 2003 and Windows 2000 Server

This setting provides the display name for Certificate Services.

**ImagePath**

**Registry Path**
\CertSvc\ImagePath

**Version**
Windows Server 2003 and Windows 2000 Server

This setting identifies where Certserv.exe has been installed on the computer running Windows Server 2003.

**ObjectName**

**Registry Path**
\CertSvc\ObjectName

**Version**
Windows Server 2003 and Windows 2000 Server

This setting specifies the security context used by Certificate Services. The default is the security context of the Local System account.

**Start**

**Registry Path**
\CertSvc\Start

**Version**
Windows Server 2003 and Windows 2000 Server

This setting specifies whether Certificate Services is started automatically when Windows Server is started.

**CertSvc\Configuration**
The registry settings in this hive contain information relating to the configuration of the Certificate Services service on the server.

**Active**

**Registry Path**
\CertSvc\Configuration\Active

**Version**
Windows Server 2003 and Windows 2000 Server

This setting records the sanitized name of the active CA on the server. The process of sanitizing the CA name is necessary to remove characters that are not valid for file names, registry key names, or distinguished name values, or that are not valid for technology-specific reasons.

**ConfigurationDirectory**

**Registry Path**
\CertSvc\Configuration\ConfigurationDirectory

**Version**
Windows Server 2003 and Windows 2000 Server

This setting specifies the location of the CA configuration file.

**DBDirectory**

**Registry Path**
\CertSvc\Configuration\DBDirectory

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines where the CA database is located in the root CA's file system. The CA must be able to get the appropriate path from the registry when the CA starts up.

**DBFlags**

**Registry Path**
\CertSvc\Configuration\DBFlags

**Version**
Windows Server 2003 and Windows 2000 Server

This setting contains options that control the logging behavior of the certificates database and the size of the database log.

**DBLastIncrementalBackup**

**Registry Path**
\CertSvc\Configuration\DBLastIncrementalBackup

**Version**
Windows Server 2003 and Windows 2000 Server

This setting records the time of the last incremental backup of the database.

**DBLastFullBackup**

**Registry Path**
\CertSvc\Configuration\DBLastFullBackup

**Version**
Windows Server 2003 and Windows 2000 Server

This setting records the time of the last full backup of the database.

**DBLogDirectory**

**Registry Path**
\CertSvc\Configuration\DBLogDiretory

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines where the CA's transaction log files are located in the root CA's file system. The CA must be able to get the path from the registry when the CA starts up.

**DBSessionCount**

**Registry Path**
\CertSvc\Configuration\DBSessionCount

**Version**
Windows Server 2003 and Windows 2000 Server

This setting controls the number of concurrent sessions to the certificates database that can be made. By default, the Windows Server 2003 CA allows only 20 concurrent sessions to the certificates database, which is sufficient for most operations. The CA itself can use several connections, and client enrollment requests or management tools used to view the database can account for additional sessions.

**DBSystemDirectory**

**Registry Path**
\CertSvc\Configuration\DBSystemDirectory

**Version**

Windows Server 2003 and Windows 2000 Server

This setting defines where the CA database is located in the root CA's file system. The CA must be able to get the appropriate path from the registry when the CA starts up.

**DBTempDirectory**

**Registry Path**
\CertSvc\Configuration\DBTempDirectory

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines where the temp directory for the CA database is located in the root CA's file system. The CA must be able to get the appropriate path from the registry when the CA starts up.

**LDAPFlags**

**Registry Path**
\CertSvc\Configuration\LDAPFlags

**Version**
Windows Server 2003 and Windows 2000 Server

You use this setting to control the security of Lightweight Directory Access Protocol (LDAP) connections. The default value is to sign all LDAP traffic and to not use SSL to secure LDAP connections. The alternative setting is to disable LDAP signing and to use SSL to secure LDAP connections.

**SetupStatus**

**Registry Path**
\CertSvc\Configuration\SetupStatus

**Version**
Windows Server 2003 and Windows 2000 Server

This setting documents the Certificate Services configuration options that have been installed.

**Version**

**Registry Path**
\CertSvc\Configuration\Version

**Version**
Windows Server 2003 and Windows 2000 Server

This setting identifies the version of Certificate Services installed on the system.

**CertSvc\Configuration\CAName**
The registry settings in this hive contain information relating to the configuration of the certification authority (CA) installed on the server.

**CACertFileName**

**Registry Path**
\CertSvc\Configuration*CAName*\CACertFileName

**Version**
Windows Server 2003 and Windows 2000 Server

On subordinate CAs, this setting identifies the name and location of the root certificate.

**CACertHash**

**Registry Path**
\CertSvc\Configuration*CAName*\CACertHash

**Version**
Windows Server 2003 and Windows 2000 Server

On subordinate CAs, this setting identifies the SHA-1 hashes used for all CA certificates.

**CACertPublicationURLs**

**Registry Path**
\CertSvc\Configuration*CAName*\CACertPublicationURLs

**Version**
Windows Server 2003 only

This setting identifies the URL of the authority information access point where a client can find a CA certificate. Because the authority information access point is the location of the certificate that was used to sign the certificate, and because a root CA issues the CA certificate to itself, you should leave this setting blank for the root CA.

**CAServerName**

**Registry Path**
\CertSvc\Configuration*CAName*\CAServerName

**Version**
Windows Server 2003 and Windows 2000 Server

This setting records the DNS name of the server on which the CA is running.

**CAType**

**Registry Path**
\CertSvc\Configuration*CAName*\CAType

**Version**
Windows Server 2003 and Windows 2000 Server

This setting records whether the CA is a root, enterprise, or stand-alone CA.

**CAXchgCertHash**

**Registry Path**
\CertSvc\Configuration*CAName*\CAXchgCertHash

**Version**
Windows Server 2003 and Windows 2000 Server

This setting identifies the hash used for the encryption certificates.

**CAXchgOverlapPeriod**

**Registry Path**
\CertSvc\Configuration*CAName*\CAXchgOverlapPeriod

**Version**
Windows Server 2003 and Windows 2000 Server

You use this setting to specify whether the overlap period for encryption certificates will be defined in days, weeks, months, or years.

**CAXchgOverlapPeriodUnits**

**Registry Path**
\CertSvc\Configuration*CAName*\CAXchgOverlapPeriodUnits

**Version**
Windows Server 2003 and Windows 2000 Server

You use this setting to specify the number of days, weeks, months, or years that encryption certificates will overlap.

**CAXchgValidityPeriod**

**Registry Path**
\CertSvc\Configuration*CAName*\CAXchgValidityPeriod

**Version**
Windows Server 2003 and Windows 2000 Server

You use this setting to specify whether the validity period for encryption certificates will be defined in days, weeks, months, or years.

**CAXchgValidityPeriodUnits**

**Registry Path**
\CertSvc\Configuration*CAName*\CAXchgValidityPeriodUnits

**Version**
Windows Server 2003 and Windows 2000 Server

You use this setting to specify the number of days, weeks, months, or years that encryption certificates will be valid.

**CertEnrollCompatible**

**Registry Path**
\CertSvc\Configuration*CAName*\CertEnrollCompatible

**Version**
Windows Server 2003 and Windows 2000 Server

This setting enables certificate compatibility with a legacy ActiveX control.

**ClockSkewMinutes**

**Registry Path**
\CertSvc\Configuration*CAName*\ClockSkewMinutes

**Version**
Windows Server 2003 and Windows 2000 Server

This setting controls the time variance allowed for certificate issuance, certificates, and CRLs. If the times on the clocks on two computers are further apart than this registry setting, a newly enrolled certificate would not be immediately valid and the client would have to wait several minutes before being able to use the new certificate. The default setting is 10 minutes. If you expect the clocks of two computers to be more than 10 minutes apart, you can increase this setting.

**CommonName**

**Registry Path**
\CertSvc\Configuration*CAName*\CommonName

**Version**
Windows Server 2003 and Windows 2000 Server

This setting lists the sanitized name of the server on which the CA is running. The process of sanitizing the CA name is necessary to remove characters that are not valid for file names, registry key names, or distinguished name values, or that are not valid for technology-specific reasons. The CommonName setting is used by several variables that you use to set the CRL and authority information access.

**CRLDeltaOverlapPeriod**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLDeltaOverlapPeriod

**Version**
Windows Server 2003 only

You use this setting to specify whether the overlap period for delta CRLs will be defined in days, weeks, months, or years.

**CRLDeltaOverlapPeriodUnits**

**Registry Path**
\CertSvc\Configuration*CAName*\CLRDeltaOverlapPeriodUnits

**Version**

Windows Server 2003 only

You use this setting to specify the number of days, weeks, months, or years that delta CRLs can overlap.

**CRLDeltaPeriod**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLDeltaPeriod

**Version**
Windows Server 2003 only

You use this setting to specify whether delta CRL lifetimes will be defined in days, weeks, months, or years. The delta CRL publication interval setting is similar to the CRL publication interval setting. If a CA is to be offline, you should disable delta CRL publication.

**CRLDeltaPeriodUnits**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLDeltaPeriodUnits

**Version**
Windows Server 2003 only

You use this setting to specify the number of days, weeks, months, or years that delta CRLs can be valid for. If a CA is to be offline, you should disable delta CRL publication.

**CRLEditFlags**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLEditFlags

**Version**
Windows Server 2003 and Windows 2000 Server

This setting enables or disables each field of the Authority Key Identifier (AKI) extension that is automatically generated by the CA for every new certificate.

**CRLFlags**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLFlags

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the oldest unexpired base CRL and includes details about critical and non-critical extensions associated with CRLs.

**CRLNextPublish**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLNextPublish

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the next time the CA expects to publish a CRL.

**CRLOverlapPeriod**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLOverlapPeriod

**Version**
Windows Server 2003 and Windows 2000 Server

This setting specifies whether the overlap period for CRLs will be defined in days, weeks, months, or years.

**CRLOverlapUnits**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLOverlapUnits

**Version**
Windows Server 2003 and Windows 2000 Server

You use this setting to specify the number of days, weeks, months, or years that CRLs can overlap. When a large number of certificates are revoked, such as during an employee layoff, the delta CRL size might increase significantly because of the large number of entries, and almost all clients will refer to the older base CRL. You can reduce the size of the overlap period to speed the propagation process for the new base CRL and help minimize the size of delta CRLs.

**CRLPeriod**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLPeriod

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to specify whether the validity period of a CRL will be defined in days, weeks, months, or years.

**CRLPeriodUnits**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLPeriodUnits

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to specify the number of days, weeks, months, or years, that a CRL will be valid.

**CRLPublicationURLs**

**Registry Path**
\CertSvc\Configuration*CAName*\CRLPublicationURLs

**Version**
Windows Server 2003 only

This setting identifies CRL distribution points where a client can find the CRL that is related to a certificate. The CRL distribution point of a root CA should be empty. For intermediate and issuing CAs, you use the Certification Authority snap-in to define CRL distribution points. These values are then stored in the registry.

A Windows Server 2003 CA maintains all distribution points in this registry key, regardless how the distribution point is accessed. In comparison, Windows 2000 CAs store CRL distribution point data in three different registry keys depending on the publication protocol that is being used: RevocationCRLURL, LDAPRevocationCRLURL, or FileRevocationCRLURL.

**DSConfigDN**

**Registry Path**
\CertSvc\Configuration*CAName*\DSConfigDN

**Version**
Windows Server 2003 and Windows 2000 Server

This setting records the fully qualified domain name of the domain namespace that the CA belongs to. The fully qualified distinguished name becomes part of the certificate issuer name and is also used by several variables that are used to set the CRL and authority information access. On an enterprise CA, this is set automatically. On an offline CA that is not a domain member, you must manually set the value of DSConfigDN so that the fully qualified distinguished name appears in certificates and CRLs.

**DSDomainDN**

**Registry Path**
\CertSvc\Configuration*CAName*\DSDomainDN

**Version**
Windows Server 2003 and Windows 2000 Server

This setting identifies the domain that is a parent to the configuration container used by the CA.

**Enabled**

**Registry Path**
\CertSvc\Configuration*CAName*\Enabled

**Version**
Windows Server 2003 and Windows 2000 Server

This setting identifies whether the CA is enabled.

**EnforceX500NameLengths**

**Registry Path**
\CertSvc\Configuration*CAName*\EnforceX500NameLengths

**Version**
Windows Server 2003 and Windows 2000 Server

This setting makes it possible for certificates issued by the CA to bypass X.500 naming restrictions. Windows Server 2003 CAs enforce X.500 naming standards by default. It is possible that deep OU paths might exceed normal length restrictions. If your organization's PKI does not need to be compatible with a non-Microsoft PKI, you can configure this registry setting to bypass the X.500 name length restriction.

**ForceTeletex**

**Registry Path**
\CertSvc\Configuration*CAName*\ForceTeletex

**Version**
Windows Server 2003 and Windows 2000 Server

This setting enables the ability to automatically change subject relative distinguished names between printable string, teletex, UTF-8, and Unicode representations.

**HighSerial**

**Registry Path**
\CertSvc\Configuration*CAName*\HighSerial

**Version**
Windows Server 2003 only

This setting enables you to choose between three different algorithms for generating fixed-length certificate serial numbers. These serial numbers can be from 10 bytes long up to 19 bytes long. This setting also allows you to generate new certificate serial numbers based on a new set of random numbers after each restart or to use the same set of random data for each certificate, even after the computer hosting the CA is restarted.

**InterfaceFlags**

**Registry Path**
\CertSvc\Configuration*CAName*\InterfaceFlags

**Version**
Windows Server 2003 and Windows 2000 Server

This setting controls whether network interfaces are enabled for performing CA database backups, processing certificate requests, and other administrative operations.

**KRACertCount**

**Registry Path**
\CertSvc\Configuration*CAName*\KRACertCount

**Version**
Windows Server 2003 only

This setting records the number of times a key recovery certificate has been issued from the CA.

**KRACertHash**

**Registry Path**
\CertSvc\Configuration*CAName*\KRACertHash

**Version**
Windows Server 2003 only

This setting defines the hash used to create key recovery certificates.

**KRAFlags**

**Registry Path**
\CertSvc\Configuration*CAName*\KRAFlags

**Version**
Windows Server 2003 only

This setting specifies the extensions that control the key recovery behavior of the CA.

**LogLevel**

**Registry Path**
\CertSvc\Configuration*CAName*\LogLevel

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines how much data to store in the CA log.

**MaxIncomingAllocSize**

**Registry Path**
\CertSvc\Configuration*CAName*\MaxIncomingAllocSize

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to limit the amount of allocated memory associated with any parameter of a certificate request.

**MaxIncomingMessageSize**

**Registry Path**
\CertSvc\Configuration*CAName*\MaxIncomingMessageSize

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to set a maximum limit on the size of a certificate request.

**PolicyFlags**

**Registry Path**
\CertSvc\Configuration*CAName*\PolicyFlags

**Version**
Windows Server 2003 and Windows 2000 Server

This setting specifies whether an optional policy module is being used.

### Note

- This setting is seldom used. However, there is a separate setting in CertSvc/Configuration/*CAName*/PolicyModules that should be used instead to enable the use of a custom policy module.

**RoleSeparationEnabled**

**Registry Path**
\CertSvc\Configuration*CAName*\RoleSeparationEnabled

**Version**
Windows Server 2003 and Windows 2000 Server

This setting determines whether role separation is enabled on the CA.

The separation of CA administrative roles enables you to assign only a single role to a user. This feature is valuable for large enterprises, because the separation of roles ensures that the compromise of a user's account does not compromise the entire CA administered by the user. Role separation is an important operating principle in Common Criteria environments. If this setting is enabled, the CA will not permit an administrator to perform multiple CA roles, such as CA administrator or certificate operator, which are defined in CA security configurations.

### Note

- Roles defined as operating system privileges — including Backup Operator and Auditor — are not affected by the RoleSeparationEnabled setting.

**Security**

**Registry Path**
\CertSvc\Configuration*CAName*\Security

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to specify the security descriptor that controls access to the CA.

**SetupStatus**

**Registry Path**
\CertSvc\Configuration*CAName*\SetupStatus

**Version**
Windows Server 2003 and Windows 2000 Server

This setting documents the configuration options that have been installed for this CA.

**SignedAttributes**

**Registry Path**
\CertSvc\Configuration*CAName*\SignedAttributes

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to specify the certificate request attributes that must be signed in order for a certificate request to be approved.

**SubjectTemplate**

**Registry Path**
\CertSvc\Configuration*CAName*\SubjectTemplate

**Version**
Windows Server 2003 and Windows 2000 Server

This setting contains an ordered list of the subject relative distinguished name elements that are allowed in the Subject field of certificates issued by the CA.

This setting can only be set to a small, fixed list of relative distinguished name elements supported by the CA. If during request processing a listed relative distinguished name field is empty, or if the field is not populated by the request Subject field or by

the policy module, the element will not be included. If the registry value is completely empty, the binary subject encoding from the request is passed through to the issued certificate unmodified.

**UseDS**

**Registry Path**
\CertSvc\Configuration*CAName*\UseDS

**Version**
Windows Server 2003 and Windows 2000 Server

This setting specifies whether the directory service is to be used for CRL publication.

**ValidityPeriod**

**Registry Path**
\CertSvc\Configuration*CAName*\ValidityPeriod

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to specify whether the validity period of certificates issued by the CA will be defined in days, weeks, months, or years. The default value depends on the type of certificate.

**ValidityPeriodUnits**

**Registry Path**
\CertSvc\Configuration*CAName*\ValidityPeriodUnits

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to define the number of days, weeks, months, or years that a certificate issued by the CA will be valid. The validity period for a certificate cannot be greater than the validity period of the CA that issued the certificate. The default value depends on the type of certificate.

**ViewAgeMinutes**

**Registry Path**
\CertSvc\Configuration*CAName*\ViewAgeMinutes

**Version**
Windows Server 2003 and Windows 2000 Server

This setting controls the refresh rate for the transaction view of the CA database. The default is 10 minutes.

**ViewIdleMinutes**

**Registry Path**
\CertSvc\Configuration*CAName*\ViewIdleMinutes

**Version**
Windows Server 2003 and Windows 2000 Server

This setting controls the refresh rate for the transaction view of the CA database when the transaction view is idle. The default is eight minutes.

**CertSvc\Configuration\CAName\CSP**
The registry settings in this hive contain information relating to the configuration of the cryptographic service provider (CSP) for the CA.

**HashAlgorithm**

**Registry Path**
\CertSvc\Configuration*CAName*\CSP\HashAlgorithm

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the hash algorithm that is used for hashing and signing certificate contents. This value, which is set when the CA is installed, is also recorded in the CA certificate.

**MachineKeyset**

**Registry Path**
\CertSvc\Configuration*CAName*\CSP\MachineKeyset

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the key sets that are stored on the computer.

**Provider**

**Registry Path**
\CertSvc\Configuration*CAName*\CSP\Provider

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the CSP used to generate the CA certificate and the key associated with the certificate. This value is set when the CA is installed.

**ProviderType**

**Registry Path**
\CertSvc\Configuration*CAName*\CSP\ProviderType

**Version**
Windows Server 2003 and Windows 2000 Server

This setting indicates the CSP family associated with the provider. When an application connects to a CSP of a particular type, each of the CryptoAPI functions operates by default in a way prescribed by the family that corresponds to that CSP type.

**CertSvc\Configuration\CAName\EncryptionCSP**
The registry settings in this hive contain information relating to the configuration of the encryption CSP for the CA.

**EncryptionAlgorithm**

**Registry Path**
\CertSvc\Configuration*CAName*\EncryptionCSP\EncryptionAlgorithm

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the hash algorithm that is used by the CA for encryption.

**KeySize**

**Registry Path**
\CertSvc\Configuration*CAName*\EncryptionCSP\KeySize

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the size of the secret key used by the encryption hash algorithm.

**MachineKeyset**

**Registry Path**
\CertSvc\Configuration*CAName*\EncryptionCSP\MachineKeyset

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the encryption key sets that are stored on the computer.

**Provider**

**Registry Path**
\CertSvc\Configuration*CAName*\EncryptionCSP\Provider

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the CSP used by the CA for encryption.

**ProviderType**

**Registry Path**
\CertSvc\Configuration*CAName*\EncryptionCSP\ProviderType

**Version**
Windows Server 2003 and Windows 2000 Server

This setting indicates the CSP family associated with the provider. When an application connects to a CSP of a particular type, each of the CryptoAPI functions operates by default in a way prescribed by the family that corresponds to that CSP type.

**CertSvc\Configuration\CAName\ExitModules**
The registry settings in this hive contain information relating to the configuration of the exit modules for the CA.

**Active**

**Registry Path**
\CertSvc\Configuration*CAName*\ExitModules\Active

**Version**
Windows Server 2003 and Windows 2000 Server

This setting lists the active exit modules.

**CertSvc\Configuration\CAName\ExitModules\CertificateAuthority_MicrosoftDefault.Exit**

**PublishCertFlags**

**Registry Path**
CertSvc\Configuration*CAName*\ExitModules\CertificateAuthority_MicrosoftDefault.Exit\PublishCertFlags

**Version**
Windows Server 2003 and Windows 2000 Server

This setting identifies whether certificates are published to a virtual root directory for use by Internet Information Services (IIS).

**CertSvc\Configuration\CAName\ExitModules\CertificateAuthority_MicrosoftDefault.Exit\SMTP**

**EventFilter**

**Registry Path**
CertSvc\Configuration*CAName*\ExitModules\CertificateAuthority_MicrosoftDefault.Exit\SMTP\EventFilter

**Version**
Windows Server 2003 and Windows 2000 Server

This setting identifies whether Simple Mail Transfer Protocol (SMTP) e-mail notifications are being sent out. For example, notification messages can be sent out when certificates are issued, when certificate requests are pending, when certificates are revoked, and so on.

**SMTPAuthenticate**

**Registry Path**
CertSvc\Configuration*CAName*\ExitModules\CertificateAuthority_MicrosoftDefault.Exit\SMTP\SMTPAuthenticate

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to enable a Windows Server 2003 CA to communicate with an Exchange Server by way of SSL.

**SMTPServer**

**Registry Path**
CertSvc\Configuration*CAName*\ExitModules\CertificateAuthority_MicrosoftDefault.Exit\SMTP\SMTPServer

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the SMTP server being used to send out CA-related messages. The SMTP registry hive also includes the following sub-hives, which can be used to issue programmatically-defined SMTP messages for each type of event:

- **CRLIssued**
- **Denied**
- **Issued**
- **Pending**
- **Revoked**
- **Shutdown**
- **Startup**

Each of the above sub-hives includes the following:

- **BodyArg.** Programmatically defined contents of the message body.
- **BodyFormat.** Programmatically defined format of the contents of the message body.
- **TitleArg.** Programmatically defined title of the SMTP message.
- **TitleFormat.** Programmatically defined format of the title of the SMTP message.

**CertSvc\Configuration\CAName\PolicyModules**
The registry settings in this hive contain information relating to the configuration policy modules for the CA.

**Active**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\Active

**Version**
Windows Server 2003 and Windows 2000 Server

This setting lists the active policy modules.

**CertSvc\Configuration\CAName\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy**

**CAPathLength**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\CAPathLength

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the maximum number of levels of subordinate CAs that can be added underneath this CA. Path length constraints can be applied to CAs at any level in a hierarchy. If a path length constraint is being applied to a root CA, it needs to be configured using the CAPolicy.inf file as part of the CA's installation or renewal. If the path length constraint is being applied to a subordinate CA, the constraint must be configured in the registry of the parent CA.

**DefaultSMIME**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\DefaultSMIME

**Version**
Windows Server 2003 and Windows 2000 Server

This setting lists — by object identifier (OID) — the supported hash algorithms, along with the bit length supported for each algorithm.

**DisableExtensionList**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\DisableExtensionList

**Version**
Windows Server 2003 and Windows 2000 Server

This setting disables the adding of a certificate extension to a certificate that is included by default in certificates issued by an enterprise CA. An example of such a certificate extension could be the S/MIME capabilities extension.

**EditFlags**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\EditFlags

**Version**
Windows Server 2003 and Windows 2000 Server

This setting enables you to identify the critical and non-critical extensions associated with policy modules, such as enabling basic constraints. The flags that can be configured include:

- **EDITF_ATTRIBUTEENDDATE.** Controls certificate validity time by certificate request. This feature is disabled by default for enterprise CAs, and enabled by default for stand-alone CAs.

  **Note**

  - Although the validity period of a certificate is normally set by the CA, the CA can be configured in a way that allows the request to specify the validity period. This CA configuration option can only reduce the validity period of certificates to be issued by a request.

- **EDITF_ENABLEAKIISSUERNAME.** Used to enable or disable the Issuer name and Issuer serial number.

  **Note**

  - You should disable the issuer name and issuer serial number if you renew CA keys when you renew CA certificates or plan to use cross-certificates.

**EnableEnrolleeRequestExtensionList**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\EnableEnrolleeRequestExtensionList

**Version**
Windows Server 2003 and Windows 2000 Server

This setting lists the OIDs of the rules extensions defined by the organization that must appear in the issued certificate. These settings apply to all requests submitted to a stand-alone CA, and to requests submitted to an enterprise CA that use a template which specifies that the request must supply the subject information.

**EnableRequestExtensionList**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\EnableRequestExtensionList

**Version**

Windows Server 2003 and Windows 2000 Server

This setting lists the OIDs of the rules extensions defined by the organization that must appear in the issued certificate. By default, extensions that are in the submitted request are added to the CA's database, but are marked as disabled, so they will not appear in the issued certificate.

**RequestDisposition**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\RequestDisposition

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to specify what the policy module should do with incoming and resubmitted requests. Options include:

- Process all certificate requests that meet applicable policy and template processing requirements.
- Place all initial certificate requests in a pending queue, and process all certificate requests that are resubmitted by an administrator, assuming the requests meet applicable policy and template processing requirements.

**RevocationType**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\RevocationType

**Version**
Windows Server 2003 and Windows 2000 Server

You can use this setting to specify an alternative certificate revocation service to function with a Windows Server 2003 CA. This setting enables CRL URLs from the following: LDAP, FTP, and file locations; CDP extensions; and ASP-based revocation.

**RevocationURL**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\RevocationURL

**Version**
Windows Server 2003 and Windows 2000 Server

This setting defines the URL for an alternative certificate revocation service that has been configured to function with a Windows Server 2003 CA.

### Note

- In order for a revocation service to work with a Windows Server 2003 CA, the application, service, or account connecting to this URL must have Read permissions in the Certification Authority snap-in.

The replacement variables that can be used in the revocation URL are listed in the following table.

**Registry Variables for Alternative Revocation Services**

| Alternative Revocation Service | Registry Variable |
|---|---|
| SERVERDNSNAME | 1 |
| SERVERSHORTNAME | 2 |
| SANITIZEDCANAME | 3 |
| CERTFILENAMESUFFIX | 4 |
| DOMAINDN | 5 |

| | |
|---|---|
| CONFIGDN | 6 |
| SANITIZEDCANAMEHASH | 7 |
| CRLFILENAMESUFFIX | 8 |
| CRLDELTAFILENAMESUFFIX | 9 |
| DSCRLATTRIBUTE | 10 |
| DSCACERTATTRIBUTE | 11 |
| DSUSERCERTATTRIBUTE | 12 |
| DSKRACERTATTRIBUTE | 13 |
| DSCROSSCERTPAIRATTRIBUTE | 14 |

In order for the revocation service to function, the application, service, or account connecting to this URL must have Read permissions in the Certification Authority snap-in. If IIS is using a local account, follow the steps for enabling anonymous access in IIS and allowing Anonymous Read access to the CA.

**Note**

- Enabling Anonymous Read access to the CA might expose privacy or security risks.

**SubjectAltName**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\SubjectAltName

**Version**
Windows Server 2003 and Windows 2000 Server

This setting uses an OID for the SubjAltName extension of an issued certificate. This setting is almost never used.

**SubjectAltName2**

**Registry Path**
CertSvc\Configuration*CAName*\PolicyModules\CertificateAuthority_MicrosoftDefault.Policy\SubjectAltName2

**Version**
Windows Server 2003 and Windows 2000 Server

This setting makes it possible for a stand-alone CA to place in the SubjAltName extension of an issued certificate the e-mail address of the authenticated user making the certificate request. This setting is rarely used.

**CryptoAPI Policy**

**ProtectedRoots**

**Registry Path**
HKEY_LOCAL_MACHINE\SOFTWARE\Policies\Microsoft\SystemCertificates\Root\ProtectedRoots

**Version**
Windows Server 2003

This setting is used to disable or enable:

- CryptoAPI applications to use the user root store in building trusted certificate chains.
- Users to add root CAs to the user trusted root store.

  **Note**

  - In Windows Server 2003, this value can also be set through Group Policy.

- Users to remove root CAs from the user trusted store that are also the local computer trusted root store.
- The requirement for NTAuth policy processing.

  **Note**

  - In Windows Server 2003, this value can also be set through Group Policy.

- Name constraint enforcement for undefined name types. By default, Windows Server 2003 rejects undefined name types in a name constraint validation. Setting this value will accept all name forms that are not explicitly defined.

For information about managing these registry settings through Group Policy, see "Trusted Root Certification Authorities" later in this document.

#### Certificate Services Group Policy Settings

Most features of a public key infrastructure and Certificate Services work without your having to configure Public Key Group Policy settings. However, you must configure Public Key Group Policy if you want to configure:

- **Automatic Certificate Request Settings** for configuring autoenrollment for computer certificates.
- **Trusted Root Certification Authorities** for adding trusted root CA certificates to the Trusted Root Certification Authorities store.
- **Enterprise Trust** for configuring CTLs.
- **Encrypted Data Recovery Agents** for configuring Encrypting File System (EFS) recovery agents. (This is the only container that appears for Local Computer policy.)

#### Automatic Certificate Enrollment

Certificate autoenrollment is based on the combination of Group Policy settings and version 2 certificate templates. This combination enables the Windows XP Professional or Windows Server 2003 client to enroll users when they log on to their domain or to a computer when it starts, and to periodically update enrollments between these events.

Autoenrollment Group Policy is an element of Public Key Policies in the Security Settings of the Group Policy object for a user or computer in a domain, site, or OU. You can configure autoenrollment policy on the **Properties** page of the **Autoenrollment Settings** item. Options that you can configure are:

- **Do not enroll certificate automatically.** Blocks attempts to configure autoenrollment for the user or computer.
- **Enroll certificates automatically.** Enables certificate autoenrollment.
- **Renew expired certificates, update pending certificates, and remove revoked certificates.** Enables automatic certificate renewal, and cleans up expired certificates.
- **Updates certificates that use certificate templates.** Updates certificates as needed to conform to the associated certificate templates.

#### Trusted Root Certification Authorities

When you install an enterprise root CA or a stand-alone root CA, the certificate of the CA is added automatically to the Trusted Root Certification Authorities Group Policy for the domain. You also can add certificates for other root CAs to Trusted Root Certification Authorities Group Policy. The root CA certificates that you add become trusted root CAs for computers within the scope of the Group Policy object. For example, if you want to use a non-Microsoft CA as a root CA in a certification hierarchy, you must add the certificate for the non-Microsoft CA to the Trusted Root Certification Authorities Group Policy.

To add a certificate for the root CA to the Trusted Root Certification Authorities Group Policy, in the **Public Key Policies** node, right-click **Trusted Root Certification Authorities**, and then click **All Tasks** and **Import**. When the Certificate Import Wizard appears, use the wizard to import a certificate file for the certificate of the root CA and add it to Group Policy. The certificate is added to the **Trusted Root Certification Authorities** store of all computers within the scope of Group Policy the next time it is

refreshed on each computer.

You can also use Trusted Root Certification Authorities Group Policy to control the changes users can make to trusted root CA options.

To modify these settings, right-click **Trusted Root Certification Authorities**, and then select **Properties**.

To prevent users making any changes to the trusted root CA store, you can clear **Allow users to select new root Certification Authorities (CAs) to trust**.

To limit client trust of alternative certificate stores, under **Client computers can trust the following certificate stores** select one of the following options:

- **Third-Party Root Certification Authorities and Enterprise Root Certification Authorities**
- **Enterprise Root Certification Authorities**

In addition, the following settings under **To perform certificate-based authentication of users and computers, CAs must meet the following criteria:** can be used to manage certificate-based authentication by certificate holders:

- **Registered in Active Directory only**
- **Registered in Active Directory and compliant with name constraints requirements for user principal names (UPNs)**

The Trusted Root Certification Authorities Group Policy settings are the counterparts to the CryptoAPI Policy\ProtectedRoots registry settings described earlier in this document.

**Certificate Trust Lists**

You can create certificate trust lists (CTLs) to trust specific CAs and to restrict the uses of certificates issued by the CAs. For example, you might use a CTL to trust certificates that are issued by a commercial CA and restrict the permitted uses for those certificates. You might also use CTLs to control trust on an extranet for certificates that are issued by CAs that are managed by your business partners. You can configure CTLs for computers and for users.

Before administrators can create CTLs, they must have a valid trust list signing certificate — such as the Administrator certificate or the Trust List Signing certificate that is issued by enterprise CAs. The trust list signing private key for the administrator is used to sign the CTL for integrity. If the trust list signing certificate for an administrator is invalid, all CTLs that have been created and signed by that administrator also are invalid.

Certificate Trust List Group Policy is configured as part of Public Key Policies\Enterprise Trust in the Security Settings of the Group Policy object for a user or computer in a domain, site, or OU.

You use the Certificate Trust Wizard to configure Certificate Trust List Group policy.

To activate the wizard, you right-click the **Enterprise Trust** node, and then click **New** and **Certificate Trust List**. The wizard enables you to configure the following options:

- **Valid duration.** An optional lifetime for the CTL. If you do not specify a lifetime, the CTL expires when the trust list signing certificate expires.
- **Designate Purposes.** The CTL establishes trust only for certificates that are valid for the selected purposes. A certificate might support all of the listed purposes, but you can restrict the purposes for which certificates are trusted.
- **Add Purpose.** Enables you to add purposes to the **Designate Purposes** box. This also requires you to enter an OID for the new purpose.
- **Current CTL Certificates.** Displays the certificates of the root CAs that are to be trusted by this CTL. Certificates with certification paths to the root CA are trusted for all designated purposes specified by the CTL.
- **Add from Store.** Adds a root certificate from the Trusted Root Certification Authorities store.
- **Add from File.** Adds a root CA's certificate from a file.

- **Remove.** Deletes the certificate that is selected in the **Current CTL Certificates** box.
- **View Certificate.** Enables you to view the certificates that are selected in the **Current CTL Certificates** box.
- **Use this certificate.** Displays the trust list signing certificate for the private key that is to be used to sign the CTL.
- **Select from Store.** Adds a trust list signing certificate from the Personal store for the administrator.
- **Select from File.** Adds the trust list signing certificate from a file.
- **View Certificate.** Enables you to view the certificate listed in the **Use this certificate** box.
- **Add a timestamp to the data.** Adds a timestamp to the CTL. The timestamp is used to determine the valid lifetime of the CTL. If a timestamp is not used, the computer clock is used instead.
- **Timestamp service URL.** Identifies the location of the timestamp service that is to be used for the timestamp.
- **Friendly Name.** The optional name that appears in MMC when the CTL is displayed.
- **Description.** An optional description to describe this CTL.

**EFS Recovery Agents**

A recovery agent is an individual authorized to decrypt data that was encrypted by another user. Recovery agents do not need any other permissions to function in this role. Recovery agents are useful, for example, when employees leave the company and their remaining data needs to be decrypted.

By default, the local Administrator users account for the first domain controller that is installed in the domain is the EFS recovery account for that domain. You can specify alternative recovery agents for EFS. Before you can add a recovery agent for a domain, you must ensure that each recovery agent has been issued a recovery agent certificate.

To add recovery agents for a domain, their certificates need to be added to the existing recovery policy. There are two ways to accomplish this. You can:

- Add recovery agent certificates that are published in Active Directory to the recovery policy.
- Add recovery agent certificates from a file that is located on a disk or in a shared folder that is available from the computer where you are configuring Public Key settings.

Encrypted Data Recovery Agent Group Policy is configured as part of Public Key Policies\Encrypting File System in the Security Settings of the Group Policy object for a user or computer in a domain, site, or OU.

You configure Encrypted Data Recovery Agent Group Policy by using the Add Recovery Agent Wizard. To activate the wizard, right-click the **Encrypted Data Recovery Agents** node and then click **Add**.

You can use the wizard to configure the following:

- **Recovery agents.** Displays the certificates you choose for recovery agents.
- **Browse Directory.** Locate and add a recovery agent certificate for a user account by browsing in Active Directory. Use this option when the certificate is published in Active Directory.
- **Browse Folders.** Locate and add a recovery agent certificate for a user account by browsing folders and files.

When you select **Encrypted Data Recovery Agents**, the EFS recovery agent certificates that are applied by Group Policy appear in the details pane of the console. These are the recovery agent certificates that are used by EFS within the scope of Group Policy.

**Note**

- Encrypted Data Recovery Agents is the only Certificate Services–related container that appears in local computer Group Policy.

# Trust Technologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Trust Technologies**

By default, all users in a specific Windows domain can be authenticated to resources contained within that domain. In this way, a domain can provide its users with secured access to all resources in that domain. To expand that access to include resources beyond the boundaries of a single domain, you need to use trust relationships. Trust relationships provide a mechanism for one domain to allow access to resources based on the logon authentications of another domain.

**Trust Concepts**

Trusts in Microsoft Windows NT version 4.0 differ from trusts in the Microsoft Windows 2000 and Windows Server 2003 operating systems. In domains that have domain controllers running Windows NT 4.0 Server and earlier, trusts are limited to two domains, and the trust relationship is one-way (only one of the two domains trusts the other domain) and nontransitive (does not extend to any other domains trusted by the two domains). With domains that have domain controllers running Windows Server 2003 or Windows 2000 Server, all trusts created within a forest are two-way (both domains trust each other) and transitive (extends to all domains in the forest). Domains that have domain controllers running Windows 2000 Server or Windows Server 2003 (domains that use the Active Directory directory service) are also referred to as Active Directory domains.

To understand trust technology, you should be familiar with basic trust concepts including the nature and purpose of trust relationships, the role of trusted authorities, the variety of trust paths, and trust transitivity.

**Trust Relationships**

A trust relationship (also called a trust) is a logical relationship established between domains to allow authentication and authorization to shared resources. The authentication process verifies the identity of the user, and the authorization process determines what the user is permitted to do on a computer system or network. Once a user requesting access to a resource computer in another domain has been authenticated by the resource domain, the resource computer compares the user's credentials to the permissions assigned within its security descriptor to help determine the user's level of authorization to that resource. A security descriptor contains access control lists (ACLs) that identify the users and groups that are assigned or denied access permissions on a resource.

In its simplest form, a trust acts as a technological drawbridge, by either allowing or disallowing authentication traffic to flow between two or more domains. When a trust relationship is created between two domains, traffic is allowed over the bridge, permitting the sharing of resources between them, as shown in the following illustration.

**Simple Trust Relationship**

The domain where the user account requesting access is located is referred to as the trusted domain. The domain that contains a shared resource that a user account is trying to access is referred to as the trusting domain.

Severing a trust removes the bridge through which authentication traffic flows, and removes all relationships to any trusted authorities located in the other domain. When this occurs, no authentication traffic originating from a user in the formerly trusted domain can cross over to the formerly trusting domain; it is no longer possible to share information across domain boundaries, as is shown in the following figure.

**Severed Trust Relationship**

**Trusted Authorities**

Active Directory domains do not unconditionally accept credentials coming from other domains; they accept credentials only from trusted authorities. In Active Directory, domain controllers act as trusted authorities for all security principals located in their domain and all security principals located within trusted domains, as long as a valid trust is present between those domains.

A trusted authority, in Active Directory, is analogous to a certificate granting agency that distributes certificates by which a sub agency can verify its authenticity. For example, when a passport is issued by a passport authority in one country (a domain controller in a trusted domain), customs officials physically located in another country (domain controllers in a trusting domain), trust the authority that issued the passport, therefore they trust the validity of the passport.

Conversely, a company might create a specific means by which to identify employees, such as employee badges issued by its various departments (domains). The manufacturing department (domain controllers in a trusting domain) might trust identification badges issued by the sales department (domain controllers in a trusted domain) for important transactions, but other companies (domains or forests that do not have a trust relationship with that company or its departments) would not trust them because they do not inherently trust the authority that issued them.

In Windows NT 4.0 or Active Directory domains, domain administrators act as the chief executive officer of the certificate granting agency by defining the policy regarding what external authorities (domains) are trusted in their domain. For example, a domain administrator in a trusting domain first identifies which other domains should be trusted to access shared resources in the domain. The administrator then establishes the trust relationships that provide a path by which authentication requests from trusted domains can travel and be verified. In this way, trusts define for each domain which authentication requests are valid. For more information about trust paths, see “Trust Paths” later in this overview.

**Trust Paths**

The direction that a trust is assigned determines the trust path used for authentication. A trust path is defined by the series of trust relationships that authentication requests must follow between domains. Before a user can access a resource in another domain, the security system on domain controllers running Windows NT 4.0, Windows 2000 Server, and Windows Server 2003 must determine whether the trusting domain (the domain containing the resource the user is trying to access) has a trust relationship with the trusted domain (the user’s logon domain). To determine this, the security system computes the trust path between a domain controller in the trusting domain and a domain controller in the trusted domain. All domain trust relationships have only two domains: the trusting domain and the trusted domain. In the following figure, the trust path is indicated by arrows showing a one-way direction of trust and the direction of access:

**Trust Path in a One-Way Trust**

**One-Way Trust**

A one-way trust is a unidirectional authentication path created between two domains (trust flows in one direction, and access flows in the other). This means that in a one-way trust between a trusted domain and a trusting domain, users or computers in the trusted domain can access resources in the trusting domain. However, users in the trusting domain cannot access resources in the trusted domain. Some one-way trusts can be either nontransitive or transitive, depending on the type of trust being created.

**Two-Way Trust**

A two-way trust can be thought of as a combination of two, opposite-facing one-way trusts, so that, the trusting and trusted domains both trust each other (trust and access flow in both directions). This means that authentication requests can be passed between the two domains in both directions. Some two-way relationships can be either nontransitive or transitive depending on the type of trust being created. All domain trusts in an Active Directory forest are two-way, transitive trusts. When a new

child domain is created, a two-way, transitive trust is automatically created between the new child domain and the parent domain.

**Trust Transitivity**

Transitivity determines whether a trust can be extended beyond the two domains between which it was formed. A transitive trust extends trust relationships to other domains; a nontransitive trust does not extend trust relationships to other domains. Each time you create a new domain in a forest, a two-way, transitive trust relationship is automatically created between the new domain and its parent domain. If child domains are added to the new domain, the trust path flows upward through the domain hierarchy, extending the initial trust path created between the new domain and its parent.

Transitive trust relationships thus flow upward through a domain tree as it is formed, creating transitive trusts between all domains in the domain tree. A domain tree can therefore be defined as a hierarchical structure of one or more domains, connected by transitive, bidirectional trusts, that forms a contiguous namespace. Multiple domain trees can belong to a single forest.

Authentication requests follow these extended trust paths, so accounts from any domain in the forest can be authenticated by any other domain in the forest. Consequently, with a single logon process, accounts with the proper permissions can access resources in any domain in the forest.

With a nontransitive trust, the flow is restricted to the two domains in the trust relationship and does not extend to any other domains in the forest. A nontransitive trust can be either a two-way trust or a one-way trust.

**Trust Architecture**

The architecture of trusts includes various interdependent technologies and processes that, when implemented together, provide cross domain resource sharing. These technologies include authentication, authorization, the Net Logon service and Active Directory, which all rely on DNS or Windows Internet Name Service (WINS) to locate domain service records. The following figure shows the various technologies that make up the trust architecture.

### Trust Architecture

Active Directory provides the foundation for trust relationships by supplying a central management system through which domain administrators can grant access to trusted authorities in other domains. Trusts then provide the mechanism through which authentication traffic between domains or forests must travel to obtain authorization for a given shared resource. Authentication and authorization are the security enforcement mechanisms within this resource access management environment.

The authentication process and the Net Logon service provide pass-through validation of credentials for users or distributed applications located in other domains, and rely on either the NTLM or Kerberos version 5 authentication protocol to transport all trust related traffic. Applications can use these protocols to securely and seamlessly integrate with the Active Directory user store for authentication, and can also use these protocols to secure application data.

**Trust Components**

The various components of trust technologies and the related components that are an important part of the Windows Server 2003 security architecture determine how trusts function. The following table provides a summary view of these components.

### Trust Technologies and Related Components

| Related components | Description |
|---|---|
| Security Identifiers (SIDs) | The Windows security model identifies account objects such as users, groups, computers, and domains by SIDs. SIDs are domain-unique values, built when the user or group is created, or when the computer or trust is registered with the domain. The components of a SID follow a hierarchical convention: A SID contains parts that identify the revision number, the authority — such as the domain — that issued the SID, and a variable number of sub authority or relative identifier (RID) values that uniquely identify the security principal relative to the issuing authority. |

| | |
|---|---|
| Access Tokens and Authentication | An essential component of the Windows-based trust model is authentication, which involves identifying the user to the local or trusted domain by presenting credentials, usually in the form of a user name and password. Assuming these credentials are acceptable, the system creates an access token for the user that contains the SID of the user (the primary SID), and the SIDs of all the local and domain groups of which the user is a member. Every process the user creates, for example by running an application, carries the user's access token. |
| Security Descriptors and Authorization | Once authenticated, the user can attempt to gain access to resources from any domain in the forest by using the Active Directory authorization process. This process determines what a user is permitted to do on a resource by using the access token to determine whether and at what level to grant the user access to system resources. The counterpart of the user's access token is the security descriptor attached to resources such as files or printers. A security descriptor contains a discretionary access control list (DACL), which consists of a list of access control entries (ACEs). Each ACE consists of a SID that identifies a security principal, together with an indicator of the specific access on that resource that is granted or denied to that security principal. |
| SIDHistory | In Active Directory, domain migration or restructuring across trusts is made considerably easier by an attribute on Active Directory security principals called SIDHistory. SIDHistory stores the former SIDs of moved objects such as users and security groups. When a user is moved, the SIDHistory attribute of the user object is updated with the former SID. When the user then logs on to the system, the system retrieves the entries in the user object and the user's SIDHistory and adds them to the user access token. In this way SIDHistory ensures that migrated users can continue to access resources located in a trusting (resource) domain, even though the user's new domain does not have a trust relationship with the resource domain. |
| SID Filtering | SID filtering prevents domains from accepting SIDs with domain SIDs from outside the sender's domain. Applying SID filtering to trusts can prevent malicious users who have domain administrator level access in the trusted domain from granting, to themselves or other user accounts in their domain, elevated user rights in the trusting domain. |

**Trust Deployment Scenarios**
There are three scenarios in Active Directory in which specific types of trusts can be used to help accommodate different resource sharing needs of an organization. These include using trusts within a forest (intra-forest trusts), using trusts across forests (inter-forest trusts), and using trusts to collaborate with Kerberos realms.

**Intra-Forest Trusts**
Intra-forest trusts are transitive trusts that can be used only within a single forest, and include tree-root, parent-child, and shortcut trusts.

**Tree-root trusts**
By default, two-way, transitive trusts are automatically created when a new domain is added to a domain tree or forest root domain by using the Active Directory Installation Wizard. When a new domain tree is created in an existing forest, a new tree-root trust is established.

**Parent-child trusts**
When a new child domain is added to an existing domain tree, a new parent and child trust is established. Authentication requests made from subordinate domains flow upward through their parent to the trusting domain.

**Shortcut trusts**
You can use shortcut trusts to improve user logon times between two domains that are located in two separate domain trees within the same forest. Authentication requests must first travel a trust path between domain trees, and in a complex forest this can take time. Using shortcut trusts helps to speed up authentication in this situation.

**Inter-Forest Trusts**
Inter-forest trusts can be nontransitive or transitive, depending on the type of inter-forest trust used, and can only be created between domains located in different forests or realms. Inter-forest trust types include external trusts and forest trusts; both of these trust types must be manually created.

**External trusts**
External trusts are nontransitive and can be created between Active Directory domains in different forests or between an Active Directory domain and a Windows NT 4.0 domain.

**Forest trusts**
With Windows Server 2003 forests, you can link two different forests to create a one-way or two-way transitive trust relationship. A two-way forest trust is used to form a transitive trust relationship between every domain in both forests. Forest trusts can be created only between two Windows Server 2003 forests and cannot be implicitly extended to a third forest.

**Kerberos Realm Trusts**

A realm trust can be established between any non-Windows-based operating system Kerberos version 5 realm and a Windows 2000 Server or Windows Server 2003 domain. This trust relationship allows cross-platform interoperability with security services based on other Kerberos version 5 implementations, such as that from the Massachusetts Institute of Technology. Realm trusts can be manually switched back and forth between nontransitive and transitive by using the Netdom.exe tool. Realm trusts can be either one-way or two-way.

# Domain and Forest Trusts Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2012, Windows Server 2012 R2

Trust technology is the foundation for the security architecture in Microsoft Windows Server 2003 networks using the Active Directory directory service. Trusts enable service administrators to implement an authentication and authorization strategy for sharing resources across domains or forests and provide a mechanism for centralizing management of multiple domains and forests.

# What Are Domain and Forest Trusts?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Trust Scenarios
- Technologies Related to Trusts

Most organizations that have more than one domain have a legitimate need for users to access shared resources located in a different domain. Controlling this access requires that users in one domain can also be authenticated and authorized to use resources in another domain. To provide authentication and authorization capabilities between clients and servers in different domains, there must be a trust between the two domains. Trusts are the underlying technology by which secured Active Directory communications occur, and are an integral security component of the Windows Server 2003 network architecture.

When a trust exists between two domains, the authentication mechanisms for each domain trust the authentications coming from the other domain. Trusts help provide for controlled access to shared resources in a resource domain (the trusting domain) by verifying that incoming authentication requests come from a trusted authority (the trusted domain). In this way, trusts act as bridges that allow only validated authentication requests to travel between domains.

How a specific trust passes authentication requests depends on how it is configured; trust relationships can be one-way, providing access from the trusted domain to resources in the trusting domain, or two way, providing access from each domain to resources in the other domain. Trusts are also either nontransitive, in which case trust exists only between the two trust partner domains, or transitive, in which case trust automatically extends to any other domains that either of the partners trusts.

In some cases, trust relationships are automatically established when domains are created; in other cases, administrators must choose a type of trust and explicitly establish the appropriate relationships. The specific types of trusts used and the structure of the resulting trust relationships in a given trust implementation depend on such factors as how the Active Directory directory service is organized, and whether different versions of Windows coexist on the network.

**Trust Scenarios**

It is possible to create a number of different domain and forest trust configurations, depending on the Active Directory structure of the organization. Windows Server 2003 domains and forests can trust other Windows Server 2003 domains and forests, as well as Windows 2000 and Windows NT 4.0 domains. For example, trust configurations vary in nature and complexity in each of the following scenarios:

**Trusts within a single Windows 2000 Server or Windows Server 2003 forest**

By default, all domain trusts within a single Active Directory forest are two-way, transitive trusts. There are three types of transitive trusts that are used within a single Windows 2000 Server or Windows Server 2003 forest. The first is the tree-root trust, which is created by default when you create a new domain tree by using the Active Directory Installation Wizard. The two-way transitive nature of intra-forest trusts such as the tree-root trust allows all domains in one tree to trust all domains in any other tree within the same forest.

The second type of trust is a parent-child trust. It is created automatically when you create a new domain in an existing domain tree by using the Active Directory Installation Wizard. When a new child domain is created, a parent-child trust is established between the new domain and the domain that immediately precedes it in the namespace hierarchy.

The last type of trust that can be used between trees is a shortcut trust, and is used to speed up access times to resources in a domain that is deep within the tree hierarchy of another domain.

**Trusts between two Windows Server 2003 forests**

It is possible to extend the transitivity of domain trusts within a single Windows Server 2003 forest to another Windows Server 2003 forest by manually creating a one-way or two-way forest trust. A forest trust is a transitive trust between a forest root domain and a second forest root domain. A one-way forest trust allows all users in one forest to trust all domains in the other forest; a two-way forest trust forms a transitive trust relationship between every domain in both forests. The transitivity of forest trusts is limited to the two forest partners; the forest trust does not extend to additional forests trusted by either of the partners.

**Trusts across Windows Server 2003 and Windows 2000 forests**

Windows Server 2003 forest trusts cannot be created between a Windows Server 2003 forest and a Windows 2000 forest. You can, however, manually create a trust relationship between any domain in a Windows Server 2003 forest and any domain in a Windows 2000 forest by using one-way or two-way external trusts. External trusts are nontransitive and provide for access to resources in another domain outside the forest that is not already joined by a forest trust.

**Trusts between Windows Server 2003 or Windows 2000 domains and Windows NT 4.0 domains**
You can manually create a one-way or two-way external trust between Windows Server 2003 or Windows 2000 domains and Windows NT 4.0 domains so that users from either domain can be authenticated to access resources in the other domain.

**Trusts between Windows 2000 or Windows Server 2003 domains and non-Windows Kerberos realms**
Windows 2000 or Windows Server 2003 domains can be configured to trust non-Windows-brand operating system Kerberos realms, and non-Windows Kerberos realms can be configured to trust Windows Server 2003 domains by manually creating one-way or two-way realm trusts. Realm trusts can also be configured to be either nontransitive or transitive, depending on the level of interoperability you require with UNIX or Massachusetts Institute of Technology implementations of the Kerberos version 5 protocol.

When the direction of a one-way trust is from a non-Windows Kerberos realm to a Windows Server 2003 domain, the user in the Windows Server 2003 domain can access resources in the non-Windows Kerberos realm. When the direction of trust is from a Windows Server 2003 domain to a non-Windows Kerberos realm, users in the non-Windows Kerberos realm can access the resources in the Windows Server 2003 domain.

**Technologies Related to Trusts**
Trusts depend on the NTLM and Kerberos authentication protocols and on Windows-based authorization and access control mechanisms to help provide a secured communications infrastructure across Active Directory domains and forests. The following diagram illustrates how authentication and authorization technologies relate to trusts and other components of the Windows distributed security model.

### Trusts and the Windows Distributed Security Model

**Applications and Net Logon**
Both applications and the Net Logon service are components of the Windows distributed security channel model. Applications integrated with Windows Server 2003 and Active Directory use authentication protocols to communicate with the Net Logon service so that a secured path can be established over which authentication can occur.

**Authentication Protocols**
Active Directory domain controllers authenticate users and applications by using one of two protocols: either the Kerberos version 5 authentication protocol or the NTLM authentication protocol. When two Active Directory domains or forests are connected by a trust, authentication requests made using these protocols can be routed to provide access to resources in both forests.

**NTLM**
The NTLM protocol is the default protocol used for network authentication in the Windows NT 4.0 operating system. For compatibility reasons, it is used by Active Directory domains to process network authentication requests that come from earlier Windows-based clients and servers. Computers running Windows 2000, Windows XP or Windows Server 2003 use NTLM only when authenticating to servers running Windows NT 4.0 and when accessing resources in Windows NT 4.0 domains.

When the NTLM protocol is used between a client and a server, the server must contact a domain authentication service on a domain controller to verify the client credentials. The server authenticates the client by forwarding the client credentials to a domain controller in the client account domain. The authentication protocol of choice for Active Directory authentication requests, when there is a choice, is Kerberos version 5. When the Kerberos protocol is used, the server does not have to contact the domain controller. Instead, the client gets a ticket for a server by requesting one from a domain controller in the server account domain; the server validates the ticket without consulting any other authority.

**Kerberos Version 5 Protocol**
The Kerberos version 5 protocol is the default authentication protocol used by computers running Windows 2000, Windows XP Professional, or Windows Server 2003. This protocol is specified in RFC 1510 and is fully integrated with Active Directory, server message block (SMB), HTTP, and remote procedure call (RPC), as well as the client and server applications that use these protocols. In Active Directory domains, the Kerberos protocol is used to authenticate logons when any of the

following conditions is true:

- The user who is logging on uses a security account in an Active Directory domain.
- The computer that is being logged on to is a Windows 2000, Windows XP or Windows Server 2003–based computer.
- The computer that is being logged on to is joined to an Active Directory domain.
- The computer account and the user account are in the same forest.
- The computer from which the user is trying to access resources is located in a non-Windows Kerberos realm.

If any computer involved in a transaction does not support the Kerberos version 5 protocol, the NTLM protocol is used.

**Authorization and Access Control**
Authorization and trust technologies work together to help provide a secured communications infrastructure across Active Directory domains or forests. Authorization determines what level of access a user has to resources in a domain. Trusts facilitate cross-domain authorization of users by providing a path for authenticating users in other domains so their requests to shared resources in those domains can be authorized.

Once an authentication request made to a resource in a trusting domain is validated by the trusted domain, it is passed to the targeted resource computer, which determines, based on its access control configuration, whether to authorize the specific request made by the user, service, or computer in the trusted domain. In this way, trusts provide the mechanism by which validated authentication requests are passed to a trusting domain, while access control mechanisms on the resource computer determine the final level of access granted to the requestor in the trusted domain.

**Note**

- "Access to resources" in any discussion of trust relationships always assumes the limitations of access control.

# How Domain and Forest Trusts Work

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Trust Architecture
- Trust Processes and Interactions
- Network Ports used by Trusts

Active Directory provides security across multiple domains or forests through domain and forest trust relationships. Before authentication can occur across trusts, Windows must first determine whether the domain being requested by a user, computer or service has a trust relationship with the logon domain of the requesting account. To make this determination, the Windows security system computes a trust path between the domain controller for the server that receives the request and a domain controller in the domain of the requesting account.

The access control mechanisms provided by Active Directory and the Windows distributed security model provide an optimal environment for the operation of domain and forest trusts. For these trusts to function properly, every workstation and server must have a direct trust path to a domain controller in the domain in which it is located. The trust path is implemented by the Net Logon service through an authenticated remote procedure call (RPC) connection to the trusted domain authority, which is the domain controller. In addition, a secured channel extends to other Active Directory domains through interdomain trust relationships. This secured channel is used to obtain and verify security information, including security identifiers (SIDs) for users and groups.

This section describes the inner workings of trusts, discusses the various types of trusts that can be used, provides a detailed list of referral and logon processes that involve trusts, and lists the network ports that trusts can use.

**Trust Architecture**

Applications integrated with Windows Server 2003 and Active Directory use components of the operating system to establish and maintain trusts. A number of these components help form the trust architecture that provides an effective communication infrastructure for Active Directory. These include authentication protocols, the Net Logon service, the Local Security Authority (LSA), and the Trusted Domain Objects (TDOs) stored in Active Directory. These trust components are shown in the following illustration.

**Trust Components**

**NTLM Protocol (Msv1_0.dll)**

The NTLM authentication protocol is dependent on the Net Logon service on domain controllers for client authentication and authorization information. This protocol authenticates clients that do not use Kerberos authentication. NTLM uses trusts to pass authentication requests between domains.

**Kerberos Protocol (Kerberos.dll)**
The Kerberos V5 authentication protocol is dependent on the Net Logon service on domain controllers for client authentication and authorization information. The Kerberos protocol connects to an online Key Distribution Center (KDC) and the Active Directory account store for session tickets. The Kerberos protocol also uses trusts for cross-realm ticket-granting services (TGS) and to validate Privilege Attribute Certificates (PACs) across a secured channel. The Kerberos protocol performs cross-realm authentication only with non-Windows-brand operating system Kerberos realms such as an MIT Kerberos realm and does not need to interact with the Net Logon service.

**Net Logon (Netlogon.dll)**
The Net Logon service maintains a secured channel from a Windows-based computer to a domain controller. It is also used in the following trust related processes:

- Trust setup and management – Net Logon helps maintain trust passwords, gathers trust information and verifies trusts by interacting with the LSA process and the TDO. For Forest trusts, the trust information includes the Forest Trust Information (FTInfo) record, which includes the set of namespaces that a trusted forest claims to manage, annotated with a field that indicates whether each claim is actually trusted by the trusting forest.

- Authentication – Supplies user credentials over a secured channel to a domain controller and returns the domain SIDs and user rights for the user

- Domain controller location – Helps with finding or locating domain controllers in a domain or across domains

- Pass-through validation – Credentials of users in other domains are processed by Net Logon. When a trusting domain needs to verify the identity of a user, it passes the user's credentials through Net Logon to the trusted domain for verification

- Privilege Attribute Certificate (PAC) verification – When a server using the Kerberos protocol for authentication needs to verify the PAC in a service ticket, it sends the PAC across the secure channel to its domain controller for verification.

**LSA (Lsasrv.dll)**
The Local Security Authority (LSA) is a protected subsystem that maintains information about all aspects of local security on a system (collectively known as local security policy) and provides various services for translation between names and identifiers. The LSA security subsystem provides services in both kernel mode and user mode for validating access to objects, checking user privileges, and generating audit messages. LSA is responsible for checking the validity of all session tickets presented by services in trusted or untrusted domains.

**Tools**
Administrators can use Active Directory Domains and Trusts, Netdom and Nltest to expose, create, remove or modify trusts. Active Directory Domains and Trusts is the Microsoft Management Console (MMC) that is used to administer domain trusts, domain and forest functional levels, and user principal name suffixes. The Netdom and Nltest command line tools can be used to find, display, create and manage trusts. These tools communicate directly with the LSA authority on a domain controller.

**Active Directory**
The Active Directory directory service stores information about objects on a network and makes this information available to users and network administrators. Trusts can be used to extend the reach of Active Directory domains and forests to other domains, forests or realms within an organization.

**Trusted Domain Object**
Each domain or forest trust within an organization is represented by a Trusted Domain Object (TDO) stored in the System container within its domain.

**TDO Contents**
The information contained in a TDO can vary depending on whether a TDO was created by a domain trust or by a forest trust. When a domain trust is created, attributes such as the DNS domain name, domain SID, trust type, trust transitivity, and the reciprocal domain name are represented in the TDO. Forest trust TDOs store additional attributes to identify all of the trusted namespaces from the partner forest. These attributes include domain tree names, user principal name (UPN) suffixes, service principal name (SPN) suffixes, and security ID (SID) namespaces.

Because trusts are stored in Active Directory as TDOs, all domains in a Windows Server 2003 forest have knowledge of the trust relationships that are in place throughout the forest. Similarly, when two or more forests are joined together through forest trusts, the forest root domains in each forest have knowledge of the trust relationships that are in place throughout all of the domains in trusted Windows Server 2003 forests. External trusts to a Windows NT 4.0 domain do not create TDOs in Active

Directory.

**TDO Passwords**

Both domains in a trust relationship share a password, which is stored in the TDO object in Active Directory. As part of the account maintenance process, every thirty days, the trusting domain controller changes the password stored in the TDO. Because all two-way trusts are actually two one-way trusts going in opposite directions, the process occurs twice for two-way trusts. A trust has a trusting and a trusted side. On the trusted side, any writable domain controller can be used for the process. On the trusting side, the PDC emulator performs the password change. To change a password, the domain controllers complete the following process:

1. The primary domain controller (PDC) emulator in the trusting domain creates a new password.

   A domain controller in the trusted domain never initiates the password change; it is always initiated by the trusting domain PDC emulator.

2. The PDC emulator in the trusting domain sets the OldPassword field of the TDO object to the current NewPassword field.

3. The PDC emulator in the trusting domain sets the NewPassword field of the TDO object to the new password.

   Keeping a copy of the previous password makes it possible to revert to the old password if the domain controller in the trusted domain fails to receive the change, or if the change is not replicated before a request is made that uses the new trust password.

4. The PDC emulator in the trusting domain makes a remote call to a domain controller in the trusted domain asking it to set the password on the trust account to the new password.

5. The domain controller in the trusted domain changes the trust password to the new password.

6. On each side of the trust, the updates are replicated to the other domain controllers in the domain. In the trusting domain, the change triggers an urgent replication of the trusted domain object.

The password is now changed on both domain controllers. Normal replication distributes the TDO objects to the other domain controllers in the domain. However, is possible for the domain controller in the trusting domain to change the password without successfully updating a domain controller in the trusted domain. This might occur because a secured channel, which is required to process the password change, could not be established. It is also possible that the domain controller in the trusted domain might be unavailable at some point during the process and might not receive the updated password.

To deal with situations in which the password change is not successfully communicated, the domain controller in the trusting domain never changes the new password unless it has successfully authenticated (set up a secured channel) using the new password. This is why both the old and new passwords are kept in the TDO object of the trusting domain. Because a password change is not finalized until authentication using the password succeeds, the old, stored password can be used over the secured channel until the domain controller in the trusted domain receives the new password, thus enabling uninterrupted service.

If authentication using the new password fails because the password is invalid, the trusting domain controller tries to authenticate using the old password. If it authenticates successfully with the old password, it resumes the password change process within 15 minutes.

Trust password updates need to replicate to the domain controllers of both sides of the trust within 30 days. If the trust password is changed after 30 days and a domain controller then only has the N-2 password, it cannot use the trust from the trusting side and cannot create a secure channel on the trusted side.

**Practical Limitations of Trusts**

While Windows Server 2003 can support a large number of trusts between many security authorities, and there are some limitations to trust functionality. These limitations are associated with the number of TDOs, the length of trust paths, and the ability of clients to discover available trusts.

**Number of TDOs**

TDOs are associated with domains, and as the number of TDOs increases, the processing performance of these links declines. Testing indicates that the time to complete operations related to TDOs, such as authentication across domains, deteriorates noticeably if the Active Directory implementation in an organization contains more than 2400 TDOs. Few organizations,

however, require such a large number of trusts, and Windows Server 2003 places no absolute limit on the number of trust links that a domain can maintain with other domains or forests.

**Trust Path Limits**
There is a limit to the number of trust links that can be used effectively in a Windows Server 2003 network. In Windows Server 2003, Kerberos clients can traverse a maximum of 10 trust links to locate a requested resource in another domain. If the trust path between the domains exceeds this limit, the attempt to access the domain fails. This problem can be addressed by creating external trusts to target domains in order to bypass excessively long trust paths.

**Trust Search Limits**
When a client searches out a trust path, the search is limited to trusts that are established directly with a domain and those that are transitive within a forest. A child domain, for example, cannot use an external trust between its parent domain and a domain in another forest. This is because a complete trust path must be constructed before a client can begin to work its way along the path to a requested resource domain. Windows Server 2003 does not support blind referrals; if a client cannot identify a trust path, it will not attempt to seek access to a requested resource in another domain. Child domains cannot identify external trusts or realm trusts to security authorities outside of their forest because the TDOs that represent those trusts are published only within the domain that shares the trust, not to Global Catalogs. Clients are therefore unaware of trusts that their domains share with security authorities other than their parent or child domains, and are thus unable to use them to access resources.

**Trust Flow**
The flow of secured communications over trusts determines the elasticity of a trust: how you create or configure a trust determines how far the communication extends within a forest or across forests. The flow of communication over trusts is determined by the direction of the trust (one-way or two-way) and the transitivity of the trust (transitive or nontransitive).

**One-Way and Two-Way Trusts**
Trust relationships that are established to enable access to resources can be either one-way or two-way. A one-way trust is a unidirectional authentication path created between two domains. In a one-way trust between Domain A and Domain B, users in Domain A can access resources in Domain B. However, users in Domain B cannot access resources in Domain A. Some one-way trusts can be either nontransitive or transitive depending on the type of trust being created.

All domain trusts in an Active Directory forest are two-way, transitive trusts. When a new child domain is created, a two-way, transitive trust is automatically created between the new child domain and the parent domain. In a two-way trust, Domain A trusts Domain B and Domain B trusts Domain A. This means that authentication requests can be passed between the two domains in both directions. Some two-way relationships can be nontransitive or transitive depending on the type of trust being created. An Active Directory domain can establish a one-way or two-way trust with:

- Windows Server 2003 domains in the same forest.
- Windows Server 2003 domains in a different forest.
- Windows NT 4.0 domains.
- Kerberos V5 realms.

**Transitive and Nontransitive Trusts**
Transitivity determines whether a trust can be extended outside of the two domains with which it was formed. A transitive trust can be used to extend trust relationships with other domains; a nontransitive trust can be used to deny trust relationships with other domains.

Each time you create a new domain in a forest, a two-way, transitive trust relationship is automatically created between the new domain and its parent domain. If child domains are added to the new domain, the trust path flows upward through the domain hierarchy extending the initial trust path created between the new domain and its parent domain. Transitive trust relationships flow upward through a domain tree as it is formed, creating transitive trusts between all domains in the domain tree.

Authentication requests follow these trust paths, so accounts from any domain in the forest can be authenticated by any other domain in the forest. With a single logon process, accounts with the proper permissions can access resources in any domain in the forest. The following figure shows that all domains in Tree 1 and Tree 2 have transitive trust relationships by default. As a result, users in Tree 1 can access resources in domains in Tree 2 and users in Tree 1 can access resources in Tree 2, when the proper permissions are assigned at the resource.

### Default Transitive Trust Relationships

In addition to the default transitive trusts established in a Windows Server 2003 forest, by using the New Trust Wizard you can manually create the following transitive trusts.

- **Shortcut trust.** A transitive trust between domains in the same domain tree or forest that is used to shorten the trust path in a large and complex domain tree or forest.
- **Forest trust.** A transitive trust between one forest root domain and another forest root domain.
- **Realm trust.** A transitive trust between an Active Directory domain and a Kerberos V5 realm.

A nontransitive trust is restricted to the two domains in the trust relationship and does not flow to any other domains in the forest. A nontransitive trust can be a two-way trust or a one-way trust.

Nontransitive trusts are one-way by default, although you can also create a two-way relationship by creating two one-way trusts. Nontransitive domain trusts are the only form of trust relationship possible between:

- A Windows Server 2003 domain and a Windows NT domain
- A Windows Server 2003 domain in one forest and a domain in another forest (when not joined by a forest trust)

By using the New Trust Wizard, you can manually create the following nontransitive trusts:

- **External trust.** A nontransitive trust created between a Windows Server 2003 domain and a Windows NT, Windows 2000, or Windows Server 2003 domain in another forest. When you upgrade a Windows NT domain to a Windows Server 2003 domain, all existing Windows NT trusts are preserved intact. All trust relationships between Windows Server 2003 domains and Windows NT domains are nontransitive.
- **Realm trust.** A nontransitive trust between an Active Directory domain and a Kerberos V5 realm.

**Trust Types**

Although all trusts enable authenticated access to resources, trusts can have different characteristics. The types of domains included in the trust relationship affect the type of trust that is created. For example, a trust between two child domains in different forests is always an external trust, but trusts between two Windows Server 2003 forest root domains can be either external trusts or forest trusts.

Two types of trusts are created automatically when you use the Active Directory Installation Wizard. Four other types of trusts can be manually created by using either the New Trust Wizard or the Netdom command-line tool.

**Automatic Trusts**
By default, two-way transitive trusts are automatically created when a new domain is added to a domain tree or forest root domain by using the Active Directory Installation Wizard. The two default trust types are parent-child trusts and tree-root trusts.

**Parent-child trust**
A parent-child trust relationship is established whenever a new domain is created in a tree. The Active Directory installation process automatically creates a trust relationship between the new domain and the domain that immediately precedes it in the namespace hierarchy (for example, corp.tailspintoys.com is created as the child of tailspintoys.com). The parent-child trust relationship has the following characteristics:

- It can exist only between two domains in the same tree and namespace.
- The parent domain is always trusted by the child domain.
- It must be transitive and two-way. The bidirectional nature of transitive trust relationships allows the global directory information in Active Directory to replicate throughout the hierarchy.

**Tree-root trust**
A tree-root trust is established when you add a new domain tree to a forest. The Active Directory installation process automatically creates a trust relationship between the domain you are creating (the new tree root) and the forest root domain. A tree-root trust relationship has the following restrictions:

- It can be established only between the roots of two trees in the same forest.
- It must be transitive and two-way.

**Manual Trusts**
In Windows Server 2003 there are four trust types that must be created manually: shortcut trusts are used for optimization between domain trees in the same forest; external, realm, and forest trusts help provide interoperability with domains outside of the forest, with other forests, or with realms. These trust types must be created by using the New Trust Wizard or the Netdom command-line tool.

**Shortcut Trusts**
Shortcut trusts are one-way or two-way transitive trusts that can be used when administrators need to optimize the authentication process. Authentication requests must initially travel a trust path between domain trees. A trust path is the series of domain trust relationships that must be traversed in order to pass authentication requests between any two domains. In a complex forest, the time required to traverse the trust path can impact performance. You can significantly reduce this time by using shortcut trusts.

Shortcut trusts speed up logon and access times to resources in a domain that is deep within the hierarchy of another domain tree. The following figure illustrates trust relationships between two trees in a Windows Server 2003 forest.

**Trusts Within a Single Windows 2000 Server or Windows Server 2003 Forest**

In this example, the following conditions are true:

- A two-way transitive tree-root trust exists between corp.tailspintoys.com and corp.wingtiptoys.com.
- Parent-child trust relationships exist between parent and child domains in both trees of the forest. Because the two trees trust each other, all domains in Tree 1 and Tree 2 have access to resources in all domains in the forest.
- A one-way shortcut trust exists between the rome.europe.corp.tailspintoys.com and usa.corp.wingtiptoys.com domains. This creates an alternate path by which users in the usa.corp.wingtiptoys.com domain can access resources in the rome.europe.corp.tailspintoys.com domain. The shortcut trust shortens the trust path needed to reach the intended domain by cutting the number of hops required for authentication from three (rome.europe.corp.tailspintoys.com to europe.corp.tailspintoys.com to corp.tailspintoys.com to corp.wingtiptoys.com) to one (rome.europe.corp.tailspintoys.com to usa.corp.wingtiptoys.com), which increases the speed of authentication.
- Because the shortcut trust is one-way, authentication requests made from the rome.europe.corp.tailspintoys.com domain to the usa.corp.wingtiptoys.com domain still need to travel the longer trust path.

When a two-way shortcut trust is established between two domains located in separate domain trees, the time needed to fulfill authentication requests originating in either domain is reduced. For example, when a two-way trust is established between the usa.corp.wingtiptoys.com domain and the rome.europe.corp.tailspintoys.com domain, authentication requests made from either domain to the other can utilize the new, two-way shortcut trust path.

**External Trusts**

An external trust is a trust relationship that can be created between Active Directory domains that are in different forests or between an Active Directory domain and a Windows NT 4.0 or earlier domain. An external trust relationship has the following characteristics:

- It is nontransitive.
- It must be established manually in each direction to create a two-way external trust relationship. In Windows Server 2003 you can create both sides of the external two-way trust at once by using the New Trust Wizard.
- It enforces SID filter quarantining by default in Windows Server 2003. External trusts created from the trusting domain use SID filter quarantining to verify that incoming authentication requests made from security principals in the trusted domain contain only SIDs of security principals in the trusted domain. SID filter quarantining ensures that any misuse of the SID history attribute on security principals (including inetOrgPerson) in the trusted forest cannot pose a threat to the integrity of the trusting forest.

External trusts provide access to resources in a domain outside of the forest that is not already joined by a forest trust. The following illustration shows how external trusts can be used between a Windows Server 2003 forest and a Windows 2000

forest.

**External trusts Between a Windows Server 2003 Forest and a Windows 2000 Forest**

In this example, two external trust relationships exist between domains in the Windows Server 2003 forest and the Windows 2000 forest. The direction of the one-way external trust arrow indicates that the sales.corp.worldwideimporters.com domain trusts the rome.europe.corp.tailspintoys.com domain, which means that users in the rome.europe.corp.tailspintoys.com domain can access resources in the sales.corp.worldwideimporters.com domain.

The direction of the two-way external trust arrow indicates that both the europe.corp.tailspintoys.com domain and the sales.corp.worldwideimporters.com domain trust each other. This relationship allows for authentication requests to be passed between the two domains, coming from either direction, to any shared resources in those two domains.

This configuration allows:

- Users in the europe.corp.tailspintoys.com domain to access resources in the sales.corp.worldwideimporters.com domain
- Users in the sales.corp.worldwideimporters.com domain to access resources in the europe.corp.tailspintoys.com domain
- Users in the rome.europe.corp.tailspintoys.com domain to access resources in the sales.corp.worldwideimporters.com domain

It does not allow:

- Users in the rome.europe.corp.tailspintoys.com domain or europe.corp.tailspintoys.com domain to access resources in the corp.worldwideimporters.com domain
- Users in the sales.corp.worldwideimporters.com domain to access resources in either the corp.tailspintoys.com or rome.europe.corp.tailspintoys.com domain

When a trust is established between a domain in a forest and a domain outside of that forest, security principals from the external domain can access resources in the internal domain. Active Directory creates a foreign security principal object in the internal domain to represent each security principal from the trusted external domain. These foreign security principals can become members of domain local groups in the internal domain. Directory objects for foreign security principals are created by Active Directory and should not be manually modified. You can view foreign security principal objects from Active Directory Users and Computers by enabling advanced features.

The following figure illustrates a trust configuration that includes an external trust relationship between a domain in a Windows Server 2003 forest and a Windows NT 4.0 domain.

**External Trust Between a Windows NT 4.0 Domain and a Child Domain in a Windows Server 2003 Forest**

This configuration allows users in the europe.corp.tailspintoys.com domain to access resources in the Windows NT 4.0 domain. It does not allow the Windows NT 4.0 domain to access resources in the europe.corp.tailspintoys.com domain or for any trusted domains that the europe.corp.tailspintoys.com domain trusts.

All forest trusts in Windows Server 2003 Active Directory enforce SID filtering. Applying SID filtering to trusts helps to prevent malicious users who have domain administrator level access in the trusted domain from granting to themselves, or other user accounts in their domain, elevated user rights to the trusting domain.

**Realm Trusts**

A trust relationship can be established between a non-Windows Kerberos realm and a Windows 2000 or Windows Server 2003 domain. This trust relationship allows cross-platform interoperability with security services based on other Kerberos V5 implementations.

A non-Windows Kerberos realm trust relationship has the following characteristics:

- It is used only by the Kerberos V5 authentication protocol. It is not used by NTLM or other authentication protocols.
- It is one-way by default. One-way trust relationships must be established in each direction to create a two-way trust relationship. In Windows Server 2003 you can create both sides of the two-way realm trust at once by using the New Trust Wizard.
- It is nontransitive by default, but can be made transitive.
- When the direction of trust is from a non-Windows Kerberos realm to a Windows Server 2003 domain, the non-Windows Kerberos realm trusts all security principals in the Windows Server 2003 domain.
- When the direction of trust is from a Windows Server 2003 domain to a non-Windows Kerberos realm, account mappings in Active Directory are used to map a foreign Kerberos identity in a trusted non-Windows Kerberos realm to a local account identity in a Windows Server 2003 domain.
- The Windows Server 2003 domain uses only the account to which the non-Windows principal is mapped (the proxy account) to evaluate access to domain objects that have security descriptors. This is required because non-Windows Kerberos tickets do not contain all of the authorization data that is needed for Windows Server 2003. All such Windows Server 2003 proxy accounts can be used in groups and on access control lists (ACLs) to control access on behalf of the non-Windows security principal. MIT account mappings are managed through Active Directory Users and Computers.
- When the direction of trust is from a non-Windows Kerberos realm to a Windows Server 2003 domain, users in the Windows Server 2003 domain can access resources in the non-Windows Kerberos realm, as is the case for Realm 1 in the following illustration. When the direction of trust is from a Windows Server 2003 domain to a non-Windows Kerberos realm, users in the non-Windows Kerberos realm can access the resources in the Windows Server 2003 domain, as is the case for Realm 1 and Realm 2.

**Transitive and Non-Transitive Realm Trusts from a Domain in a Windows Server 2003 Forest**

This configuration allows:

- Users in Realm 1 and Realm 2 to access resources in the europe.corp.tailspintoys.com domain
- Users in the europe.corp.tailspintoys.com domain to access resources in Realm 1

It does not allow users in the europe.corp.tailspintoys.com domain to access resources in Realm 2.

**Note**

- In Windows 2000, if you create a non-Windows Kerberos realm trust relationship by using Active Directory Domains and Trusts, the trust is one-way and nontransitive. To work around this, you can use the Netdom tool (Netdom.exe) to establish two-way, transitive, non-Windows Kerberos realm trust relationships. In Windows Server 2003, you can use the New Trust Wizard to create one-way or two-way and transitive or nontransitive realm trusts.

Realm trusts are not as comprehensive as domain trusts. For instance, user principals from the Kerberos realm do not have the authorization data that Windows Server 2003-based services need for access control. In order for this authorization data to be added to the user's ticket, an account mapping mechanism is used. Selected domain user accounts are used to provide identity for Kerberos principals in the trusted realm. These mappings are kept on the SecurityID property on the user account object. They can be managed through Active Directory Users and Computers.

**Forest Trusts**

Forest trusts help you to manage a segmented Windows Server 2003 Active Directory infrastructure within your organization by providing support for accessing resources and other objects across multiple Windows Server 2003 forests. Forest trusts are useful for Application Service Providers, companies undergoing mergers or acquisitions, collaborative business extranets, and companies seeking a solution for administrative autonomy.

Forest trusts can provide the following benefits:

- Simplified management of resources across two Windows Server 2003 forests by reducing the number of external trusts necessary to share resources.
- Complete two-way trust relationships with every domain in each forest.
- Use of user principal name (UPN) authentication across two forests.
- Use of both the Kerberos V5 and NTLM authentication protocols to improve the trustworthiness of authorization data transferred between forests.
- Flexibility of administration. Administrative tasks can be unique to each forest.
- Secured data within each forest. Sensitive data can be protected so that only users within that forest can access it.
- Isolated directory replication within each forest. Schema changes, configuration changes, and the addition of new domains to a forest have forest-wide impact only within that forest, not in a trusting forest.
- Enforcement of SID filtering in Windows Server 2003. SID filtering ensures that any misuse of the SID history attribute on

security principals (including inetOrgPerson) in the trusted forest cannot pose a threat to the integrity of the trusting forest.

Enforcing SID filtering on forest trusts does not prevent use of SID history in migrations to domains within the same forest and does not affect your universal group access control strategy.

By using forest trusts you can link two different Windows Server 2003 forests to form a one-way or two-way transitive trust relationship. A forest trust allows administrators to federate two Active Directory forests with a single trust relationship to provide a seamless authentication and authorization experience across the forests.

A forest trust can be created only between a forest root domain in one Windows Server 2003 forest and a forest root domain in another Windows Server 2003 forest. Forest trusts can be created between two forests only and cannot be implicitly extended to a third forest. This means that if a forest trust is created between Forest 1 and Forest 2, and another forest trust is created between Forest 2 and Forest 3, Forest 1 does not have an implicit trust with Forest 3. The following figure shows two separate forest trust relationships between three Windows Server 2003 forests in a single organization.

**Two Forest Trusts Between Three Windows Server 2003 Forests**

In this example, a two-way transitive forest trust exists between the forest root domains in Forest 1 and Forest 2, and another two-way transitive forest trust exists between the forest root domains in Forest 3 and Forest 2. This configuration allows:

- Users in Forest 2 to access resources in any domain in either Forest 1 or Forest 3
- Users in Forest 3 to access resources in any domain in Forest 2
- Users in Forest 1 to access resources in any domain in Forest 2

This configuration does not allow users in Forest 1 to access resources in Forest 3 or vice versa. To allow users in both Forest 1 and Forest 3 to share resources, a two-way transitive trust must be created between the two forests.

If a one-way forest trust is created between two forests, members of the trusted forest can utilize resources located in the trusting forest. However, the trust operates in only one direction. For example, when a one-way, forest trust is created between Forest 1 (the trusted forest) and Forest 2 (the trusting forest), members of Forest 1 can access resources located in Forest 2, but members of Forest 2 cannot access resources located in Forest 1 using the same trust.

Consequently, as shown in the example, a two-way forest trust between two forests allows members from either forest to utilize resources located in the other forest; domains in each respective forest trust domains in the other forest implicitly.

There are specific requirements that must be met for using forest trusts. Before you can create a forest trust, you need to verify that all domain controllers in both forests are running Windows Server 2003. You also need to verify that you have the correct Domain Name System (DNS) infrastructure in place and that you have established the appropriate functionality level for Active Directory. This means that the forest must be raised to the Windows Server 2003 functional level and that you cannot install additional Windows 2000 or Windows NT Server 4.0 domain controllers in the forest.

Forest trusts can only be created when one of the following DNS configurations is in place in your infrastructure:

- A single root DNS server is the root DNS server for both forest DNS namespaces: the root zone contains delegations for each of the DNS namespaces and the root hints of all DNS servers include the root DNS server.
- Where there is no shared root DNS server, and the root DNS servers for each forest DNS namespace are running a member of the Windows Server 2003 family, DNS conditional forwarders are configured in each DNS namespace to route queries for names in the other namespace.
- Where there is no shared root DNS server, and the root DNS servers for each forest DNS namespace are not running a member of the Windows Server 2003 family, DNS secondary zones are configured in each DNS namespace to route

queries for names in the other namespace.

To create a forest trust, the administrator creating the trust must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory. Each trust is assigned a password that the administrators in both forests must know. Members of Enterprise Admins in both forests can create the trusts in both forests at once and, in this scenario, a password that is cryptographically random is automatically generated and written for both forests.

Members of the Incoming Forest Trust Builders group can create one-way, incoming forest trusts. For example, members of this group residing in Forest A can create a one-way, incoming forest trust from Forest B. This one-way, incoming forest trust allows users in Forest A to access resources located in Forest B. Members of this group are granted the permission Create Inbound Forest Trust on the forest root domain. This group has no default members.

All Windows NT Server 4.0, Windows 2000, Windows XP clients can use the forest trust for authentication. However, Windows NT Server 4.0 clients support only NTLM and they do not support user principal names (UPNs) for logging on to the network. Windows Server 2003 forest trusts cannot be created between a Windows Server 2003 forest and a Windows 2000 forest.

**Trust Processes and Interactions**
Many inter-domain and inter-forest transactions depend on domain or forest trusts in order to complete various tasks. This section describes the processes and interactions that occur as resources are accessed across trusts and authentication referrals are evaluated.

**Overview of Authentication Referral Processing**
When a request for authentication is referred to a domain, the domain controller in that domain must determine whether a trust relationship exists with the domain from which the request comes, as well as the direction of the trust and whether the trust is transitive or nontransitive, before it authenticates the user to access resources in the domain. The authentication process that occurs between trusted domains varies according to the authentication protocol in use. The Kerberos V5 and NTLM protocols in Windows 2000 Server and Windows Server 2003 process referrals for authentication to a domain differently, as do the other authentication protocols, such as Digest, and SChannel, that Windows 2000 Server and Windows Server 2003 support.

**Kerberos V5 Referral Processing**
If the client uses Kerberos V5 for authentication, it requests a ticket to the server in the target domain from a domain controller in its account domain. The Kerberos Key Distribution Center (KDC) acts as a trusted intermediary between the client and server; it provides a session key that enables the two parties to authenticate each other. If the target domain is different from the current domain, the KDC follows a logical process to determine whether an authentication request can be referred:

1. Is the current domain trusted directly by the domain of the server that is being requested?

    - If yes, send the client a referral to the requested domain.
    - If no, go to the next step.

2. Does a transitive trust relationship exist between the current domain and the next domain on the trust path?

    - If yes, send the client a referral to the next domain on the trust path.
    - If no, send the client a logon-denied message.

**NTLM Referral Processing**
If the client uses NTLM for authentication, the initial request for authentication goes directly from the client to the resource server in the target domain. This server creates a challenge to which the client responds. The server then sends the user's response to a domain controller in its computer account domain. This domain controller checks the user account against its security accounts database. If the account does not exist in the database, the domain controller determines whether to perform pass-through authentication, forward the request, or deny the request by using the following logic:

1. Does the current domain have a direct trust relationship with the user's domain?

    - If yes, the domain controller sends the credentials of the client to a domain controller in the user's domain for pass-

through authentication.

- If no, go to the next step.

2. Does the current domain have a transitive trust relationship with the user's domain?

    - If yes, pass the authentication request on to the next domain in the trust path. This domain controller repeats the process by checking the user's credentials against its own security accounts database.

    - If no, send the client a logon-denied message.

**Other Authentication Protocol Referral Processing**
Windows 2000 Server and Windows Server 2003 also support both Digest and Schannel authentication across forest trusts. This enables technologies such as Web servers to complete their tasks in a multiple domain environment. The Secure Sockets Layer (SSL) protocol and certificate mapping to Active Directory user accounts use Schannel, and Internet Information Services (IIS) uses Digest. Digest and SChannel authentication between trusted domains might be required in cases where a firewall between trusting forests or domains allows only HTTP traffic through. Digest can be carried in HTTP headers.

The Windows 2000 Server and Windows Server 2003 authentication negotiation determines the authentication protocol that is used over trusts, as long as the generic pass-through mechanism can find the appropriate domain controller in the target domain. Administrators can also choose to implement a security support provider (SSP) for another authentication protocol. If the SSP is compatible with the Windows 2000 Server and Windows Server 2003 distributed systems, it will work over trusts across domain boundaries in the same way that standard Windows 2000 Server and Windows Server 2003 SSPs work across domains.

**Kerberos-Based Processing of Authentication Requests Over Domain Trusts**
Active Directory domains within the same forest are implicitly connected by two-way, transitive trusts, so that authentication requests from one domain to another are routed to provide a seamless access to resources across domains. Domain controllers running Windows 2000 or Windows Server 2003 authenticate users and applications using one of two authentication protocols: Kerberos V5 or NTLM. Once authenticated in their own domain, users can attempt to gain access to resources from any domain in the forest using the Active Directory authorization process.

To access a shared resource in another domain by using Kerberos authentication, a user's computer first requests a ticket from a domain controller in its account domain to the server in the trusting domain that hosts the requested resource. This ticket is then issued by an intermediary trusted by both the user's computer and the server. The user's computer presents this trusted ticket to the server in the trusting domain for authentication.

The following illustration and corresponding steps provide a detailed description of the Kerberos authentication process that is used when a computer running Windows 2000 Professional, Windows 2000 Server, Windows XP Professional, or a member of the Windows Server 2003 family attempts to access resources from a server located in another domain.

**Kerberos Authentication Process Over Domain Trusts**

1. User1 logs on to Workstation1 using credentials from the europe.corp.tailspintoys.com domain. As part of this process, the authenticating domain controller issues User1 a ticket-granting ticket (TGT). This ticket is required for User1 to be authenticated to resources. The user then attempts to access a shared resource (\\fileserver1\share) on a file server located in the asia.corp.tailspintoys.com domain.

2. Workstation1 contacts the Kerberos Key Distribution Center (KDC) on a domain controller in its domain (ChildDC1) and requests a service ticket for the FileServer1 service principal name (SPN).

3. ChildDC1 does not find the SPN in its domain database and queries the global catalog to see if any domains in the forest contain this SPN. The global catalog sends the requested information back to ChildDC1.

4. ChildDC1 sends the referral to Workstation1.

5. Workstation1 contacts a domain controller in ForestRootDC1 (its parent domain) for a referral to a domain controller (ChildDC2) in the Child2 domain. ForestRootDC1 sends the referral to Workstation 1.

6. Workstation1 contacts the KDC on ChildDC2 and negotiates a ticket for the user to gain access to FileServer1.

7. Once Workstation1 has a service ticket, it sends the ticket to FileServer1, which reads the user's security credentials and constructs an access token accordingly.

Each domain has its own set of security policies governing access to resources. These policies do not cross from one domain to another.

**Kerberos-Based Processing of Authentication Requests Over Forest Trusts**
When two Windows Server 2003 forests are connected by a forest trust, authentication requests made using the Kerberos V5 or NTLM protocols can be routed between forests to provide access to resources in both forests.

When a forest trust is first established, each forest collects all of the trusted namespaces in its partner forest and stores the information in a TDO. Trusted namespaces include domain tree names, user principal name (UPN) suffixes, service principal name (SPN) suffixes, and security ID (SID) namespaces used in the other forest. TDO objects are replicated to the global catalog.

Before authentication protocols can follow the forest trust path, the service principal name (SPN) of the resource computer must be resolved to a location in the other forest. An SPN can be one of the following: the Domain Name System (DNS) name of a host, the DNS name of a domain, or the distinguished name of a service connection point object.

When a workstation in one forest attempts to access data on a resource computer in another forest, the Kerberos authentication process contacts the domain controller for a service ticket to the SPN of the resource computer. Once the domain controller queries the global catalog and determines that the SPN is not in the same forest as the domain controller, the domain controller sends a referral for its parent domain back to the workstation. At that point, the workstation queries the

parent domain for the service ticket and continues to follow the referral chain until it reaches the domain where the resource is located.

The following illustration and corresponding steps provide a detailed description of the Kerberos authentication process that is used when computers running Windows 2000 Professional, Windows XP Professional, Windows 2000 Server, or a member of the Windows Server 2003 family attempt to access resources from a computer located in another forest.

**Kerberos Authentication Process Over Forest Trusts**

1. User1 logs on to Workstation1 using credentials from the europe.corp.tailspintoys.com domain. The user then attempts to access a shared resource on FileServer1 located in the usa.corp.wingtiptoys.com forest.

2. Workstation1 contacts the Kerberos Key Distribution Center (KDC) on a domain controller in its domain (ChildDC1) and requests a service ticket for the FileServer1 SPN.

3. ChildDC1 does not find the SPN in its domain database and queries the global catalog to see if any domains in the tailspintoys.com forest contain this SPN. Because a global catalog is limited to its own forest, the SPN is not found. The global catalog then checks its database for information about any forest trusts that are established with its forest, and, if found, it compares the name suffixes listed in the forest trust trusted domain object (TDO) to the suffix of the target SPN to find a match. Once a match is found, the global catalog provides a routing hint back to ChildDC1. Routing hints help direct authentication requests toward the destination forest, and are only used when all traditional authentication channels (local domain controller and then global catalog) fail to locate a SPN.

4. ChildDC1 sends a referral for its parent domain back to Workstation1.

5. Workstation1 contacts a domain controller in ForestRootDC1 (its parent domain) for a referral to a domain controller (ForestRootDC2) in the forest root domain of the wingtiptoys.com forest.

6. Workstation1 contacts ForestRootDC2 in the wingtiptoys.com forest for a service ticket to the requested service.

7. ForestRootDC2 contacts its global catalog to find the SPN, and the global catalog finds a match for the SPN and sends it back to ForestRootDC2.

8. ForestRootDC2 then sends the referral to usa.corp.wingtiptoys.com back to Workstation1.

9. Workstation1 contacts the KDC on ChildDC2 and negotiates the ticket for User1 to gain access to FileServer1.

10. Once Workstation1 has a service ticket, it sends the service ticket to FileServer1, which reads User1's security credentials and constructs an access token accordingly.

**Network Ports used by Trusts**
Because trusts must be deployed across various network boundaries, they might have to span one or more firewalls. When this is the case, you can either tunnel trust traffic across a firewall or open specific ports in the firewall to allow the traffic to pass through. In Windows Server 2003, this procedure is simplified through configurable remote procedure call (RPC) ports for the main trust services. The two main configurable RPC ports are the Local Security Authority RPC port and the Net Logon RPC port.

**The Local Security Authority (LSA) RPC port.**
This port is used for trust creation and other access to the LSA policy database.

**The Net Logon RPC port.**
This port is used for NTLM authentication and secured channel communications.

The following table shows the list of ports that might need to be opened before you establish trusts.

### Ports Required for Trusts

| Task | Outbound Ports | Inbound Ports | From–To |
|---|---|---|---|
| Set up trusts on both sides from the internal forest | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution — portmapper (135 TCP)<br>Net Logon fixed port | N/A | Internal domain domain controllers–External domain domain controllers (all ports) |
| Trust validation from the internal forest domain controller to the external forest domain controller (outgoing trust only) | LDAP (389 UDP)<br><br>Microsoft SMB (445 TCP)<br><br>Endpoint resolution — portmapper (135 TCP)<br>Net Logon fixed port | N/A | Internal domain domain controllers–External domain domain controllers (all ports) |
| Use Object picker on the external forest to add objects that are in an internal forest to groups and DACLs | N/A | LDAP (389 UDP and TCP)<br><br>Windows NT Server 4.0 directory service fixed port<br><br>Net Logon fixed port<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution portmapper (135 TCP) | External server–Internal domain PDCs (Kerberos)<br><br>External domain domain controllers–Internal domain domain controllers (Net Logon) |
| Set up trust on the external forest from the external forest | N/A | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP) | External domain domain controllers–Internal domain domain controllers (all ports) |
| Use Kerberos authentication (internal forest client to external forest) | Kerberos (88 UDP) | N/A | Internal client–External domain domain controllers (all ports) |

| | | | |
|---|---|---|---|
| Use NTLM authentication (internal forest client to external forest) | N/A | Endpoint resolution – portmapper (135 TCP)<br>Net Logon fixed port | External domain domain controllers–Internal domain domain controllers (all ports) |
| Join a domain from a computer in the internal network to an external domain | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution — portmapper (135 TCP)<br>Net Logon fixed port<br><br>Windows NT Server 4.0 directory service fixed port | N/A | Internal client–External domain domain controllers (all ports) |

| **Note** |
|---|
| Port 445 and potentially TCP port 139 are required for backward compatibility. |

To specify the services that you want to run on a fixed port, you must appropriately configure the registry for that port.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

Settings for the Local Security Authority (LSA) RPC port are stored in the **TCP/IP Port** entry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters** registry key.

Settings for the Net Logon RPC port are stored in the **DCTcpipPort** entry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters** registry key.

# Domain and Forest Trust Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Trust Tools
- Trust WMI Classes
- Network Ports used by Trusts
- Related Information

Administrators can use a number of methods to configure and manage trust relationships in Active Directory environments. This section discusses the tools that can be used to create, view and modify trusts, as well as the WMI classes and network ports that are associated with trusts.

**Trust Tools**

The two principal Microsoft tools that can be used to create and manage trusts are Active Directory Domains and Trusts (Domain.msc) and Windows Domain Manager, also called Netdom (Netdom.exe). In addition, there are three other Microsoft tools that administrators can use to help troubleshoot trust related issues. These are Nltest (Nltest.exe), Network Connectivity Tester, also called Netdiag (Netdiag.exe) and the Domain Controller Diagnostic tool, also called Dcdiag (Dcdiag.exe). Each trust management tool has its own primary purpose, but can also be used for other purposes. The following table briefly describes these tools and their different purposes.

**Trust Tools and Purposes**

| Microsoft Tool | Primary Purpose | Other Purpose |
|---|---|---|
| Active Directory Domains and Trusts | Create and manage trusts | Manage functional levels (Windows Server 2003 only) and user principal name suffixes |
| Netdom | Manage domains and trust relationships from the command-line | Join computers to a domain and manage computer accounts |
| Nltest | Test secured channels | View or record trust information and verify trusts |
| Netdiag | Test network health | Help troubleshoot client connectivity by testing the secured channel |
| Dcdiag | Test domain controller health | Verify some trust information and monitor trust related replication |

Netdom, Nltest, Dcdiag, and Netdiag are command-line support tools that can be installed from the Support\Tools folder on the Windows Server 2003 product CD. (To do this, in the Support\Tools folder, right-click the Suptools.msi file and then click Install.) The following table lists common trust related tasks and indicates which tools can be used to perform them. Detailed descriptions of each tool follow the table.

**Trust Tools Comparison by Task**

| Trust Task | Active Directory Domains and Trusts | Netdom | NLTest | Netdiag | Dcdiag |
|---|---|---|---|---|---|
| Create an external trust | • | • | | | |
| Create a realm trust | • | • | | | |

| | | | | | |
|---|---|---|---|---|---|
| Create a shortcut trust | ● | ● | | | |
| Create a forest trust | ● | | | | |
| Create both sides of a trust at once | ● | ● | | | |
| Troubleshoot client network connectivity over a secured channel | | | | ● | |
| Batch manage trusts | | ● | | | |
| View and record all trust relationships | ● | | ● | | |
| Change transitivity of a non-Windows Kerberos realm trust | ● | ● | | | |
| Change the direction of a trust (one-way to two-way and back) | ● | ● | | | |
| Enable or disable selective authentication for external and forest trusts | ● | ● | | | |
| Change the routing status of a name suffix | ● | ● | | | |
| Enable or disable an existing name suffix from routing | ● | ● | | | |
| Verify all trust types | ● | ● | ● | | |
| Verify only external trusts | | | | | ● |
| Reset a secured channel | | ● | ● | | |
| Remove a trust | ● | ● | | | |
| Enable or disable SID Filtering | ● | ● | | | |
| Display the contents of a Forest Trust Information (FTInfo) record | | ● | | | |

**Domain.msc: Active Directory Domains and Trusts**

**Category**
Active Directory Domains and Trusts is a Microsoft Management Console (MMC) snap-in that is installed automatically on computers running Windows Server 2003 when you install Active Directory. You can open Active Directory Domains and Trusts by clicking **Start**, **Programs**, **Administrative Tools,** and clicking **Active Directory Domains and Trusts.**

**Version compatibility**
This tool is compatible with domain controllers running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition. You can also use Active Directory Domains and Trusts with the Windows Server 2003 Administration Tools pack to remotely administer Active Directory from a computer that is not a domain controller, such as a computer running Windows XP Professional. You can use this tool to target any domain controller in either Windows 2000 Server or Windows Server 2003 domains.

### Note

- When using Windows Server 2003 Active Directory administrative tools to connect to a domain controller running Windows 2000 you must first make sure that the Windows 2000–based domain controller to which your are connecting has Service Pack 3 or later installed. This is because Windows Server 2003 administrative tools sign and encrypt all LDAP traffic by default. If business reasons do not permit the installation of Service Pack 3 or later on domain controllers running Windows 2000 it is possible to disable this default behavior.

Active Directory Domains and Trusts provides a graphical interface in which you can view all domains in the forest. Using this tool, an administrator can manage each of the domains in the forest, trust relationships between domains, configure the functional level for each domain or forest, and configure the alternative user principal name (UPN) suffixes for a forest.

Active Directory Domains and Trusts can be used to accomplish most trust related tasks. It can be used to target all Active Directory domain controllers and can verify all Active Directory trust types. Trust verification takes place between two domains by enumerating all of the domain controllers in each domain. If you choose to have Active Directory Domains and Trusts create both sides of the trust at once, the trust password is automatically generated.

For the various trust related tasks that can be performed using this tool, see the table Trust Tools Comparison by Task earlier in this section. For more information, see Help in Active Directory Domains and Trusts.

**Netdom.exe: Windows Domain Manager**

**Category**
The Windows Domain Manager command-line tool (Netdom) is included when you install Windows Server 2003 Support Tools.

**Version compatibility**
This tool is compatible with computers running Windows XP Professional, Windows Server 2003, Standard Edition; Windows Server 2003, Web Edition, Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition.

Netdom is a command-line tool that allows you to create and manage Active Directory trust relationships (except forest trusts) and can help reduce the number of steps needed to create a trust by using Active Directory Domains and Trusts. You can also use the Netdom command line tool to complete batch management of trusts, join computers to domains, verify trusts (including forest trusts) and secured channels, and obtain information about the status of trusts.

Netdom can be targeted at all Active Directory domain controllers and can verify all Active Directory trust types. Verification is accomplished between two domains by enumerating the domain controllers in each domain. If you choose to have Netdom create both sides of the trust at once the trust password is automatically generated.

For the various trust related tasks that you can perform using this tool, see the table Trust Tools Comparison by Task earlier in this section. To find more information about Netdom, see “Support Tools Help” in the Tools and Settings Collection.

**Nltest.exe: NLTest**

**Category**
The NLTest command-line tool is included when you install Windows Server 2003 Support Tools.

**Version compatibility**
This tool is compatible with computers running Windows XP Professional, Windows Server 2003, Standard Edition; Windows Server 2003, Web Edition, Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition.

You can use the NLTest command-line tool to perform trust-related network administrative tasks such as testing the trust relationship between a Windows–based computer that is a member of a domain and the domain controller on which its computer account is located. In domains where an external trust is defined, NLTest can be used to test the trust relationship between all domain controllers in the trusting domain and a domain controller in the trusted domain. Nltest can also be used to verify any secured channel.

To view the various trust related tasks that can be performed using this tool, see the table Trust Tools Comparison by Tasks earlier in this section.. To find more information about NLTest, see “Support Tools Help” in the Tools and Settings Collection.

**Netdiag.exe: Network Connectivity Tester**

**Category**
The Network Connectivity Tester command-line tool (Netdiag) is included when you install Windows Server 2003 Support Tools.

**Version compatibility**
This tool is compatible with computers running Windows XP Professional, Windows Server 2003, Standard Edition; Windows Server 2003, Web Edition, Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition.

The Netdiag command-line tool examines .dll files, output from other tools, and the system registry to find potential problems. You can use Netdiag to troubleshoot connectivity over the secured channel that exists between a workstation and a domain controller.

For the various trust related tasks that can be performed using this tool, see the table Trust Tools Comparison by Task earlier in this section. To find more information about Netdiag, see “Support Tools Help” in the Tools and Settings Collection.

**Dcdiag.exe: Domain Controller Diagnostic Tool**

**Category**
The Domain Controller Diagnostic Tool command-line tool (Dcdiag) is included when you install Windows Server 2003 Support Tools.

**Version compatibility**
This tool is compatible with computers running Windows XP Professional, Windows Server 2003, Standard Edition; Windows Server 2003, Web Edition, Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition.

You can use the Dcdiag command line tool to verify external trusts. The Dcdiag tool cannot be used to verify Kerberos-based trust relationships; to verify Kerberos-based trust relationships, the recommended method is to use the Netdom tool. Using Dcdiag you can; scope your external trust verification by site or by domain controller, check for trust establishment, check secured channel setup, and check for ticket validity between each pair of domain controllers. By default, errors are flagged. In verbose mode, the successes are printed as well.

For the various trust related tasks that can be performed using this tool, see the table Trust Tools Comparison by Task earlier in this section. To find more information about Dcdiag, see "Support Tools Help" in the Tools and Settings Collection.

**Trust WMI Classes**
Windows Management Instrumentation (WMI) provides access to information about certain objects in a Windows 2000 Server or Windows Server 2003 operating system. WMI providers and classes represent the managed resources on a computer and are used by administrators and developers for scripting and monitoring purposes.

TrustMon is the WMI provider that can access health information about the trusts between domains and the secured channels between domain controllers. Enterprise Administrators can use the TrustMon provider and its associated WMI classes to monitor and troubleshoot trusts remotely and to create scripts that will help automate trust related administrative tasks. Consequently, developers can use the TrustMon provider and classes to create trust related event monitoring applications that will alert an administrator when an important incident occurs and, when appropriate, supply the necessary troubleshooting details.

TrustMon registers three WMI classes that can be used to retrieve information about trust properties for a given domain. These are Microsoft_TrustProvider, Microsoft_DomainTrustStatus and Microsoft_LocalDomainInfo. The following table lists and describes these WMI classes.

### WMI Classes Associated with Trusts

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| Microsoft_TrustProvider | root\microsoftactivedirectory | Windows 2000 Server and Windows Server 2003 |
| Microsoft_DomainTrustStatus | root\microsoftactivedirectory | Windows 2000 Server and Windows Server 2003 |
| Microsoft_LocalDomainInfo | root\microsoftactivedirectory | Windows 2000 Server and Windows Server 2003 |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports used by Trusts**
Because trusts must be deployed across various network boundaries, they might have to span one or more firewalls. When this is the case, you can either tunnel trust traffic across a firewall or open specific ports in the firewall to allow the traffic to pass through. In Windows Server 2003, this procedure is simplified through configurable remote procedure call (RPC) ports for the main trust services. The two main configurable RPC ports are the Local Security Authority RPC port and the Net Logon RPC port.

**The Local Security Authority (LSA) RPC port.**
This port is used for trust creation and other access to the LSA policy database.

**The Net Logon RPC port.**
This port is used for NTLM authentication and secured channel communications.

The following table shows the list of ports that might need to be opened before you establish trusts.

### Ports Required for Trusts

| Task | Outbound Ports | Inbound Ports | From–To |
|---|---|---|---|

| | | | |
|---|---|---|---|
| Set up trusts on both sides from the internal forest | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution — portmapper (135 TCP)<br>Net Logon fixed port | N/A | Internal domain domain controllers–External domain domain controllers (all ports) |
| Trust validation from the internal forest domain controller to the external forest domain controller (outgoing trust only) | LDAP (389 UDP)<br><br>Microsoft SMB (445 TCP)<br><br>Endpoint resolution — portmapper (135 TCP)<br>Net Logon fixed port | N/A | Internal domain domain controllers–External domain domain controllers (all ports) |
| Use Object picker on the external forest to add objects that are in an internal forest to groups and DACLs | N/A | LDAP (389 UDP and TCP)<br><br>Windows NT Server 4.0 directory service fixed port<br><br>Net Logon fixed port<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution portmapper (135 TCP) | External server–Internal domain PDCs (Kerberos)<br><br>External domain domain controllers–Internal domain domain controllers (Net Logon) |
| Set up trust on the external forest from the external forest | N/A | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP) | External domain domain controllers–Internal domain domain controllers (all ports) |
| Use Kerberos authentication (internal forest client to external forest) | Kerberos (88 UDP) | N/A | Internal client–External domain domain controllers (all ports) |
| Use NTLM authentication (internal forest client to external forest) | N/A | Endpoint resolution – portmapper (135 TCP)<br>Net Logon fixed port | External domain domain controllers–Internal domain domain controllers (all ports) |
| Join a domain from a computer in the internal network to an external domain | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution — portmapper (135 TCP)<br>Net Logon fixed port<br><br>Windows NT Server 4.0 directory service fixed port | N/A | Internal client–External domain domain controllers (all ports) |

To specify the services that you want to run on a fixed port, you must appropriately configure the registry for that port.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

Settings for the Local Security Authority (LSA) RPC port are stored in the **TCP/IP Port** entry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters** registry key.

Settings for the Net Logon RPC port are stored in the **DCTcpipPort** entry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters** registry key.

# Security Considerations for Trusts

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Potential Threats to Interforest Trusts
- Security Settings for Interforest Trusts
- Minimum Administrative Credentials for Securing Trusts
- Trust Security and Other Windows Technologies
- Related Information

The threat scenarios outlined in this section apply only to trusts made between two forests (also known as interforest trusts), including external and forest trusts. All other trusts made within a forest (also known as intraforest trusts), including parent-child, tree-root, and shortcut trusts, are optimally secured by default and do not require further planning to mitigate any known threat. As with intraforest trusts, there are no known threats to realm trusts that require mitigation.

You should be familiar with these threats before you deploy or configure a Windows Server 2003 network environment.

**Potential Threats to Interforest Trusts**

There are two potential threats to interforest trust relationships in Windows Server 2003. These threats can disrupt or undermine the integrity of interforest trusts.

- **Attack on trusting forest by malicious user in a trusted forest.** A malicious user with administrative credentials who is located in a trusted forest could monitor network authentication requests from the trusting forest to obtain the security ID (SID) information of a user who has full access to resources in the trusting forest, such as a Domain or Enterprise Administrator. SID filtering is set on all trusts by default to help prevent malicious users from succeeding with this form of attack. For more information about how SID filtering works, see "Security Settings for Interforest Trusts."

- **Attack on shared resources in a trusting forest by malicious users in another organization's forest.** Creating an external or forest trust between two forests essentially provides a pathway for authentications to travel from the trusted forest to the trusting forest. While this action by itself does not necessarily create a threat to either forest, because it allows all secured communications to occur over the pathway, it creates a larger surface of attack for any malicious user located in a trusted forest. Selective authentication can be set on interforest trusts to help minimize this attack surface area. For more information about how to mitigate this threat, see "Security Settings for Interforest Trusts."

**Security Settings for Interforest Trusts**

There are two security settings in Windows Server 2003 that can be used to enhance the integrity of communications made over interforest trusts. SID filtering helps prevent malicious users with administrative credentials in a trusted forest from taking control of a trusting forest. Selective authentication lessens the attack surface by restricting the quantity of authentication requests that can pass through an interforest trust.

**SID Filtering**

SID filtering is set on all trusts to prevent malicious users who have domain or enterprise administrator level access in a trusted forest from granting (to themselves or other user accounts in their forest) elevated user rights to a trusting forest. It does this by preventing misuse of the attributes containing SIDs on security principals (including inetOrgPerson) in the trusted forest. One common example of an attribute that contains a SID is the SID history attribute (sIDHistory) on a user account object. The SID history attribute is typically used by domain administrators to seamlessly migrate the user and group accounts that are held by a security principal from one domain to another.

When security principals are created in a domain, the domain SID is included in the SID of the principal to identify the domain in which it was created. The domain SID is important because the Windows security subsystem uses it to verify the identity of the security principal, which in turn determines what resources in the domain the principal can access.

**How SID History is used to migrate accounts**
Domain administrators can simplify account migration by using the SID history attribute to migrate permissions, either automatically by using the Active Directory Migration Tool (ADMT) or manually by adding SIDs from an old user or group account to the SID history attribute of the new, migrated account. With either method, the new account retains the same level of permissions or access to resources as the old account. If domain administrators could not use the SID history attribute in this way, they would have to determine and reapply permissions on each network resource to which the old account had access. For more information about the SID history attribute, see "Trust Security and Other Windows Technologies."

**How SID History can be used to elevate privileges**
Although SID history has legitimate and important uses, it can also pose a security threat when used to exploit an unprotected trust. A malicious user with administrative credentials who is located in a trusted forest could monitor network authentication requests from the trusting forest to obtain the SID information of a user, such as a domain or enterprise administrator, who has full access to resources in the trusting forest. After obtaining the SID of an administrator from the trusting forest, a malicious user with administrative credentials can add that SID to the SID history attribute of a security principal in the trusted forest and attempt to gain full access to the trusting forest and the resources within it.

This method of gaining access by granting unauthorized user rights to a user is known as an elevation of privilege attack. In an elevation of privilege attack, an attacker might apply the SID of a domain administrator located in a trusting forest to the SID history attribute of the attacker's own account located in a trusted forest, get a ticket that would automatically include the new SID, and then use the ticket to access resources in the trusting forest. When the attacker requests the use of a resource, the access control mechanism considers all SIDs in the authorization data to determine if the principal has the rights to complete the requested action.

In an external trust scenario, a malicious user who has domain administrator credentials in the trusted domain is a threat to the entire trusting forest. In a forest trust scenario, a malicious user who has domain or enterprise administrator credentials in the forest root domain of the trusted forest is a threat to the entire trusting forest. Although the concept of elevating privileges by modifying SIDs is relatively easy to understand, it is quite difficult to implement. Attackers can use various technologies together with SID history to accomplish an elevation of privilege attack.

**Application Programming Interfaces (APIs)**
Windows includes APIs that facilitate account migration. These APIs are not exposed and can only be accessed on a system that has been patched to allow access to them. In this case, the APIs could be misused to add SIDs for a user from one domain to the SID history of a user in another domain. This is unlikely because these APIs require domain administrative credentials for both domains, including the domain being attacked. In order to overcome that security measure, malicious users would need to get the password of an account with domain administrative credentials before adding the SID. Attackers with access to such an account could more easily use it to accomplish their ultimate goal, rather than having to carry out an elevation of privilege attack to achieve the goal.

**Disk Editors**
A disk editor, such as the DiskProbe utility included in the Windows Server 2003 support tools, could also be used to mount an attack. A malicious user could boot into another operating system and use a disk editor to modify an offline Active Directory database. With a disk editor, the user could modify the SID history attribute, modify replication attributes so the change would be replicated, and calculate a new directory checksum so as to prevent Active Directory from detecting that the directory was improperly modified. This attack is difficult not only because it requires physical access to a domain controller, but all of the tasks are technically complex.

**Debuggers**
Debuggers can also be used maliciously. A user could attach a debugger to a domain controller and use it to modify the copy of the directory loaded in memory. This method is also technically sophisticated. It requires the attacker to have unrestricted physical access, be a domain administrator, and be able to use system APIs to modify system-level code that is not publicly available.

**How interforest trusts use SID Filtering**
Even though a sophisticated attacker might be able to exploit the SID history attribute to gain unauthorized access to resources, SID filtering can provide an effective countermeasure. An outgoing external or forest trust created from a trusting domain can use SID filtering to verify that incoming authentication requests made by security principals in the trusted domain contain only SIDs of security principals in the trusted domain.

The trust compares the SIDs of the requesting security principal to the domain SID of the trusted domain. Any SIDs from domains other than the trusted domain are removed, or filtered. When this happens the request for authentication will fail and the resource will not be accessed.

A stricter form of SID filtering is SID filter quarantining. When a SID filter quarantine is applied to a trusted domain (using the trust relationship between the two domains), only SIDs from the trusted domain are allowed to traverse the trust relationship.

This prevents inbound communications (across the trust relationship) from the trusted domain to claim an identity that belongs to any other domain.

SID filter quarantining was designed to be applied to external trust relationships. It should not be applied to forest trust relationships, trusts within a domain, or trusts within a forest that has a forest functional level of Windows 2000.

External trusts created from domain controllers running Windows 2000 Service Pack 3 (or earlier) do not enforce SID filter quarantining by default. To improve the security of Active Directory forests, domain controllers running Windows Server 2003 and Windows 2000 Service Pack 4 or later enable SID filter quarantining on all new outgoing interforest trusts by default.

**Note**

- The following restrictions and recommendations apply to using SID filtering to mitigate security threats to external and forest trusts:

- You cannot turn off the default behavior that enables SID filter quarantining for newly created external trusts.

- To further secure your forest, you should consider enabling SID filter quarantining on all existing external trusts that were created by domain controllers running Windows 2000 Service Pack 3 (or earlier). You can do this by using Netdom.exe to enable SID filter quarantining on existing external trusts, or by recreating these external trusts from a domain controller running Windows Server 2003 or Windows 2000 Service Pack 4 (or later). Domain controllers running Windows NT Server 4.0 do not take part in the trust creation process when existing domain controllers in the same domain are running Windows 2000 or Windows Server 2003.

**How SID filtering impacts operations**

SID filtering can affect your existing Active Directory infrastructure in the following two ways:

- Users who use SID history data for authorization to resources in the trusting domain no longer have access to those resources.

  Because SID history that contains SIDs from any domain other than the trusted domain is removed from authentication requests made from the trusted domain, the user is denied access to resources that reference the old SID.

- Universal group access control strategy between forests will require changes.

  If you typically assign universal groups from a trusted forest to access control lists (ACLs) on shared resources in the trusting domain, SID filtering will have a significant impact on your access control strategy.

  Because universal groups must adhere to the same SID filtering guidelines as other security principal objects (that is, the universal group object SID must also contain the originating domain SID), you should verify that any universal groups that are assigned to shared resources in the trusting domain were created in the trusted domain.

  If the universal group in the trusted forest was not created in the trusted domain, even though it might contain users from the trusted domain as members, authentication requests made by members of that universal group will be filtered and discarded. Therefore, before assigning access to resources in the trusting domain for users in the trusted domain, you should confirm that the universal group containing the trusted domain users was created in the trusted domain.

  **Note**

  - The default SID filtering on forest trusts does not prevent migrations to domains within the same forest (intraforest migration) from using SID history, and it will not affect your intraforest universal group access control strategy. You should not apply SID filter quarantining on trusts between forests (that is, forest trusts or interforest trusts).

**Disabling SID Filter Quarantining on External Trusts**

Although it reduces the security of your forest (and is therefore not recommended), you can disable SID filter quarantining for an external trust by using the Netdom.exe tool. You should consider disabling SID filter quarantining only in the following situations:

- You have an equally high level of confidence in the administrators who have physical access to domain controllers in the

trusted domain and the administrators with such access in the trusting domain.

- You have a strict requirement to assign universal groups to resources in the trusting domain, even when those groups were not created in the trusted domain.

- Users have been migrated to the trusted domain with their SID histories preserved, and you want to grant them access to resources in the trusting domain based on the SID history attribute.

Only domain administrators or enterprise administrators can modify SID filtering settings. To disable SID filter quarantining for the trusting domain, type a command using the following syntax at a command-prompt:

**Netdom trust** *TrustingDomainName* **/domain:** *TrustedDomainName* **/quarantine:No /usero:** *domainadministratorAcct* **/passwordo:** *domainadminpwd*

To re-enable SID filtering, set the **/quarantine:** command-line option to **Yes**. For more information about Netdom, see "Domain and Forest Trust Tools and Settings."

**Allowing SID History to Traverse Forest Trusts**

If users are migrated from one domain to another in different forests, you may want to allow the migrated users to access resources in their original forest using their migrated (SID history) credentials. The default SID filtering applied to forest trusts prevents user resource access requests from traversing the trusts with the credentials of the original domain. If you want to enable users to use the credentials that were migrated from their original domain, you can allow SID history to traverse forest trusts by using the Netdom command.

Only domain administrators or enterprise administrators can modify SID filtering settings. To allow SID history credentials to traverse a trust relationship between two forests, type a command using the following syntax at a command-prompt:

**Netdom trust** *TrustingDomainName* **/domain:** *TrustedDomainName* **/enablesidhistory:Yes /usero:** *domainadministratorAcct* **/passwordo:** *domainadminpwd*

To re-enable the default SID filtering setting across forest trusts, set the **/enablesidhistory:** command-line option to **No**. For more information about Netdom, see "Domain and Forest Trust Tools and Settings."

**Note**

- The same security considerations for removing SID filter quarantining from external trusts apply to allowing SID history to traverse forest trusts.

**Selective Authentication**

Selective authentication is a security setting that can be set on interforest trusts. It provides Active Directory administrators who manage a trusting forest more control over which groups of users in a trusted forest can access shared resources in a trusting forest. This increased control is especially important when administrators need to grant access to shared resources in their organization's forest to a limited set of users located in another organization's forest, because creating an external or forest trust provides a pathway for all authentication requests to travel between forests.

While this action by itself does not necessarily cause a threat to either forest, because all secured communications occur over the pathway, an external or forest trust exposes a larger surface to attack by any malicious user located in a trusted forest. Selective authentication helps to minimize this exposed area by enabling Active Directory administrators to grant a new authentication permission — to computer objects in the resource domain — for specific user accounts located in another organization's forest.

This new authentication permission is set on the security descriptor of the computer object located in Active Directory, not on the security descriptor physically located on the resource computer in the trusting forest. Controlling authentication in this way provides an extra layer of protection to shared resources by preventing them from being randomly accessed by any authenticated user working in a different organization, unless the user has been granted this permission explicitly by someone with write access to the computer object in Active Directory.

**Note**

- To enable selective authentication on forest trusts, the trusting forest in which shared resources are located must have the forest functional level set to Windows Server 2003. To enable selective authentication on external trusts, the trusting domain in which shared resources are located must have the domain functional level set to Windows 2000 native.

**Authentication Settings for Interforest Trusts**

When the forest functional level is set to Windows Server 2003, Active Directory Domains and Trusts recognizes three authentication settings that can be set on interforest trusts: Domain-wide Authentication, Forest-wide Authentication, and Selective Authentication. The following table describes these authentication settings in more detail.

Authentication Settings Used on Interforest Trusts

| Authentication Setting | Interforest Trust Type | Description |
|---|---|---|
| Domain-wide Authentication | External | Permits unrestricted access by any users in the trusted domain to all available shared resources located in the trusting domain. This is the default authentication setting for external trusts. |
| Forest-wide Authentication | Forest | Permits unrestricted access by any users in the trusted forest to all available shared resources located in any of the domains in the trusting forest. This is the default authentication setting for forest trusts. |
| Selective Authentication | External and Forest | Restricts access over an external or forest trust to only those users in a trusted domain or forest who have been explicitly given authentication permissions to computer objects (resource computers) residing in the trusting domain or forest. This authentication setting must be manually enabled. |

**Domain- and forest-wide authentication settings**

Domain and forest-wide authentication provide an unrestricted pathway in which all authentication requests made by users in a trusted forest will be successfully authenticated by a domain controller in the trusting forest where the shared resource is located. The following illustration shows how the domain controller in the trusting forest authenticates and routes authentication requests made by users in the trusted forest.

**Authentication Requests Are Authenticated and Routed**

When domain or forest-wide authentication is enabled, users who are authenticated over an interforest trust are automatically provided the Authenticated Users SID of the trusting forest in their authorization data. The Authenticated Users SID is used to grant many of the default rights for users in a forest.

Because the Authenticated Users group is a computed group, and its SID is added on the server to which the user authenticates, you cannot change the membership of the group. Because of this, after you set up a interforest trust, users from the other forest receive some default rights to all of the resources in the trusting forest that are accessible by the Authenticated Users group. Consequently, you might not want to use the domain-wide or forest-wide authentication setting if the trust is set up only to allow access to a small subset of users who are in the trusted forest.

Once an authentication request made to a resource in a trusting forest is validated by the trusted forest, it is routed to the targeted resource computer, which determines, based on its access control configuration, whether to authorize the specific request made by the user, service, or computer in the trusted forest. In this way, interforest trusts provide the mechanism by which validated authentication requests are passed to a trusting forest, while access control mechanisms on the resource computer determine the final level of access granted to the requestor in the trusted forest.

Once the authentication request reaches the resource computer, that computer must determine whether the user who initiated the authentication request is authorized to access the shared resource it is hosting. It does this by comparing the SIDs provided in the access token of the authentication request with the SIDs in the security descriptor that has been granted access to the

shared resource.

**Selective authentication setting**

Unlike domain and forest-wide authentication, selective authentication provides a more restrictive pathway in which only authentication requests made from users in a trusted forest, who have been granted access to the Active Directory objects hosting the resources in a trusting forest, can be authenticated by the domain controller in the resource domain. The following illustration shows how the domain controller in the trusting forest can restrict the flow of authentication requests made by users in the trusted forest to shared resources in the trusting forest when those users have not been granted the appropriate permissions.

**Authentication Requests Are Not Authenticated or Routed**

**How selective authentication affects domain controller behavior**

When selective authentication is enabled, all authentication requests made over a trust to the trusting forest are tagged with an identifier that subjects the request to closer scrutiny by the domain controllers in the domain where the target resource is located. This is important because the mere presence of this identifier triggers the domain controller in the resource domain to first check whether the user requesting the access has been given explicit permissions to the Active Directory object where the resource is hosted. The appropriate permission to the resource object in Active Directory is verified before the domain controller sends a service ticket back to the requesting workstation in the trusted forest. The following illustration summarizes how domain controllers in the trusting forest are affected when selective authentication is enabled.

**Effect of Selective Authentication on Domain Controllers in the Trusting Forest**

The steps by which domain controllers process authentication requests when selective authentication is enabled are as follows:

1. **All domain controllers in the domain where the trust is established detect authentication requests made from the other organization.**

When selective authentication is enabled all domain controllers in the forest root domain of a trusting forest (with a forest trust) or all domain controllers in a resource domain in the trusting forest (with an external trust) are aware that all authentication requests coming in over that trust are coming from a different organization. This means that when a user from a different organization authenticates across a trust with the selective authentication option enabled, the domain controller that receives the request in the trusting domain recognizes this user as other than an authenticated user located in the trusting forest.

2. **Receiving DC in the domain where trust is established tags an identifier to the authorization data of the trusted user.**

   Once a domain controller receives the request it adds an identifier to the authorization data of the trusted user. This identifier is known as the Other Organization SID. The Other Organization SID is used to identify users making requests across a trust with selective authentication enabled.

3. **All domain controllers in the resource domain detect requests originating from the other organization, and the receiving domain controller in the resource domain performs an access check.**

   When a domain controller in a resource domain detects an Other Organization SID in the authorization for the trusted user, the domain controller is alerted to first check whether the requesting user has been granted explicit permissions to the Active Directory object where the resource is hosted. The appropriate permission to the resource object in Active Directory must be verified before the domain controller can authenticate the access request and send a service ticket back to the requesting workstation in the trusted forest.

   This verification process works by checking the access permissions set on the Allowed to Authenticate permission on the discretionary access control list (DACL) on the computer object in Active Directory. When you set selective authentication on an outgoing interforest trust, you need to manually assign access to the Allowed to Authenticate permission on each computer object, which physically represents a member server to which you want users in the trusted forest to authenticate.

   You must grant access to this permission in order for users located in a trusted forest to authenticate to the shared resources hosted by the server computer. If this permission has not been granted to a user whose authorization data contains the Other Organization SID, the service ticket to the server hosting the shared resource is not granted and the authentication process fails.

   **Note**

   - The following restrictions apply to the Allowed to Authenticate authorization permission:
   - By default, only members of the Account Operators, Administrators, Domain Administrators, Enterprise Administrators, and SYSTEM security groups located in the trusting domain can modify the Allowed to Authenticate authorization permission.
   - When Kerberos is used for authentication, the Allowed to Authenticate permission should be enabled on computer accounts when the service that hosts the resource is running as Local System or Network Service. If the service that hosts the resource is running as a Domain Service account, the permission should be configured on that account. For example, if the SQL service is running under the account SQLServer, the SQL Server account has to have the Allowed to Authenticate permission enabled for users to be able to authenticate to that account across trusts that have selective authentication enabled.
   - When NTLM is used for authentication, the Allowed to Authenticate permission should be granted to the computer account, even if the service that you want to connect to is using a domain user account.

When a Windows NT 4.0, Windows 2000 Server, or Windows Server 2003 member server receives an authentication request from a user, regardless of whether that user is identified with the Other Organization SID, the member server automatically adds the Authenticated Users SID for the trusting forest to the authorization data for that user.

**How selective authentication affects Windows Server 2003 member server authentication**

When users who are located in a domain within the trusting forest (or in a trusted domain that does not have selective authentication enabled) authenticate to local Windows Server 2003 member servers, the Authenticated Users SID and a new identifier indicating that they belong to the same organization are placed in their authorization data. This new identifier is known as the This Organization SID. Only the Other Organization SID or the This Organization SID can be present in the authorization data of an authenticated user along with the Authenticated Users SID. The following table describes the SIDs that can be added to the authorization data of a user throughout the entire selective authentication process and shows when they are added.

SIDs Added to Authorization Data During the Selective Authentication Process

| SID | Purpose | When Added to User Authorization Data |
|---|---|---|
| Authenticated Users | Adds default access rights to resources in the trusting forest. Because this SID is mandatory for all incoming authentication requests, it prevents all anonymous access to resources in the trusting forest. | Added when any incoming authentication request to a member server is made from a user who has been identified with the Other Organization SID. This SID is always applied by the member server to the authorization data of an incoming user, in addition to one of the other SIDs in this table. |
| This Organization | Identifies users who access resources locally within a trusting forest or across a trust that is not marked for selective authentication. | Added when users who are located in any of the domains within a trusting forest authenticate to a local Windows Server 2003 member server. This SID and the Authenticated Users SID are added by the member server. The Other Organization SID cannot be added to this authorization data of this user. |
| Other Organization | Identifies users coming across a trust that is marked for selective authentication. | Added when any incoming authentication request is made from a user located in a trusted forest to a domain controller in the domain in the trusting forest where the trust is established. This SID is added by the domain controller that initially receives the authentication request. The Authenticated Users SID is not added to the authorization data of the user until the member server has authenticated the user. |

**Note**

- The Allowed to Authenticate permission can be set on computer objects that represent member servers running Windows NT Server 4.0, Windows 2000 Server, and Windows Server 2003. However, only member servers running Windows Server 2003 can provide the This Organization SID to the authorization data of a user.

**Processing authentication requests made over forest trusts with selective authentication enabled**

Before an authentication request made with the Kerberos version 5 authentication protocol can follow the forest trust path, the service principal name (SPN) of the resource computer must be resolved to a location in the other forest. A SPN is a multicomponent name that is used to identify a service that is associated with a computer account. When a workstation in one forest attempts to access data on a resource computer in another forest, the Kerberos authentication process contacts the domain controller for a service ticket to the SPN of the resource computer. Once the domain controller queries the global catalog and determines that the SPN is not in the same forest as the domain controller, the domain controller sends a referral back to the workstation for its parent domain. The workstation queries its parent domain for the service ticket and continues to follow the referral chain until it reaches the domain where the resource is located.

Once the workstation reaches a domain controller in the root domain of the resource forest where selective authentication is enabled, the domain controller adds the Other Organization SID to the authorization data for the user. After the Other Organization SID is added, the domain controller in the resource domain checks the Allowed to Authenticate permission on the computer object (located in Active Directory) that is hosting the resource. If the user has been granted access the domain controller issues a service ticket back to the workstation. This is an important part of the selective authentication process, because if the user does not have permission to authenticate to the computer object, a service ticket will not be granted and access to the target resource computer fails. In this way, the selective authentication setting restricts what authentication requests can pass through a trust and obtain a ticket for a target resource computer.

The following figure and corresponding steps provide a detailed description of the Kerberos authentication process that is used when computers running Windows 2000 Professional, Windows XP Professional, Windows 2000 Server, or Windows Server 2003 attempt to access resources from a computer located in another forest when selective authentication is enabled.

**Kerberos authentication process over a forest trust with selective authentication enabled**

This illustration incorporates images from Active Directory Users and Computers in the Microsoft Management Console to help you better understand at what point during the authentication process a domain controller queries the Allowed to Authenticate permission for the resource object.

1. Acctuser1 logs on to Workstation1 using credentials from the Sales.tailspintoys.com domain. The user then attempts to access a shared resource on FileServer1 located in the WingtipToys forest. Acctuser1 is also a member of the Accounting global group in the Sales.tailspintoys.com domain.

2. Workstation1 contacts the Key Distribution Center (KDC) on a domain controller in its domain (TailspinDC1) and requests a service ticket for the FileServer1 SPN. FileServer1 is located in the Mktg.wingtiptoys.com domain and is a member server.

3. TailspinDC1 does not find the SPN in its domain database and queries the global catalog to see if any domains in the TailspinToys forest contain this SPN. Because a global catalog is limited to its own forest, the SPN is not found. The global catalog then checks its database for information about any forest trusts that are established with its forest, and, if any are found, it compares the name suffixes listed in the forest trust trusted domain object (TDO) to the suffix of the target SPN to find a match. Once a match is found, the global catalog provides a routing hint back to TailspinDC1.

4. Using the information in the routing hint, TailspinDC1 sends a referral for a domain controller located in the forest root domain of the WingtipToys forest back to Workstation1.

5. Workstation1 contacts a domain controller in the forest root domain (WingtipDC1) of the Corp.wingtiptoys.com forest and requests a service ticket to the Fileserver1 resource computer.

6. WingtipDC1 contacts its global catalog to find the SPN, and the global catalog finds a match for the SPN and sends it back to WingtipDC1.

7. Because the authentication request originated from the TailspinToys forest and selective authentication is enabled WingtipDC1 applies the Other Organization SID to the user's authorization data and then sends a referral for the mktg.wingtiptoys.com domain back to Workstation1.

8. Workstation1 contacts the KDC on WingtipDC2 and attempts to negotiate a ticket for Acctuser1 to gain access to FileServer1.

9. WingtipDC2 detects the Other Organization SID in the authorization data of Acctuser1, which requires the domain controller to first locate the computer object of the resource computer (Fileserver1) before providing a ticket back to the requesting computer.

10. Once the computer object is located, the domain controller must check whether the user requesting access to the resource computer has been explicitly granted the **Allowed to Authenticate** permission on the Fileserver1 computer object located in the Mktg.wingtiptoys.com domain. This process must complete successfully before WingtipDC1 can provide a ticket back to the requesting computer.

    **Note**

    - In this example, Acctuser1 is a member of the Accounting group in the TailspinToys forest and that group has been explicitly granted the **Allowed to Authenticate** permission to this computer object residing in Active Directory.

11. After WingtipDC1 determines that Acctuser1 has the required permission to Filerserver1, it sends a service ticket back to Workstation1 permitting it to gain access to FileServer1.

12. Now that Workstation1 has a service ticket, it sends the server service ticket to FileServer1, which reads the security credentials for Acctuser1 and constructs an access token accordingly.

**Impact of Selective Authentication**

Because all verification of incoming interforest authentication requests is done locally on the receiving domain controller in the trusting forest, access to resources in the trusting forest is likely to be extremely limited for a broad set of users on the network (which is the purpose of this security setting). Consequently, implementing selective authentication might require user education, particularly due to the following reasons:

- Users browsing network resources through My Network Places to resources located in a trusting forest might get access denied messages when attempting to access those resources.

- Resources in the trusting forest that were once available to users in a trusted forest might no longer be available.

**Note**

- As a security best practice it is recommended that resource administrators in a trusting forest remove the default access rights granted to the Authenticated Users group in all of the shared resources in the trusting forest. This practice will help to further minimize the possibility of authenticated users inside and outside of a forest from accessing protected resources.

**Enabling and Disabling Selective Authentication**

Selective authentication must be manually enabled or disabled by using Active Directory Domains and Trusts or the Netdom.exe tool. To enable selective authentication for the trusting domain, type a command using the following syntax at a command-prompt:

**Netdom trust** *TrustingDomainName* **/domain:** *TrustedDomainName* **/SelectiveAuth:Yes /usero:** *domainadministratorAcct* **/passwordo:** *domainadminpwd*

To disable selective authentication, set the **/SelectiveAuth:** command-line option to **No**. For more information about the Netdom tool, see "Domain and Forest Trust Tools and Settings."

You can enable or disable selective authentication only from the trusting side of a trust. If the trust is a two-way trust, you can also enable or disable selective authentication in the trusted domain by using the credentials of the domain administrator for the trusted domain and reversing the values of TrustingDomainName and TrustedDomainName in the command.

### Note

- You can further increase security in a forest by enabling selective authentication on all external and forest trusts used to connect forests that are not managed by the IT department in your organization.

#### Minimum Administrative Credentials for Securing Trusts

The following table lists the minimum administrative credentials necessary to enable or disable the SID filtering and selective authentication security settings in Active Directory.

Minimum Administrative Credentials Necessary To Secure Trusts

| SID Filter Quarantining - External Trusts | Allowing SID History - Forest Trusts | Selective Authentication - External Trusts | Selective Authentication - Forest Trusts |
|---|---|---|---|
| You must be a member of the Domain Admins group in the trusting domain or the Enterprise Admins group in the trusting forest. | You must be a member of the Domain Admins group in the forest root domain or the Enterprise Admins group in the trusting forest | You must be a member of the Domain Admins group in the trusting domain or the Enterprise Admins group in the trusting forest. | You must be a member of the Domain Admins group in the forest root domain or the Enterprise Admins group in the trusting forest |

#### Trust Security and Other Windows Technologies

Trust security can be affected or enhanced by other technologies built into the Windows operating system. These include SID history and the Lightweight Directory Access Protocol (LDAP).

#### SID History

SID History is used to store the former SIDs of moved objects such as users and security groups. Prior to Windows 2000, restructuring a domain generally meant the creation of new accounts that needed to be placed in the same groups the old accounts were placed in. Since Windows 2000, domain restructuring is considerably easier because of SIDHistory, which is an attribute of Active Directory security principals.

As part of the move operation for the user or group, Application Programming Interfaces (APIs), or tools and support utilities built from these APIs, update the SIDHistory attribute of the object, representing it in Active Directory with its former SID. When the user next logs on to the system, not only the new SID, but also the old SID retrieved from the SIDHistory attribute is added to the user's access token and serves to determine the user's group memberships. The SIDs of the groups of which the user is a member (through either the new SID or the old SID) are also added to the access token, together with any SIDHistory those groups might have.

Groups have a SIDHistory attribute because they also can be moved. The system retrieves the SIDHistory attributes of all the groups of which the user is a member and adds these attributes to the user's access token. Because these SIDHistory entries in the token look to the operating system like normal group memberships during authorization checks, the token can grant appropriate access even on earlier versions of the operating system.

Because old SIDs can be stored in SIDHistory, the user can continue to access resources after a move without requiring administrators to modify ACLs. Once a migration is complete, if all needed resources are in the new domain, use of SIDHistory can be phased out if desired.

### Note

- The SIDHistory attribute can be updated only in native mode Windows 2000 or Windows Server 2003 domains, which requires all migration operations relying on SIDHistory to have a native mode target.

For more information about the security threat that exploits SID history, see "Security Settings for Interforest Trusts."

#### LDAP Sign and Encrypt

When using Windows Server 2003, secure LDAP traffic is enabled so that Active Directory administrative tools sign and encrypt all LDAP traffic by default. In this way, secured LDAP traffic enhances the security of communications that can occur

between trusts.

Active Directory Domains and Trusts signs and encrypts all LDAP traffic by default. Signing LDAP traffic guarantees that the packaged data comes from a known source and that it has not been tampered with. Active Directory administrative tools in Windows 2000 do not sign and encrypt all LDAP traffic by default. In order to maintain a secure network, it is strongly recommended that you upgrade all domain controllers running Windows 2000 to Service Pack 3 or later.

You can use the corresponding Active Directory administrative tools in Windows 2000 to manage Windows 2000 domain controllers that do not have the Windows 2000 Server Service Pack 3 or later installed. However, traffic is not signed and encrypted by LDAP on domain controllers running Windows 2000.

**Resource Kit Tools**
You can install the Resource Kit tools on a local computer. Click the following link to go to the download site for the Windows Server 2003 Resource Kit tools, including a searchable Help file of technical information about this collection of tools (included with the Windows Server 2003 Deployment Kit) that can help you deploy, configure, maintain, and troubleshoot Windows Server 2003:

- Windows Server 2003 Resource Kit Tools Download

To view this technical reference information locally, download the Windows Resource Kit Tools for Windows Server 2003 and install them on a computer running either Windows XP Professional or Windows Server 2003.

To view Resource Kit Tools Help in Windows XP:

- In Help and Support Center, under **Pick a Task**, click **Use tools to view your computer information and diagnose problems**, and then click **Windows Resource Kit Tools**.

To view Resource Kit Tools Help in Windows Server 2003:

- Help and Support Center, under **Support Tasks**, click **Tools**, and then click **Windows Resource Kit Tools**.

**Resource Kit Tool Updates**
Click the following link to go to the download site for updated Windows Server 2003 Resource Kit tools. System administrators, developers, and power users can use these tools to streamline a wide range of administrative tasks.

- Windows Server 2003 Resource Kit Tool Updates

**Support Tools Help**
A searchable Help file of technical information about the Support Tools included with Windows Server 2003. Support Tools are intended to assist Microsoft support personnel and network administrators in diagnosing and resolving computer problems.

Click the following link to go to the online version of Support Tools Help:

- Windows Support Tools

To view Support Tools Help from a local computer, install the Support Tools from the \Support\Tools folder on the Windows Server 2003 installation disc on a computer running either Windows XP Professional or Windows Server 2003.

To view Support Tools Help in Windows XP:

- In Help and Support Center, under **Pick a Task**, click **Use tools to view your computer information and diagnose problems**, and then click **Support Tools**.

To view Resource Kit Tools Help in Windows Server 2003:

- In Help and Support Center, under **Support Tasks**, click **Tools**, and then click **Windows Support Tools**.

**Windows Firewall Settings**
Click the following link to go to a searchable online reference that tells you how to configure Windows Firewall so it works with Windows Server 2003 remote administration tools, optional components, server roles, and services. Most remote administration tools, optional components, server roles, and services will not function properly when Windows Firewall is turned on unless you configure Windows Firewall settings.

- Windows Firewall Settings

# Windows Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Introduction to Windows Support Tools**
The Windows Support Tools assist support personnel and network administrators in managing their networks and troubleshooting problems. They are not installed with the Windows operating system; you must install them separately from the \Support\Tools folder of the Windows operating system CD. This Help file provides information on the tools and shortcuts for opening or running these tools.

To install Windows Support Tools, see Install Windows Support Tools on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=62270).

**Getting Help on Support Tools**

### To find Help for a tool

- Click the Alphabetical List of Tools topic on the **Contents** tab to display a list of tools by the file names of the tools.
- Click a category on the **Contents** tab and then click the file name of the tool.
- Use the **Index** tab to locate a tool by either tool name or file name.

Each tool is covered in a main Help topic. Links to associated topics covering syntax, examples, or other features of the tool are available at the top of each topic for that tool. Tools with Windows interfaces may include a separate Help file available from the Help menu in the tool window. For command-line tools, Help is also available by typing *FileName* **/?** at the command prompt.

An extensive Support Tools Glossary is available from the **Contents** tab. Links to glossary definitions that appear as pop-up windows are formatted in underlined dark green text.

**Troubleshooting with Support Tools**
Many Support Tools provide diagnostic features that are useful for troubleshooting Windows operating system configurations. However, because these tools have been designed primarily for system administrators and support personnel, their output may be difficult to analyze. In these cases, you can consult the Microsoft Windows Deployment and Resource Kits Web site for troubleshooting information.

**Understanding Notation and Terminology**
The following topics cover the conventions for usage and notation that are observed in this document:

Procedural Conventions

Notational Conventions

This documentation assumes you are already familiar with the Windows operating system. For more general information about Windows, including keyboard equivalents to menu and mouse actions, see Windows Help.

**Printing Topics**
When you print from HTML Help, a dialog box opens asking whether you want to print the selected topic or to print the selected heading and all subtopics. Printing the selected topic is recommended. If you print a heading and subtopics, you may encounter error messages and special formatting will be lost, but the topics still print.

Printing from Help and Support Center (HSC) results in similar behavior, except the dialog box only opens when a heading or topic has subtopics.

# Notational Conventions

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Notational Conventions**

| Convention | Meaning |
|---|---|
| **bold** | In syntax, characters that you type exactly as shown, including commands and parameters. In text, menu names and menu commands are also bold. |
| **`bold monospace`** | Commands that you must type exactly as shown to get the results being discussed. |
| *italic* | Variables for which you supply a specific value. For example, *Filename.ext* represents any valid file name. |
| Initial Capitals (Filename.ext) | Names of files should begin with an initial capital letter, for example, Filename.ext. Paths and folders can be uppercase, lowercase, or mixed, according to how they actually appear in a standard installation of the application or the operating system. |
| ALL CAPITALS | Used for acronyms. |
| `monospace` | Examples of code. |
| [ ] (square brackets) | In syntax descriptions, square brackets enclose optional items. If you include the item, type only the information between them, not the square brackets themselves. |
| {*choice1* \| *choice2*} (braces) | In syntax descriptions, braces enclose items which require a choice, such as {**yes** \| **no**}. Type only one of the choices, not the braces or the dividing line. |

# Procedural Conventions

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Procedural Conventions**

| Convention | Meaning |
|---|---|
| type | An instruction to **type** information means to press the key or keys and then press the ENTER key. |
| select | An instruction to **select** information means to highlight folders, file names, text boxes, menu bars, and options, or to select options in a dialog box. |
| + | A plus sign ( + ) between two or more key names indicates that you must press the keys at the same time; for example, ALT + TAB. |
| , | A comma ( , ) between two or more key names indicates that you must press each key consecutively; for example, ALT, F, X. |
| Note | Alerts you to supplementary information. |
| Important | Alerts you to essential information. |
| Caution | Alerts you to possible data loss, breaches of security, or other more serious problems. |
| Operating system reference conventions | The following conventions in this documentation are used to mean the indicated groups of Windows products.<br>1. References to "Windows Server 2003" include the following products:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>2. References to "Windows Server 2003 family" include the following products:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition |

# Related Information on the Internet

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Related Information on the Internet**
There are many Microsoft Web sites that provide information and updates regarding Microsoft products and operating systems, including Windows Server 2003, Windows XP, Windows 2000, Windows NT, and Windows 98.

If you have an Internet connection and a Web browser, you can click the following links to visit these sites.

# New and Removed Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New and Removed Support Tools**
Windows Server 2003 Support Tools include new tools that are not available in Windows 2000 Server Support Tools, and tools have been removed from Windows Server 2003 Support Tools that were available in Windows 2000 Server Support Tools.

**Installation of Windows Server 2003 SP1 Support Tools**
You can install the version of Windows Support Tools that ships with Windows Server 2003 Service Pack 1 (SP1) by using Suptools.msi only on computers running Windows Server 2003 with SP1. You can install individual tool executable files on computers running Windows Server 2003 with no service pack installed and on computers running Windows XP Professional by copying the executable files to the computers. However, you cannot use Suptools.msi to install the entire tool set on any computer that is not running Windows Server 2003 with SP1.

**Tools Added to Support Tools**
The tools in the following table have been added to the Windows Server 2003 Support Tools.

| Tool name | Descriptive name | Primary category |
|---|---|---|
| Addiag.exe | Application Deployment Diagnostics | Software and System Deployment |
| Apmstat Overview | Advanced Power Management Status | Configuration and Management |
| Bindiff Overview | Binary File Difference Finder | File and Folder Management |
| Bitsadmin Overview | BITS Administration Utility | File and Folder Management |
| Cabarc Overview | Cabinet Tool | File and Folder Management |
| Connstat Overview | FRS Connection Status Report | Disk and Data Management |
| Dhcploc Overview | DHCP Server Locator Utility | Network Services Management |
| Diruse Overview | Directory Disk Usage | File and Folder Management |
| Dmdiag Overview | Disk Manager Diagnostics | File and Folder Management |
| Efsinfo Overview | Encrypting File System Information | File and Folder Management |
| Exctrlst Overview | Extensible Performance Counter List | Performance Monitoring |
| Filever Overview | File Version | File and Folder Management |
| Ftonline Overview | Fault Tolerant Disk Mounter | File and Folder Management |
| Getsid Overview | Get Security ID | Network Services Management |
| Health_chk Overview | FRS Connection Status Report | Disk and Data Management |
| Httpcfg Overview | HTTP Configuration Utility | Internet Services Management Tools |
| Iasparse Overview | IAS Parse Tool | Network Services Management |
| Iologsum Overview | FRS Health Check | Disk and Data Management |
| Netcap Overview | Network Monitor Capture Utility | Network Services Management |
| Portqry Overview | Port Query | Network Services Management |
| Setspn Overview | Manipulate Service Principal Names for Accounts | Active Directory Management |

| | | |
|---|---|---|
| Spcheck Overview | Service Pack Checker | Configuration and Management |
| Topchk.cmd | DFS and SYSVOL Replication Topology Analysis | Disk and Data Management |

**Debugging Tools**
The following debugging tools have been moved from Windows Support Tools to Microsoft Debugging Tools:

- Apcompat.exe
- Dumpchk.exe
- Kill.exe

To obtain debugging tools and documentation, and for information about debuggers, see Microsoft Debugging Tools.

**Tools Removed from Support Tools**
The tools in the following table have been removed from Windows Server 2003 Support Tools:

| Tool name | Descriptive name | Disposition |
|---|---|---|
| Apcompat.exe | Application Compatibility Toolkit | Microsoft Debugging Tools. |
| Dommig.exe | Domain Migration Tool | See Active Directory Migration Tool (ADMT) on the Windows Server 2003 operating system CD. |
| Dumpchk.exe | Dump Check Utility | Obsolete. See Microsoft Debugging Tools. |
| Kill.exe | Process Kill Utility | Replaced by TaskKill.exe, which is in %windir%\system32. |
| Msinfo32.exe | Msinfo32 | Moved to Program Files\Common Files\Microsoft Shared\MSInfo. |
| Pmon.exe | Process Resource Monitor | Use Pviewer Overview instead. Pmon.exe is included in the Windows Server 2003Resource Kit Tools. |
| Pptpclnt.exe and Pptpsrv.exe | Point-to-Point Tunneling Protocol Ping Utilities (PPTP Ping) | Removed. |
| Reg.exe | Registry Console Tool | Moved to %windir%\system32. |
| Tlist.exe | Task List Viewer | Replaced by Tasklist.exe, which is in %windir%\system32. |
| Wsremote.exe | Wsremote | Use Remote Overview instead. |

# Alphabetical List of Tools

# Active Directory Management Support Tools

Updated: July 13, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: Active Directory Management Tools for Windows Server 2003**
This topic provides links to Active Directory Management Tools for Windows Server 2003. These tools are available in Windows Support Tools that is included on the Windows Server 2003 operating system disk on Microsoft Download Center.

For more information about tools for managing Active Directory, see How to Administer Microsoft Windows Client and Server Computers Locally and Remotely (http://go.microsoft.com/fwlink/?LinkID=177813).

For more information about tools for managing Active Directory Domain Services in Windows Server 2008 and Windows Server 2008 R2, see Active Directory Domain Services Command Reference (http://go.microsoft.com/fwlink/?LinkId=197167).

The following topics provide more information about the tools available in Windows Support Tools for managing Active directory in Windows Server 2003:

- Acldiag Overview
- ADSI Edit (adsiedit.msc)
- Clonepr Overview
- Dsacls Overview
- Dsastat Overview
- Ldp Overview
- Movetree.exe
- Ntfrsutl Overview
- Repadmin Overview
- Replmon Overview
- Sdcheck Overview
- Search Overview
- Setspn Overview

# Acldiag Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The AclDiag command-line tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Acldiag.exe: ACL Diagnostics**
This command-line tool detects and reports discrepancies in the access control lists (ACLs) of objects in Active Directory. It can also reapply a security delegation template to an ACL, eliminating special permissions and restoring incomplete delegations.

With AclDiag, you can:

- Display the access control entries (ACEs) in the ACL, and inheritance and audit settings.
- Display the effective permissions of users and groups to an Active Directory object.
- Compare the ACL for an object in Active Directory to the default permissions defined in the schema.
- Compare the ACL of an Active Directory object to a delegation template.
- Reapply the delegation template to the ACL of an Active Directory object.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
For more information about Active Directory, see the Active Directory Overview.

**System Requirements**
The following are the system requirements for Acldiag:

- Windows 2000, Windows XP Professional, or Windows Server 2003.
- The user must have read permissions on Active Directory objects. To reapply a delegation template, the user must have modify permissions to the Active Directory object.

**File Required**

- Acldiag.exe

# Acldiag Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Acldiag Remarks**

AclDiag displays only the permissions of objects the user has the right to view. Because Group Policy objects are virtual objects that have no distinguished name, this tool cannot be used on them.

For general purpose ACL reporting and setting from the command prompt, you can also use DsAcls, another Windows Support Tool.

# Acldiag Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Acldiag Syntax**

Acldiag Overview | Acldiag Remarks | Acldiag Syntax | Acldiag Examples

**acldiag** *ObjectDN* [**/schema**] [**/chkdeleg**] [**/geteffective:**{*User* | *Group* | *}] [**/fixdeleg**] [**/skip**] [**/tdo**]

**Parameters**

**Note**

- If you specify an object without additional parameters, AclDiag lists the access control entries (ACEs) in the ACL, and inheritance and audit settings.

***LDAP-URL***

Identifies the Active Directory object to investigate. Enter the LDAP URL for an object in Active Directory. The LDAP URL format consists of the name of the LDAP server followed by the distinguished name of the object. The string must be enclosed in quotation marks. For example:

**"LDAP://domain.test.microsoft.com/CN=Test Admin,CN=Users,DC=domain,DC=test,DC=microsoft,DC=com"**

**/geteffective:{*User* | *Group* | *}**

Adds an effective rights diagnosis to the display. The effective rights diagnosis displays the effective permissions to the object held by specified users or groups. Effective permissions are the permissions that are enforced after precedence is applied and conflicts in rights are resolved.

| Value | Description |
|---|---|
| *User* \| *Group* | Displays the effective permissions held by the specified user or group. |
| * | Displays the effective permissions of all users and groups in the access control list (ACL) for the object. |

**/schema**

Adds a schema diagnosis to the display. The schema diagnosis reports whether the object ACL includes the ACEs that are in the schema defaults.

**/chkdeleg**

Adds a delegation diagnosis to the display. The delegation diagnosis reports whether the object ACL includes the ACEs that are in the delegation template. A status of **misconfigured** indicates that at least one, but not all, ACEs in a delegation template (and in the schema default) are included in the ACL.

**/fixdeleg**

Directs AclDiag to reapply the delegation template to the object ACL, eliminating special permissions and restoring incomplete delegations. When the specified object inherits delegated permissions, this parameter reapplies the delegation template to the object for which the delegated permissions are explicitly defined. The **/fixdeleg** parameter is interactive, it gives the user an opportunity to fix each misconfigured delegation.

**Note**

- This parameter is effective only when used with the **/chkdeleg** parameter. Without **/chkdeleg**, **/fixdeleg** is ignored, but AclDiag does not report an error.

**/skip**

Omits the security description from the display. The security description is a list of the ACEs in the object ACL.

**/tdo**

Displays output in tab-delimited format. Fixed-width format is the default. Tab-delimited format is useful when the output is destined for a database or spreadsheet.

# Acldiag Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Acldiag Examples**

Acldiag Overview | Acldiag Remarks | Acldiag Syntax | Acldiag Examples

**Example 1: Display the ACL of a user object in Active Directory**

To display the ACL of a user object in Active Directory, type:

```
acldiag CN="Test Admin",CN=Users,DC=domain1,DC=test,DC=fourthcoffee,DC=com
```

**Example 2: Display a Schema Analysis of a Computer Object in Active Directory**

To display a schema analysis of a computer object in Active Directory, type:

```
acldiag CN=MACHINE-TEST,CN=Computers,DC=domain1,DC=test,DC=fourthcoffee,DC=com /schema
```

**Example 3: Display ACL, Permissions, and Delegation Information for a Computer Object**

To display the ACL, the effective permissions for all users and groups in the security descriptor, and the delegation analysis of a computer object in tab-delimited format, type:

```
acldiag CN=MACHINE-TEST,CN=Computers,DC=domain1,DC=test,DC=fourthcoffeeDC=com /chkdeleg /geteffective:* /tdo
```

**Example 4: Reapply a Delegation Template to a Group Object**

To reapply a delegation template to a group object, type:

```
acldiag CN="Domain Computers",CN=Users,DC=domain1,DC=test,DC=fourthcoffee,DC=com /chkdeleg /fixdeleg
```

ADSI Edit (adsiedit.msc)

# ADSI Edit (adsiedit.msc)

Updated: April 25, 2012

Applies To: Windows SBS 2008, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

Active Directory® Service Interfaces Editor (ADSI Edit) is a Lightweight Directory Access Protocol (LDAP) editor that you can use to manage objects and attributes in Active Directory. ADSI Edit (adsiedit.msc) provides a view of every object and attribute in an Active Directory forest. You can use ADSI Edit to query, view, and edit attributes that are not exposed through other Active Directory Microsoft Management Console (MMC) snap-ins: Active Directory Users and Computers, Active Directory Sites and Services, Active Directory Domains and Trusts, and Active Directory Schema.

This topic includes the following sections:

- Installing ADSI Edit
- Using ADSI Edit
- Adding ADSI Edit to MMC
- Missing Commands
- Other Topics with ADSI Edit Usage Scenarios

**Note**

Another LDAP editor that Microsoft provides is Ldp. To learn more about Ldp, see Ldp Overview (http://go.microsoft.com/fwlink/?LinkId=143517). For an example of Ldp being used, see article 224543 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=23064).

**Installing ADSI Edit**

To install ADSI Edit on computers running Windows Server® 2003 or Windows® XP operating systems, install Windows Server 2003 Support Tools from the Windows Server 2003 product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

On servers running Windows Server 2008 or Windows Server 2008 R2, ADSI Edit is installed when you install the Active Directory Domain Services (AD DS) role to make a server a domain controller. You can also install Windows Server 2008 Remote Server Administration Tools (RSAT) on domain member servers or stand-alone servers. For specific instructions, see Installing or Removing the Remote Server Administration Tools Pack (http://go.microsoft.com/fwlink/?LinkId=143345).

To install ADSI Edit on computers running Windows Vista® with Service Pack 1 (SP1) or Windows 7, you must install RSAT. For more information and to download RSAT, see article 941314 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=116179).

**Note**

- Adsiedit.msc will not run unless the Adsiedit.dll file is registered. This happens automatically if the support tools are installed. However, if the support tool files are copied instead of installed, you must run the **regsvr32** command to register Adsiedit.dll before you run the Adsiedit.msc snap-in. To register adsiedit.dll, type the following command (you must navigate to the directory containing the adsiedit.dll file):

  ```
  regsvr32 adsiedit.dll
  ```

- You can run ADSI Edit from a client computer or server. The computer does not have to be a member of a domain. However, to see domain objects using Adsiedit.msc, you must have the rights to view the Active Directory domain that you connect to. By default, members of the Domain Users group have these rights. To modify objects using ADSIEdit, you must have at least the Edit permission on the Active Directory objects that you want to change. By default, members of the Domain Admins group have this permission.

**Using ADSI Edit**

ADSI Edit (Adsiedit.msc) is an MMC snap-in. You can add the snap-in to any .msc file through the **Add/Remove Snap-in** menu option in MMC, or just open the Adsiedit.msc file from Windows Explorer. The following figure illustrates the ADSI Edit interface. In the console tree on the left, you can see the major partitions Domain, Configuration, and Schema. The figure shows the Builtin container of the Contoso.com domain selected. In the details pane on the right, you can see the Builtin groups of Active Directory.

**Note**

Adsiedit.msc automatically attempts to load the current domain to which the user is logged on. If the computer is installed in a workgroup or otherwise not logged on to a domain, the message "The specified domain does not exist" displays repeatedly. To resolve this issue, you may want to open an MMC, add the ADSI Edit snap-in, make connections as appropriate, and then save the console file.

**ADSI Edit Node**

To view the following commands, in the console tree click the **ADSI Edit** node, click the **Action** menu, and then click one of the following:

- Connect To
- Refresh

**Connect To**

The **Connection Settings** dialog box appears. You can use the **Connection Settings** dialog box to create a connection point to an object in Active Directory. The following text boxes are located in the **Connection Settings** dialog box:

**Name**. You should not change the text in this box because it might cause an error when you attempt to make a connection. The text in this box is updated automatically, if necessary, when you configure or select a Connection Point.

**Path**. Displays the URL for the selected object. It cannot be edited. If the path is not correct, click **Cancel**, and then select the correct object.

**Connection Point Section**

Click either **Select or type a Distinguished Name or Naming Context** or **Select a well known Naming Context**.

- If you click the **Select or type a Distinguished Name or Naming Context** radio button, type the distinguished name of the object that will be the connection point in Active Directory. For example, if your domain name is contoso.com and you want to connect to the **Users** container, type **cn=users,dc=contoso,dc=com**.
- If you click the **Select a well known Naming Context** radio button, select the directory partition that will be the connection point in Active Directory in the list of partitions in the selection menu.

**Tip**

Previous LDAP connections are remembered by the ADSI Edit tool. In versions earlier than Windows Server® 2008, the tool automatically attempts to load the current domain to which the user is logged on. If the computer is installed in a workgroup or otherwise not logged on to a domain, the message "The specified domain does not exist" appears repeatedly. To avoid these issues, open Mmc.exe, add the ADSI Edit snap-in manually, make any connections that are appropriate for you with whatever credentials are necessary, and then save the console file. This gives you your own default console that works with ADSI Edit.

**Computer Section**
Specifies whether you connect to the local computer or a remote computer. Click either **Default (domain or server that you are logged in to**) or **Select or type a domain or server**. You can enter the domain name or computer name in Domain Name System (DNS) format or NetBIOS format, or you can enter an IP address.

**Advanced Button**
Click the **Advanced** button to specify alternate credentials or alternate port numbers or to change the protocol that is used to connect to Active Directory. The **Advanced** dialog box contains the following text boxes:

**Specify Credentials**. Use this box to specify alternate credentials. Unless otherwise specified, the currently logged-on user's credentials are used.

**Port Number**. Type a port number if you do not want to use the default port for the LDAP or the LDAP Global Catalog protocol. The default LDAP port is 389. The default port for the Global Catalog is 3268.

**Protocol Section**
Click either **LDAP** or **Global Catalog**. The URL in **Path** might change, based on your selection. LDAP is used by default. To view the **Path** box, on the **Advanced** tab, click **OK** or **Cancel**.

**Refresh**
To update the object from Active Directory, right-click an object, and then click **Refresh**. The **Refresh** command removes the current objects in the container and repopulates the container with updated information from Active Directory.

**Directory Partition Node**
To view the following commands, select the directory partition node that you want to manage (that is, **Domain**, **Configuration**, and **Schema**), click the **Action** menu, and then click one of the following:

- Settings
- Remove
- Update Schema Now
- New
- Refresh

**Settings**
The **Connection Settings** dialog box appears, which provides the same configuration options as previously discussed in the Connect To section.

**Remove**
Removes the connection point that connects ADSI Edit to a directory partition or container within Active Directory. This command affects only what is shown in the ADSI Edit console. To remove objects from Active Directory, use the **Delete** command.

**Update Schema Now**
Reloads the schema information from Active Directory into the local computer's cache.

**New**
Click **Query** to create a new query. For more information about creating LDAP queries, see LDAP Query Basics (http://go.microsoft.com/fwlink/?LinkId=143553).

**Refresh**
To update the object from Active Directory, right-click an object, and then click **Refresh**. The **Refresh** command removes the current objects in the container and repopulates the container with updated information from Active Directory.

**Object Node**
To view the following commands, click an object in the details pane (for example, **Account Operators** is an object in the previous figure), click the **Action** menu, and then click one of the following:

- Move
- New Connection From Here
- New
- Delete
- Rename
- Refresh

**Move**

Moves the object to another container in Active Directory. Opens a dialog box that you can use to select the destination container.

**New Connection From Here**
Creates a new connection point node and adds it to the console.

**New**
The **New** menu command reveals another menu that contains the **Object** command, which creates a new child object in the selected container. This command opens a set of chained dialog boxes that begins with the class of the object. If you do not have the appropriate permissions to create an object in the selected container, no classes will be listed. After you select a class, a dialog box opens for each required attribute. In the final dialog box, click **More** to view and edit any optional attributes.

**Delete**
Deletes the selected object from Active Directory. A dialog box appears asking you to confirm the deletion. This command does not appear in the menu if you do not have permissions to delete an object from Active Directory.

**Rename**
Changes the name of the object in Active Directory.

**Refresh**
To update the object from Active Directory, right-click an object, and then click **Refresh**. The **Refresh** command removes the current objects in the container and repopulates the container with updated information from Active Directory.

**Adding ADSI Edit to MMC**

If you are running ADSI Edit on a computer that is not logged on to a domain or if you want to create a customized MMC, you may want to add the ADSI Edit snap-in to the console.

**To add the ADSI Edit Snap-in to MMC**

1. Open your existing console or create a new console. To create a new console, click **Start**, click **Run**, type **mmc**, and click **OK**, or at a command line, type **mmc**, and then press ENTER.
2. Click **Add/Remove Snap-in**, and then click **Add**.
3. In the **Add Standalone Snap-in** dialog box, click **ADSI Edit** in the list. If ADSI Edit does not appear here, see Installing ADSI Edit at the beginning of this topic.
4. Click **Add**, click **Close**, and then click **OK**.

**Missing Commands**
The **Action** menus in MMC are context sensitive. If you do not have permission to perform an action, the action might not appear in the menu.

**Other Topics with ADSI Edit Usage Scenarios**
Although ADSI Edit is not intended for regular management of your Active Directory environment, there are instances in which you may need to use it. The following topics include procedures that use ADSI Edit.

- Weaken security using ADSI Edit (http://go.microsoft.com/fwlink/?LinkId=143425)
- Manage an AD LDS Instance Using ADSI Edit (http://go.microsoft.com/fwlink/?LinkId=143426)
- Using ADSI Edit to Edit Active Directory Attributes (http://go.microsoft.com/fwlink/?LinkId=143427)
- Article 822444 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=143428)
- Step 1: Create a PSO (http://go.microsoft.com/fwlink/?LinkId=143555)

# ADSI Edit UI: Graphical Representation

Published: June 11, 2010

Updated: April 26, 2012

Applies To: Windows Server 2003, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

## ADSI Edit

Active Directory® Service Interfaces Editor (ADSI Edit) is a Lightweight Directory Access Protocol (LDAP) editor that you can use to manage objects and attributes in Active Directory. ADSI Edit (adsiedit.msc), a Microsoft Management Console (MMC) snap-in, provides a view of every object and attribute in an Active Directory forest. You can use ADSI Edit to query, view, and edit attributes that are not exposed through the other Active Directory MMC snap-ins: Active Directory Users and Computers, Active Directory Sites and Services, Active Directory Domains and Trusts, and Active Directory Schema.

### Installing ADSI EDIT

**Windows Server 2003/Windows XP** - Install Windows Server 2003 Support Tools from the Windows Server 2003 product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114).
**Windows Server 2008/Window Server 2008 R2** - ADSI Edit is installed when you install the Active Directory Domain Services (AD DS) role to make a server a domain controller. You can also install Windows Server 2008 Remote Server Administration Tools (RSAT) on domain member servers or stand-alone servers.
**Windows Vista/Windows 7** - Install RSAT. For more information and to download RSAT, see article 941314 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=116179).

**Using ADSI Edit**
Add the ADSI Edit (adsiedit.msc) snap-in to any .msc file through the Add/Remove Snap-in menu option in MMC, or open the Adsiedit.msc file in Windows Explorer.

**Missing Commands**
The Action menus in MMC are context sensitive. If you do not have permission to perform an action, the action might not appear in the menu.

Adsiedit.msc automatically attempts to load the current domain to which the user is logged on.

Adding ADSI Edit to MMC
If you are running ADSI Edit on a computer that is not logged on to a domain or if you want to create a customized MMC, you may want to add the ADSI Edit snap-in to the console.

### ADSI Edit UI

#### Three Main Nodes

**ADSI Edit**
To view the commands in the ADSI Edit node, click the Action menu, and then click Connect To.

**Name** – The display name for the connection point.

**Path** – Displays the URL for the selected object.

**Connection Point** – Select either Distinguished Name or Naming Context.

**Computer** – Specifies whether you connect to the local computer or a remote computer.

**Advanced** – Click to specify alternate credentials or alternate port numbers, or to change the protocol used to connect to Active Directory.

**Directory Partition**
To view the following commands, select the directory partition node that you want to manage (that is, Domain, Configuration, and Schema), and then click the Action menu.

**Settings** – Displays the same information as the UI for the ADSI Edit node.

**Remove** – Displays the URL for the selected object.

**Update Schema Now** – Select either Distinguished Name or Naming Context.

**New** – Specifies whether you connect to the local computer or a remote computer.

**Refresh** – To update the object from Active Directory, right-click an object, and then click Refresh.

**Object**
To view the following commands, click an object in the details pane.

**Move** – Moves the object to another container in Active Directory.

**New Connection from Here** – Creates a new connection point node and adds it to the console

**New** – Reveals another menu that contains the Object command, which creates a new child object in the selected container.

**Delete** – Deletes the selected object from Active Directory.

**Rename** – Changes the name of the object in Active Directory.

**Refresh** – To update the object from Active Directory, right-click an object, and then click Refresh.

# Clonepr Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The ClonePrincipal tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Clonepr: ClonePrincipal**
This tool assists administrators in migrating users from Windows NT to Windows 2000 or Windows Server 2003 by creating clones of the Windows NT 4.0 users and groups in the new Windows 2000 or Windows Server 2003 environment.

**Concepts**
Customers deploying Windows 2000 or Windows Server 2003 might want to migrate users incrementally to a new Windows 2000 or Windows Server 2003 environment without impacting their existing Windows NT 4.0 production environment. This allows users to be introduced gradually to Windows 2000 or Windows Server 2003, and allows them an emergency fallback to their old account during the trial period. It enables administrators to consolidate multiple groups from different source domains into a single destination group and old resource domains into a single organizational unit. It eliminates the need to update group memberships and access control lists (ACLs), preserving uninterrupted network access for users in the new domain structure.

ClonePrincipal must be run on a destination domain controller running Windows 2000 or Windows Server 2003.

ClonePrincipal performs tasks related to those performed by another Windows 2000 and Windows Server 2003 Support Tool, Movetree.exe, with the following differences:

- ClonePrincipal is exclusively for interforest use. It copies security Principals between forests only. MoveTree is exclusively for intraforest use. It moves security Principals within the same forest only. This means that for ClonePrincipal, the source domain can be Windows NT 4.0 or Windows 2000 (mixed or native mode), while MoveTree relies on a Windows 2000 source domain.

- ClonePrincipal duplicates objects from the source domain in the target domain rather than moving them to it, so the source domain is unaffected. MoveTree moves objects, which means that the operations it performs destroy objects in the source domain. Both, however, add the old security identifier (SID) to the SIDHistory.

- ClonePrincipal does not maintain users' existing passwords, and MoveTree does.

To move users or groups within a Windows 2000 or Windows Server 2003 domain (for example, from one organizational unit to another), use Active Directory Users and Computers, a Microsoft Management Console snap-in that is part of Windows 2000 and Windows Server 2003.

**Files Required**

- Clonepr.dll. Component Object Model (COM) object with methods to support ClonePrincipal operations.

- Clonegg.vbs. Sample script that clones all the Global Groups in a domain.

- Cloneggu.vbs. Sample script that clones all the Global Groups and Users in a domain.

- Clonelg.vbs. Sample script that clones all the Local Groups in a domain.

- Clonepr.vbs. Sample script that clones a single security Principal.

- Sidhist.vbs. Sample script that adds the SID of a source account to the SIDHistory of a destination account.

**For More Information**
For more information about ClonePrincipal, read Clonepr.doc in the Program Files\Support Tools directory.

### Note

- You need Microsoft Word or a compatible viewer to view Clonepr.doc. You can download a free version of Microsoft Word Viewer from the Microsoft Office Download Center.

For more information about Active Directory, visit the Active Directory page on the Microsoft Windows 2000 Server Web site.

# Dsacls Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Dsacls command-line tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Dsacls.exe: DsAcls**
This command-line tool displays and changes permissions (access control entries) in the access control list (ACL) of objects in Active Directory.

Note

- The ACEs that you add by using DsAcls must be object-specific permissions that override the default permissions defined in the Active Directory schema for that object type. Do not add ACEs unless you are well-informed about security for Active Directory objects.

**Corresponding UI**
DsAcls is the command-line equivalent of the **Security** tab in the **Properties** dialog box for an Active Directory object in Active Directory tools, such as Active Directory Users and Computers. You can use either tool to view and change permissions to an Active Directory object.

**Concepts**
For more information about Active Directory, see Deploying Active Directory.

**System Requirements**
The following are the system requirements for DsAcls:

- DsAcls runs on Windows 2000, Windows XP Professional, and Windows Server 2003.
- To view an ACL, the user must have read permissions on Active Directory objects. To change an ACL, the user must have write permissions to the Active Directory object.

**File Required**

- Dsacls.exe

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DsAcls Examples**

**Examples of valid permissions**

```
SDRCWDWO;;user
```

Delete, read security information, change security information, and change ownership permissions on objects of type "user."

```
CCDC;group;
```

Create child and delete child permissions to create or delete objects of type "group."

```
RPWP;telephonenumber;
```

Read property and write property permissions on telephone number property.

# Dsacls Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DsAcls Syntax**

DsAcls uses the following general syntax:

**dsacls** "[*****Computer*****]*ObjectDN*" [**/A**] [**/D** *PermissionStatement* [*PermissionStatement*]...] [**/G** *PermissionStatement* [*PermissionStatement*]...] [**/I:**{**T** | **S** | **P**}] [**/N**] [**/P:**{**Y** | **N**}] [**/R** {*User* | *Group*} [{*User* | *Group*}]...] [**/S** [**/T**]] [**/?**]

**Parameters**

**Note**

- If you specify an object without additional parameters, DsAcls displays the access control entries (ACEs) in the ACL.

**"[*Computer*\]*ObjectDN*"**

Identifies the Active Directory object to investigate. Type the distinguished name of the object. To specify an object on a remote computer, type the computer name followed by the distinguished name. This parameter must be enclosed in quotation marks. For example:

```
"CN=Jeff Akers,CN=Users,DC=domain,DC=test,DC=microsoft,DC=com"
```

or

```
"\\Server01\CN=Jeff Akers,CN=Users,DC=domain,DC=test,DC=microsoft,DC=com"
```

**/A**

Adds ownership and auditing information to the display.

**/D PermissionStatement[*PermissionStatement*]**

Denies the specified permissions to the user or group.

You can deny permissions to multiple users in each **/D** command, for example:

```
/D Domain1\User1:CCDC Domain1\User2:DC;computer
```

**/G PermissionStatement[*PermissionStatement*]**

Grants specified permissions to the user or group.

You can grant permissions to multiple users in each **/G** command, for example:

```
/G Domain1\User1:CCDC Domain1\User2:DC;computer
```

**/I:{T | S | P}**

Specifies the objects to which the permissions are applied. This parameter determines whether the permissions are inheritable. **T** is the default.

| Value | Description |
|---|---|
| **T** | This object and subobjects. |
| **S** | Subobjects only. |
| **P** | Propagate inheritable permissions one level only. |

**/N**

Provides that the specified ACE replaces the ACEs in the ACL. By default, the ACE is added to the ACL.

**/P:{Y | N}**

Determines whether the object can inherit permissions from its parent objects. If you omit this parameter, the inheritance properties of the object are not changed.

| Value | Description |
|---|---|

| | |
|---|---|
| **Y** | The object is protected and cannot inherit permissions. |
| **N** | The object is not protected and can inherit permissions. |

**>Note**

- This parameter changes a property of the object, not of an ACE. To determine whether an ACE is inheritable, use the **/I** parameter.

**/R {*User* | *Group*} [{*User* | *Group*}]...**
Deletes all ACEs for the specified users or groups. *User* can be specified as *User***@***Domain* or as *Domain******User*. *Group* can be specified as *Group***@***Domain* or as *Domain******Group*.

You can delete ACEs for multiple users and groups in a single **/R** parameter, for example:

```
/R Domain1\User1 Domain1\User2
```

**/S**
Restores the security on the object to the default for that object class as defined in Active Directory schema.

**/T**
Restores the security on the tree of objects to the default for each object class. This parameter is valid only with the **/S** parameter.

**/?**
Displays help for DsAcls.

**Syntax for PermissionStatement**
*PermissionStatement* values use the following format:

{*User* | *Group*}**:***Permissions*[**;**{*ObjectType* | *Property*}][**;***InheritedObjectType*]

**Parameters**
**{*User* | *Group*}**
Specifies the user or group to whom the rights apply. *User* can be specified as *User***@***Domain* or *Domain******User*. *Group* can be specified as *Group***@***Domain* or *Domain******Group*.

***Permissions***
Type one or more of the following values (without spaces).

**Generic Permissions**

| Value | Description |
|---|---|
| **GR** | Generic Read |
| **GE** | Generic Execute |
| **GW** | Generic Write |
| **GA** | Generic All |

**Specific Permissions**

| Value | Description |
|---|---|
| **SD** | Delete. |
| **DT** | Delete an object and all of its children. |
| **RC** | Read security information. |
| **WD** | Change security information. |

| | |
|---|---|
| **WO** | Change owner information. |
| **LC** | List the children of an object. |
| **CC** | Create child object.<br><br>If {*ObjectType* \| *Property*} is not specified to define a specific child-object type, this applies to all types of child objects; otherwise, it applies to the specified child-object type. |
| **DC** | Delete a child object.<br><br>If {*ObjectType* \| *Property*} is not specified to define a specific child-object type, this applies to all types of child objects; otherwise, it applies to the specified child-object type. |
| **WS** | Write to self object.<br><br>This is meaningful only on Group objects and when {*ObjectType* \| *Property*} is a "member." |
| **RP** | Read property.<br><br>If {*ObjectType* \| *Property*} is not specified to define a specific property, this applies to all properties of the object; otherwise, it applies to the specified property of the object. |
| **WP** | Write property.<br><br>If {*ObjectType* \| *Property*} is not specified to define a specific property, this applies to all properties of the object; otherwise, it applies to the specified property of the object. |
| **CA** | Control access right.<br><br>If {*ObjectType* \| *Property*} is not specified to define the specific extended right for control access, this applies to all meaningful control accesses on the object; otherwise, it applies to the specific extended right for that object. |
| **LO** | List the object access.<br><br>Can be used to grant list access to a specific object if List Children (**LC**) is not granted to the parent as well. Can also be denied on specific objects to hide those objects if the user/group has **LC** permission on the parent.<br><br>Note<br><br>• Active Directory does not enforce this permission by default. The Active Directory must be configured to check for this permission. |

***{ObjectType | Property}***

Limits the permission to the specified object type or property. Enter the display name of the object type or of the property. If an object type or property is not specified, the permission applies to all object types and properties.

For example, the following command permits the user to create all types of child objects:

```
/G Domain\User:CC
```

However, the following command permits the user to create only child computer objects:

```
/G Domain\User:CC;computer
```

***InheritedObjectType***

Limits inheritance of the permission to the specified type of object. Enter the display name of the object type. If an object type is not specified, the permission can be inherited by all object types. This parameter is used only when permissions are inheritable.

For example, the following command permits all types of objects to inherit the permission:

```
/G Domain\User:CC
```

However, the following command permits only user objects to inherit the permission:

```
/G Domain\User:CC;;user
```

# Dsastat Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Dsastat command-line tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Dsastat.exe: Directory Services Utility**
This command-line diagnostic tool compares and detects differences between naming contexts on domain controllers.

DsaStat can be used to compare two directory trees across replicas within the same domain or, in the case of a global catalog, across different domains. The tool retrieves capacity statistics such as megabytes per server, objects per server, and megabytes per object class, and performs comparisons of attributes of replicated objects.

### Note

- You must run DsaStat from the command window.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
The user specifies the targeted domain controllers and additional operational parameters from the command line. DsaStat determines whether domain controllers in a domain have a consistent and accurate image of their own domain. In the case of Global Catalogs, DsaStat checks to see if the Global Catalog has a consistent image with domain controllers in other domains. As a complement to the replication-monitoring tools, Repadmin Overview and Replmon Overview, DsaStat can be used to ensure that domain controllers are up to date with one another.

**System Requirements**
The following are the system requirements for DsaStat:

- Windows Server 2003 or
- Windows XP Professional or
- Windows 2000

**File Required**

- Dsastat.exe

**See Also**

# Dsastat Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DsaStat Syntax**

DsaStat uses the following syntax:

**dsastat** [**/loglevel:**{**INFO**|**TRACE**|**DEBUG**}] [**/output:**{**SCREEN**|**FILE**|**BOTH**}] [**/s:***ServerName*[*PortNumber*] [**;***ServerName*[*PortNumber*]...]] [**/t:**{**TRUE**|**FALSE**}] [**/sort:**{**TRUE**|**FALSE**}] [**/p:***PageSize*] [**/scope:**{**BASE**|**ONELEVEL**|**SUBTREE**}] [**/b:***SearchPath*] [**/filter:***LdapFilter*] [**/gcattrs:**{[*LDAPAttributes*[*Attribute;Attribute* [**Auto**]|[**All**]} [**/u:***UserName*] [**/pwd:***Password*] [**/d:***Domain*]

**Parameters**

**/loglevel:{INFO|TRACE|DEBUG}**
Specifies the extent of logging that is performed during execution. The default option is INFO.

**/output:{SCREEN|FILE|BOTH}**
Specifies where the results of DsaStat are displayed. If **FILE** is selected, the output is saved to a file named Dsastat.log.*nnnnn*. The default option is **BOTH**.

**/s: *ServerName*[*PortNumber*][;*ServerName*[*PortNumber*]...]**
Specifies the names of the servers on which the comparison is performed. Separate each server name with a semicolon (**;**). The server name can be appended with the TCP/IP port number. If *PortNumber* is 3268, the comparison is performed against the global catalog of that server. The default port number is the default LDAP port (389).

**/t:{TRUE|FALSE}**
Specifies whether to perform a statistics comparison or a full-content comparison. Setting **/t:** to **TRUE** performs a statistical comparison. Setting **/t:** to **FALSE** performs a full-content comparison. The default is **TRUE**. The statistical comparison merely counts the objects. It does not compare the attributes of the objects that have been retrieved from the domain controllers and it ignores the **/gcattrs** parameter. A full-content comparison retrieves every object with attribute values and performs a comparison of the attributes of the same object from different domain controllers.

**/sort:{TRUE|FALSE}**
Determines whether the search operations are performed with sorting based on object GUID. Setting **/sort:** to **TRUE** performs sorted queries. Setting **/sort:** to **FALSE** does not perform sorted queries. The default value is **FALSE**. Performing a sorted query by setting this option to **TRUE** has a negative impact on performance; however, it complements the full-content comparison because it ensures that objects are returned in nearly the same order from different servers and improves the performance of full-content comparison.

**/p: *PageSize***
Sets the number of entries to be returned per page for ldap_search operation. The valid range for *PageSize* is 1-999. The default value is 64. If the directory objects are large (such as user objects with many of their attributes populated with values), it is advisable to use a smaller page size.

**/scope:{BASE|ONELEVEL|SUBTREE}**
Specifies the extent of scope for the search operation. The default option is **SUBTREE**.

**/b: *SearchPath***
Sets the distinguished name of the base search path. This allows DsaStat to perform the comparison against any subtree of the directory.

**/filter: *LdapFilter***
Sets LDAP filter used in the LDAP search operation. The filter must conform to LDAP search syntax as specified in RFC 2254. The default filter is (objectclass=*).

**/gcattrs:{[*LDAPAttributes*[*Attribute;Attribute...*]]| [ObjectClass]|[Auto]|[All]}**
Specifies attributes to be returned from search. This option is used only if the comparison parameter **/t** is set to **FALSE**: *LDAPAttributes* specifies any LDAP attribute available. Multiple attributes may be specified separated by semicolons. **ObjectClass** specifies that no attributes be displayed. **Auto** specifies that only the attributes replicated to the global catalog be displayed. **All** specifies that all attributes contained in an object be displayed

**/u: *UserName***
Specifies the user name to use for the query.

**/pwd: *Password***
Specifies the password to use for authenticating the user name. Must be used with the **/u** parameter.

**/d: *Domain***
Specifies the domain to use for authenticating the user name. Must be used with the **/u** parameter.

# Dsastat Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DsaStat Examples**

**Example 1: Object Count Comparison**

Your network has the following domains and servers:

- **Domain**, with two domain controllers:
  - **DomainS1** (which is also a global catalog)
  - **DomainS2**

  The distinguished name of the domain is **DC=Domain,DC=com**.

- **Child.Domain**, a child domain of Domain, with one domain controller:
  - **ChildS1** (which is also a global catalog)

  The distinguished name of the domain is **DC=Child,DC=Domain,DC=com**.

To compare the number of objects in the directory for the domain **Domain**, type the following at the command line:

```
dsastat -s:DomainS1;DomainS2 -b:DC=Domain,DC=com -gcattrs:objectclass -
p:999
```

This search merely keeps a count of the different types of objects in each of the replicas and then compares the count for each object class.

**Example 2: Full Comparison**

Your network has the following domains and servers:

- **Domain**, with two domain controllers:
  - **DomainS1** (which is also a global catalog)
  - **DomainS2**

  The distinguished name of the domain is **DC=Domain,DC=com**.

- **Child.Domain**, a child domain of Domain, with one domain controller:
  - **ChildS1** (which is also a global catalog)

  The distinguished name of the domain is **DC=Child,DC=Domain,DC=com**.

To perform a full comparison of each object in the domain **Domain**, type the following at the command line:

```
dsastat -s:DomainS1;DomainS2 -b:DC=Domain,DC=com -gcattrs:all -sort:true -
t:false -p:16
```

This search does a full content search and comparison of all the objects in the domain **Domain**. Because the default filter is **"**

**(objectclass=*)**," all objects are retrieved by this search. The objects are also sorted based on objectGUID to improve the performance of the comparison operation.

**Example 3: User Comparison**
Your network has the following domains and servers:

- **Domain**, with two domain controllers:
    - **DomainS1** (which is also a global catalog)
    - **DomainS2**

  The distinguished name of the domain is **DC=Domain,DC=com**.

- **Child.Domain**, a child domain of Domain, with one domain controller:
    - **ChildS1** (which is also a global catalog)

  The distinguished name of the domain is **DC=Child,DC=Domain,DC=com**.

To perform a comparison of all users in the Sales organizational unit in the **Domain** domain, type the following at the command line:

```
dsastat -s:DomainS1;DomainS2 -b:OU=Sales,DC=Domain,DC=com -gcattrs:all -
sort:true -t:false -p:16 -filter:"(&(objectclass=user)(!objectClass=computer))"
```

This example illustrates the specification of the base search path at a subtree of the domain, in this case the organizational unit named **Sales**. In addition, the filter specifies that the comparison is only concerned with user objects and not computer objects. Note that since computer objects are derived from user objects in the class hierarchy, a search filter specifying **objectclass=user** will return both user and computer objects.

**Example 4: DC Comparison**
Your network has the following domains and servers:

- **Domain**, with two domain controllers:
    - **DomainS1** (which is also a global catalog)
    - **DomainS2**

  The distinguished name of the domain is **DC=Domain,DC=com**.

- **Child.Domain**, a child domain of Domain, with one domain controller:
    - **ChildS1** (which is also a global catalog)

  The distinguished name of the domain is **DC=Child,DC=Domain,DC=com**.

To perform a comparison between a domain controller in the **Child** domain and a global catalog server in the domain **Domain**, type the following at the command line. (Note that the global catalog server **DomainS1** in the domain **Domain** holds a partial replica of all objects from the domain **Child**.)

```
dsastat -s:DomainS1:3268;ChildS1 -b:DC=Child,DC=Domain,DC=com -
gcattrs:objectclass -p:999
```

This search compares the global catalog on **DomainS1** and checks to see if it has a consistent partial image of the domain

**Child**. This search does not perform a full-content comparison, but simply checks that the object count is the same between the global catalog and the domain controller **ChildS1** in the domain **Child**.

**Example 5: Full Content Comparison**
To perform a full content comparison between a domain controller in the **Child** domain and a global catalog server in the domain **Domain**, type the following at the command line:

```
            dsastat -s:DomainS1:3268;ChildS1 -b:DC=Child,DC=Domain,DC=com -gcattrs:auto
-sort:true -t:false -p:16
```

In this example, DsaStat performs a full content comparison between all the objects that have been replicated to the global catalog. Specifying the **auto** option for **/gcattrs** ensures that only the attributes replicated to the global catalog are retrieved.

# Ldp Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Ldp GUI tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Ldp.exe: LDP Tool**
This GUI tool is a Lightweight Directory Access Protocol (LDAP) client that allows users to perform operations (such as connect, bind, search, modify, add, delete) against any LDAP-compatible directory, such as Active Directory. LDP is used to view objects stored in Active Directory along with their metadata, such as security descriptors and replication metadata.

### Note

- LDP is a GUI-based, Windows Explorer–like utility with a scope pane on the left that is used for navigating through the Active Directory namespace, and a details pane on the right that is used for displaying the results of the LDAP operations. Any text displayed in the details pane can be selected with the mouse and "copied" to the Clipboard.

**Corresponding UI**
LDP comes with its own user interface. For more information about the LDP user interface, read LDP.doc in the Program Files\Support Tools directory.

### Note

- You need Microsoft Word or a compatible viewer to view Ldp.doc. You can download a free version of Microsoft Word Viewer from the Microsoft Office Download Center.

**Concepts**
It is highly recommended that you read the Understanding LDAP white paper on the Microsoft Web site before continuing with this document.

**System Requirements**
The following are the system requirements for LDP:

- A connection to an LDAP server
- Windows Server 2003

**File Required**

- Ldp.exe

# Ldp Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**LDP Remarks**

**Finding Required and Optional Values for an Attribute**

The schema defines objects as well as the attributes and permissible values for each. Schema classes that contain attribute information about objects can be viewed. To view this information, search cn=Schema,cn=Configuration,dc=ForestRootDomain for classSchema objects.

**Understanding Bind Options for LDAP Authentication**

There are several authentication methods available in LDP that allow a client to bind to an LDAP server. The best method depends on several factors.

| Method | Description |
|---|---|
| Simple | Cleartext password. Try not to use this, as it is not secure. |
| MSN | MSN (Microsoft Network) authentication. This package brings up a dialog box to prompt the user for MSN credentials. |
| DPA | Normandy authentication, new MSN authentication. Same usage as MSN. |
| NTLM | Windows NT domain authentication. Use NULL credentials and attempt to use default logged-in user credentials. |
| Sicily | Negotiate with the server for any of: MSN, DPA, NTLM. Should be used for LDAPv2 servers only. |
| Negotiate | Use GSSAPI Negotiate package to negotiate security package of either Kerberos V5 or NTLM (or any other package the client and server negotiate). Pass in NULL credentials to specify default logged-in user. If Negotiate package is not installed on server or client, this will fall back to Sicily negotiation. |

# Ldp UI

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**LDP UI**

**LDP Dialog Box**
The LDP dialog box consists of two panes. The left navigation pane lists the base object and any child objects. The right details pane lists the results of the LDAP operations.

**Connection Menu**
**Connection** menu options:

| Option | Description |
|---|---|
| **Connect** | Opens a dialog box that you can use to open a session with a specified LDAP server. A connection must be established with an LDAP server before any other LDAP commands can be run. Enter the appropriate port number for the service you are connecting to. By default, LDAP uses TCP for a connection-oriented session. To use UDP for a connectionless session, select the **Connectionless** check box. By default, a successful connection results in the display of the RootDSE information in the details pane. |
| **Bind** | Opens a dialog box you can use to authenticate a specified LDAP server. Enter a user name and password of an account that has permissions to the LDAP server. If you enter an invalid user name, then you will be connected with anonymous credentials. As a shortcut, use the **Bind** option without using the **Connect** option to connect, and authenticate with the server last connected to. |
| **Advance** | Opens a dialog box that you can use to set options for the authentication methods. See **Bind Options** under the **Options** menu. |
| **Disconnect** | Terminates an open session with a specified LDAP server. Closing the LDP application automatically disconnects any open sessions. |
| **New** | Keeps the currently connected session, but clears the details pane. The keyboard shortcut for this action is CTRL+N. By default, the details pane is accumulative. |
| **Open** | Opens text files and places the information in the details pane. |
| **Save** | Saves changes to a previously saved file. |
| **Save as** | Saves the contents of the details pane to a text file. Use the **Open** command to view the contents of this file in the details pane later. |
| **Print** | Prints the details pane. |

Note

- LDP can connect to only one LDAP server at a time. If you use the **Connect** command while connected to a server, the current session is disconnected.

**Browse Menu**
**Browse** menu options:

**Add**
Opens a dialog box that you can use to add objects to Active Directory. You must enter the full distinguished name of the object, as well as all the mandatory attributes for the class of object being added.

| Option | Description |
|---|---|
| **DN** | Enter the full distinguished name of the new object. |

| | |
|---|---|
| **Attribute** | Enter the required or optional attribute. |
| **Values** | Enter the value(s) associated with the attribute. Separate multiple values for a single attribute with a semicolon. No spaces are required. |
| **Enter** | Adds the entered attribute and value(s) to the **Entry List** section of the dialog box, and clears the **Attribute** and **Value** fields. Continue entering attributes and values until all required and desired optional attributes are on the Entry List. |
| **Insert File** | Opens a dialog box that allows you to use a text file with the appropriate attributes and values. |
| **Entry List** | Displays entered attributes and values. |
| **Edit** | Opens a dialog box that you can use to enter changes to the selected entry from the Entry List. |
| **Remove** | Deletes the selected entry from the Entry List. |
| **Extended** | Select this check box if the object being added is part of an extended control. |
| **Synchronous** | If selected (the default), requires LDP to wait for a response from the destination server before continuing. If you clear this check box, LDP continues before a response is received. Clear this check box when slow WAN connections are causing LDP commands to time out. |
| **Run** | Adds the current attributes and values in the Entry List to Active Directory. If LDP encounters any errors, then the object is not added and the error message displays in the details pane. |
| **Delete** | Opens a dialog box that you can use to delete an object from Active Directory. Attributes can be deleted only if they are defined as optional and contain no values. Use the **Edit** command to delete an attribute's values. |

**DN**

| Option | Description |
|---|---|
| **Dn** | Enter the full distinguished name of the new object. |
| **Extended** | Select this check box if the object being deleted is part of an extended control. |
| **Synchronous** | If selected (the default), requires LDP to wait for a response from the destination server before continuing. If you clear this check box, LDP continues before a response is received. Clear this check box when slow WAN connections are causing LDP commands to time out. |
| **Recursive (client)** | Deletes all objects in a container, but does not delete the container. |

**Modify**

Opens a dialog box you can use to change attributes of an object stored in Active Directory.

| Option | Description |
|---|---|
| **Dn** | Enter the full distinguished name of the new object. |
